SIR,—Though it is evident from the correspondence in the *Journal* that the hazards of fluoridation are a subject of controversy among the scientific experts, the question is not one really of science but of medical ethics and of the freedom of the practitioner to give what he judges to be the best advice in the interests of his patient, and of the patient to carry it out.

It is, at any rate, legitimate for any one, medical or lay, to hold that we already absorb a sufficient level of toxins, and that a small but daily addition through the water supply is inadvisable, especially to anyone in poor health. There is no medical indication whatever for the administration of fluorides to adults, and for local councillors to make the decision to do this, and to impose it upon the patients of those medical practitioners who may consider it inadvisable in individual cases, is a dangerous precedent for interference in the medical field by the political power. I can see no reason why the treatment of dental caries should make an exception to the rule that consent to any form of treatment should be essential, and that no one should be subjected to any treatment which offers him no expectation of benefit.

I understand that enthusiasts for fluoridation will not be content until the benefits of fluorides are made available to children who do not drink the public water supply; and if

this can be done, they can be made available to all children whose parents consent. When the same amount of attention has been paid to finding legitimate ways of making this treatment available to children, without forcing it on everyone else, as has been paid to studying this illegitimate method of dosing everybody, including unwilling people, through the public water supply, I do not believe that the difficulties will be found insuperable.—I am, etc.,

London, S.W.1.

FREDERICK C. ENDEAN.

Relationship Between Menstruation, Urine Acidity, and Ovulation

SIR,—When investigating the pH of the first morning urine specimen of a representative sample of schizophrenics and healthy normals, a significant difference in acidity (measured with the potentiometer) was found between the two groups ($P=0.05$), the urine of schizophrenics being the more acidic.

During the course of these studies I made the following observation: the pH of the first morning urine specimen of a healthy female drops to pH values around 5.2 to 5.0 24 to 12 hours before the onset of menstruation; for instance, pH=5.8 two days prior, pH=5.25 one day prior, and pH=5.1 about three hours prior to the arrival of menstruation. There is also an increase in urine acidity (drop in pH) before the onset of ovulation, though this is less marked than that occurring shortly before the onset of menstruation.

These preliminary observations need, of course, confirmation and extension before their usefulness can be assessed in terms of practical applicability—for example, by use of a special paper pH-indicator revealing the varying degrees of acidity in the first morning urine by different colours.—I am, etc.,

Regina, Canada.

ROLAND FISCHER.

Heatstroke or Malaria?

SIR,—Under the heading "Lowering the Body Temperature," Dr. C. E. H. Milner writes a letter (*Journal*, October 9, 1954 p. 872) which includes some of his experiences of hyperpyrexial heatstroke in Mesopotamia in the summer of 1917 during the first world war.

He states: "About 5 p.m. the ambulances began to roll up . . . full of blue, unconscious, naked soldiers, suffering from alleged heatstroke. These proved in reality to be cases of hyperpyrexial cerebral malignant tertian malaria." His letter, however, does not state the proportion of blood smears that proved to be positive. Also, about 36 years ago, in an article on this same epidemic, Dr. Milner¹ expressed the view "that heatstroke, as a clinical entity, is non-existent; and is nothing more than a symptom, on a hot day, of malignant tertian malaria."

This would appear to mean that, in Dr. Milner's opinion, it is impossible for any person to be attacked by hyperpyrexial heatstroke unless he has previously been infected with the parasite of malignant tertian malaria. This point, because of its obvious bearing upon immunity and treatment, is one of considerable practical importance. The truth of it would be difficult to prove conclusively, and equally difficult to disprove. However, the following evidence may help to clarify the situation. While in Mesopotamia in 1917 I dealt with an exceptionally large number of heatstroke cases during this memorable epidemic, and found many instances where no evidence of malaria could be obtained despite careful search for it. I have no record of the proportion of positive malarial blood smears that occurred in my cases, but, from memory, I doubt if they exceeded 25%. I regarded the malaria merely as a complication which would naturally be expected among a community of soldiers, many of whom had lived for a considerable time in India or Mesopotamia.

In August, 1917, several troopships arrived at Basra from England at intervals of about a week. In the first ship-load an appalling outbreak of heatstroke with a very high mortality rate

occurred during the ten-hour journey up the Shatt-el-Arab river. Following this I received instructions to meet the remaining ships at the head of the Persian Gulf, and to deal with the heatstroke problem during the journey up river to Basra.

The occurrence of fully developed cases of heatstroke on these latter ships was greatly modified by a system of prevention which had already proved thoroughly successful in my 60-bed hut at the hospital in Basra, which I described in 1919.¹ Nevertheless, on each of these latter ships about four or five actual heatstrokes occurred, and about 40 others certainly would have occurred had the patients not been placed under preventive treatment (all of the prevented cases had complete suppression of sweating, and a temperature of at least 103° F. (39.4° C.)).

Here we have a series of instances where heatstrokes and potential heatstrokes occurred in large numbers at the final stage of a voyage from England before any of the troops had set foot on Mesopotamian soil. And the question arises—Were all or any of these heatstroke patients malarial subjects? There was no opportunity to examine blood films during the river journey.

The S.M.O. of one of these ships told me that no attacks of malaria had been treated on the voyage.

This ship came via the Cape, and the only stoppages were a couple of days at Capetown and Durban which took place in July, during the southern mid-winter. The troops, therefore, could not have picked up malarial infection during the voyage. Consequently, if there were any malarial soldiers among them they could have become infected only through a previous visit to some malarial country. But changes of climate are said to precipitate malarial attacks in infected persons, and as no such attacks occurred on a long voyage, which crossed the Equator twice, and spent some time in the fairly cold region of Capetown in mid-winter, it seems that there were few, if any, infected soldiers on board. Unfortunately, I did not ask the heatstroke patients on my ships if they had ever left England before. Their replies might have produced conclusive evidence regarding their freedom from infection. However, the troops were not British "regulars," and I formed the opinion that this ship, at any rate, provided an example of heatstroke occurring under circumstances in which the influence of malaria could be fairly and reasonably eliminated.

Results of treatment throw some further light upon this subject. All of the heatstroke patients on my ships had recovered consciousness before the ships reached Basra; and none of them received a single grain of quinine, nor was any venesection done. The treatment given served no purpose other than to remove their hyperpyrexia: they recovered quickly. Furthermore, I have been fortunate enough on several occasions to be present (with the means of treating the hyperpyrexia ready at hand) at the moment that the patient became unconscious, and have proved that the immediate application of treatment to such early cases can restore consciousness within 20 to 30 minutes. Such a quick result is possible when the superheated blood has been allowed to affect the brain for only a minimum length of time; but it seems highly improbable that a similar result could be obtained by hyperpyrexial treatment alone (and no antimalarial therapy included) if the unconsciousness was due to cerebral malignant tertian malaria.

A heatstroke country is, generally, also a malarial country. It is therefore not surprising to find heatstroke and malaria co-existing in people who have lived in a malarial district long enough to become infected. But I feel quite sure that heatstroke can, and often does, occur alone without any necessary association with malaria.—I am, etc.,

Chicken Anti-ulcer Factors in the Treatment of Gastric Ulcer

SIR.—The question whether nutritional factors which counteract gizzard ulcer in chicks may cure gastric or duodenal ulcer in man is of considerable interest to the clinician. We have therefore carried out a series of experiments in order to test this problem. One group of ulcer patients was given a dietetic preparation containing milk and cream powder, vitamins, a decholesterolized lipid extract of calf's brain, and defatted calf's brain. A control group was given a corresponding preparation from which the latter two components were omitted. Calf's brain or a lipid extract thereof together with the defatted calf's

brain have previously been found to counteract gizzard ulcer in chicks.¹ Until now 22 hospitalized patients with roentgenologically verified ulcer have been treated.

In both groups most of the patients became free of subjective symptoms during four weeks of treatment. After treatment x-ray examination showed that ulcer had disappeared in about half of the patients in both groups. This is the same result as that obtained by common dietetic treatment. Thus the presence in the preparation of the above-mentioned chicken anti-ulcer factors had no influence on the results.—We are, etc.,

Copenhagen.

Eclampsia

SIR.—Dr. John Sophian (*Journal*, March 12, p. 666), in his criticism of my letter (*Journal*, February 19, p. 481), flatters me unduly in supposing that I have established a new hypothesis of eclampsia. I have but pointed to new evidence in the aetiology, and—as I have no possibility of testing it—I have asked the profession—that is, the clinicians—to confirm or refute Grauert's claim. Far be it from me to exchange one hypothesis for another one. On the contrary, I fully agree with Dr. Sophian that the right way of combating disease can only be attained by search for aetiological factors. And this is just what I proposed. Unfortunately, the Editor, for brevity's sake, asked me to cut that part of my letter in which I pointed to the contradictory premises on which the endocrinological hypothesis is based.

Dr. Sophian's reference to the well-known cases of eclamptic fits in the absence of a foetus does not invalidate the theory of endogenous toxins. Modern pathology knows by comparative study of other diseases that abnormal reactions can continue automatically even after the "focus" has ceased to act.

In his criticism of the diet I am advising Dr. Sophian has overlooked the much more important items of avoidance of all overheated fats and the increased intake of proteins and roughage (recently also advised by Australian clinicians). The low salt consumption is only one part of the diet.—I am, etc.,

ALBERT W. BAUER.

Night Cramps

SIR.—I was interested to read the annotation on night cramps (*Journal*, March 12, p. 653). From time to time I have read of various treatments and have often wondered when I would see mephenesin recommended. It has always seemed to me that if night cramps were actually cramps this would be a rational treatment though not a cure.

Since 1952 I have done various locums in general practice and have met with about a dozen cases; unfortunately I have kept no exact record, but every case had complete relief, the dose of mephenesin being one tablet at night or a dessertspoonful of the elixir unless it caused a burning sensation in the throat. All the cases of cramp were in old people. I would be most interested to hear whether I have been just lucky with mephenesin so far, whether it is just a placebo, or whether it has a therapeutic value.—I am, etc.,

Woodbridge, Suffolk.

H. R. ODLUM.

Management of Brain Abscess

SIR.—The article by Mr. Walpole Lewin (*Journal*, March 12, p. 631) on his series of cases of brain abscess was most interesting and instructive, and his wise conclusions based on his excellent results are admirable. However, I cannot agree with his advice on the management of all cases of otogenic abscess. It has been known for many years, and discussed in detail by Macewen,¹ that many of these abscesses

arise by direct continuity of the disease through the bony confines of the temporal bone, the dura mater, and the arachnoid and pia mater membranes. It is possible to call these abscesses subdural, but the fact remains that an area of brain tissue is eroded away and that pus and granulation tissue are situated in the geographical space of the brain, separated from the neural tissue by a capsule of varying thickness. This type of abscess is very much commoner than the more deeply seated one which arises probably by thrombophlebitis. I have given fuller details elsewhere² of these processes.

I maintain that, in those abscesses which arise in continuity with chronic infection in the mastoid bone, the route of access to them is the route by which they arrived, whereas the deep-seated abscesses are in the nature of intracranial neoplasms and can best be discovered and treated by surgeons like Mr. Lewin skilled in these particular techniques. It is unfortunate that many neurosurgeons have not recognized that there are at least these two types of abscess, widely differing in aetiology and therefore, I believe, in treatment. Mr. Lewin's only reference to the matter is the sentence: "The operation is conducted through a clean incision, and we have long since abandoned attempts to drain an abscess along the entry track, as, for example, through a mastoid wound, which may lead to cerebral fungus." This cannot be reconciled with my own personal experience, or with that of many of my colleagues. I have never yet seen a cerebral fungus arise in this way and I have always understood from neurologists, even if not from neurosurgeons, that a cerebral fungus is an indication of a persisting rise in intracranial pressure probably indicating a persisting intracranial lesion. I was sorry to see that this statement about cerebral fungus is still being made and is being passed on as common knowledge. I would say that the condition is unknown in modern otological practice conducted in properly equipped departments.—I am, etc.,

Early Cancer Detection

SIR.—Very few articles have been published which deal seriously with the psychological aspect of cancer and cancer education, and it is a pleasure to read the one by Miss Jean Aitken-Swan and Mr. Ralston Paterson (*Journal*, March 12, p. 623), which will be most helpful to those of us who are trying to carry out cancer education among the public.

The authors point out that among the patients suffering from cancer of the breast, and who delayed in seeking advice, 80% "knew" that they might have cancer, and later in the discussion it is stated that "prima facie, it might be argued from this that people are better left in ignorance." This argument will certainly be seized upon and accepted by the "anti-cancer educationists," and therefore it must be answered at once. The answer is simple; there is no evidence that any of the 80% were educated concerning cancer. Before attaching any importance to this figure it would be necessary to discover what proportion of the female adult population "know" that they have cancer—that is, think they have—never go to a doctor, and never develop the disease.

The authors seem to admit this when they say: "Our study has shown no ground for assuming that, given adequate information on the significance of symptoms, people in this area—particularly women with cancer of the breast—would as yet react 'rationally.'" Even knowledge of certain facts is not "cancer education," and it will take many years of "education" before cancer apprehension is sufficiently diminished so that public opinion and other factors will help the sufferer to report at once. There is little doubt that in America this has been accomplished, and the Americans are willing to talk as freely about cancer as they do about other diseases, a fact which has often been erroneously interpreted by doctors in this country as being due to cancer-

phobia. Whilst congratulating the authors on the article, there is still great need to study the psychological outlook towards cancer of people who have no symptoms or disease, and are, in fact, the people whom we are trying to educate.

After many years of experience of cancer education, including two years' whole-time intensive work on the "Yorkshire experiment"—a full report of which it is hoped will be available in a few weeks' time—I am convinced that cases of true cancerphobia, which in any case are rare, are not created by cancer education. Such people are phobia-minded from the start, and if it is not fear of cancer it will be heart disease or fear of being buried alive. On the other hand, "cancer apprehension," which is almost universal, can be and is being diminished by well-planned cancer education.

I should also like to congratulate Dr. J. Walter and Dr. E. C. Atkinson (p. 627) on their pilot experiment on early cancer detection based on periodic examination of apparently healthy people, which must have been carried out at much personal sacrifice of their leisure hours. Space does not permit a detailed discussion on this large subject, but my impression is that in America and Canada they are beginning to consider that the small number of unsuspected cases discovered does not justify the cost in medical man hours or money. In my opinion, Dr. Walter and his colleague have made one appalling psychological blunder during their experiment. They state: "The word 'cancer' was avoided at all times, if possible, as being in itself a potent agent of distress." It is this policy of hush-hush, particularly on the part of the profession, that is doing untold harm, and is one of the main factors which keeps cancer apprehension in existence, which in turn is the chief cause for the delay in visiting a doctor.

The statement that "the Ministry of Health, in a recent circular, considers public propaganda inadvisable at present" may lead to misinterpretation as to the desire of the Ministry. As I understand the position, the Ministry feels that the time has not yet arrived for the Ministry itself to carry out a nationwide campaign, but that public propaganda (education is a better term) should be carried out by each individual local health authority, using its own methods.

Mr. R. M. Vick also published an article in the same number of the *Journal* (p. 660). He kindly sent me the full report in which, in the case of cancer of the breast and uterus, he correlates the five-year survival rate with the stage of the disease and the delay in seeking advice. A careful study of these figures—space does not permit of the reporting of the calculations—suggests that if all accessible cancers were treated immediately the symptoms were first noticed (a quite impossible achievement) it would be found that the disease was present in all four of the recognized clinical stages, but that in reality there would be three types of clinical stage I, depending on the rate of growth: (a) those that had already disseminated; (b) clinical stage I about to disseminate; (c) those clinical stage I, slow-growing, well-differentiated growths of which there were still 147 in Mr. Vick's series at one year or more after symptoms had been noticed with a five years' survival of 59.8%. It is the clinical stage I (b) type that education hopes to get treated at once, but what proportion of that type exists at present quite unknown; indeed, it is unknown in what proportion the various stages are represented at the time symptoms are first noticed. Mr. Vick's figures record the delay 0-3 months, but if sufficient figures of delays 0-1 month, with the correlated "stage" and five-year survival rate, could be obtained, then some clue might be forthcoming as to the proportion of the various stages likely to be found when the disease is first noticed, and some idea of how many lives might be saved by cancer education could be calculated. It should be noted that in Mr. Vick's figures, taking all stages, the five-year survival rates fell from 52% with delays of 0-3 months to 37.6% with delays of one year or longer.—I am, etc.,

York.

MALCOLM DONALDSON.

SIR.—The article on March 12 (p. 627) entitled "Early Cancer Detection" by Drs. J. Walter and E. C. Atkinson gives rise to a most disturbing line of thought. Eight hundred and thirty-seven patients were examined to detect early cases of carcinoma; this examination was full and painstaking, and in this examination only one or two new cases were found. Yet in the next year and a half, in that same series, eight cases of carcinoma occurred.

On the surface there does appear to be justification for the line of thought that the examination and warnings given to the patients gave rise to an alarming increase in the incidence of cancer. The figure of 2 in 837 is in line with the figures given in the same issue of the *British Medical Journal* in the article "Progress in Cancer Registration" by Mr. Reginald Vick. He has a total of 39,000 cases registered in a population of 2,897,000, or 1 in 700, but the occurrence of eight more cases in the next year and a half is most alarming.

We have no proof and can obtain none that early discovery of cancer results in a decrease in the morbidity rate of cancer. We cannot say that the early investigation and treatment of cancer is not detrimental, and here we have grounds for believing that it is actually detrimental. If we accept, even partially, Selye's stress syndrome theory we must accept that stress causes imbalance of the hormones. We treat carcinoma with large doses of hormones. Is there a connexion between the stress of cancer diagnosis and treatment, and the morbidity of cancer? When a new drive to diagnose a type of carcinoma commences the morbidity rate rises to a surprising extent and later wanes; this is exemplified by the recent rise in cases of lung carcinoma, and the fall in cases of uterine growths, in this area.

These statements are not put forward as a reasoned argument but as foundation for thought. But the fact remains that, when 837 patients were carefully examined, only one case of carcinoma of the breast and one minor rodent ulcer of the face were discovered, but that within 18 months of this examination eight fresh cases had occurred (of which three died). To the unbiased observer such examination does seem to be a very uncertain procedure.—I am, etc.,

Pertworth, Sussex.

W. A. BALL.

Treatment of Pulmonary Tuberculosis

SIR,—Dr. T. W. Lloyd (*Journal*, February 26, p. 538) thinks that the time has come to abandon pneumatic treatment (pneumothorax and pneumoperitoneum) in favour of prolonged chemotherapy, while Dr. T. V. R. Philip (*Journal*, March 12, p. 665) still finds the former methods useful and points out some of the disadvantages of prolonged chemotherapy. Dr. J. F. Brailsford (p. 665) appositely draws attention to the outstanding importance of building up and maintaining resistance to the disease by good nutrition and hygienic ways of living. These various views are of interest, but they deal with isolated points and do not reach the heart of the problem. This is that treatment need no longer be empirical, but can be reasoned out and its effects studied, not in a vague way for the disease in general, but specifically for each of its two types and four forms, by taking into account their distinctive natural histories. The first step, therefore (which cannot be dodged), is to make a correct classification of every case according to the type and form of the disease. The second step is to take into account the epidemiological factors influencing infection on the one hand, and acquired resistance on the other. Management of tuberculosis then becomes to a great extent standardized.

It is impossible to judge between the conflicting views expressed by your correspondents as applied to any case without considering whether the case is primary in type and benign or malignant in form, or whether it is secondary in type and fibro-carcinoma or fibrous in form; and also whether the treatment is aimed at controlling the original initial lesion without or with its associated foci. Benign primary disease does not need either chemotherapy or collapse therapy. Malignant primary disease requires prompt and prolonged chemotherapy, and, when by this means the associated foci are healed, the original lesion, whether then visible or invisible, can be controlled better and more cheaply by pneumoperitoneum than by prolongation of chemotherapy. Although cases of malignant primary disease are now infrequent in Britain, they are still quite common in many countries. I recently saw some hundreds of them in South Africa. In this form there is very little fibrosis in the progressive stage to hinder the action of chemotherapy. It is quite a different matter with secondary tuberculosis, where fibrosis is present

almost from the beginning and where it permeates at least the initial lesion to the end. It is the associated foci which are most amenable to chemotherapy, especially when they are fresh. Chemotherapy should be used, intermittently if necessary, to deal with any fresh foci resulting from fluctuating activity, but prolonged chemotherapy is unnecessary and undesirable. Fibrous lesions may be active for a long time and yet inaccessible to chemotherapy. Such cases are best controlled by collapse therapy until acquired resistance can be built up and maintained so strongly that the fibrosis becomes converted into non-active sclerosis.

Some cases, therefore, require "pneumatic treatment" as well as chemotherapy, and all cases should have their acquired resistance maintained at a high enough level to prevent relapse. In an analysis of 2,008 chest clinic cases, in which all forms of existing treatment, singly or in various combinations, had been tried, I have shown in my recent book¹ that the best results were obtained by "rest treatment" alone in benign primary disease, by rest and chemotherapy followed by collapse therapy (children excepted) in malignant primary disease, and rest, intermittent chemotherapy, and collapse therapy (especially pneumoperitoneum) in both forms of secondary disease.—I am, etc.,

MILOSH SEKULICH.

Oesophageal Atresia

SIR,—Mr. E. R. Lecutier's description (*Journal*, March 12, p. 647) of haematemesis occurring in a case of oesophageal atresia, where the fistula from the lower oesophageal segment into the trachea was of a considerable size, prompts me to mention a case of oesophageal atresia I had under my care 2½ years ago.

In June, 1952, a baby boy was admitted to the department of thoracic surgery at the Leeds General Infirmary when he was 11 days old. He was born in a small maternity home. His doctor noticed that he was unable to swallow his saliva and choked when an attempt was made to feed him. A paediatrician was consulted, who suspected the child had oesophageal atresia, but he was surprised to find that he was able to pass a catheter down the child's mouth into the stomach without much difficulty and aspirate gastric contents. A few ml. of water were introduced into the stomach and the catheter withdrawn. Atresia was therefore considered impossible. Further attempts at feeding all failed; the catheter was passed again without difficulty and more fluid introduced into the stomach. The child continued to deteriorate, so he was transferred to the Leeds General Infirmary, where an x-ray revealed a blind upper oesophageal segment. Bronchopneumonia was present in both lungs due to inhalation of attempted feeds. At operation, when the child was 11 days old, a wide lower oesophageal segment was found entering the posterior wall of the lower end of the trachea. It was detached and anastomosed to the upper segment. The child survived and has continued to thrive. He can eat anything, but he has bronchiectatic changes in his right upper lobe following the lung infection.

I know of no other case of oesophageal atresia where it has been possible to pass a catheter into the stomach via the trachea and aspirate gastric contents. It is surprising that this child did not have acid digestion of its bronchial mucosa in the presence of such a large oesophago-tracheal fistula.—I am, etc.,

Leeds.

GEOFFREY H. WOOLER.

Sudden Death in Labour

SIR,—I was interested to read the letters commenting on my report (*Journal*, January 8, p. 87) of "Sudden Death in Labour Following Penicillin Injection." In view of the suggested diagnosis of amniotic fluid embolism, or amniotic fluid infusion, I would add that one relevant finding was that the uterus was intact and the membranes ruptured only at the cervix. I realize that this does not exclude amniotic fluid infusion, but in the cases reported, where the membranes had ruptured at the normal site, there was overaction of the uterus, forcing the fluid into the cervical vessels. Reid *et al.*¹ state that the usual sequence of events in amniotic

fluid infusion is premature rupture of the membranes, vigorous labour, cyanosis, and anoxic convulsions. In the case I reported the uterus was not hypertonic, the contractions were, in fact, weak, and the uterus relaxed normally between contractions. She was not at any time given "pitocin."

I agree that the time element is against the diagnosis of penicillin anaphylaxis, but the absence of an overactive uterus is surely against that of amniotic fluid infusion. Histology of the lungs would, of course, have been conclusive in the latter case, and I regret that I am unable to give further details of the necropsy. The post-mortem report was loaned to me by the coroner and contained no histological data.—I am, etc.,

Palwal, Punjab, India.

P. E. CAMPBELL.

Natural Childbirth

SIR,—I was very interested to read Dr. Constance Beynon's (*Journal*, February 19, p. 475) and Grantly Dick Read's (*Journal*, March 5, p. 604) letters, and feel that as I have very recently gone through a series of classes during pregnancy to prepare me for "natural childbirth" I can give a true and tried viewpoint of this subject, which at least one of the above-mentioned cannot.

Under the eager supervision and with the enthusiastic encouragement of my husband (a G.P.), I most diligently went to weekly relaxation classes, where I and a band of other pregnant women were given exercises and instructive talks on the processes taking place within us by a most competent instructress. I carried these out to the best of my ability daily in my home. I read a great deal of the available literature, and so enthused did I become in this subject that I preached to the unconverted and rounded up many more mothers-to-be for the classes. I felt I had got it down to a fine art, and I awaited childbirth in a completely happy, relaxed, and elated frame of mind. I admitted myself to hospital in this state and contentedly awaited events.

Let me state categorically that a great deal of what I was taught to do was physically impossible in labour, and much of what was possible one hadn't the inclination to do at that time. It is one thing to do these "exercises" on the floor of the local welfare centre, and quite another to try to do them in labour. Furthermore, I found that so becalmed and relaxed and optimistic of the easiness of childbirth had I become that I was totally unprepared for the really serious and hard business involved. I am afraid, therefore, that after being Dr. Grantly Dick Read's most ardent and loudest fan I can now say that Dr. Beynon summarizes my thoughts. I have changed to her way of thinking merely by attempting to put into practice the theories of Dr. Grantly Dick Read. The point is: is it worth having one's morale high in pregnancy, only to be battered in labour, and very low post-natally? I would add that I have checked my reactions with quite a few other recent mothers, all former advocates of Dr. Grantly Dick Read's teachings, and in each case my own experience was confirmed.—I am, etc.,

Harold Wood, Essex.

CONSTANCE LYNN.

Salicylates in Anticoagulant Therapy

SIR,—In considering the treatment of a patient with coronary thrombosis in general practice, I have often wondered if there is not some safer form of anticoagulant therapy which could be instituted in the home without the constant vigil of the clinical pathologist.

In this respect I would like to make a suggestion the efficiency of which perhaps may not approach that possible in hospital, yet, weighed against the risk of transfer to hospital, may be at least a step in the right direction. It is well known that salicylates lower the level of plasma prothrombin and so reduce coagulation time. So far as

I can see there are very few contraindications to the administration of salicylates to patients who must be nursed at home. Perhaps one disadvantage would be the fact that the drug administered as sodium salicylate would increase the plasma volume by virtue of the sodium ion. This difficulty may not be completely overcome by administering the drug in the form of the acetyl derivative, since much of this would be converted into sodium salicylate before absorption. Anyhow, this disadvantage would be important only in the case of the larger infarcts associated with cardiac failure, and in all other cases it is reasonable to suppose that the anticoagulant effect would far outweigh the effect of the increased circulatory volume.

I would be extremely interested to hear comments on this therapy.—I am, etc.,

Wembley.

M. H. SINGER.

Primary Aldosteronism

SIR,—I wish to congratulate Dr. J. W. Conn (*Journal*, December 11, 1954, p. 1415) on his fine clinical achievement in reporting to the Central Society for Clinical Research in Chicago (October 29, 1954) the paper in which he characterized a new syndrome in endocrinology: primary aldosteronism. Since I have been referred to in Dr. Conn's letter I would like to make some additional remarks.

First of all, an increased production of aldosterone (at that time called electrocortin) in the patient suffering from a so-called "potassium-losing nephritis" was first reported by Dr. C. L. Cope and myself (patient Mrs. A) in the *Journal* (June 5, 1954, p. 1290). At the time that paper was sent for publication I—and I want to emphasize that this is my personal opinion, as I do not want to commit Dr. Cope in what I am going to say—was not aware of the possible significance of the fact. At the beginning of 1954 I moved to New Zealand and I proceeded with my experiments on the excretion of aldosterone after surgical trauma. It is a very well known fact that all relatively major operations are followed by a loss of potassium. As a result of my experiments I have been able to report in a preliminary communication to the Otago Medical School Research Society (October 21, 1954)¹ that the loss of potassium and retention of sodium which follows an operation are associated with an increased excretion of electrolyte-regulating corticoid, statistically highly significant when compared with the pre-operative level, and that, what is still more interesting, the increased level of this corticoid returns to its pre-operative level when the urinary electrolyte values in the operated patient recede to the pattern before operation (unpublished data).

These findings seem to prove that a hyperproduction of aldosterone is a constant feature after operation, when electrolyte alterations are present. Thus at the time I obtained these results I fully realized the significance of the increased excretion of aldosterone in the patient Mrs. A. In the middle of August, 1954, I wrote a personal letter to Dr. M. D. Milne communicating to him the result of my experiments in the surgical field, telling him my conviction that the main trouble in Mrs. A's case was hyperproduction of aldosterone, and suggesting to him to re-study the patient according to this line. What Dr. Milne thought of this suggestion I cannot ascertain, but as far as I know the study was not carried out, as in the otherwise most interesting paper by Miss B. M. Evans and Dr. M. D. Milne (*Journal*, November 6, 1954, p. 1067) "no further comment was made upon this finding," to quote Dr. Conn's own words.

Another case reported as of unknown cause, which I undoubtedly believe must be considered as primary aldosteronism, has been mentioned by Dr. M. Taubenhaus, of Chicago.² To my knowledge the first detailed clinical description of a case of this peculiar condition is due to Kjerulf-Jensen, Krarup, and Warming-Larsen.³ Although they stated that the excretion of corticoids was rather low in their patient, aldosterone was not known at that time (1951), and, further, this steroid has such a surprisingly strong activity in very minute amounts that, even when

excreted in sufficient quantities to produce biological disturbances, its presence does not influence the total amount of urinary corticoids.

I am not writing in order to claim any priority at all in the description of the syndrome of primary aldosteronism, but, first, to afford some data—hidden from the limelight—which later on, when the importance and frequency of this fascinating syndrome are fully appreciated, may help to record the successive steps which have led to the establishment of primary aldosteronism as a clinical entity; and, secondly, to make it clear that at least someone amongst the clinical and research workers involved in the case reported by Miss Evans and Dr. Milne became fully aware of the significance of the increased excretion of aldosterone in that case as early as the middle of 1954. Ethical considerations deprived me of making any comment before Dr. Milne published his case. He has produced an impressive collection of biochemical data in the paper with Miss Evans, but I feel that they have missed the point, indeed the main point. I am very glad that the syndrome has now been fully segregated by Dr. Conn, who has done an excellent piece of work.—I am, etc.,

Dunedin, New Zealand.

Mental Symptoms Caused by Carbronal

SIR.—It might be of interest to note that carbromal, in addition to producing purpuric eruptions as described by Dr. Peter Borrie (*Journal*, March 12, p. 645), may also cause acute and chronic mental symptoms of a non-specific kind.

A number of such cases have been described by G. Magnussen.¹ Reviewing cases of acute poisoning of demonstrable origin, admitted to Copenhagen hospital over a period of one year, he found that carbromal was the third commonest agent responsible.

In a patient seen recently carbromal medication was no doubt a contributing factor to the picture of depressive illness with which the patient presented. She had been taking "persomnia" tablets (which contain carbromal) most days for six to seven months, usually not more than six to eight tablets daily, at one time "a couple of bottles full" within a few days. This produced an acute toxic episode lasting for about two to three days characterized by feeling extremely sleepy, relaxed, muddled, "as if drunk"; her speech was slurred. During the last few months she had become increasingly quarrelsome, irritable, undecided, listless, and feeling depressed—features which Magnussen described in cases of chronic poisoning.

On admission the bromide level of the blood was elevated to 125 mg.%. This finding, as well as the raised bromide level in the C.S.F., is a constant feature of chronic carbromal poisoning and may be also of diagnostic help in cases where skin eruption is the presenting feature. Four weeks after admission her serum bromide had returned to normal and her mental state greatly improved.

It is felt that because carbromal drugs are freely available in this country (as Dr. Borrie has pointed out) its potential dangers should be more widely known.—I am, etc.,

Diet and Coronary Artery Disease

SIR.—I should like to comment on your report (*Journal*, March 12, p. 662) on the meeting at the Royal Society of Medicine. Professor H. W. Fullerton emphasized the importance of increased fat intake in the production of hypercholesterolaemia and its possible influence on atherogenesis, a concept to which I referred in the past in some detail.^{1,2} During the last few years further research into the cholesterol problem has shown that cholesterol is transported by different fractions of the plasma proteins and is kept in solutions by phospholipids. The percentage of total cholesterol

carried by *alpha*-lipoproteins was found to be higher in women under the menopausal age than in men, but it was approximately the same in women and men above 45. In survivors from coronary infarction, however, the *alpha*-lipoprotein fraction diminished markedly and the *beta*-lipoproteins increased correspondingly. Oestrogen administration in patients who survived myocardial infarction increased the *alpha*-lipoprotein fraction and decreased the *beta*-lipoproteins³ and at the same time diminished the total blood cholesterol level.⁴ Withdrawal of oestrogens was quickly followed by re-establishment of the previous conditions.

These blood lipid changes might give some explanation for the well-known male preponderance in coronary disease. There is in fact much to indicate that Paul D. White's "coronary individual" is characterized by physical and mental masculinity, and that the condition of "oestrogenicity" is associated with relative immunity to coronary disease.⁵ The corresponding lipoprotein pattern for the latter would be an increase of the *alpha*-lipoproteins, and this was found indeed in castrates.⁶ Further, in extensive necropsy studies (1) an apparent diminution of coronary atherosclerosis was evident in males treated with oestrogens on account of prostate cancer; (2) a significant increase in coronary atherosclerosis was demonstrated in oophorectomized (hypo-oestrogenic) women; and (3) less atherosclerosis was found in hyper-oestrogenic women suffering from breast cancer than in normal controls.⁷

All these seem to indicate that sex hormones may influence atherogenesis by a mechanism which includes the distribution of lipoproteins in the blood, in addition to other aetiological factors like increased fat intake and hypercholesterolaemia. Whether the disturbance of fat metabolism is a fundamental defect in atheroma formation or only secondary to other causes, further histochemical research as outlined by Professor T. Crawford at the meeting may clarify.—I am, etc.,

The Aftermath of Hysterectomy

SIR.—I recently took part in a television programme as a doctor—I am retired—in which the operation of hysterectomy was discussed. The discussion arose after a letter from a viewer in which she said that a surgeon had advised her to have the operation and she had gone into hospital afraid and worried because she really did not understand what was going to be done. She also stated that many of the women in her ward were in the same position.

Arising out of the discussion were further letters. Here is an extract from one: "Three years ago I had my uterus and ovaries removed, and was told on leaving hospital that it would make no difference to my married life. This was very wrong and I have been very worried for almost three years. Recently I had occasion to go to hospital again and on mentioning the matter I was immediately given a course of hormone treatment. This has certainly made all the difference, and I cannot believe the change it has made to my married life. . . . I wonder why in one of the biggest London hospitals this was not mentioned to me after the operation?" Another letter says that the writer had a subtotal hysterectomy and one ovary removed for a large fibroid at the age of 39 years. The letter goes on to say: "Tragically for me, my husband changed completely from a loving and devoted husband to a morose, bad-tempered and, in fact, cruel man almost immediately upon my return from hospital. He moved into a separate room and has stayed there ever since, yet before the operation we were inseparable and devoted to each other."

These letters give one a great deal of food for thought, at least if one is a woman. In the first place, are we doing our duty as doctors if we allow people to be operated on not knowing in the least what the operation involves? If any doctor or surgeon

tells me that patients are too unintelligent to understand, I do not agree. Unless the person is a mental defective, one can explain any operation in simple language with benefit, for a worried patient is not going to recover as well as an unworried one. Then whose duty is it to prescribe hormone therapy for a woman who has had her ovaries removed? If the surgeon does not do so, how is it that the patient's G.P. does not do so? Does it benefit a woman to get rid of her troublesome symptoms if by doing so her whole nature as a woman changes and her marriage cracks up?

Finally, is the husband sufficiently considered in this matter? Does he have the matter explained to him, and is he told that in certain operations, as for instance subtotal hysterectomy, his relations with his wife will not be affected? There is another aspect to this husband question. I know at least one other case when the husband turned completely against the wife after hysterectomy, saying that the idea of having intercourse with a woman who had been mutilated by removal of the womb revolted him. A last point: I have been told by a number of women who have had removal of the uterus in early middle age that they suffer the most acute depression after the operation at the times when normally they would have menstruated. None of them had been told of this beforehand. Is there anything to be said for this policy?—I am, etc.,

Dunmow, Essex.

WINIFRED COPPARD.

Treatment of Coughs

SIR.—I have read with interest your leading article (*Journal*, March 12, p. 651) on the treatment of "winter cough." While I must agree wholeheartedly with the necessity for antitussive measures, especially in the chronic bronchitic with cor pulmonale, I feel that the measures outlined are merely an acquiescence in a chronically unfavourable state of affairs. We must do better than that. Many of these cases are, through economic necessity, dragging themselves to work despite the warnings of tired hearts and bodies, and of physicians who find themselves forced to tender advice even though they know it will be unacceptable. Are these cases to be treated with opiates which, while smothering the racking cough, smother the patient also? What is gained by suppressing cough is lost by increasing dyspnoea, retained sputum, constipation, and asthenia.

I admit that I myself prescribe small quantities of tr. camph. co. or syr. codein. on occasion, but with the pharmacological advances which offer us antitussives—for example, "taoryl," "benylin," "becantyl"—which are not fraught with these disadvantages, is it not time that we rid ourselves of the habit of prescribing linct. scill. opiat., m. ammon. chlor. c. morph., etc., except in the most hopeless cases? I must confess that I have not yet had time to evaluate becantyl, but I have for over two years used taoryl with great success in these cases, and many between 55 and 65, and over, owe their continuance of useful work to this drug. I have seen no untoward results whatever, even with maximum dosage. Benylin I have also used, but with less spectacular results.

I must apologize for stressing a proprietary by name, but there is, as far as I know, no analogous preparation. I admit to being biased against "reputed therapeutically equal or analogous results"—to me the proof of the pudding is in the eating, not in the "Cohen category number."—I am, etc.,

London, E.2.

MORGAN D. KAVANAGH.

Lead-poisoning in Children

SIR.—We would like, if we may, to add an amendment to our article on "Lead-poisoning in Children" (*Journal*, February 5, p. 324). We felt that the danger of lead-poisoning should be stressed at an early date, although at the time of writing it seemed unlikely that we would be able to find the source of the metal in Case 2. However, this has now been traced to a repainted cot.

We do not think that it is only children with pica who get lead-poisoning, as it is not unusual for an infant, whether

from boredom or due to teething, to suck the cot side. This is the most probable source of the metal in cases of poisoning in young children, so that the repainted cot may be regarded as a dangerous article.—We are, etc.,

H. B. MARSDEN.

Speaking Up

SIR.—It has long been my opinion that something ought to be done to improve the deportment of medical people who appear on public and lecture platforms. We often hear about the illegibility of doctors' prescriptions, but nothing is said about their behaviour as public speakers. When a good paper is marred, as it often is, by poor delivery, a great deal of the value of the contribution is lost to the audience.

A clear, confident, and well-pitched voice (which does not necessarily mean a loud one) will carry conviction to the audience. Fidgeting movements of the hands (and often legs) are usually the outcome of nervousness and lack of elocutionary experience. It is not to be expected that the medical curriculum, already overloaded in its programme, will cater for possible orators among its trainees. Students and young graduates, however, would find ample recompense for their pains if they were to attend a course of elocution "off the record." The gain to them when the time came for entry into the domain of lectureship or teaching would be inestimable. A feeling of competence to "get across" and create a favourable impression would react immeasurably on themselves and their listeners and facilitate the message they wish to convey.—I am, etc.,

London, W.1.

J. HAMILTON MCILROY.

SIR.—Recently at the Royal Society of Medicine there was a joint meeting of general practitioners and dermatologists. There were about eight speakers on either side. The dermatologists, with perhaps one exception, spoke with hushed voices, as if they were holding a very private consultation which the patient—who was not present—must on no account overhear. The general practitioners, on the other hand, again with perhaps one exception, spoke up and clearly, with refreshing audibility. Let me add that the dermatologists are by no means the only specialists who at their own meetings are inclined to speak in a whispering conversational style as though they were talking to one person only, with no regard for the periphery of their audience. Is it a reflection, carried into the lecture theatre, of the subdued manner of the consultant at his clinic as compared with the free and hearty bedside manner of the family doctor? The explanation is anybody's guess; the fact remains.—I am, etc.,

London W.C.2.

H. COOPER.

Boxing Injuries

SIR.—I am most grateful to you for having published my short note on boxing injuries under "Points from Letters" (*Journal*, January 29, p. 292). In the meantime I came across a publication in the German journal *Die Medizinische* about observations of kidney damage through boxing in 103 American professional boxers during 1952 and 1953.

Urine tests were done and were normal before the fight. Urine tests were done 5 minutes after the fight, and the findings were as follows: albumin in 68%; traces of acetone in 14%; rise of specific gravity in 80%; pH reduction in 39%; glucose in 9%; red cells in 73%; casts (granulated and hyaline) in 26%.

Nothing was known about delayed kidney damage, whilst acute kidney damage was present very often. It was suggested that all ex-boxers should be subjected to medical examination and every boxer should only be admitted to another fight if the urine tests are within normal limits.—I am, etc.,

Advertising by Post

SIR,—Dr. A. K. Jones's letter (*Journal*, March 5, p. 599) about advertisements has drawn timely attention to a problem which is becoming of increasing importance to doctors and manufacturers alike. It is said that our mail from the drug firms weighs about 3 lb. (1.36 kg.) a month, and when one realizes that this goes to every doctor in the country the cost in postage alone seems fantastic (as a source of revenue to the Post Office it must be a rival to the football pools). The manufacturers must realize that a busy doctor has neither the time nor the energy to wade through a pile of advertising literature every morning, so why do they waste their shareholders' money sending them? Surely here is an ideal opportunity for the B.M.A. to do something before the daily flood of pamphlets becomes even more out of hand than it is now. (I believe it is even worse in America.) Perhaps discussions could be held with the Pharmaceutical Society and the drug houses persuaded to make their advertisements more uniform, rational, and rationed. Dr. Jones's suggestion of a card system is excellent (to his list of headings on the card might I add references to relevant articles in the *Journal*, etc.?).

I would like to mention that other form of advertising that afflicts us, the drug-firm travellers. I have nothing against them personally, for they are all models of politeness. But they are quite unnecessary. And, frankly, when one is very busy they are nothing but a nuisance. I feel the firms should ask us by post if we are prepared to receive their representatives. If we do not wish to see them it is rather discourteous to send them. Few of us are rude enough to bang the door in their faces once they have arrived.

Recently I have been wearied by the conflicting claims of rival firms as to the superiority of their own particular brand of oral penicillin. In the long run we must decide for ourselves what is best for our patients, partly from what we read in textbooks and journals, and partly from our own experience. Advertising must be left out of it as much as possible except to give us the basic information about preparations. It would be a good thing if all drug firms had a strict code of ethics and agreed to plague us as little as possible.—I am, etc.,

Penrhyneddudraeth, Merioneth.

CLAUD C. M. WATSON.

SIR,—I would like to support the idea proposed by Dr. A. K. Jones (*Journal*, March 5, p. 599) about postal advertising by means of standard cards. For the past eight months I have been returning the bombardment of the pharmaceutical manufacturers with a pamphlet recommending the same sort of thing—lately suggesting that the most suitable size of card would be that of the N.H.S. patients' record card (E.C. 8) for which most general practitioners already have potential filing space in their surgeries. The response has been much the same as that described by Dr. Jones. Certain organizations do produce index cards, but it would be much more useful if the job could be done through the co-operation of all the manufacturing firms.—I am, etc.,

Walsall.

J. P. LESTER.

SIR,—I, as a manufacturer of medical products, can readily sympathize with the views of Dr. A. K. Jones (*Journal*, March 5, p. 599) on the question of advertising material sent to the profession, if indeed the majority of doctors discard unopened as high a proportion of such literature as he suggests—namely, 90%. Although many manufacturers will doubtless give serious consideration to his suggestion of standardizing the size and style of informative literature, I am not convinced that this is necessarily the solution to the problem, or whether the method would in fact enable the doctor to select any more easily the information on a particular proprietary product he wishes to study.

In their efforts to avoid being included in the unfortunate proportion of discarded literature, many manufacturers are constantly adopting more original techniques of getting their

information over to the doctor in the hope that such will be among the favoured proportion singled out for detailed study. In attempting such an objective, however, manufacturers may sometimes run the risk of incurring disfavour or even annoyance among doctors, and even when occasions arise no one is more full of regret than the manufacturer concerned, as no ethical firm has the wish to disturb the good relationship that has, in general, existed over the years between the industry and the practitioner. It would enable manufacturers to co-operate more closely with the profession in providing the literature required if other doctors would express their views on the question of standardization of size and style as suggested by Dr. Jones.—I am, etc.,

London, E.1.

Chairman and Managing Director,
Harker Stagg Ltd.

Nasal Catarrh and Electric Razors

SIR,—I feel it is worth putting on record an unusual case of allergic rhinitis. The patient was a man of about 50 who suddenly developed the most distressing nasal catarrh, for no obvious reason. He went for a cruise to Madeira, and noticed that while he was symptom-free on the boat he was just as bad whilst there and on returning. At this point he noticed a large amount of dust in the nasal secretion after using an electric razor, and realized that he had been unable to use it on board ship. Also, looking back, it was at the time of starting to use this method of shaving that the symptoms were first noticed. Since reverting to soap and a razor he has been quite well.—I am, etc.,

Hitchin, Herts.

A. S. PORTER.

Cases of Pentosuria, Cystinuria, and Alkaptonuria

SIR,—My colleagues and I are investigating the population genetics of three rather rare metabolic disorders: pentosuria, cystinuria, and alkaptonuria. We would be very grateful if general practitioners and consultants could put us in touch with any patients known to have any of these disorders.—I am, etc.,

London Hospital Medical College,
Turner Street, London, E.1.

H. HARRIS.

Muscular Dystrophy Group

SIR,—The Central Council for the Care of Cripples has decided to form a group or association of patients suffering from muscular dystrophy, and has already found that there is considerable interest in such a development, particularly among the patients and their parents. Numerically the problem is not a large one, but the people concerned are often isolated, and it is the Central Council's intention to establish a friendly link; to provide interest and amusement for the children; and to distribute leaflets of general information to parents, members, and others.

It is beyond dispute that research is of paramount importance, and your readers will agree, we feel, that there can be no firmer basis on which to develop the work which is contemplated than through the advice and support of the many distinguished neurologists and other specialists who have accepted appointment to the Medical Advisory Committee which the council has set up.

The chief difficulty from the Central Council's point of view as a voluntary society is to find the people it wishes to help. Nevertheless, ascertainment of the extent of the problem is an essential if real progress is to be made. I am therefore writing to ask anyone in sympathy with this movement to put their patients or others known to them in touch with the Central Council for the Care of Cripples. I must emphasize that the group will remain within the aegis of the council, which intends to use its existing county associations rather than to superimpose a new organization.—I am, etc.,

34, Eccleston Square,
London, S.W.1.HARRY PLATT,
President, Muscular Dystrophy Group,
Central Council for the Care of Cripples.

Obituary

C. J. A. WOODSIDE, M.B., F.R.C.S.I.

Mr. C. J. A. Woodside, senior surgeon to the Royal Victoria Hospital, Belfast, and to the Craigavon Hospital, Belfast, died suddenly on February 14 at his home at Belfast. He was 60 years of age. Born at Ballymena, Co. Antrim, Cecil John Alexander Woodside was educated at Ballymena Academy, Campbell College, and Queen's University, Belfast, where he graduated M.B., B.Ch., with first-class honours in medicine, and with the award of an exhibition in 1917. He then received a commission in the R.A.M.C. and served abroad, being demobilized in 1919 with the rank of captain. On returning to civilian life, he became house-surgeon at his teaching hospital, and, later, surgical registrar, a post which he held for a number of years. In 1925 he obtained the Fellowship of the Royal College of Surgeons in Ireland. Though he took an active part in clinical surgery, he always maintained an interest in the academic side. After two years as demonstrator in anatomy at Queen's University, he was appointed as assistant to the lecturer in operative surgery. He was elected to the staff of the Royal Victoria Hospital in 1933 and was senior surgeon for the past few years. Woodside was a skilful and dextrous surgeon, experienced in all branches of the art, but he had a special interest in urology from the early days of his career, and was a member of the British Association of Urological Surgeons. His administrative ability was put freely at the disposal of his teaching hospital, and after the passing of the Health Services Act in 1948 he assisted the Northern Ireland Hospitals Authority by serving on several of its committees and by acting as chairman of its hospital staffs committee. He was a Fellow of the Ulster Medical Society, and an active member of the British Medical Association for over 30 years. He acted as honorary secretary of the Ulster Branch of the B.M.A. from 1927 to 1934, and was president of the Northern Ireland Branch in 1943-4. A member of the Council of the Association from 1943 to 1947, he also served for a number of years on the old Irish Committee (later, the Northern Ireland Committee) and on the Central War Emergency Committee.

Of a shy and retiring disposition, Woodside's main interest was in his profession, but he sought his recreation in literature and art. He was held in great admiration by colleagues and patients, and the Royal Victoria Hospital and all associated with it are the poorer for his passing.

AGNES C. SCOTT, C.B.E., M.B.

Dr. Agnes Scott, formerly chief medical officer of the Women's Medical Service in India, died at the Hostel of St. Luke, London, on March 22. She was 79 years of age.

Agnes Catharine Scott was born on October 26, 1875, the second daughter of Canon John Scott, and was educated at Leeds Girls' High School and at the Yorkshire College, now the University of Leeds. She then entered the London (Royal Free Hospital) School of Medicine for Women, in order to equip herself for work as a medical missionary, and obtained her M.B. in 1901. After graduation she was obstetric assistant at the New Hospital for Women (now known as the Elizabeth

Garrett Anderson Hospital) and then went to India in 1903 to work at St. Stephen's Hospital for Women in Delhi under the Cambridge Mission. A few years later she was posted to the hospital at Karnal under the same mission, but returned to Delhi to superintend the building of the new St. Stephen's Hospital, of which she was subsequently in charge. The call for an experienced medical woman in the Punjab made her decide to enter the Women's Medical Service, and she went to Lahore as assistant to the inspector-general of civil hospitals in 1917. She remained in that post until 1923, and in the following year succeeded Dr. Margaret Balfour as chief medical officer of the Women's Medical Service. She left India in 1932, but continued to work until 1939 as medical adviser to the Countess of Dufferin's Fund at the India Office in London.

Agnes Scott was peculiarly fitted by her early experience for the important work she did later. She had been in charge of a small hospital in a country town (Karnal), had superintended the building of a large (for those days) hospital in the capital of India, and had been superintendent of this hospital. Her own experience in running two different types of hospitals enabled her to grasp the needs of such hospitals in personnel, equipment, and methods of working. All this knowledge was put to very good use in both the posts she held after leaving the service of the mission. She was also much interested in the training of midwives, and forwarded this good cause in India with wisdom and sympathy.

When she became chief medical officer of the Women's Medical Service, Agnes Scott became also a member of the council and executive committee of the Lady Hardinge Medical College, then still a young institution, and it fell to her to staff the college from the cadre of the Women's Medical Service. This was no easy task, since there were few specialists available in those days. Partly in order to meet this difficulty and partly because she wished to increase the number of Indians in the service, she instituted a training reserve. Young doctors who had been educated in India were admitted to this reserve, and after proving themselves suitable by working as assistants in the larger hospitals for women they were sent to the United Kingdom with scholarships for further training. This enabled promising young women to gain additional experience and higher qualifications, thus fitting them for responsible posts on their return to India. The scheme was a noteworthy contribution to the training of Indian medical women for work in India.

Agnes Scott was of a quiet and reserved nature, but her reserve hid a very warm heart. Though the officers of the Women's Medical Service may have found her a little awe-inspiring during inspections, they recognized the wisdom behind her advice, her strong sense of justice, and her appreciation of all work faithfully performed, sometimes in loneliness and difficulty. To the end she retained her interest in medical missions and was chairman of the medical mission committee of the Society for the Propagation of the Gospel from 1937 to 1947. She was awarded the Kaisar-i-Hind gold medal in 1926 and was appointed C.B.E. in 1931.—R. Y.

Dr. G. H. H. MANFIELD died at Nottingham General Hospital on March 17 at the age of 77. George Herbert Hind Manfield was born at Ixworth Thorpe, Suffolk, on July 24, 1877, and was educated at Framlingham College and at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. After holding a number of house appointments he

went into general practice at Shenstone, Staffordshire, where he soon acquired a reputation not only as an excellent doctor but also as a horticulturist, a tennis player, and a keen captain of the local cricket club. His slight lameness had prevented him from being accepted for Guy's Hospital Volunteers, but when the first world war broke out in 1914 he joined the R.A.M.C. and served in France, being awarded the Military Cross for gallantry in 1916, and in Salonika. In 1919 he returned to Guy's for a year, and then worked for the Ministry of Pensions at Derby and Nottingham, finally taking over a practice at Nottingham, where he remained for 32 years. For more than half that time he was honorary surgeon to the Nottingham and Notts Hospital for Diseases of the Throat, Ear, and Nose until its amalgamation with the General Hospital under the National Health Service. Despite the increasing strain of a growing practice and service on numerous medical boards during the second world war, he continued to display the same energy in his work as always. Service to others was the keynote of his life.

The obituary of Professor PETER PATERSON was printed in the *Journal* of March 19 (p. 735). Mr. DAVID RANKINE writes: Many of his old students will have learned with sorrow of the death of Peter Paterson—a born surgeon if ever there was one, and an enthusiastic teacher. He took a very keen and personal interest in any student who himself was keen, and he was always delighted to have his ex-students visit him. True he might greet one with such a quotation as "The dog that was sick has returned to his vomit and the pig that was washed to its wallowing in the mire," but this was but an aspect of his kindly humour. He was impatient with humbugs, and would say that he would prefer a student to give a wrong diagnosis with good reasons than a right one with no reasons at all. For years the third floor in the Glasgow Royal Infirmary was a by-word under the regime of Peter Paterson, and the late Milne McIntyre—both of whom will be ever remembered by us of their time.

Medico-Legal

DAMAGES FOR HOT-WATER BOTTLE BURNS

Damages of £770 with costs were awarded to George Brown, aged 46, a North Staffordshire butcher's assistant, who alleged at Stafford Assizes on March 21 that he was burned on the leg by a hot-water bottle when being rushed to hospital in an ambulance after an accident at his work in January, 1953. Brown claimed damages from Staffordshire County Council alleging negligence.

He told the court that while working in a Newcastle butcher's shop his knife slipped and pierced his right groin. He fainted, but remembered being in the ambulance with a burning pain in his legs. He was unable to speak. In hospital he could still feel the pain in the calves of his legs. When he regained consciousness after an operation his right leg was bandaged near the calf, and two or three days later another burn was found on his left leg. He had had treatment for the burns for six months after the accident and went back to work on June 20, 1953.

In answer to Mr. Norman Carr, for the defendants, Brown agreed it was vital to rush him to hospital in order to save his life. Also for the defendants, ambulance driver G. E. Roberts said that he had been told that the bottles had been filled by the previous shift at 1.30 p.m. The call to go to the plaintiff was received about 2.50 p.m. When the bottles were applied they had covers and Brown was wearing trousers and socks. Another ambulance driver who attended the accident said that during the journey to hospital Brown told him he was cold, but said nothing about being hot.

Giving judgment for Brown, Mr. Justice Hilbery said there was no doubt that one of the hot-water bottles applied

was so hot as actually to burn the plaintiff's right leg badly and his left leg less so. While he was satisfied the bottle was covered, the Judge added that if a hot-water bottle seriously burned a patient unable to look after himself it was impossible to say sufficient care had been taken. A scar left by one of the burns, he said, might reopen at any time.

The Judge refused an application for a stay of execution pending consideration of an appeal.

Medical Notes in Parliament

EFFECTS OF RADIOACTIVITY ON MAN

The concern that has been increasingly expressed, in Parliament and outside, about the possible effects on mankind of radioactivity released in thermonuclear experiments was concentrated into a motion and an amendment which were debated in the House of Commons on March 22.

The motion, signed by Dr. EDITH SUMMERSKILL (Fulham, West, Lab.) and six other women Labour M.P.s, urged on the Government the need for further consideration of the long-term effects of nuclear explosions, expressed fears about the dangers facing humanity from continuing radioactive contamination of the atmosphere, and pressed for a conference of American, Russian, British, and French scientists—as suggested by Mr. Attlee in the recent defence debates.

The amendment was the Government rejoinder to this, and was moved by the Minister of Health, Mr. IAIN MACLEOD. It placed the first importance on efforts to achieve comprehensive disarmament, and welcomed the Government's decision to continue and expand research on the medical and biological aspects of nuclear energy, and to collaborate by every practical means with countries with whom arrangements already existed or who could usefully be brought into consultation. His assessment of things, based on expert advice, seemed to be summed up in the observation that at present levels of irradiation it seemed improbable that there was anything more than an interesting basic scientific problem and a situation that must be watched very carefully.

Radiation Effects Cumulative

Dr. SUMMERSKILL said that man had invented a lethal weapon the properties of which offered a threat to the procreative powers of women. If that was proved conclusively, and the evidence so far filled them with the gravest misgivings, the instinctive aversion to fighting which prompted every normal woman might find world-wide expression.

She had no intention of making sensational statements about the genetic effects of experiments with the hydrogen bomb. Her desire was to convince the House and the Government that there was a *prima facie* case for an examination of the whole problem by scientists of the highest repute. The Prime Minister had recently quoted the United States Atomic Energy Commission report that the amount of radiation so far released by nuclear explosions was no greater than that to which a patient having an x-ray of the chest was exposed. But they overlooked the fact that the effect of radiation in the atmosphere was cumulative. It was wrong to talk about permissible levels of radioactivity, because uranium and radium were found all over the earth, and any addition to the existing store of radiation might be responsible for an increase in the incidence of some disease. Some scientists were of opinion that here might lie the key to the development of cancerous growth, which so far had baffled research workers.

There had been 65 nuclear explosions so far—50 American, 12 Russian, and 3 British. Scientists were expressing the opinion that these explosions could not continue without the danger of serious damage to health. The

professor of biophysics in the Medical School of Osaka University had reported, after examining the people exposed to the Bikini test explosion of March, 1954, that the most seriously injured fishermen had their blood-forming function seriously impaired and their reproductive organs seriously affected. In some of them the number of sperms was 100 to 700 per cubic millimetre compared with the normal 50,000 to 100,000, and in addition there were abnormal types of sperm. There was evidence that a pregnant woman who was exposed to only a moderate dose of radiation ran the risk of aborting or giving birth to a stillborn child.

The danger that lurked in the fall-out of radioactive particles after nuclear explosions was serious; they could be blown for thousands of miles, and they might remain active for years. It was said that radiostrontium could fall out at great distances and later could be eaten—through being in vegetables—by humans and by grazing animals, which in turn provided human food. Bone had a special attraction for radiostrontium, and the human foetus was highly sensitive to radiation. It was therefore argued that the foetus might be destroyed through milk obtained from cattle which had grazed in infected grass. Mr. Strauss, chairman of the U.S. Atomic Energy Commission, had sought to be reassuring, but he could not prophesy what would happen in a hydrogen bomb war, when abortion and stillbirths might become almost universal. Lord Adrian, one of Britain's most famous scientists, had said that such a war might "lead to a degree of radioactivity which no one can tolerate or escape, and thus end the human race."

A Permissible Level?

Mr. MACLEOD, who described the subject as a strange and difficult one to debate, had armed himself with the best advice he could get, and, while acknowledging that what he said must be the responsibility of the Government, claimed that it would not be in conflict with the views of the Medical Research Council and its committees, which had been considering the matter for eight or ten years. Comment and controversy had been caused by the pronouncement of the United States Atomic Energy Commission that the total amount of radiation received by people in the U.S. from all nuclear detonations so far—Russian and British included—was about 0.1 r, or about one-hundredth of the average natural exposure during a person's reproductive lifetime. British calculations, derived from monitoring measurements taken by the Atomic Energy Authority, showed that the figure here would be about one-third of the American figure. Even this figure of 0.03 r was artificially high, because it assumed that a man stood outside in the open for 24 hours a day for about 50 years (to the extent that he was indoors or under cover the figure would be greatly reduced), and that none of the activity weathered away from the surface of the ground, which of course would happen. The effective average dose received by someone in this country from all the bombs so far exploded was therefore a great deal less than 0.03 r.

The real question was—What level is permissible? What is the threshold of radioactivity beyond which man's genetic constitution might stand at risk? The accepted international dose for workers on radioisotopes and radiologists was 0.3 r a week, or about 15 r a year. That was enormously greater than the figures they had been discussing; but it was also fair to point out that in a whole community the number of genes at risk was enormously increased, and therefore the number of matings that might conceivably be harmful was also considerably increased. The more he went into the subject the more he found that the scientists disagreed. Estimates of the dose of radiation over a generation that was likely to double the spontaneous mutation rate varied from 3 r to 300. He was told that a figure of 50 r over 25 years was as good a guess as could be made. The increase in the United States had been only a tiny fraction of this, and in Britain it had been much smaller still. Perhaps that would bring a little comfort and a sense of balance.

A great deal of research went on in the M.R.C. unit at Harwell, and there were other institutions at Hammersmith Hospital and in Leeds. The work was being supported in many university departments. The M.R.C. expenditure for work in its own establishments on all aspects of the effects of radiation was £208,000 in the provisional estimates for 1955-6. He was authorized to say that if the Council, after examining its research programme in the light of this new commitment, reported that an increase in its expenditure was essential this would have favourable consideration from the Chancellor of the Exchequer.

He summarized his argument in four conclusions: (1) radiation produces genetic effects, and the radioactivity of the planet has slightly increased as a result of nuclear bomb explosions; (2) present knowledge is insufficient to fix at all precisely the level of radioactivity above which genetic damage would significantly affect the well-being of populations; (3) research in genetic changes is inevitably slow; (4) it most unlikely that the increase in radioactivity which has occurred so far will have any appreciable genetic effect.

Finally he expressed the Government's doubts about the two current suggestions being canvassed—the proposal for a scientific conference; and the extension of the agenda for the international conference at Geneva in August to explore the benign and peaceful uses of atomic energy. He asked the House to support the Government in seeking the extension of the methods of collaboration which already existed. In medical knowledge and information these were reasonably full and satisfying, and it was hoped to see them extend into other spheres. There had never been a power which at the same time held such possibilities of doom or bright hope. The Government accepted the responsibility to tell the country all the facts that could properly be disclosed, and in the defence debates they had done that.

Among the nine other speakers, of whom six were women, Mr. WALTER ELLIOT (Glasgow, Kelvingrove, Con.), claiming his qualification as a certified midwife, suggested that a White Paper embodying and perhaps extending the facts given by Mr. Macleod—the *ipsissima verba* of the scientists instead of the Minister's quotations from them—would be useful. There was no need to bother too much about the effect of atomic war on the genes of the human race a thousand years hence. The damage would be much more immediate to the bone marrow and its blood-forming cells than the later effect on the reproductive cells. Miss ELAINE BURTON (Coventry, South, Lab.), concluding the debate for the women, took the Minister to task for the inhuman statement that this was an interesting scientific problem. The objections to a conference she regarded as the negation of doing anything. A conference might help eventually to bring about disarmament. The Minister of Works, Mr. NIGEL BIRCH, in the final speech, added the information that there was no danger of radioactivity from the use of atomic power for civil purposes. Such radioactive materials as were emitted were very weak and their effect was not cumulative.

The motion was rejected by 290 votes to 250, and the amendment agreed to.

Research in Britain

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) on March 22 asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, what official research was being conducted in Britain on the effects of radioactivity on reproductive cells; and to what extent this research was being conducted on mammals. Mr. J. R. BEVINS told him that a large programme of research on the effects upon the germ cell of exposure to radiation was being undertaken at the Medical Research Council's Radiobiological Research Unit at Harwell, and related studies were in progress at several other establishments of the Council. Most of the work was carried out with mice.

Dr. STROSS asked what research had been conducted into the danger threshold beyond which the radioactive contamination of the atmosphere might damage mankind's genetic

constitution. Mr. BEVINS said that the M.R.C. programme of research on radiobiology aimed at extending knowledge on all the hazards which radiation might hold for human beings. There was, however, no way at present in which direct evidence of genetic damage to human beings from radiation could be obtained.

Mr. W. WELLS (Walsall, Lab.) asked the Minister of Defence on March 23 whether he would arrange for experiments to test the uses of smoke in counteracting the effects of nuclear and thermonuclear explosions. Mr. H. MACMILLAN stated that experiments had already been started under the authority of the Minister of Supply, the results of which would be of interest both to Civil Defence and to the Services.

Rising Standard of Living

Mr. HEATHCOAT AMORY, Minister of Food and Agriculture, put up to answer a detailed arraignment of the Government on March 23 for their management of the national housekeeping, claimed that the standard of living was higher than it had ever been.

Mr. F. T. WILLEY (Sunderland, North, Lab.) produced a catalogue of price increases to support his case that the Tory policy had resulted in the food trades becoming a profiteers' paradise.

Mr. AMORY admitted an increase in the cost of living, but between 1949 and 1951 prices rose on average slightly over 6% a year, and wages rose on average by 5½%. Between 1952-4 the average increase in prices was a little over 3% a year, and the average increase in wages by 5% a year.

Food accounted for about 30% of total private expenditure. In terms of calories, the consumption per head was at the rate of 3,120 a day, the highest figure ever recorded. The diet of the nation was more palatable and more nutritious. More of the calories were being obtained from meat, and less from bread and other starchy foods. In 1954 the country ate 50% more meat, 30% more bacon, and 15% more sugar, and drank 20% more tea than in 1951. It was significant that even in cases where some foodstuffs had increased sharply in price, as for tea and home-killed meat, consumption had increased. In 1954 the nation spent £49m. more on sweets and ice-cream than it spent on milk and £130m. more than on bread. Consumption of sweets was 7 oz. a head before the war, and 8.5 oz. in 1954. The B.M.A. figures recorded the diets of pensioners as being adequate both in energy value and in all the important nutrients.

Diminishing Demand on Swiss Sanatoria

The impending termination of the schemes for sending tuberculosis patients for treatment in Swiss sanatoria was announced on March 22.

Mr. IAIN MACLEOD, in a statement on the scheme covering England and Wales, said that they began to send patients to Davos in the autumn of 1951, when waiting-lists for tuberculosis beds stood at over 7,000. The provisional figure for the end of 1954 was 2,500, and this of course included a large number of patients who were on the point of being admitted at once. Several hospital regions now had virtually no waiting-list. Some were closing tuberculosis beds or turning them over to other purposes. Well over 900 patients from England and Wales had been sent to Switzerland by the Health Service, and this had been a most valuable contribution to the work against respiratory tuberculosis. But taking into account the diminished pressure to-day on tuberculosis beds at home, and the recent difficulty in finding enough suitable patients who were willing to go to Switzerland for their treatment, he was satisfied that there was no necessity to extend the scheme beyond this autumn, when contracts with the sanatoria expired. Suitable arrangements would be made for winding it up so as not to discharge patients from the sanatoria in Davos before they were fit.

To this announcement he added his thanks, and those of the patients who had been sent, to the Sanatorium Angletterre

and the Park Sanatorium for the welcome they had given and the efforts they had made on the patients' behalf.

Commander T. D. GALBRAITH, Under Secretary of State for Scotland, in a corresponding statement, said that when this scheme began in June, 1951, the Scottish waiting-list for hospital treatment for respiratory tuberculosis, which had reached a peak of over 3,000 in June, 1949, had stood at over 2,000 for five years. Over 900 patients had gone to Switzerland under the scheme, which had thus provided a valuable supplement to Scottish hospital resources at a time when they had been under extreme pressure. It was clear that they could not usefully send any more patients to the Sanatorium Wolfgang, where they had had the use of 70 beds. Most, if not all, of the patients now in that sanatorium would remain there until the time when they would come back to Scotland in the ordinary course. For the present they were continuing to send patients to the Sanatorium du Mont Blanc, where they had the use of 120 beds, which would be sufficient to accommodate all the patients coming forward under the scheme.

Commander GALBRAITH stated in reply to Mrs. JEAN MANN (Coatbridge and Airdrie, Lab.) that the number of staffed beds available for the treatment of respiratory tuberculosis in Scotland had increased from 5,335 at the end of 1950 to 6,098 at the end of 1954. The number of patients awaiting admission had dropped from 2,303 in December, 1950, to 486 in January, 1955.

Thoracic Surgeons

Mr. H. BOARDMAN (Leigh, Lab.) asked the Minister of Health on March 21 how the four surgeons exclusively employed on thoracic surgery in the Manchester Region compared with the number so employed in each other region, and giving the estimated population figures in each case. Mr. MACLEOD gave the following figures:

Region	No. of Surgeons	Estimated Population Mid 1953
Newcastle	6	2,911,200
Leeds	6	3,044,900
Sheffield	7	4,172,700
East Anglia	4	1,462,900
N.W. Metropolitan ..	9	3,874,600
N.E. "	5	3,039,800
S.E. "	6	3,197,400
S.W. "	9	4,620,900
Oxford	2	1,458,000
South-western	7	2,768,200
Welsh	5	2,594,000
Birmingham	8	4,470,000
Manchester	4	4,372,800
Liverpool	6	2,102,600

The figures include surgeons employed at teaching hospitals except in London, as these do not serve any one region. They do not distinguish between whole-time and part-time appointments. In addition, there are in some regions surgeons engaged in thoracic surgery and in other branches of surgery.

Care of the Aged

The House of Lords, at the instance of Lord BEVERIDGE, discussed on March 23 the social and human problems of old age, as noted in the Phillips report. He said that the decay of physical and mental faculties meant that increasing care by others was as necessary in the last years of life as in the first. The change in the age structure meant that whereas in 1901 there were 10 people of working age to every one of pensionable age, the ratio was now three to one, and in 1979 would be less than two and a half to one.

The right policy was to keep elderly people as far as possible in their own homes; but to make the home the right place there must be adequate machinery for discovering the failing strength of old people, which might make a transfer to hospital necessary, before it led to tragedy. There should be some known person in every neighbourhood to whom the need for care could be reported. He criticized

as ludicrously inadequate the 30,000 home helps; and suggested that the industrial life offices might use their money and organization to make it easy for everyone while of working age to pay an insurance entitling them to a place in a home when they came to need it. He also criticized the Government's refusal to spend £1m. for a chiropody service for old people while spending £14m. on cheaper tobacco for them.

Lord WISE, among others, opposed the proposal of the Phillips Committee for raising the age at which pensions should be payable. Lord BURDEN said there were hundreds of elderly people in mental hospitals who were there simply because there was nowhere else for them to go and no relatives to look after them. Lord AMULREE emphasized the necessity of finding out in time when an old person was in need of care and attention. The borough in which he worked had a population of 140,000. In the past six months roughly 200 pensioners aged 60 to 65 had applied for admission to hospital. They were the type who in the old days would have gone into the Poor Law hospital rather than the voluntary hospital. Ninety of the 200 were living by themselves. Fifty of the 90 were living comfortably and well. Forty were living in conditions of dirt, squalor, and neglect that one would not have believed possible in 1955. Many of them were starving, but, having had suitable treatment and rehabilitation, they could again take up some kind of normal life. If the same proportion was applied to the rest of the country there must be an enormous reservoir of human misery.

The Earl of SELKIRK, replying for the Government, said the aim should be to enable the aged to remain at work as long as possible, to keep in their own houses, and to ensure that they never felt that they had no further contribution to make. He agreed that the volume of assistance and domiciliary services was not adequate, but they were expanding, and there were many opportunities for voluntary organizations to take a full part. He had been disturbed by what Lord Amulree and other peers had said, and sought to make it clear that anyone who knew of someone needing assistance, financial or otherwise, should inform the National Assistance Board or the local authority.

Thoracic Surgery.—There are four surgeons in the Manchester region exclusively employed on thoracic surgery, representing 0.91 per million estimated population. The figure is lower than that of neighbouring regions (see table on p. 858) and the national average, and the regional board is arranging to improve it.

Leprosy.—In England and Wales there are 164 notified leprosy patients and two special hospitals for them, one near Redhill (Surrey) and the other near Chelmsford (Essex).

Scottish Doctors' Lists.—The average number of patients on doctors' lists in January, 1955, was 1,976, compared with 2,016 in April, 1953, and 2,152 in January, 1952.

Dental Courses.—The number of courses of dental treatment in Scotland, other than emergency extractions and the supply of dentures, increased from 603,000 in 1951 to 715,000 in 1954.

Ancillary Dental Workers.—No extension of the use of ancillary dental workers in any part of the dental services is possible pending further legislation.

Universities and Colleges

UNIVERSITY OF LONDON

The degree of Ph.D. in the Faculty of Medicine was awarded to A. H. Kitchin, M.B., Ch.B. (St. Thomas's Hospital Medical School), on February 1, and to H. H. Khalil (Guy's Hospital Medical School) on February 15.

UNIVERSITY OF MANCHESTER

The Council of the University has approved the following changes in status of members of the staff, to take effect from October 1, 1955: Dr. J. N. Mills, Senior Lecturer in Human Physiology; Dr. J. E. Kench, Senior Lecturer in Biochemistry in the Department of Occupational Health; Dr. N. W. Preston, Lecturer in Bacteriology; Mr. D. C. Racker and Mr. C. E. B. Rickards, part-

time Lecturers in Obstetrics and Gynaecology; Dr. Alexander Nicol and Dr. Tom Wade-Evans, Assistant Lecturers in Pathology; Dr. Kenneth Bloor, Assistant Lecturer in Surgery; Dr. D. J. Rose, special Lecturer (part-time) in Mental Deficiency (instead of Mental Diseases); Dr. R. M. Young, Assistant Lecturer (part-time) in Clinical Psychiatry (instead of Mental Diseases).

Vital Statistics

Week Ending March 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 839, whooping-cough 1,924, diphtheria 10, measles 29,018, acute pneumonia 980, acute poliomyelitis 13, dysentery 1,816, paratyphoid fever 7, and typhoid fever 2.

Infectious Diseases

The largest variations in the number of infectious diseases in England and Wales during the week ending March 12 were increases of 142 for dysentery, from 1,265 to 1,407, 132 for scarlet fever, from 648 to 780, 43 for whooping-cough, from 1,838 to 1,881, and a decrease of 1,132 for measles, from 26,453 to 25,321.

The fall in the incidence of measles was largely confined to the northern and southern sections of the country, while in the midlands substantial increases were recorded. The largest rises in the number of notifications of measles were 346 in Warwickshire, from 1,774 to 2,120, 239 in Middlesex, from 808 to 1,047, 212 in Staffordshire, from 666 to 878, 167 in Essex, from 1,738 to 1,905, 149 in Lincolnshire, from 328 to 477, and 100 in Hertfordshire, from 195 to 295, and the largest falls were 801 in Lancashire, from 2,924 to 2,123, 786 in London, from 3,412 to 2,626, 444 in Kent, from 1,432 to 988, 343 in Derbyshire, from 1,222 to 879, 149 in Yorkshire West Riding, from 3,886 to 3,737, 118 in Northumberland, from 827 to 709, and 117 in Durham, from 925 to 808. No large fluctuations were recorded in the trends of scarlet fever. The largest fluctuation in the trends of whooping-cough was a fall of 44 in Lancashire, from 211 to 167, 9 cases of diphtheria were notified, being 8 fewer than in the preceding week. The only areas with multiple cases were Plymouth C.B. and Hull C.B. with 2 cases each.

11 cases of acute poliomyelitis were notified, and these were 2 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. Yorkshire West Riding with 3 notifications was the only area with more than 1 case.

The largest rises in the incidence of dysentery were Durham 52, London 49, Leicestershire 40, and Norfolk 30. The chief centres of infection during the week were Lancashire 494 (Blackpool C.B. 108, Oldham C.B. 99, Blackburn C.B. 79, Manchester C.B. 53, Liverpool C.B. 36, Lytham St. Anne's M.B. 18, Royton U.D. 15, Chadderton U.D. 13), Durham 114 (Felling U.D. 28, Easington R.D. 22, Sedgefield R.D. 18), London 113 (Hackney 58, Southwark 11), Northumberland 95 (Morpeth M.B. 23, Newcastle-upon-Tyne C.B. 21, Whitley Bay M.B. 15, Ashington U.D. 13), Norfolk 80 (Norwich C.B. 47, St. Faith's and Aylsham R.D. 13), Leicestershire 76 (Leicester C.B. 58, Wigston U.D. 10), Cheshire 55 (Stockport C.B. 38), Northamptonshire 46 (Northampton C.B. 25, Kettering M.B. 17), Glamorgan-shire 46 (Cardiff C.B. 24, Swansea C.B. 14), Yorkshire West Riding 45 (Leeds C.B. 23), Lincolnshire 35 (Scunthorpe M.B. 26), Nottinghamshire 23 (East Retford M.B. 10), Staffordshire 22 (Stoke-on-Trent C.B. 10), and Surrey 22.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus -----, the

figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 12 (No. 10) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

World Health Day.—The anniversary of the official adoption of the World Health Organization's constitution on April 7, 1948, is being celebrated this year under the slogan "Clean Water Means Better Health." The purpose of World Health Day, 1955, writes Dr. M. G. CANDAU, director-general of W.H.O., in his message, "is to help stimulate understanding of the basic relationship between water resources, health, and civilization itself." Describing the outlook in many Asian countries, Dr. Candau quotes expert opinion as believing that "the sickness rate could be halved by protecting water supplies and providing proper facilities for the disposal of wastes." Turning to the "privileged citizens who can unquestioningly trust the water which flows from their household taps," Dr. Candau bids them remember the army of scientists, laboratory workers, engineers, health administrators, and others whose constant labours make this possible, and to realize their responsibility in avoiding pollution of their natural water reserves.

Mental Health.—Last week there were two meetings in London concerned with mental health. On March 22 the Lord Mayor of London presided at a meeting at the Mansion House to raise money for the Mental Health Research Fund, and on March 24 and 25 the National Association for Mental Health held its annual conference. The Research Fund was founded in 1949 by a small body of professional and lay men and women who believed that mental health and mental illness were not receiving the share of attention in research that their immense importance demanded. At the Mansion House meeting, Sir GEOFFREY VICKERS, V.C., chairman of the Fund's research committee, justified the Fund's separate existence by saying that he thought it wrong, in any field, for research to be dependent on a State source, however well administered; and, secondly, he held that interest in particular fields of research gained by being canalized. The other speakers were the hon. Dr. WALTER MACLAY, Dr. DENIS HILL, and Dr. ELIOT SLATER. It was announced at the meeting that the Fund's first Fellowship had been awarded to Dr. J. D. MONTAGU, of Runwell Hospital, Essex. The annual conference of the National Association for Mental Health, held at County Hall, Westminster, was opened by the Minister of Health, Mr. IAIN MACLEOD. The conference discussed the preventive aspects of mental health work. After the opening ceremony Professor F. A. E. CREW, F.R.S., professor of public health at Edinburgh, gave an address on "Opportunities for Preventive Work in the Health and Education Services." The subjects of the other sessions were "Practical Problems in the Local Authority Services," "New Schemes in Practice," and "Promoting Mental Health in a Local Community."

Industrial Health and Safety Centre.—When the Factory Department of the Home Office was transferred to the Ministry of Labour and National Service during the last war, the industrial museum at 97, Horseferry Road, London, S.W.1, was included in the transfer. The lay-out of this museum has now been redesigned greatly for the better, and many new exhibits added. To mark the revolution that has taken place there the name of the museum has been changed to the Industrial Health and Safety Centre, and on March 22 the new centre was formally declared open by Sir WALTER MONCKTON, the Minister of Labour and National Service. Everything that can be done to safeguard and improve the health of industrial workers is demonstrated at the centre—from first-aid to feeding, from safety in foundries to safety at sea—and different aspects of industrial health will be chosen for special display from time to time. Doctors with an interest in occupational health can be shown round the centre by the inspectors of factories on duty there, or, if a special appointment is made, by one of the medical staff of the Ministry.

Faculty of Anaesthetists Dinner.—Over two hundred were present at the Seventh Anniversary dinner of the Faculty of Anaesthetists of the Royal College of Surgeons held at the College on March 23. The Dean of the Faculty, Dr. BERNARD JOHNSON, presided. Sir CHARLES DODDS, F.R.S., proposed the toast of the Faculty, and the DEAN, in reply, outlined some of the aims of the Faculty and what it had already achieved. It was concerned, he said, mainly with three things—education, clinical standards, and scientific research. With regard to the latter, he paid tribute to the generous financial support given by leading pharmaceutical firms, who had, between them, so far contributed £65,000 to research in anaesthesia. Sir RUSSELL BRAIN, P.R.C.P., acknowledging the toast of the guests, proposed by the Vice-Dean of the Faculty, Dr. R. F. WOOLMER, referred to the fact that anaesthesia was now coming to the help of the physician, notably in cases of bulbar poliomyelitis and tetanus. The more specialized specialists become, said Sir Russell, the more dependent they are on each other.

Royal College of Obstetricians and Gynaecologists.—Mr. VINCENT MASSEY, Governor-General of Canada, and Dr. GEORGE W. CORNER, of Baltimore, have accepted the Honorary Fellowship of the College, and will attend for formal admission on July 22. The William Meredith Fletcher Shaw Memorial Lecture for 1955 will be delivered by Professor B. P. WATSON, of Columbia University, New York.

Edinburgh University.—Among those who will receive the honorary Doctorate in Law of Edinburgh University at the graduation ceremony on July 8 are Dr. J. G. GREENFIELD, consultant pathologist to the National Hospital for Nervous Diseases, Professor J. B. S. HALDANE, F.R.S., Professor of Biometry at University College, London, and Sir SYDNEY SMITH, Rector of Edinburgh University.

British Society for Research on Ageing.—The following honorary officers and members of the executive committee have been elected: *Chairman*, Sir CHARLES DODDS, F.R.S.; *Vice-Chairman*, Sir FRANCIS FRASER; *Secretary*, Dr. G. H. BOURNE; *Treasurer*, Professor P. L. KROHN; *Members of Committee*, Professor J. F. DANIELLI, Dr. H. B. FELL, F.R.S., Professor K. J. FRANKLIN, F.R.S., Professor P. B. MEDAWAR, F.R.S., and Professor R. E. TURNBIDGE. Inquiries concerning the Society should be addressed to the hon. secretary, Dr. G. H. BOURNE, London Hospital Medical College, London, E.1.

Pamphlets for Parents.—The National Association for Mental Health is issuing a series of pamphlets for parents having difficulties with their children. The latest is called "Children Who Dislike Their Food," and is written by a lay psycho-analyst, formerly on the staff of the association. Other titles in the series are "Children's Fears," "Children's Jealousies," "Temper Tantrums," "Breast Feeding," and "Habit Training," and more are to come. The pamphlets, which cost 1s. 3d. (by post 1s. 4½d.) each, are said to be specially suitable for distribution through child welfare clinics.

Professor Robert Cruickshank, director of the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, has arranged a three-week lecture tour of medical schools in Canada. After that he will go to New York for a week. He will leave London on June 16 and plans to be back on August 2.

Change of Title of a Medical Journal.—At the beginning of this year the *Philippine Journal of Surgery* altered its title to the *Philippine Journal of Surgery, Obstetrics and Gynecology* to indicate its wider coverage. The volume numbering will be continuous with that of earlier issues.

COMING EVENTS

Association of Clinical Pathologists.—The 54th general meeting will be held at Douglas, Isle of Man, on April 13, 14, and 15. Scientific papers will be read. Details

from the honorary secretary, Dr. W. H. McMENEY, Maida Vale Hospital for Nervous Diseases, London, W.9.

South-West Metropolitan Chest Diseases Group.—Inaugural meeting at 2.30 p.m. on April 23 at St. James' Hospital, Balham (see *Journal*, March 12, p. 677). Sir CLEMENT PRICE THOMAS will speak on "Carcinoma of the Lung."

Concert in Aid of R.M.B.F.—Mr. STEPHEN WEARING will give a pianoforte recital at Oatlands Park Hotel, Weybridge, at 8.30 p.m. on May 6 in aid of the Royal Medical Benevolent Fund. Tickets (£1 ls. and 10s. 6d.) from Dr. ROLLO BALLANTYNE, 20, Hersham Road, Walton-on-Thames, Surrey.

Congress of French-speaking Endocrinologists.—The third congress will be held in Brussels from June 18 to 20. Details from Professor J. LEDERER, 233, Avenue de Tervueren, Brussels.

International Society of Surgery.—The sixteenth congress will be held in Copenhagen, July 24-31, under the presidency of Professor EVARTS A. GRAHAM (U.S.A.). Two subjects to be discussed will be "The Risks of Surgical Operations" and "Hepatectomy." The congress is open only to members of the society. Surgeons wishing to join should apply to Mr. H. W. S. WRIGHT, F.R.C.S., 9, Weymouth Street, London, W.1, from whom full details may be obtained.

Health Education.—Summer school on "Opportunities and Methods in Health Education," at Reichel Hall, University of North Wales, Bangor, August 16 to 26. Details from Central Council for Health Education, Tavistock House North, Tavistock Square, London, W.C.1.

International Society for the Study of Biological Rhythm.—Fifth conference at the Karolinska Institute, Stockholm, September 15-17. Main items: "Rhythmical Phenomena in the Nervous System," "Cybernetics," and "Rhythm and Industrial Medicine."

European Haematological Society.—Fifth Congress in Freiburg-im-Breisgau, Germany, September 20-25. Details from Dr. A. PINEY, 152, Harley Street, London, W.1.

Medical Association of South Africa.—The 40th Medical Congress will be held at Pretoria on October 17-22. Details from the Joint Organizing Secretaries, Room 28, Administrative Building, General Hospital, Pretoria.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, April 4

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS.—At 11, Chandos Street, W., 5 p.m., annual general meeting.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. Osmond-Clarke: Fractures of the Upper End of the Femur; 6.30 p.m., Professor Ian Aird: Management of the Pancreas in Upper Abdominal Surgery.

Tuesday, April 5

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Lister Oration by Mr. V. E. Negus: Comparative Anatomy and Physiology of the Respiratory Tracts in Relation to Clinical Problems.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.15 p.m., Dr. C. E. Dukes: Tumours of the Colon and Rectum.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., neurological demonstration by Dr. C. C. Edwards.

Wednesday, April 6

INSTITUTE OF ORTHOPAEDICS.—8 p.m., senior clinical conference. MIDLAND MEDICAL SOCIETY.—At Dudley Road Hospital, Birmingham, 8.15 p.m., clinical meeting; 9.30 p.m., annual general meeting.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. J. B. Atkins: Carcinoma of the Breast; 6.30 p.m., Mr. D. H. Patey: Mixed Tumours of the Parotid Gland.

ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. F. D. Wide: Psychoanalysis and General Practice.

SOCIETY FOR VISITING SCIENTISTS, LTD.—7.30 p.m., discussion: Allergy—Current Conceptions. Speakers, Dr. B. N. Halpern, Professor J. R. Marrack, and Dr. J. Pepys.

Thursday, April 7

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Professor Alexander Kennedy: Human Reactions to Danger.

APPOINTMENTS

ANDERSON, NORMAN ERIC WILSON, M.B., Ch.B., D.P.H., D.T.M.&H., Group Medical Superintendent, Southern Lanarkshire Hospitals.

BALL, J. D., M.B., M.R.C.P., Physician in Charge of the Miners' Chest Diseases Treatment Centre at Llandough Hospital (United Cardiff Hospitals).

CARROLL, JAMES, M.B., B.Ch., D.P.H., D.C.H., District Medical Officer of Health and Assistant County Medical Officer of Health, Burton Latimer, Corby, Desborough and Rothwell Urban Districts and Kettering Rural District.

DREW, CHARLES EDWIN, M.V.O., M.B., B.S., F.R.C.S., Part-time Consultant Thoracic Surgeon, St. George's Hospital, London, S.W.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—R. H. Gaman, B.M., B.Ch., D.P.M., Consultant Psychiatrist/Medical Superintendent, Risbridge Hospital and Riversfield Home; P. A. H. Clements, M.R.C.S., L.R.C.P., Assistant Senior Medical Officer, Board's Headquarters Staff; A. M. Jatoi, M.B., B.S., Surgical Registrar, West Norfolk and King's Lynn General Hospital; L. Essex, M.R.C.S., L.R.C.P., Anaesthetic Registrar, West Norfolk and King's Lynn General Hospital; J. D. Culligan, L.R.C.P.&S.I., Anaesthetic Registrar, East Suffolk and Ipswich Hospital.

GORDON, RONALD M., M.B., Ch.B., D.P.H., Medical Officer, Department of Health for Scotland.

HARMAN, JOHN W., M.B., B.Ch., Director of Pathology, St. Kevin's Hospital, Dublin.

MANCHESTER REGIONAL HOSPITAL BOARD.—A. A. Cashmore, M.D., Consultant Child Psychiatrist, Booth Hall Hospital; F. J. Hebbert, M.D., F.R.F.P.S., Consultant in Geriatrics, Blackburn and District Hospitals; B. O'Hare, M.B., B.Ch., D.M.R.D., Assistant Radiologist, Bolton and District Hospitals; H. I. Heffernan, L.R.C.P.&S.I., D.A., Assistant Anaesthetist, Ashton, Hyde, and Glossop Hospitals; D. L. Fox, M.B., Ch.B., D.P.M., Assistant Psychiatrist, Lancaster Moor Hospital. All whole-time appointments.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—P. M. Tow, Ph.D., M.B., B.S., Consultant Psychiatrist, Hill End Hospital; T. H. S. Burns, B.M., B.Ch., F.F.A.R.C.S., Consultant Anaesthetist, Royal Northern Hospital and City of London Maternity Hospital; D. A. Davies, M.D., M.R.C.O.G., Consultant Gynaecologist, St. Mary's Cottage Hospital, Hampton, R. G. Law, M.D., M.R.C.O.G., Consultant Obstetrician and Gynaecologist, Whittington Hospital, including duties at New End Hospital; W. M. McIntyre, M.D., M.R.C.P.Ed., Consultant Psychiatrist, St. Marylebone Hospital; Dorothea B. J. Halstead, M.B., Ch.B., F.F.A.R.C.S., D.C.H., Consultant Anaesthetist, Hounslow Hospital; Betty E. Powe, M.D., D.C.H., Admissions Officer (S.H.M.O.), Central Middlesex Hospital; S. H. Lucas, M.R.C.S., L.R.C.P., D.P.M., Consultant Psychotherapist, Portman Clinic; J. G. Sommerville, M.B., Ch.B., Assistant Physician (S.H.M.O.), in Physical Medicine, Medical Rehabilitation Centre, Camden Road, N.W.

PARKEN, DOUGLAS STUART, M.B., B.S., D.P.H., D.C.H., Deputy Medical Officer of Health, Swindon Municipal Borough.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Ajrekar.—On March 10, 1955, at 319, Aldborough Road, Seven Kings, Ilford, Essex, Mukund Shripad Ajrekar, M.B., B.S., of Poona, India.

Banham.—On March 17, 1955, at 16, King's Drive, Eastbourne, Sussex, Cecil Walter Ramsay Banham, M.R.C.S., L.R.C.P., formerly of Hurstmonceux, Sussex, aged 85.

Brand.—On March 18, 1955, at 25, Froggatt Court, Finchley Road, London, N.W., Hamish Douglas Ferguson Brand, M.B., Ch.B., Colonel, late R.A.M.C., retired.

Collingham.—On March 19, 1955, David-Horace Collingham, M.R.C.S., L.R.C.P., of 27, Maid Causeway, Cambridge, formerly of Lincoln.

de Boer.—On March 17, 1955, at Shirley, Adesfield Road, Hemel Hempstead, Herts, Alice de Boer, L.R.C.P.&S.I., L.R.F.P.S., aged 83.

Dunne.—On March 4, 1955, at Winchester, Hants, James Stuart Dunne, D.S.O., F.R.C.S.I., Lieutenant-Colonel, R.A.M.C., retired, of Whitechurch, Hants, aged 77.

Edwards.—On March 19, 1955, Edward Charles Edwards, M.D., of 33, The Green, Shaldon, Devon, late of Penzance, Cornwall, aged 83.

Fitch.—On March 19, 1955, in New Zealand, Keith Simpson Fitch, O.B.E., F.R.C.S.Ed., Lieutenant-Colonel, I.M.S., retired.

Goodchild.—On March 7, 1955, Nathaniel John Goodchild, M.R.C.S., L.R.C.P., of 2, Templars Crescent, Finchley, London, N., late of Sidney House, Highgate Road, London, N.W., aged 89.

Hodges.—On March 17, 1955, George Montague Williams Hodges, M.B., B.S., of Dallington, Sussex, formerly of Deddington, Oxon.

Killard-Leavey.—On March 10, 1955, at a nursing-home, Barnstaple, Devon, Timothy Joseph Killard-Leavey, M.R.C.S., L.R.C.P., aged 84.

Lakin.—On March 13, 1955, in the Private Patients' Home, Robert Lakin, M.D., of 12, Heaton Moor Road, Stockport, Cheshire.

Lucas.—On March 6, 1955, at Eskbank, Midlothian, Frederick Richard Lucas, L.R.C.P.&S.I., L.R.F.P.S., of Rerwick Lodge, Eskbank.

McLaren.—On March 14, 1955, at Edinburgh, Robert McLaren, L.R.C.P.&S.I., L.R.F.P.S., of 28, Oxbgangs Road, Edinburgh, aged 83.

McLean.—On March 15, 1955, at St. Mary's Hospital, Newport, Isle of Wight, Neil McLean, M.B., Ch.B., D.T.M., D.T.H.

Manfield.—On March 17, 1955, at the General Hospital, Nottingham, George Herbert Hind Manfield, M.C., M.R.C.S., L.R.C.P., of 64, Clarendon Street, Nottingham.

Marshall.—On March 10, 1955, at 5, Christchurch Road, Worthing, Sussex, Reginald Prynn Marshall, M.R.C.S., L.R.C.P.

Metcalfe.—On March 17, 1955, George Metcalfe, M.B., Ch.B., of 56, Higher Reedley Road, Brierfield, Lancs, aged 53.

Shearer.—On March 9, 1955, at Myrtle Cottage, Carbis Bay, Cornwall, Donald Francis Shearer, M.B., F.R.C.S., aged 90.

Stein.—On February 21, 1955, at 1, The Orchard, Blackheath, London, S.E., Charles Stein, O.B.E., M.D., late of Shipston-on-Stour, Worcs, aged 93.

Straus.—On February 22, 1955, at Paynes Farm, North Curry, near Taunton, Somerset, Willi Straus, M.D., aged 81.

Tabuteau-Herrick.—On February 27, 1955, at Warrington, Surrey, Augustus William Tabuteau-Herrick, F.R.C.S.I.

Turner.—On February 28, 1955, at his home, "Heddingham," First Avenue, Middleton-on-Sea, Sussex, Joseph George Turner, F.R.C.S., F.D.S. R.C.S., aged 85.

Vickers.—On March 4, 1955, Thomas Hedley Vickers, M.R.C.S., L.R.C.P., D.O.M.S., Surgeon Commander, R.N., retired, of Jetwells, Goudhurst, Kent, aged 77.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Dangers of Intravascular Penicillin

Q.—How common are serious reactions to penicillin if it is given accidentally into a vein? Does their incidence warrant any further precautions than attempting to aspirate blood into the syringe before injecting the penicillin? Are some preparations of penicillin more apt to lead to these serious reactions than others?

A.—Considering the enormous quantities of penicillin administered by intramuscular injection and the comparatively few reports of reactions occurring following accidental intravascular administration, no further precaution other than attempting to withdraw the plunger of the syringe need be taken.

The consequences of intravascular administration, however, depend very considerably on the type of preparation used. In the great majority of cases an aqueous suspension could be injected intravenously with little danger, whereas the oily suspensions and emulsions, and in particular those containing procaine, would produce serious and sometimes fatal reactions.

Influenza and Epistaxis

Q.—In the recent influenza epidemic I have noticed that in a number of cases a spontaneous epistaxis has occurred about the second or third day of the disease. Could you tell me if this has been seen generally and if any cause can be suggested?

A.—In about 20% of young adults with influenza there is epistaxis. The actual numbers vary from epidemic to epidemic, and in some large series of cases epistaxis has not been noted. Several observers have commented on its occurrence during the recent influenza B outbreak in children. Epistaxis is presumably due to the intense engorgement in the submucosa of the upper respiratory tract which accompanies the virus infection of the epithelium.

Lipoid Pneumonia from Nasal Drops and Sprays

Q.—Has the use of oily nasal drops and sprays been shown to be directly responsible for the development of lipoid pneumonia? In those patients who have developed the condition were there significant contributory factors depressing the cough reflex? What is the incidence of lipoid pneumonia?

A.—The evidence relating the use of oily nasal drops or sprays to the development of lipoid pneumonia is circumstantial rather than direct. Although disorders of the cough reflex and of deglutition predispose to aspiration from the upper into the lower respiratory tract, lipoid pneumonia has been reported in patients without any interference with these functions. Exogenous lipoid pneumonia must be clearly distinguished from endogenous lipoid pneumonia; in any chronic pneumonic condition, such as may occur behind a bronchial obstruction, fatty change may occur in the chronic inflammatory cells, giving rise to an endogenous lipoid pneumonia. The most frequent sources of the oil in exogenous lipoid pneumonia are oily nasal drops or sprays and mineral oil taken by mouth, in both instances over a prolonged period. It has been shown that iodized oil introduced into the nose of a sleeping person can be demonstrated in the lungs on the following morning. The localized nature of some exogenous lipoid pneumonias suggests that oil from the nose or pharynx may have been aspirated in this way during

sleep into the broncho-pulmonary segment which is most dependent in the patient's customary sleeping posture. The incidence of exogenous lipoid pneumonia is difficult to assess, largely because diagnosis is usually impossible without the opportunity for histological examination which may be afforded either by lung resection or as a result of post-mortem examination. With this proviso, the condition appears to be rare. However, in view of the possible dangers, and of the little evidence of positive benefit from their use, oily nasal drops and sprays are best avoided.

Hypertrophied Labia

Q.—I have a female patient of 16 who complains of discomfort from swelling of the labia—according to the mother, the labia minora. It is now brought on only by exercise, such as badminton and especially cycling. It was at its worst 18 months ago, when the labia would swell after exercise sufficiently to cause difficulty in walking. The patient (and her mother) say that at that time her periods were abnormal, occurring fortnightly and lasting for a week; now she has them for five days in 28. I could find nothing abnormal on examination except that the labia minora were possibly rather large for the patient's age. I should be very interested to have comments on this case.

A.—This girl probably has a moderate degree of hypertrophy of the nymphae, a not uncommon condition. It is sometimes alleged to be a sign of masturbation, but it is more likely a developmental anomaly. Often it is symptomless, but it can be troublesome in that the labia tend to get chafed and sore during exercise, and sometimes they react by becoming oedematous and painful. Symptoms are most often seen during adolescence, and this may be because of the increased activity of the sebaceous and sweat glands in the skin of the vulva and of a tendency to leucorrhoea at that age. Failure to realize the need to wash carefully in the folds of the vulva may also be a factor.

If the symptoms are improving active treatment is probably unnecessary. The girl should be advised to wash and dry the skin carefully and often, and to avoid powder, which tends to cake in the crevices. Before exercise she should apply a barrier cream such as zinc and castor oil or one of the proprietary preparations, and this may prevent chafing. If the labia continue to cause trouble the ultimate line of treatment is to reduce their size by a plastic operation.

Methonium Compounds in Left Ventricular Failure

Q.—In what circumstances are methonium compounds indicated in left ventricular failure? Are there any special dangers, and what results may be expected?

A.—Methonium compounds (for example, hexamethonium, pentolinium) will lower the blood pressure and relieve the strain on the heart in hypertensive left ventricular failure. The dosage required is variable and should be determined by the sphygmomanometer in the individual. In acute left ventricular failure 2.5 mg. pentolinium can be given intravenously and repeated in ten minutes if the pressure does not fall with the first dose. If a profound drop in pressure takes place this can be corrected by changing the posture towards recumbency. The effect of methonium can be one of dramatic relief: owing to the uncertainty of dose-response, however, it is not likely to displace morphine as the most effective remedy for emergency use.

Methonium compounds have a real place in the management of chronic hypertensive left ventricular failure. If begun in the early stages before gross enlargement has occurred symptomatic relief may be dramatic and sustained for years. They are especially valuable in the younger age groups before extensive arteriosclerotic changes have developed. A single large injection on going to bed may prevent nocturnal dyspnoea. Methonium should be regarded as a supplement to digitalization rather than an alternative form of treatment. The difficulties and dangers

of methonium treatment are now well known, and recent papers should be consulted for details—for example, that by Brenda Morrison.¹

Efforts have been made to reduce the work of the failing heart with methonium in non-hypertensive cases. These trials are as yet inconclusive.

Acid Urine

Q.—I would be glad if you could tell me if there is any dietary method of keeping an extremely acid urine nearer neutrality. At present 40–60 gr. (2.7–4 g.) potassium citrate is needed daily for this purpose.

A.—The amount of acid excreted in the urine in health depends very largely on the amount of animal protein consumed, and a low-protein vegetarian diet does make the urine more alkaline. Before recommending such a treatment, however, one would have to know whether the presence of "extremely acid urine" was in fact responsible for the patient's symptoms; if these are really due to urinary infection, this should be treated by antibiotics and not by potassium citrate. It is assumed that the common causes of a metabolic acidosis—diabetes, diarrhoea, anorexia—have been excluded. If the patient has no symptoms, and a normal alkali reserve, the finding of a urinary pH down to 4.5 has no pathological significance, and no treatment is required.

Treatment of a Phantom Leg

Q.—I would appreciate advice on the treatment of a phantom leg in a man of 65 who was wounded in the first world war. So far I have not tried any of the long-acting local analgesics, and I have been wondering whether it would be worth trying one, and, if so, what methods to adopt.

A.—Phantom leg sensations are of no importance unless they are painful, but it seems likely in this case, as the phantom sensation has either persisted since the first world war or has developed as a delayed effect in recent years, that in fact the patient is complaining of one of the several types of phantom pain, probably a sudden neuralgic sensation with a jerking of the stump.

It is most helpful in the handling of this type of case to observe the effects of blocking the nerves to the end of the stump. The nerve concerned is identified by the position in the phantom to which the pain is referred, and if, as usually, the pain is referred to some part in the sciatic nerve distribution, then a sciatic nerve block with procaine may be a very instructive procedure. If, as often happens, this procedure causes numbing or disappearance of the phantom sensation, then this indicates that most of the abnormal neural discharges are originating at the neuromata at the end of the stump, and in this type of case repeated injections with procaine may give lasting relief. However, this type of case is also very suitable to treatment by percussion, either with a mallet and applicator or by a mechanical vibrator. Both of these measures gradually destroy the fine nerve fibres in the neuroma. So successful has been this treatment in many instances that a small type of vibrator is now supplied by the Ministry of Pensions on loan to cases of painful amputation stump or phantom pain. Further information with regard to this treatment can be found in a paper by Russell and Spalding.¹

NOTES AND COMMENTS

Static Electricity and Car Sickness.—Dr. W. E. HICK (Cambridge) writes: I disagree with your expert's remarks on "the present opinion" of the cause of motion sickness ("Any Questions?" March 12, p. 680). There are two aspects—the eliciting conditions and the physiological mechanisms. With regard to the latter, I should be interested to hear of any reasonable evidence that the possession of "hypersensitive labyrinths" is a necessity. Even the weaker postulation of "hypersensitivity to labyrinthine stimulation" is dubious. The effects of the "magic swing" and similar devices which only produce an illusion of body movement would have to be explained away. "Over-stimulation" is also a somewhat unfortunate expression. Taking vertical acceleration alone, the values during running are very much greater than are commonly experienced in a large ship. The lower frequency in a ship (of the order of 0.1 c/s) is relevant, but not because it causes over-stimulation. Slow rotation at constant speed with the gaze directed upwards or downwards can also be extremely unpleasant; but it can only stimulate the labyrinths when starting and stopping (and not abnormally, even then).

I think the most useful summary of the evidence is that motion sickness is just a variety of the more general phenomenon vertigo sickness. Everybody knows that vertigo, whether caused by vestibular disease, drugs, motion, anomalous behaviour of the visual world, or anything else, tends to produce vomiting. "Vertigo" here denotes a confusion in spatial orientation, particularly with respect to gravity; the apparent magnitude of the latter is to be remembered, as well as its direction. Whether the word "giddiness" is used by the sufferer depends on the situation and on certain linguistic factors. "Vibrations affecting the eyeball" would shift the image on the retina, and thus possibly add to the confusion. But this is a minor contribution in the usual "sick-making" conditions.

Individual differences in susceptibility are probably due to the sensitivity of the vomiting reflex to vertigo, and to practice. Medical palliation is, of course, mostly limited to attacks on the former, but it is worth remembering that the latter is an active process of learning to achieve orientation by making a better selection from the total sensory information. As a skill, it is largely unconscious; but, like other skills, it is more quickly acquired when there is conscious effort directed by insight, as many people have found out for themselves.

Aphthous Ulcers.—Dr. GEORGE GRAHAM (London, W.1) writes: I have been troubled with these ulcers (*Journal*, January 22, p. 242, and March 5, p. 618) ever since I was a small boy—two or three times a year for many years, but now much less frequently. For the last thirty years or so I have always touched the ulcer with a silver nitrate stick, which I carry in my dressing-case. The actual application is exceedingly painful, but is followed by an immediate relief of pain, the ulcer being covered with a white coagulum. The pain may return after 24 hours or so and is again at once relieved by another application. I have never had to repeat the treatment a third time, as the ulcer is no longer painful and heals rapidly. I have treated successfully many patients in this way, but I always warn them that the initial pain is very great. I have used 2% gentian violet if many ulcers were present, but it is not so good as a silver nitrate stick for a single ulcer.

OUR EXPERT writes: The application of silver nitrate, either in solution or as a stick, to the aphthous ulcers appears to have many adherents. It is, of course, a painful procedure, but may have the benefit in single ulcers, as some correspondents have pointed out, of relieving pain. The ulcers frequently appear in crops of several at a time, and it was in this type of case that silver nitrate was not recommended, as the majority of opinion is against its use. It is unfortunate that a common and painful condition still has an obscure aetiology and somewhat empirical treatment.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

THE DEVELOPMENT OF BRITISH ENDOCRINOLOGY*

BY

P. M. F. BISHOP, D.M., M.R.C.P.

Endocrinologist, Guy's Hospital, Chelsea Hospital for Women, and the Obstetric and Gynaecological Department of the Postgraduate Medical School of London, W.12

Few, I suppose, to-day would deny that endocrinology is a branch of the biological and medical sciences, integrated as a coherent whole to form the subject of textbooks, journals, and societies, and indeed to constitute the professional vocation of a small group of workers who call themselves endocrinologists. Nevertheless it has from the beginning so permeated many other branches of science and medicine as to become an integral part of them. This it will continue to do more and more as the subject unfolds under the warm sunshine of advancing knowledge. Thus it is physicians and physiologists, biologists and biochemists, pathologists and pharmacologists who by their contributions have founded and established endocrinology so that its study and practice have now become essential not only to their own but to other specialties. Should this need, however, be neglected, not only will their own branches of science and medicine suffer, but endocrinology will wither.

British workers have played a distinguished part in the development of endocrinology both in the past and during the present generation, and to-day, with a journal, a society, and a section at the Royal Society of Medicine, endocrinology in this country would seem to flourish and prosper and to be firmly established. Will it continue so in the future? This is the theme I wish to develop.

"Internal Secretions" and "Hormones"

So far as I can discover, the earliest British contributors to endocrinology were Thomas Willis and Richard Lower, both of whom hinted at the possibility of some mechanism of internal secretions. Willis was at school in Oxford and became batteler to a canon of Christ Church and thus matriculated from "the House" in 1636 and took the degree of B.M. ten years later. He was a contemporary of Robert Boyle, John Locke, and other future Fellows of the Royal Society, which received its charter in 1662. When the monarchy was restored Willis was rewarded for his loyalty by being appointed Sedleian Professor of Natural Philosophy at Oxford. During the time he held this chair he wrote much on anatomy, describing of course, among other things, the circle of Willis, and taught a number of students who were subsequently to become famous, such as Christopher Wren. In 1666 he moved to London and built

up a lucrative practice. His reputation is difficult to assess. Was he the inventor of the nervous system, the founder of biochemistry (he tasted the urine for diabetes), the peer of Sydenham, Heberden, and Bright, or a parasite living on his pupils' ideas? It is said that he refused a knighthood because he had been declared by the Merry Monarch to have killed more of his subjects than an invading army. Richard Lower, his pupil, who may well have inspired some of his ideas, including those concerning internal secretions, followed Willis to London in 1666 and eventually became the "most noted physician in Westminster and London" and a confidant of Nell Gwynne. He fell foul of the King, however, and his practice and reputation suffered accordingly. In 1675 he was expelled from the Royal Society, probably for not paying his subscription. Nevertheless he was one of the many physicians who attended the royal deathbed and tortured the wretched Charles, as Macaulay says, "like an Indian at a stake," while he was being "a most unconscionable time a-dying." The first contributors to British endocrinology were therefore colourful, successful, and worldly.

Though endocrinology made few advances during the next 200 years, the conception of internal secretions kept recurring, and George Gulliver, who enjoyed the curious distinction of being surgeon to "the Blues" as well as a Fellow of the Royal Society and a Foundation Fellow of the Royal College of Surgeons, was one of those who played upon this theme by postulating in 1840 that the adrenal glands elaborate a substance which they discharge into the venous blood. The term "internal secretion" was first used by Claude Bernard in a lecture at the Collège de France in 1855, but the word "hormone" was introduced half a century later by Bayliss and Starling. In 1902 they discovered secretin, and felt that its production in one part of the body and its transport to other parts on which it effected changes were not adequately described by calling it an "internal secretion." In their search for a more appropriate term the word "hormone" was suggested, and Starling used it in 1905 in his Croonian Lectures at the Royal College of Physicians. Starling had carved out a distinguished career for himself in the Physiology Department at Guy's, but as the authorities were unwilling to give him full control of the department he left in 1900 to become Jodrell Professor of Physiology at University College. He was succeeded at Guy's by M. S. Pembrey, who from the first took undisputed command of his department. Two years earlier Guy's had lost another distinguished physiologist through inadequately defining his ultimate prospects, for Gowland Hopkins had been enticed

*Based on the Presidential Address to the Section of Endocrinology of the Royal Society of Medicine, delivered on October 27, 1954.

+Sir Charles Symonds, in his recent Harveian Oration (*British Medical Journal*, 1955, 1, 119), has refuted this suggestion and has borne testimony to Willis's high repute.

to Cambridge by Michael Foster to undertake research in chemical physiology. I mention these facts because they are relevant to my theme.

History of British Endocrinology

The history of endocrinology consists of accounts of the achievements of men who did not call themselves endocrinologists, but were physicians, therapists, chemists, pharmacologists, pathologists, and experimental physiologists.

Physicians

From the physicians I choose Addison and Gull, for the circumstances leading up to the descriptions of Addison's disease and myxoedema are characteristic of the atmosphere of the second half of the last century when men had nothing but their eyes, their ears, their finger-tips, and their clinical sense to rely upon. Thomas Addison had spent all his life studying disease at the bedside and in the post-mortem room before he published, at the age of 62, his celebrated monograph in 1855. He was a distinguished dermatologist, and it was under his direction that Joseph Towne modelled in wax the superb collection of specimens of skin disorders which are still to be seen in the Gordon Museum at Guy's Hospital. He had long been intrigued by the morbid state characterized by "anaemia, general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change of colour in the skin, occurring in connexion with a diseased condition of the suprarenal capsules." Six years previously he had communicated a paper concerning "a remarkable form of anaemia" occurring in patients the whole surface of whose bodies "bears some resemblance to a bad wax figure." Addison wrote sparingly, and it must have taken considerable persuasion on the part of Samuel Wilks, his junior colleague, to get him to produce the finely worded and beautifully illustrated monograph which is to-day such a highly treasured gem among the exhibits of British endocrinology. Unfortunately Addison was to derive little pleasure or satisfaction from it. It is true that Trousdale, during the next year, hailed the monograph and christened the condition Addison's disease. It is also true that, after reading Addison's monograph, Brown-Séquard, later to become physician to the National Hospital for Nervous Diseases, Queen Square, an F.R.C.P. and F.R.S., founded experimental endocrinology by removing the adrenals from a curious assortment of animals and by deducing from the consequently high mortality rate that these glands were essential to life. Nevertheless the medical fraternity at Edinburgh, where Addison had obtained his M.D., would not acknowledge the disease, and two or three papers read before the Medico-Chirurgical Society were not accepted for publication in its *Transactions*. Addison was deeply hurt by this, as he had not long before been president of the society. In 1860 he retired from public life and his beloved Guy's, and shortly afterwards committed suicide.

How different was the background of Gull's disease! In 1850, at a meeting of the Medico-Chirurgical Society, with Addison in the chair, Thomas Curling, a surgeon at the London Hospital, reported two cases of sporadic cretinism with absence of the thyroid gland. No one paid much attention, and it was 21 years before a further five cases of sporadic cretinism were reported to the same society by Hilton Fagge, of Guy's Hospital, ironically with Curling himself in the chair. Fagge recalled Curling's cases and the fact that the thyroid was absent, giving credit to his senior colleague and late teacher, Dr. Gull, for having acquainted him with the principal features of the condition. One of Fagge's patients was obviously suffering from juvenile myxoedema, and this led him "to speculate as to what characters would be present, should the disease (if that be possible) arise still later in the course of adult life." Two years later, in 1873, Sir William Gull read a paper to the same society "On a cretinoid state supervening in adult life in women." In it he described five cases, referred to Fagge's paper, and

expressed the belief that these cases were examples of the condition which Fagge had predicted. Gull's paper was brief, and would probably have attracted little attention but for the forcefulness of his character and the fact that he was at this time the most famous physician in the country. Two years previously he had been called in by Sir William Jenner to attend the Prince of Wales, who was suffering from typhoid fever. Seeing that the Queen had lost her beloved husband from the same complaint, it is understandable that when the Prince recovered Gull received not only the heartfelt thanks and gratitude of the nation and the Queen but also a baronetcy. Gull resigned from Guy's at the age of 50 to attend to his busy practice, and died in 1890 following the third of a series of cerebral haemorrhages. On recovering from the first he is said to have remarked, "One arrow has missed its mark, but there are more in the quiver." He left £344,000.

It was, however, William Ord, of St. Thomas's Hospital, who in 1877 gave a full and classic account of the condition and called it "myxoedema." During the next five or six years studies were being made on the Continent of the results of total extirpation of goitrous thyroid glands, and Sir Felix Semon, the laryngologist, on reading Kocher's paper on "cachexia strumipriva," recognized in the description the classic picture of myxoedema, and drew the attention of the Clinical Society of London to the matter. Though Semon's idea that cachexia strumipriva, myxoedema, and cretinism were all due to the same cause was at first ridiculed, eventually the Clinical Society set up the Myxoedema Committee in 1883, with Ord as chairman and Sir Victor Horsley as one of the members. Semon was obviously more familiar with the Continental literature than most of his colleagues, for he was in fact German, and when he came to this country in 1875 he spoke hardly a word of English.

Therapists

Treatment, other than empirical quackery, was practically non-existent in those days, and in endocrinology the first to succeed in carrying out a rational form of therapy was George Murray, of Manchester. Here is Sir Walter Langdon-Brown's description of what happened, as recounted to him by Murray himself. At the time of the setting up of the Myxoedema Committee there was a tendency to regard myxoedema as a failure of excretion, hence the patient's bloated appearance. Murray, however, after consulting Horsley, with whom he had worked at University College Hospital, suggested it was due to loss of an active internal secretion; and in 1891 he demonstrated a case of the disease to the Newcastle and Northumberland Medical Society and announced that he proposed to treat it by means of an extract of thyroid gland. A senior member of the society said that it would be just as sensible to treat a case of locomotor ataxia with an emulsion of the spinal cord. Murray arranged with a slaughterhouse to be allowed to dissect out sheep's thyroid glands, of which he proposed to make an extract. The Newcastle Medical School refused to give him facilities for this, but Armstrong College provided him with a room in which to prepare his extracts. Towards the end of that year he triumphantly demonstrated the same patient, now an active and sprightly woman of 46 as the result of injections of his extracts, to the same society. The patient lived to be 74, by which time she had received the equivalent of 870 sheep's thyroids.

Murray was, of course, lucky, for a crude extract of sheep's thyroid glands is as good a therapeutic agent for thyroid deficiency as any other. The therapists of the present generation usually have to rely upon the physiologist or the chemist to supply them with their active principle. Thus Lawrence, the pioneer and leading exponent of the treatment of diabetes in this country, had to wait for Banting and Best to introduce insulin before his own life could be saved and he could alleviate the sufferings of so many diabetics during the past 30 years. It was necessary for Reichstein to synthesize deoxycorticosterone acetate before

Leonard Simpson could apply it to the treatment of Addison's disease; and until Dodds had made stilboestrol available oestrogen therapy was virtually ineffective.

Chemists

Chemists, indeed, have played a particularly distinguished part in the history of British endocrinology, as the following examples will show.

On Christmas Day, 1914, a pure, crystalline, and physiologically active protein was isolated from the thyroid gland by the American chemist E. C. Kendall, who, believing that the essential component was oxyindole, christened it "thyroxindole," which was later shortened to "thyroxine." (The terminal *e* was added to conform to the British system of nomenclature of this class of compound.) In 1926 Harington showed that the active principle was a derivative of tyrosine, indeed a condensation product of 3:5-diiodo-tyrosine, and not of indole, and in 1927 Harington and Barger synthesized thyroxine. It is peculiarly fitting, therefore, that it was in Sir Charles Harington's laboratory that Dr. Rosalind Pitt-Rivers conducted the studies which led to the realization that triiodothyronine is in fact the true hormone of the thyroid gland. By 1929 and 1930 pure crystalline oestrogens were being extracted from the urine of pregnant mares, and G. F. Marrian succeeded in obtaining oestriol from human pregnancy urine. In the same year Marrian isolated pregnandiol, the inert urinary metabolite of progesterone, subsequently to be isolated in pure crystalline form five years later. The elucidation, in 1932 and 1933, of the structure of the cyclopentenophenanthrene ring system cleared the decks for an intensive chemical study of the steroids, including the sex hormones, in which an important part was played by J. W. Cook and his collaborators, who were largely responsible for determining the structure of the natural oestrogens. Struck by the existence of no fewer than five natural oestrogenic substances, Dodds and his colleagues began to wonder how specific was the molecular structure for oestrogenic activity, and they soon found a compound, 1-keto-1:2:3:4-tetrahydrophenanthrene, which did not contain the cyclopentenophenanthrene skeleton but which was weakly oestrogenic. They subsequently established the fact that the phenanthrene structure was not essential for oestrogenic activity, and they eventually tested the potency of the very simple compound anol (*p*-hydroxypropenyl benzene) and found it to be highly active. However, when attempts were made to repeat the work, some batches of anol were found to possess only very slight activity, and it was obvious that the activity in the first batch must have been due to a contaminant. The work was continued in collaboration with Sir Robert Robinson, and it was shown that the active compound was in reality 4:4'-dihydroxy- α - β -diethylstilbene. The introduction of this cheap and highly potent oral compound completely revolutionized oestrogen therapy.

In the androgen field Leonard Simpson, Alison Macbeth, and de Fremery had reported abnormal quantities of male hormone in the urine of certain cases of virilism from 1933 onwards, but the chief credit for developing a reliable and accurate method of estimating urinary neutral 17-ketosteroids belongs to Callow. It is of some interest to note how this came about. In 1936 Professor A. W. M. Ellis (now Sir Arthur Ellis), of the London Hospital, appeared before the Hormones Committee of the Medical Research Council and pressed strongly for the establishment, under the Council's auspices, of an endocrine laboratory institute in which hormone assays and estimations could be carried out to assist clinicians in the diagnosis and treatment of endocrine disorders. The Committee considered the proposal and decided that a useful start could be made by trying to find a method of determining the urinary metabolites of the androgens produced by the gonads and adrenal cortex. The task was placed in the capable hands of Dr. R. K. Callow, and his staff was augmented by an additional biochemist, whom he subsequently married. Callow and

his colleagues modified the Zimmermann colorimetric method for determination of urinary androgens and put it on a secure basis.

The most recent chemical achievement of which British endocrinologists may be proud is the discovery by S. A. Simpson, J. F. Tait, and H. M. Grundy of the very potent adrenocortical hormone, aldosterone.

Pharmacologists

Pharmacologists have also made valuable contributions to British endocrinology. Dr. George Oliver, a physician who practised in Harrogate during the summer months, had gained the impression that patients suffering from low blood pressure would derive benefit from injections of an extract of the adrenal gland. Trying this out on his son, he thought he detected a contraction of the radial artery. In considerable excitement he rushed up to London to tell his friend Professor Schäfer (Starling's predecessor in the Chair of Physiology at University College) about it. Schäfer was actually conducting an experiment which involved measuring the blood pressure of an anaesthetized dog, and, polite though incredulous, he injected some of the extract into the animal and was astonished to see the mercury almost shoot out of the top of the manometer. The date was 1894, and in the following year Benjamin Moore, working in Schäfer's laboratory, correlated this pressor substance with the adrenomedullary chromagen. Later adrenaline was isolated and its relationship with the sympathetic nervous system remarked upon. A little later still Sir Henry Dale pointed out that noradrenaline reproduced the actions of the sympathetic impulses with even greater fidelity. In 1906 W. E. Dixon obtained from a heart which had been subjected to vagus stimulation an extract which inhibited frog's heart muscle. This substance, subsequently known as acetylcholine, was discovered by accident in ergot of rye by Dale and identified by Dale and Ewins in 1914; it was found to be released at parasympathetic nerve-endings by Dale and Dudley in 1929 when, as Sir Henry has modestly put it, they "were looking for something else."

Pathologists

Pathology, perhaps, has contributed surprisingly little to British endocrinology. Nevertheless there are three exceptions. The first is the detailed description of the histology of the thyroid gland by Wilkinson King in 1836. He described the colloid and showed that it passed into the lymphatics and so into the great veins, adding that "whilst the nourishment of a part is indispensable to its existence, the influence which it exerts upon the circulating fluid may be more or less needful for the healthy subsistence of the entire animal"—a prophetic forecast of the principle of internal secretions. King succeeded Thomas Hodgkin as curator of the museum at Guy's at the age of 28, and his literary output was very considerable; but, as Wilks said, "though young he had an aged worn look and a chronic cough," and he died of pulmonary tuberculosis at the early age of 38. The second exception is the description by A. C. Crooke in 1935 of hyaline changes in the basophil cells of the pituitary in cases of Cushing's syndrome, and the third the observation by H. L. Sheehan that the majority of cases of panhypopituitarism are due to post-partum necrosis of the gland and present clinically as cases of secondary myxoedema and not, as described by Simmonds, as pituitary cachexia.

Experimental Physiologists

Last I come to a group of endocrinologists whom I find difficult to classify, and I think perhaps I can best describe them as experimental physiologists. Actually they may be surgeons, like Astley Cooper and Victor Horsley, performing thyroidectomy on puppies or monkeys; or they may be anatomists, like Zuckerman, whose contributions and those of his school have always been careful, painstaking, and prolific, and yet have ranged over a surprising variety of subjects from the menstrual cycle and the functions of the prostate to the interactions of the hypothalamus and the

pituitary; or neurophysiologists, like G. W. Harris, whose studies of the hypothalamus and the pituitary have been outstanding. They may be engaged on agricultural research, like S. J. Folley, whose studies at Reading have laid the foundations of modern lactational physiology. They may be biochemists, like F. G. Young, whose fascinating studies of the role of the pituitary in carbohydrate metabolism have identified the diabetogenic hormone with the growth hormone. Or they may be truly experimental physiologists, such as the late F. H. A. Marshall and his disciple, A. S. Parkes, whose work on the physiology of reproduction virtually created this branch of endocrinology and has certainly maintained its standard unsurpassed throughout the world.

The object of this historical review has been to point out that the contributions of the British school were noteworthy and important and have gained for British endocrinology a high reputation. The following account suggests that that reputation has been maintained during the last quarter of a century.

The "Journal of Endocrinology"

By the late 1930's it was becoming obvious to a few workers actively engaged in various fields of endocrine research that there was a growing need for a journal in which their results could be published. A small group of ten therefore decided to launch a British journal devoted to the publication of original work in endocrinology. Each of these ten individuals having guaranteed a certain sum of money, the *Journal of Endocrinology* eventually came into being. Sir Henry Dale acted as chairman of the committee which conceived, devised, and launched the project, but, at his own request, he was not appointed chairman of the council of management. Dr. A. S. Parkes was accordingly elected to this post, and Professor F. G. Young became the secretary. With Sir Charles Dodds as editor, the first number of the journal was published in June, 1939. It could hardly have appeared at a less propitious moment. Before the next number was printed the second world war had broken out. Many of the journal's subscriptions came from overseas and therefore promptly ceased at the outbreak of hostilities. Had it not been for the subventions granted from time to time by the Royal Society the journal would assuredly have succumbed. Indeed, at one stage during the war the treasurer was obliged, in order to keep the journal afloat, to call upon the guarantors to pay up half the money they had guaranteed. However, it seems to have been endowed with a miraculous buoyancy, and to-day it is a flourishing concern which publishes four or more numbers a year under the editorship of Professor Zuckerman.

The Society for Endocrinology

Once the war was over, one or two members of the council of management felt the need for periodic symposia on endocrine subjects and suggested that a society should be formed to deal with the organization of such gatherings. The council recognized the rapid expansion that was taking place in endocrinology and the desirability of founding a society membership of which should be open to the many workers now actively engaged in the study of this subject. They felt that this society should take over management of the journal, which should become its official publication. The treasurer, however, insisted that the society should repay the guarantors the money they had individually disbursed to keep the journal alive during the days of its financial difficulties. This money having in due course been repaid, the Society for Endocrinology was founded and held its first meeting at Guy's Hospital in July, 1946, when Sir Charles Harington delivered the inaugural address. Dr. Parkes became chairman of the committee of the society and Dr. S. J. Folley the honorary secretary. The society's first symposium was held in December, 1946. Dr. Folley became chairman of the committee in 1951, and with the two present secretaries, Professor C. H. Gray and Professor N. F. MacLagan, has led the society forward to become the

flourishing and respected body that it now is, upholding the highest traditions of academic endocrinology, and enjoying a reputation certainly equal to that of any society of endocrinology throughout the world.

The Section of Endocrinology of the Royal Society of Medicine

In the meantime the clinicians were not inactive. Towards the end of 1944 Dr. Raymond Greene was exploring the possibilities of establishing a Section of Endocrinology of the Royal Society of Medicine and was not finding his task easy. There were some who disapproved of carving another slice off the body medical, and there were others who felt that the creation of a Section of Endocrinology might deprive existing sections of many subjects that they themselves would like to discuss. There were still others who felt that clinical endocrinology was not yet based on a scientific foundation, that most clinical endocrinologists were quacks, and that a Section of Endocrinology would become a sounding-board for their "hot air." On the other hand, Dr. Greene had one or two loyal supporters, particularly Mr. L. R. Broster, who was able to plead the case before the Council of the Royal Society of Medicine. Thus it is almost entirely due to these two enthusiastic pioneers that this section came into existence on January 26, 1946, exactly six months before the Society for Endocrinology held its inaugural meeting. The first president of the section was Sir Walter Langdon-Brown, the two vice-presidents were Mr. Broster and Dr. Gardiner-Hill, and the senior secretary was Dr. Raymond Greene. Indeed, the new section emerged as such a smart equipage that a certain wit christened it "the Section of West-Endocrinology." Sir Walter Langdon-Brown was unfortunately prevented by illness from making a personal appearance before the section, and his presidential address was read for him by Dr. Raymond Greene. On the death of Sir Walter, Mr. Broster became president.

The section flourished from the start, and its meetings were attended by large gatherings which filled the Barnes Hall. Almost immediately all resistance, resentment, and opposition disappeared. The section has always been on the most cordial terms with the Society for Endocrinology, and during the year 1948-9 Dr. Parkes was president of the Section of Endocrinology and chairman of the committee of the Society for Endocrinology. From time to time the section and the society have held combined symposia, and the council of the one and the committee of the other have on occasions met together—for instance, when they asked the Medical Research Council to consider providing facilities for certain laboratory investigations, such as urinary hormone assays, to clinical departments which were unable to have these carried out in their own hospitals. As the result of this approach the Medical Research Council set up a Clinical Endocrinology Committee, which has, among other things, published a standard method of determining urinary 17-ketosteroids. It has also made arrangements to distribute certain steroid reference standards otherwise difficult to obtain. In 1952 the section and the society set up a committee under the chairmanship of Mr. Broster to consider how best to encourage progress in endocrinological research in this country in the future.

The Addison Lecture

As the result of a benefaction to the medical school by one of its old students, Guy's Hospital established an annual lecture to commemorate the part played by Thomas Addison in the foundation of modern endocrinology. The inaugural Addison Lecture was delivered by Sir Charles Dodds in 1946. It has been the custom to select the lecturers alternately from this country and from overseas, and the subsequent lecturers have been Professor E. B. Astwood, of Boston; Sir Henry Dale; Professor G. W. Corner, of Baltimore; Professor F. G. Young, of Cambridge; Professor T. Reichstein, of Basle; Professor S. Zuckerman, of Birmingham; and Professor Lawson Wilkins, of Baltimore. Among

those who have taken the chair at these lectures have been Sir Charles Harington and Dr. E. D. (now Lord) Adrian.

Whither Endocrinology?

At the present time clinical endocrinology has not acquired the status of a specialty to the same extent as has neurology or orthopaedic surgery or psychiatry or paediatrics; the number holding appointments on hospital staffs as endocrinologists can be counted on the fingers of one hand. But, with due respect to the other three, it is fair, I think, to say that this small handful cannot claim the credit for the high record in which British endocrinology is held. As I have already pointed out, there are anatomists, experimental physiologists, biochemists, clinical pathologists, pharmacologists, therapists, physicians, surgeons, and even professors of social medicine, who by their research work, their writing, their teaching, their inspiration, and their flair for organizing have raised its standard and made its great reputation.

How can this be maintained? How are future scientists to be trained in, and future doctors to be taught, endocrinology? Above all, what inducements exist at the moment, or are likely to arise in the near future, to attract recruits into endocrinology? Is there to be an Institute of Endocrinology established for postgraduate training? I think not. To be comprehensive, its laboratories, its wards, its clinics, and its specialist departments for the study of diabetes and other metabolic disorders, thyroid disease, paediatrics, neuro-endocrinology, gynaecological and obstetric endocrinology, let alone the more abstruse biological and biochemical research, would spread and sprawl to such an extent that if grafted on to a certain famous postgraduate hospital they would land up in the neighbouring gaol. Furthermore, one could not hope to concentrate the present generation of established endocrinologists in such an institute. Most of them are comfortably ensconced in the departments they have already built up for themselves through their own enterprise and the good will and personal interest of their colleagues. In fact such centralization would be a retrograde step. Regionalization is the modern policy of medical planning.

Is there to be a special course in endocrinology for premedical students, a diploma in endocrinology, a College of Endocrinologists? Again, I think not, for endocrinology is not a pigeonhole specialty, but rather a cross-section of the biological sciences and of medicine, surgery, and gynaecology. We who are specially interested in endocrinology do not want to confine it to ourselves; we want to spread our gospel. We want to collaborate, not to insulate; to co-operate, not to isolate.

Nevertheless we are firmly convinced that endocrinology is an established, respectable, orthodox, and rapidly expanding biological and clinical science. We would do much to prevent it from being stifled, swallowed up, derided, or ignored. So what must we do? Those of us who hold appointments in undergraduate teaching hospitals must select from our collection a few only of our most classic cases of common endocrine disorders and demonstrate them to the students simply and attractively. These demonstrations should be memorable but infrequent, for the medical student has more than enough to learn already, and endocrinology is only a very limited part of that amount. In postgraduate teaching it might be an advantage to arrange a systematic course of lecture-demonstrations given by those who have made a special study of this specialty.

Recruitment

There are physicians and others who are members of the Section of Endocrinology who have established themselves and made their names famous as endocrinologists, whatever they may officially call themselves. There are younger and more junior Fellows of the Royal Society of Medicine who attend the meetings of the section simply because they wish, quite rightly, to broaden their medical education. A few, however, may be genuinely interested in endocrinology and

would like to specialize in it, if only they dare take the risk. And the question is, dare they take the risk? Of course, if you want to be successful in life you must always take a risk. You must take a risk if you aspire one day to become a consultant physician, for there are not nearly enough consultant posts in internal medicine to accommodate the many hundreds of hard-worked, underpaid, and well-qualified medical registrars. And you of the present generation live in a competitive age in which only a few can reach the top in whatever walk of life you choose. Nevertheless there are sufficient consultant posts in medicine, surgery, obstetrics and gynaecology, neurology, dermatology, ophthalmology, oto-rhino-laryngology, orthopaedics, genito-urinary surgery, paediatrics, anaesthetics, radiology, radiotherapy, and psychiatry to attract recruits who are prepared to spend more years in training for them than they took to become qualified doctors.

But what of endocrinology? There are, I think, opportunities for training. In most schools of medicine there are posts to be held in the departments of clinical chemistry or clinical pathology where the basic technique may be learnt, and there should be vacancies for men so trained to work at registrar level in the departments of those who have established themselves as experts in some branch of clinical endocrinology. Another method—though I am not suggesting that it is necessarily the only method—of obtaining such training has been provided by the Medical Research Council. In 1951 this body launched a scheme of Clinical Research Fellowships. The holder of one of these Fellowships is paid at registrar level and is given the opportunity of acquiring the techniques and disciplines of those basic sciences relevant to his clinical interests, or of working in a department of recognized standing already engaged in clinical research, such as the clinical units of the Universities or the Medical Research Council. If he makes a success of his Fellowship, there is the possibility that he might obtain one of the Council's Rockefeller or other Travelling Fellowships and thus have the opportunity of broadening his outlook by working in the department of some distinguished foreign expert in the particular specialty he has chosen. Furthermore, he may do this without losing his place in the queue, for the Council has insisted on a promise from the applicant's sponsor of an appointment at the end of the training period. But what appointments are, in fact, available at the present moment, either in general clinical endocrinology or in some branch of endocrinology? The answer is, I am afraid, "None." Now this is disastrous, for unless you can offer the trainee some prospects, some goal to aim at after you have so carefully, arduously, and expensively trained him, you will find no recruits, and clinical endocrinology in this country will wither and die.

How is this very serious and urgent situation to be remedied? Not, I think, by setting up a whole crop of new departments of clinical endocrinology, for this would take more time than, in our urgent predicament, we can afford. It would require a large capital grant and a substantial endowment, which are most unlikely to be provided either by the National Health Service or by the University Grants Committee in these stringent times. It would need the greatest good will and active co-operation of the clinical staff of the hospitals in which the new departments are to be set up, and indeed it is very doubtful whether one could "sell" the scheme to medical committees and boards of governors of hospitals, already short of beds and with the present drastic cuts in their maintenance costs, even supposing they were sympathetically attuned to the idea of creating and expanding a new specialty. This does not mean that I do not hope that existing departments of endocrinology will flourish to the mutual benefit of themselves and the hospitals in which they are established, and by their example prepare the way for the foundation of other such departments at the earliest expedient moment. I hope also that existing departments of endocrinology may be given the opportunity of playing their part in training future endocrinologists.

But at the moment, I think, our best chance of overcoming the serious predicament of lack of recruits in endocrinology is to encourage the establishment and expansion of the endocrine aspects of certain branches of the medical sciences which cannot afford to ignore endocrinology if they are to make their proper contributions and retain their high reputation in this age of rapid scientific advances. I will take two examples to illustrate what I mean. The first is paediatrics. Lawson Wilkins has shown the close relationship between paediatrics and endocrinology, and through his inspiration, enthusiasm, and hard work he has made far-reaching contributions, not only to paediatrics, but to endocrinology. He has broadened the scope of paediatrics and, far from snatching the livelihood from the mouths of the paediatricians, he has presented them with a new stock-in-trade, and on account of his work and that of others like him paediatricians throughout the world are being consulted more and more about endocrine problems. If the paediatricians of this country would select and encourage one or two of their promising young registrars and have them fully and carefully trained as endocrinologists, and then be prepared to give them consultant status with charge of beds and full responsibility for the care of patients, I feel sure that this step would redound to the credit of British paediatrics. My other example is gynaecology. In my view there is need for more gynaecological endocrinologists. In the first place, disorders of menstruation constitute a rather complex aspect of applied physiology which can be thoroughly comprehended only by someone with a fair knowledge of general endocrinology and biochemistry, and it is seldom that the gynaecologist has this knowledge. His training and outlook are totally different. The surgical skill and technique of the gynaecologist, the mechanical manipulations of the obstetrician, and the necessarily rapid repetition of pelvic examinations in the out-patient clinic are unlike the careful recording of menstrual cycles and the precise timing in relation to the menstrual cycle of endocrine therapy, familiarity with the dosage, potency, toxicity and efficacy of different preparations, and the complementary activities of the adjoining endocrine laboratory unit. Nevertheless endocrinology is playing an increasing part in gynaecology. Let the gynaecologists single out and encourage a few of their promising young registrars and have them fully trained as endocrinologists, and then appoint them with consultant rank to gynaecological professorial units or special gynaecological hospitals. Then give them an endocrine laboratory, and they will provide an added stimulus to the work and enhance the reputation of the department or hospital concerned.

I have chosen only two examples: I could develop my theme further. Clinical endocrinologists are needed in thyroid clinics, fertility clinics, and departments of internal medicine, rheumatology, urology, dermatology, allergy, and even surgery. They may be purely clinical endocrinologists with a background training in either physiology or internal medicine, or they may be recruited from the ranks of the specialty on to which it is intended to graft endocrinology. In either case they should have full consultant status. This is not, in my view, an unrealistic dream. It needs enlightened boards of governors and tolerant and sympathetic medical committees, and heads of departments with a determination to carry out their plan. Unless in some such way consultant posts are created soon, endocrinology in this country will surely wither.

The *British Journal Photographic Almanac* for 1955 (Henry Greenwood and Co., 5s., or cloth-bound 7s. 6d.) has several articles on recent progress, both in techniques and apparatus, which will be of interest in hospital radiography departments. It is pointed out how much radiography has benefited from new advances in isotope production, and how photochemistry is helping to unravel complex chemical problems. A six-page table gives summary information about materials for medical photography. The photographic reproductions are excellent.

PNEUMOCOCCAL MENINGITIS

A SHORT SURVEY OF 78 PATIENTS IN THE BRISTOL CLINICAL AREA

BY

C. D. R. PENGELLY, M.B., M.R.C.P.
M.R.C.P.Ed.Senior Medical Registrar, West Cornwall Clinical Area;
lately Medical Registrar, Bristol Royal Infirmary

In general the prognosis in pneumococcal meningitis has been poor; indeed, before the availability of the sulphonamides it was almost hopeless, 100% mortality having been recorded by Toomey and Roach (1939) and Silverthorne (1948), and a review of 631 cases from the literature revealed but one survival (Waring and Weinstein, 1948). After the introduction of the sulphonamides the mortality remained at about 60 to 80% (Table I), but marked improvement followed the introduction of penicillin, although very varied results have been reported (Table II). In some the mortality is 20% or less, but the average for the results quoted is 40% (Table II).

TABLE I.—Mortality of Pneumococcal Meningitis Treated with Sulphonamides Alone (Various Authors)

Authors	No. of Cases Treated	Mortality
Appelbaum (1945)	139	65%
Dowling <i>et al.</i> (1942)	72	94%
Hartmann <i>et al.</i> (1945)	34	63%
Hodes <i>et al.</i> (1943)	60	58%
Jackson (1950)	82 (excluding those treated with sulphonamide only)	79%
Neal <i>et al.</i> (1940)	30	67%
Rhoads <i>et al.</i> (1940)	22	68%
Sweet <i>et al.</i> (1945)	40	92%
Walker and James (1945)	28 (one patient treated with penicillin)	64%

TABLE II.—Mortality of Published Series of Cases of Pneumococcal Meningitis Treated with Penicillin

Authors	No. of Cases	Mortality
Appelbaum and Nelson (1945)	67	61%
Appelbaum <i>et al.</i> (1949)	125	26%
Bunn and Peabody (1952)	20	35% (25% if 2 patients who died during treatment from other causes are excluded)
Dowling <i>et al.</i> (1949)	87	56%
Feibush <i>et al.</i> (1952)	22	68%
Galloway and Chambers (1953)	27	33%
Gibson and James (1952)	31	10%
Hall <i>et al.</i> (1946)	17	24%
Jackson (1950)	51	43%
Lowrey and Quilligan (1948)	17	18%
Nemir and Israel (1951)	15 (all infants and children)	7%
Ross and Burke (1946)	19	16%
Smith <i>et al.</i> (1946)	38	24%
Sweet <i>et al.</i> (1945)	16	56%
White <i>et al.</i> (1945)	50	64%
Total	602	40%

Present Series

During the period January 1, 1946, to May 31, 1953, pneumococcal meningitis was diagnosed in 78 patients in hospitals for acute cases in Bristol. Hospitals for chronic cases were not included in the survey. A number of recurrences brought the total number of attacks of meningitis to 84, in 82% of which the pneumococcus was cultured from the C.S.F. either in life or at necropsy, and in the remainder it was seen in a stained smear.

Mortality.—Of the 78 patients 38 died, a mortality of 49%. A necropsy was performed on 28 (74%). The mortality calculated according to the number of attacks of meningitis was 45%.

Age Distribution.—The age distribution of the patients in 10-year periods is shown in Table III. In addition the period from birth to 1 year of age is included. The

TABLE III.—Age Distribution of 78 Cases of Pneumococcal Meningitis in Bristol

Age	No. of Patients	No. Dying	No. Recovering	Mortality
0-1 year	20	7	13	35%
0-9 years	42	15	27	36%
10-19	6	3	3	50%
20-29	2	1	1	50%
30-39	9	5	4	55%
40-49	3	1	2	33%
50-59	7	7	0	100%
60-69	8	5	3	62%
70+	1	1	0	100%
Total	78	38	40	49%

mortality for each age group is shown. Notable features are the relatively large number of infants and children under 10 years old and the steep rise in mortality for those patients aged 50 and over. Only 3 recoveries occurred in 15 patients in the latter group (82% mortality). For infants the mortality was 35%, or rather below the average (49%).

Cause of Meningitis.—In many of the patients there was a demonstrable primary focus of infection, in some it was apparent during life and in others only at necropsy. In a few trauma was the immediate cause and in a large group no cause was found (Table IV). Cases with a clear terminal

TABLE IV.—Apparent Primary Cause of Meningitis in 78 Patients

Apparent Primary Cause	No. of Patients	No. Dying	No. Recovering	Mortality
Middle ear or mastoid infection	30	12	18	40%
Pneumonia	8	4	4	50%
Nasal sinus infection	3	3	0	100%
Panophthalmitis	1	0	1	0%
? Bacterial endocarditis	1	0	1	0%
Trauma	9	4	5	44%
No cause found	26	15	11	58%
Total	78	38	40	49%

bronchopneumonia only have been excluded from the "pneumonia" group. In the "trauma" group six had head injuries, in two the meningitis followed nasal operations, and in one it followed a perforating injury of one internal ear.

Level of Consciousness on Admission to Hospital.—In 37 of the attacks the patient was either fully conscious or at worst stuporous on admission to hospital, and death followed in 9 (24% mortality). In 31 attacks the patient was delirious or comatose when admitted and death followed in 19 (61% mortality). In 12 attacks continuous convulsions were occurring at the time of admission and death followed in 8 (66% mortality). (Two attacks occurring in patients

TABLE V.—Distribution of Attacks of Pneumococcal Meningitis According to the Length of Illness Before Admission to Hospital*

* Excluding four attacks, two of which developed in patients who were being treated in hospital for another condition and two in patients transferred from outside the area for operation.

transferred to the area for operation and two in patients admitted to hospital for a condition other than meningitis have not been included.)

Duration of Illness Before Admission to Hospital.—An analysis of attacks according to the number of days of illness before the patient's admission to hospital is shown in Table V.

Treatment

Chemotherapy and Antibiotics

Table VI shows the sulphonamide and antibiotic treatment given. There are four groups: the first, designated "standard therapy," consists of attacks treated with a sulphonamide together with penicillin by both the intramuscular and the intrathecal routes. Group 2, designated

TABLE VI.—Sulphonamide and Antibiotic Treatment of 84 Attacks of Pneumococcal Meningitis

Treatment	No. of Attacks of Meningitis	No. of Attacks with Fatal Outcome	No. of Attacks with Recovery	Mortality
1. Standard treatment	54	20	34	37%
2. Incomplete treatment	14	11	3	79%
3. Additional treatment	13	4	9	31%
4. No specific treatment	3	3	0	100%
Total	84	38	46	45%

Occasionally one of the items of the "standard" treatment was omitted in patients in group 3.

"incomplete therapy," contains those attacks treated as in group 1 but incomplete in some respect—for example, no sulphonamide, no intrathecal penicillin, etc. Group 3 shows those attacks treated as in the preceding groups, but with one or more additional antibiotic. Group 4 shows those attacks not specifically treated.

The additional therapy in Group 3 consisted of intramuscular streptomycin in two attacks, intrathecal streptomycin in two, chlortetracycline (orally) in four, chloramphenicol (orally) in two, and chlortetracycline (orally) with intrathecal streptomycin in one.

The majority of patients receiving penicillin were given an intrathecal dosage of 5,000 to 30,000 units, once or at most twice daily. In two cases 500,000 units was given in error at a single injection and in both death followed within 24 hours preceded by generalized convulsions. Sulphonamides were used as for any acute infection, and intramuscular penicillin was given in a dosage which varied from about 100,000 to 1,000,000 units in 24 hours divided usually into three- or four-hourly doses. In 45 attacks under 250,000 units in 24 hours was given, and in the remaining 39 more than this amount was used. The mortality was 45% in the group receiving the smaller amount and 46% in that receiving the bigger dose. If the 10 attacks in which no penicillin was given intrathecally are excluded from the lower-dosage group the mortality in the remaining 35 attacks was 34%. Two of the patients receiving no intrathecal penicillin recovered.

Surgical Measures

The operation of mastoidectomy was performed five times in the series, being done 38, 8, 7, and 2 days after the patient's admission to hospital in the four cases which recovered. In the one fatal case, that of a baby aged 4 months, it was done on the day of admission. Burrholes were made in the skull for penicillin administration after the development of a block in the spinal theca on three occasions; one patient recovered. In one of the others the meningitis was apparently controlled after this treatment, but the patient remained comatose and died possibly with a cerebral abscess; there was no necropsy. Three further patients were investigated by ventriculography to exclude an intracranial abscess, but none was found. One had developed a right arm paresis which slowly recovered, and the other two were recurrent cases and are mentioned below.

Recurrent Cases

In five patients in the series recurrences occurred. In one, that of a boy aged 8 years when he had his first attack in 1947, recurrences occurred five times, with long intervals between attacks. Only in the first was an infective focus discovered and this eliminated by mastoidectomy. The second patient, a man aged 30, was reinfected through defects in the floor of the anterior cranial fossa. Removal of nasal polypi and a bilateral Horgan's operation were carried out in 1949, following which he had C.S.F. rhinorrhoea. Three weeks after the operation he developed a purulent meningitis from which no organisms were isolated. Two months later a proved attack of pneumococcal meningitis occurred, and after preliminary medical treatment an exploration revealed a hole in the right side of the floor of the anterior cranial fossa which was covered by a graft. After 18 months of good health another attack of pneumococcal meningitis occurred and yet another six months later. In March, 1951, further exploration revealed another hole in the floor of the anterior cranial fossa, this time on the left side, which was also covered by a graft. He remained free from further attacks of meningitis following this, only to die in May, 1953, from a spindle-cell sarcoma arising in his abdominal wall.

The third patient, a lad aged 16, was admitted to hospital with a purulent meningitis the day following a minor head injury in January, 1949; there was no radiological evidence of fracture. No organism was isolated. After a rapid recovery he remained well until 18 months later, when he had a proved attack of pneumococcal meningitis. A good response to medical treatment occurred and he has remained well since.

The fourth patient, a man aged 30, was admitted to hospital with pneumococcal meningitis after a history of 24 hours' headache and vomiting. He was in coma. He responded to treatment and no focus of infection was discovered. He remained well until four years later, when he had another attack, coma occurring only a few hours after the onset of headache. In spite of early treatment he died within 24 hours of admission. Necropsy revealed a purulent meningitis and an astrocytoma of the mid-brain causing obstruction of the aqueduct and internal hydrocephalus. There was no infective focus.

The last patient, a girl aged 16, had a splenectomy for Banti's disease at the age of 12 years and developed a meningitis one year later. No organisms were isolated. An attack of pneumococcal meningitis occurred after another two years (1950) and failed to respond well to medical treatment. She was therefore transferred to the Bristol Neurosurgical Unit for investigation, where ventriculograms were negative and the meningitis slowly responded to continued sulphonamide and penicillin therapy. A relapse occurred as soon as treatment was stopped, but she responded well to chloramphenicol. The presence of an apical systolic murmur in her heart suggested the presence of bacterial endocarditis and she was accordingly given a six-weeks course of penicillin, 2,000,000 units a day. She remained well until 1952, when she died at home after a short illness, possibly another attack of meningitis.

Associated Diseases and Conditions

The meningitis was found in association with other conditions in 10 cases: diabetes mellitus twice, Parkinsonism, cirrhosis of the liver, astrocytoma of the mid-brain, hydro-nephrosis and chronic pyelonephritis, right upper lobe bronchiectasis, Banti's disease, situs inversus totalis, and familial acholuric jaundice. All except the last two of these patients died.

Discussion

The present series of cases of pneumococcal meningitis is entirely unselected and includes patients already suffering from a serious disease, which accounts for the high mortality. If only those attacks in which full sulphonamide and penicillin therapy was given are considered the mortality is 37% of 54 attacks (Table VI), and, furthermore, excluding those cases in which death occurred within 24 hours of admission to hospital, the mortality becomes 28% of 43 attacks, a figure comparable with all but the very best results (Table II).

Age is a very important factor in relation to prognosis in the disease, particularly poor results occurring in patients aged 50 or more. This is not only the impression from the present series (Table III) but has also been the experience of others (Table VII), although it was not a notable feature

TABLE VII.—Relationship Between Age and Mortality Rate in Pneumococcal Meningitis. Percentages Calculated from Figures Given by Various Authors

Authors	No. of Cases	Mortality in Ages (Years)			
		Under 40	Over 40	Under 50	Over 50
Appelbaum (1945)	67	44%	73%	54%	72%
Feibush <i>et al.</i> (1952)	22	45%	80%	44%	85%
Jackson (1950)	125	67%	76%	—	—
Lepper and Dowling* (1951)	43	—	—	23%	41%

Present series	78	41%	74%	40%	81%

* Not including chlortetracycline-treated cases.

of the series of Smith *et al.* (1946). Very young patients had a poor prognosis before penicillin became available (Cooke, 1941; Waring and Weinstein, 1948; Jackson, 1950), but the prognosis for infants when penicillin is used appears fairly good. With penicillin treatment, Waring and Weinstein (1948) noted a 69% recovery for patients under 2 years old (58 cases), while Nemir and Israel (1951) lost only one of nine infants, and Ross and Burke (1946) achieved a recovery of all nine infants. In the present series also the prognosis for infants with penicillin therapy was better than average (Table III).

The commonest predisposing cause of the meningitis in the present series was middle ear and mastoid infection (38%) (Table IV), but in 33% no cause could be found. Pneumonia has often been noted as a common if not the commonest cause of pneumococcal meningitis (Table VIII) but accounted for only 10% of the cases in this series.

Trauma is evidently a rare cause (Tables IV and VIII) but is, however, a very important one, as recurrences are

apt to occur, especially if the thin floor of the anterior cranial fossa has been fractured. The covering of the damaged bone with a graft of fascia lata proves an effective means of preventing further attacks. Defects in the floor of the anterior cranial fossa causing meningitis may be congenital in origin (Galloway and Chambers, 1953).

Coma and convulsions at the time of admission to hospital indicated a poor prognosis in this series, the difference in mortality between those fully conscious or only stuporous on admission and those having convulsions or comatose being statistically significant. This result might be reasonably anticipated; it was also found by Lepper and Dowling (1951), but was not confirmed by Feibush *et al.* (1952) in a small series of cases.

It is apparent from Table V that those patients who were ill for three days before admission to hospital had the best prognosis. There was only one patient older than 50 years in that group, but even after removing all patients aged 50 or more the mortality for those ill less than three days before admission was 61% (31 cases), for those ill more than three days 24% (21 cases), and for those ill just three days 7% (14 cases). All the fulminating cases are obviously included in the first group, in which 62% were in coma or having convulsions when admitted. Twenty-seven per cent. of the 14 cases ill for three days and 52% of those ill for more than three days before admission to hospital were in coma or having convulsions when admitted. It is probable that more of the last group would have recovered had full medical treatment been started earlier.

Combined sulphonamide and penicillin therapy still remains the treatment of choice in pneumococcal meningitis, and the penicillin should be given by both the intramuscular and the intrathecal routes. Excellent results have been obtained by this method (Ross and Burke, 1946; Smith *et al.*, 1946; Gibson and James, 1952) (Table II). Sulphonamides should be given as for any acute infection, but the daily intramuscular requirement of penicillin is not clear. Smith *et al.* (1946) were using at first about 120,000 units daily in three- or four-hourly doses or by continuous intramuscular infusion, while Gibson and James (1952) were using latterly 1,600,000 units daily. As already shown, in the present series those cases receiving more than 250,000 units daily fared no better than those receiving less, and the two groups appear comparable so far as age distribution and level of consciousness on admission to hospital are concerned. Dowling *et al.* (1949) have said that intrathecal penicillin administration is unnecessary provided that large enough doses are given intramuscularly. They treated 66 cases by the ordinary method and 21 cases without intrathecal therapy and 2,000,000 units of penicillin every two hours intramuscularly: the mortality of the first group was 66% and of the second 38%, results which are not good and can hardly be used as an argument for rejecting intrathecal therapy. Smith (1951) found a clinical and bacteriological relapse in a baby with pneumococcal meningitis when given a non-potent dose of intrathecal penicillin in spite of massive intramuscular penicillin dosage every two hours.

In spite of the 75% cure of 20 cases without intrathecal penicillin by Bunn and Peabody (1952), there is no convincing evidence that intrathecal therapy with penicillin should be abandoned. It should remain part of the routine management in pneumococcal meningitis, and should be given in daily doses of about 20,000 units for about 7 to 10 days or until the meningitis is obviously under control. Much larger doses should not be used, as they are known to produce damage to the spinal cord and cauda equina or even convulsions and death. As little as 50,000 units intraventricularly has produced convulsions (Johnson and Walker, 1945). Gibson and James (1952) thought the dangers were exaggerated and gave even their infants 50,000 units at a single dose.

Although there is no clear-cut evidence in favour of giving very large intramuscular penicillin doses when intrathecal

treatment is being given, it is probably wise to give at least 2,000,000 units daily in divided doses with intervals of not more than four hours between injections. Fortunately the pneumococcus is usually highly sensitive to penicillin and does not develop resistance during treatment.

There is no evidence in the literature that treatment with antibiotics in addition to penicillin will improve the prognosis. On the contrary, there is evidence that the addition of chlortetracycline therapy leads to a worsening of the prognosis. Lepper and Dowling (1951) treated 43 cases with the usual intramuscular and intrathecal penicillin and 14 with the addition of chlortetracycline. In the first group 30% of the patients died, and in the second 79%, a statistically significant difference.

Surgical treatment for the elimination of foci of infection in the ears, mastoids, or sinuses was regarded as a mainstay of treatment in pneumococcal meningitis before penicillin was available (Neal *et al.*, 1940; Walker and James, 1945), but with the use of penicillin Smith *et al.* (1946) never found such operations necessary in the acute phase and often not at all. Ross and Burke (1946) found no surgery necessary in their 19 cases. Mastoidectomy was required five times in the present series in spite of penicillin therapy. A certain number of recurrences can probably be prevented by the removal of chronic sepsis in ears, mastoids, and sinuses after treatment of the meningitis.

Burr-holes are made in the skull for the intraventricular administration of penicillin or for the diagnosis of an intracranial abscess. Penicillin may be given intraventricularly if a block with exudate prevents its free access to the brain when administered by the lumbar route. Cisternal administration of penicillin may suffice but does not guarantee that it will reach the ventricles. Spinal block is not common in pneumococcal meningitis. Intraventricular penicillin administration was needed in only two of the last 19 cases of Smith *et al.* (1946) and was required only three times in the present series. Intracranial abscess is also a rare complication. Smith *et al.* (1946) found this only twice in their 38 cases, and in reviewing the literature Waring and Weinstein (1948) found only 3.6% of 386 cases and none in 86 treated with both penicillin and sulphonamides.

Pneumococcal meningitis may complicate other and serious diseases as previously shown, when the prognosis is correspondingly poor. The association with diabetes mellitus and hepatic cirrhosis in this series led to diagnostic difficulties and delay in treatment.

Summary

A short survey of 78 cases of pneumococcal meningitis in the Bristol Clinical Area is presented with a discussion of certain aspects of aetiology, prognosis, and treatment.

The mortality was 49%, or 45% in 84 attacks of meningitis, as there were some recurrences. The cases were unselected, and included those already with chronic and wasting diseases.

It has been shown that the prognosis was much worse in patients over 50 years of age, but that the results in infants and young children were better than the average; also that coma or convulsions occurring at the time of admission to hospital influenced the prognosis very unfavourably.

Middle ear or mastoid disease was the commonest primary source of infection, but almost as frequently no source of infection or other predisposing cause could be demonstrated. Pneumonia was an uncommon source of the infection.

Prognosis was worse in those cases with a period of illness greater or less than three days before hospital admission, presumably because the fulminating cases

DESACETYL METHYLCOLCHICINE IN TREATMENT OF MYELOID LEUKAEMIA

BY

B. J. LEONARD, M.D.

Sybil Mary Pilkington Research Fellow

AND

JOHN F. WILKINSON, M.D., M.Sc., Ph.D.
F.R.C.P., F.R.I.C.

Physician and Director

(From the Department of Haematology, Manchester Royal Infirmary and Manchester University)

In 1953 Moeschlin and colleagues reported that desacetylmethylcolchicine ("colcemid") had beneficial effects on a group of patients with chronic myeloid leukaemia, while some encouraging results were also noted in a few cases of acute myeloid leukaemia and in two patients in the acute myeloblastic phase of chronic myeloid leukaemia. On the other hand, chronic lymphatic leukaemia failed to respond and might even have been made worse. The profound depressive effects on the granulocytogenesis were accompanied simultaneously by a reduction in the size of the spleen and an increase in the red blood cell count and haemoglobin values.

Desacetylmethylcolchicine was isolated in a pure form by Santavy and Reichstein (1950) from the mixed alkaloid extract of *Colchicum autumnale* and was found to have a relatively low general toxicity, some 30-40 times less than colchicine (Schär *et al.*, 1954), which, although having a very marked inhibitory effect on cell mitosis, is too toxic for safe clinical use (Jacobj, 1890; Dustin, 1938; Bucher, 1939).

Lichtman (1954) has described in detail the effects of desacetylmethylcolchicine on the blood cellular elements in rabbits and cats, producing a diminution of total leucocyte count in two days after intravenous administration and in 12-14 days after oral treatment. With cessation of treatment the leucocytes rapidly returned to normal levels.

We have been able to repeat the observations of Moeschlin and his colleagues in a series of leukaemias and leukaemoid conditions, and are reporting here some of our results with chronic and acute myeloid leukaemias.

Dosage and Control

The initial oral dose of 3 mg. of colcemid daily was increased after three to four days to a total of 7-10 mg. daily according to the white-cell count. This dosage was continued until the leucocytes dropped to approximately 25,000 per c.mm., and was then stopped for three to four days. A daily maintenance dose of 3-5 mg. was then instituted. Daily white-cell counts, platelet counts, and haemoglobin estimations were performed until the maximal effect on the white cells had been attained; thereafter counts were done twice weekly and finally every one to two weeks.

Chronic Myeloid Leukaemia (8 cases)

Of eight patients with chronic myeloid leukaemia there was a distinct clinical improvement in six (Cases 1-6); their appetites improved, they gained weight and experienced far more energy; their spleens rapidly decreased in size and became barely palpable. In the remaining two (Cases 7

Previous treatment: Cases 2, 3, 7, and 8 had had myleran; Cases 3, 7, and 8 had also had 6-mercaptopurine.

and 8), colcemid had little effect on the splenomegaly, but these two had also become resistant to "myleran" and 6-mercaptopurine, both of which had failed to influence the degree of splenomegaly. In Case 7, in spite of a reduction in the white-cell count from 57,000 to 6,950 per c.mm., there was no improvement in the clinical condition.

In Table I details of these cases are shown. Cases 2, 3, 7, and 8 had received previous medication with myleran, and Cases 3, 7, and 8 had also had 6-mercaptopurine and had become resistant to treatment; one of these (Case 8) also failed to respond to colcemid. So far, Cases 1-6 have been maintained in satisfactory clinical and haematological states for periods of four to nine months on maintenance doses of 3-10 mg. All were treated as out-patients and carried on with their normal household duties or occupations.

In Case 5, in spite of a very satisfactory remission, colcemid had to be discontinued owing to an allergic reaction, but the patient maintained his improvement after a further three months. At the height of the depressant action on the granulocytes (white cells 11,400 per c.mm.) the patient experienced difficulty in swallowing and had scrotal tenderness and some loss of scalp hair. On examination there

was a generalized congestion of the fauces and erythema of the scrotum. This rapidly subsided on discontinuing treatment, and was thought to be a sensitivity reaction to colcemid.

It is important to institute a maintenance dose as soon as the white cells have reached the desired level; failure to do so may result in a rising white-cell count that may be resistant to treatment for several weeks. Fig. 1 shows the effects of instituting a maintenance dose at the correct time, and Fig. 2 shows the effects of withholding an early maintenance dose. It is interesting to note that the second course of colcemid found necessary to restore a normal white-cell count was much greater in total dosage than that required initially—229 mg. as against 63 mg.

In spite of the dramatic effect on the total white cells, in no case did the differential picture return completely to normal. In the majority there was a considerable reduction in the percentage of promyelocytes and myelocytes, but they persisted to a lesser degree when the white cells were restored to a more normal level; in several the initial basophilia persisted.

Marrow biopsies performed after treatment showed reduced cellularity and fewer promyelocytes and myelocytes, but the overall picture still remained that of chronic myeloid leukaemia.

There was a rise in the haemoglobin values and red-cell counts, but their maxima were not reached for several weeks after the white cells had reached their maximal fall. The platelet counts in all were unaffected by the treatment, many remaining at the original high levels.

Myelofibrosis

The effects of colcemid on two patients with myelofibrosis are shown in Table II. The two cases are described separately because, although presenting like chronic myeloid leukaemia, the clinical and haematological findings suggested that these were actually examples of myelofibrosis.

Case A.—A housewife aged 64, who had had rickets in her childhood, had received x-ray treatment for chronic myeloid leukaemia before she was referred to us; attempts to obtain a marrow specimen had been repeatedly unsuccessful. Five months after x-ray treatment she was admitted to hospital complaining of severe bone pains in the limbs, loss of energy, and dyspnoea. The spleen was enlarged 13 cm. below the subcostal margin; red cell count, 3,320,000 per c.mm.; haemoglobin, 60%; platelets, 130,000 per c.mm.; total leucocyte count, 56,400 per c.mm. (polymorphs 4.5%, lymphocytes 2%, monocytes 0.5%, eosinophils 0.5%, basophils 0.5%, "blasts" 3%, promyelocytes 3.5%, myelocytes 11.5%, metamyelocytes 3%, atypical cells 71%). The atypical cells resembled normoblasts but were found to be peroxidase-positive. Attempts to obtain marrow from the sternum and iliac crest were repeatedly

FIG. 2.—Case 2. Effects of colcemid on the total white cells and haemoglobin levels.

TABLE II.—Myelofibrosis Treated with Colcemid

Case	Age and Sex	Before Treatment		After Treatment		Duration of Initial Treatment (Days)	Total Dose (mg.)	Maintenance Dose (mg.)	Effects on Splenomegaly (cm. Below Costal Margin)
		W.B.C.	Hb	W.B.C.	Hb				
A	64 F	56,400	60%	7,200	56%	3	3	1	13 to 8
B	40 F	75,000	62%	26,100	56%	5	15	2-3	15, 11, 12

unsuccessful: the bones were found to be extremely hard, but x-ray films of the skeleton showed no detectable abnormality.

Colcemid was administered cautiously in a dose of 1 mg. daily, and after a total dosage of 3 mg. the white cells were 7,200 per c.mm., red cells 3,010,000 per c.mm., haemoglobin 54%, and platelets 125,000 per c.mm. The differential count showed a persistence of the atypical granulocytes: polymorphs 5.5%, lymphocytes 1%, monocytes 0.5%, eosinophils 1%, basophils 0.5%, "blasts" 2%, promyelocytes 2%, myelocytes 9%, atypical cells 78.5%. Transfusions were given and the haemoglobin eventually rose to 81%, and the loss of energy and dyspnoea subsided. The bone pains were controlled with phenylbutazone 200 mg. twice daily. She has been maintained in this improved clinical state for six months on a daily dose of colcemid 1 mg. The white-cell count has been kept within normal limits, but the abnormal differential has remained more or less unchanged.

Case B.—A housewife aged 40 was referred to us with a history of sudden haemoptyses and was found to have anaemia and considerable splenomegaly (15 cm. below the subcostal margin). A blood count showed: red cells, 4,550,000 per c.mm.; haemoglobin, 62%; platelets, 305,000 per c.mm.; white cells, 75,000 per c.mm. (polymorphs 54%, lymphocytes 11%, eosinophils 3.5%, basophils 4%, myeloblasts 13.5%, promyelocytes 1.5%, myelocytes 8%, metamyelocytes 4.5%); there were 6 nucleated red cells per 200 white cells. The marrow biopsies in several different bones were repeatedly unsuccessful; with the use of considerable force the needle entered the marrow cavity, but no marrow was ever aspirated. Radiological examination of the skeleton and chest was negative. After a total dosage of 15 mg. of colcemid, the white-cell count fell to 26,100 in five days (polymorphs 31.5%, lymphocytes 8.5%, monocytes 0.5%, eosinophils 3%, basophils 17.5%, "blasts" 14%, promyelocytes 4%, myelocytes 14%, metamyelocytes 7%); haemoglobin, 56%; red cells, 4,540,000 per c.mm.; platelets, 300,000 per c.mm. The patient felt improved in herself, had far more energy, and there were no further bleeding episodes. On a daily maintenance dose of 2-3 mg. this clinical improvement has been maintained for five months, the total white cell count has been kept within normal limits, but the abnormal differential count has remained unchanged.

Chronic Lymphatic Leukaemia

Case X.—A man aged 63 presented with generalized lymphadenopathy, splenomegaly (5 cm. below costal margin), and blood and marrow pictures of chronic lymphatic anaemia. The blood picture before treatment was red cells, 3,670,000 per c.mm.; haemoglobin, 83%, white cells, 224,000 per c.mm. (polymorphs 5%, lymphocytes 91%, lymphoblasts 3%, metamyelocytes 1%).

Colcemid, 3 mg., was given daily, and after six days' treatment the white cells had risen to 326,000 per c.mm., while the differential count showed 17% lymphoblasts. His general condition deteriorated with pyrexia, anorexia, and malaise. Treatment was discontinued and within seven days the "blasts" disappeared from the peripheral blood and the white-cell count dropped to its initial level, while his clinical condition slowly improved.

There is no doubt that colcemid aggravated the condition, and if treatment had not been discontinued an irreversible acute leukaemic phase might well have persisted. This experience is similar to that of Moeschlin *et al.* (1953), and we feel that colcemid should not be given to patients with lymphatic leukaemia.

Acute Myeloid Leukaemia

In Table III Cases I, II, and III had acute myeloblastic leukaemia which had failed to respond to other forms of therapy, and Case IV had received no previous treatment. Cases V and VI had suffered from long-standing chronic myeloid leukaemia which had developed an acute myeloblastic phase.

Colcemid was given in doses of 3 mg. daily and increased to a maximum of 5 mg. a day, while supportive therapy with transfusions and antibiotics was also given.

Colcemid had little effect on the clinical condition in Cases I-III; there was no improvement in general well-being and no effect on the bleeding diathesis. However, in all three

TABLE III.—Acute Myeloid Leukaemia Treated with Colcemid

Case No.	Before Treatment		After Treatment		Time taken (Days) for Blood Changes in the Previous Column	Previous Treatment	Duration of Leukaemia from Start of Treatment and Present Clinical Condition
	"Blast" W.B.C.	"Blast" Cells	"Blast" W.B.C.	"Blast" Cells			
I	37,100	95%	26,000	49%	14	6-Mercaptopurine, Cortisone A.C.T.H. gel	Died 3 months
II	18,100	13%	7,400	30%	17	"	" 3 "
III	24,000	54%	7,950	32%	27	"	" 5 "
IV	9,200	69%	2,400	19%	14	None	" 3 "
V	148,000	38%	253,000	32%	31	Myleran, 6-Mercaptopurine	Still living 4 months. Very poor condition
VI	57,000	42%	90,000	32%	21	Myleran	Still living 5 months. Very poor condition

was a fall in the total white-cell counts and a decrease in the number of myeloblasts. The red cells and platelets were reduced in numbers, and this would probably have been more pronounced had transfusions not been given.

Colcemid did not have any beneficial effect in Cases V and VI; in fact, their white-cell counts increased and their clinical condition deteriorated.

Discussion

The results of treating chronic myeloid leukaemia with colcemid are encouraging. It appears that this compound is a more selective granulocyte depressant than other chemotherapeutic agents. The disadvantage of myleran in producing thrombocytopenia and aplastic anaemia, and in some cases precipitating an acute myeloblastic leukaemia, have so far not been seen in any of this small group of cases after treatment with colcemid. This drug is more effective in the early stages of chronic myeloid leukaemia, but in one patient who had survived for four years (on a variety of chemotherapeutic agents) it was completely ineffective. The clinical effects are just as striking as the effects on the blood; with reduction of splenomegaly, improvement in appetite and increase in weight and general well-being were very notable features. From the early results with colcemid it would appear worthy of further trial in chronic myeloid leukaemia, so that its long-term effects may be compared with other well-tried forms of therapy.

In both the patients with myelofibrosis the white cells were extremely sensitive to colcemid and dropped to low levels in three and five days respectively. This is in sharp contrast to the effects on the white cells in the more typical chronic cases of myeloid leukaemias.

The results of treating acute myeloid leukaemia and the acute phase of chronic myeloid leukaemia were disappointing. In spite of some reduction in the number of myeloblasts in the differential counts clinical deterioration continued, and in no case was a complete or even temporary remission obtained.

Summary

The effects of desacetylmethylcolchicine ("colcemid") on some cases of chronic myeloid leukaemia, myelofibrosis, chronic lymphatic leukaemia, and acute myeloblastic leukaemia are described.

Colcemid is of greatest value in chronic myeloid leukaemia, having a distinct depressant action on the

granulocytes and producing rapid reduction of splenomegaly and a marked clinical improvement in six of eight such treated cases.

The disadvantage of many other agents such as myleran in producing thrombocytopenia and aplastic anaemia was not seen in cases of chronic myeloid leukaemia treated with colcemid.

The effects of colcemid on myelofibrosis are considered.

Colcemid would seem to be contraindicated in the treatment of chronic lymphatic leukaemia, and evidence suggests that it may even produce an acute change.

Colcemid has little or no beneficial effects on acute myeloblastic leukaemia.

This work has been done during the tenure by one of us (B.J.L.) of the Sybil Mary Pilkington Research Fellowship, and we would thank Messrs. Ciba Ltd. for the supply of colcemid.

TEN-YEAR RECOVERY FROM CHRONIC LYMPHOCYTIC LEUKAEMIA

BY

MAX SCHOTT, M.D.
Bradford

Reports of recovery from leukaemia are extremely rare. I wish to present the case of a patient who undoubtedly suffered from chronic lymphocytic leukaemia eleven years ago, but has since recovered both clinically and haematologically and has so far survived for ten years. I wish to stress that the point here is not the time of survival. Many patients have survived for ten and more years, but they have always shown signs of the disease, at least as far as an abnormal blood picture.

Case Report

The patient, a female textile worker, was born in 1882. In April, 1940, she had a severe attack of faucial diphtheria with pharyngeal palsy, diaphragmatic palsy, head-drop, and brachial palsy. There was nothing else relevant in her past history.

When seen on July 7, 1943, she complained of lassitude, dyspnoea, sweating, cramps in the legs, and indigestion for about one year. For the same period she had had two lumps in the left armpit.

Examination showed enlarged cervical, supraclavicular, axillary, and inguinal lymph nodes. They were firm, discrete, and quite painless. The spleen extended as far as the left iliac fossa, the notched medial border reaching the umbilicus. It was not tender. The sternum and tibiae were tender on tapping. There were some bluish nodules under the nail-bed of some toes. The urine showed a trace of albumin. There was no excess of urobilinogen or urobilin, and nothing abnormal in the deposit. Blood: R.B.C., 3,480,000; Hb, 70%; C.I., 1; W.B.C., 224,000 (polymorphs 3,360, lymphocytes 219,520, monocytes 1,120). The lymphocytes were fairly mature cells bigger than normal. The stain was taken well by the red cells. There were no nucleated red cells.

The patient was admitted for x-ray therapy, eight doses of 50 r each being given to the spleen. Thereafter the margin of the spleen was just palpable below the ribs, and the W.B.C. numbered 17,100, with 13,766 lymphocytes.

She began to lose her tiredness, dyspnoea, and abdominal pain, and started to feel well. The lymph nodes became gradually smaller, without, however, returning to normal size. The spleen was firm and painless and remained palpable three fingerbreadths below the left costal arch. Serial blood counts (see Table I) showed normal haemoglobin and red cells, with slightly raised total leucocytes, of which 75-80% were lymphocytes.

It was decided to give a further series of x rays to the cervical and axillary glands, and 50 r to four fields twice weekly to a total of 400 r was applied in May, 1944. Thereafter the glands were smaller, soft, discrete, freely mobile, painless, and about the size of a pea. The inguinal glands were no longer palpable. The size of the spleen was unchanged. The patient felt well in herself and did her housework and shopping.

In February, 1945, she developed a lower respiratory infection, the first of many more to follow. She made a slow recovery on symptomatic treatment, the blood picture being unchanged. After this the margin of the spleen could only just be felt below the ribs. The glands were unchanged in size. Further serial blood counts throughout 1945 and 1946 were normal (see Table I). In January, 1947, she again developed bronchopneumonia. In April the blood picture returned to normal. Cervical and axillary glands were palpable, and the spleen could not be felt. At the end of June, 1947, she again developed bronchitis, and a further bronchopneumonic attack occurred in December, 1947, and again in June, 1948. No glands could be felt anywhere, nor was the spleen palpable in December, 1948. In March, 1949, she started once more to cough and was feverish. She again had pneumonia in April, 1950, in January, 1951, and in April, 1952. She had a *Haemophilus influenzae* infection in January, 1953. In January, 1954, she developed erysipelas of the right cheek and forehead.

A blood count in July, 1954, revealed a hypochromic anaemia (Hb 65%). Seven weeks later, after iron medication, the haemoglobin was 83%.

Cases from the Literature

It is difficult to find sufficiently well-documented cases in the literature for comparison. Forkner (1938) quotes quite a number of cases, but most of these do not bear close scrutiny. Naegeli (1931), referring to chronic lymphocytic leukaemia, states that "published cures relate probably always to lymphatic reactions." Heilmeyer and Bege-mann (1951) in the latest German textbook do not even mention cure. Kolmer (1949) states that true leukaemia is invariably fatal, alleged recovery being due to errors in diagnosis. Wintrobe (1951) merely states that there are a number of reports of cure, but does not give his own opinion. So much for the rarity, even denial, of the possibility of recovery.

One case of recovery was described by Schiassi (1933).

A man aged 20 developed right pleurisy in 1911. In 1923 he developed left pleurisy with fluid. An enlarged spleen was found. A blood count in 1924 showed 200,000 leucocytes, of which 40% were immature granulocytes. Chronic myelocytic leukaemia was then diagnosed and a series of x-ray treatments were given. On his discharge in December, 1924, the leucocytes numbered 25,200, with 10% immature granulocytes. The spleen and liver were reduced to nearly normal limits. He returned to work. In July, 1928, he suffered from lassitude, loss of appetite, and pains in the right leg. He had 120,000 leucocytes (12% immature). Further x-ray therapy was given and the leucocytes fell to 12,400 on discharge. In December, 1931, he again felt weak and had pain in the left hypochondrium. The spleen and liver were not palpable. He had 18,740 leucocytes, with some myelocytes. In February, 1933, he had a haemoptysis. There were no palpable lymph nodes anywhere. The liver and spleen could not be felt. There was diminished air entry over the left lower chest and an x-ray film showed pleural thickening at the left base. The lung

fields were otherwise clear. No tubercle bacilli were found in the sputum. The blood (see Table II) showed a slight hypochromic anaemia. The number of leucocytes was normal. The differential count was normal except for an increased percentage of neutrophils and a decrease of lymphocytes.

Another case was reported by Gloor (1930) from Naegeli's clinic, but was followed up for only two years.

Discussion

The case of chronic myelocytic leukaemia reported by Schiassi seems the only one comparable to the case reported here. I have quoted it more extensively because I think it is not as well known as it deserves to be, possibly owing to the fact that it was published in a little-known journal. Schiassi himself concludes that one can no longer talk of leukaemia or a leukaemic myelosis, but that it is now a case of a chronic respiratory affection with slight hypochromic anaemia. The fact remains that his case shows five years' remission with clinical and haematological recovery.

With regard to the case now reported, I do not think that the diagnosis of chronic lymphocytic leukaemia is in doubt at all. The clinical findings, enlarged lymph nodes, and enlarged spleen, together with the blood picture of moderate orthochromic anaemia and 219,520 lymphocytes, represent a classical case.

The patient has twice been subjected to x-ray therapy. There was a steady decline in the number of lymphocytes after the first course, and after the second course the blood picture became normal and has remained so. It would be impossible now to make a diagnosis of chronic lymphocytic leukaemia from the blood picture. The spleen and lymph nodes were a little slower in regressing, but the spleen has been palpable since April, 1947, and the lymph nodes since August, 1948. A remarkable feature of this patient is her proneness to infections, almost wholly respiratory. It is not clear whether this is due to leukaemia or whether she has a diminished resistance, or whatever one likes to call it. It must be pointed out, however, that she did not suffer from these infections before she had leukaemia.

There is a voluminous literature covering the influence of infections on leukaemia. As regards the effect of infections, Jaffé (1932) found the normal defence reaction lacking in the absence of myeloid tissue. Wintrobe (1951) states that this is consistent with his findings of a higher incidence of infections in cases of lymphocytic as compared with myelocytic leukaemia, and an unusual vulnerability to infections in the former. My patient with chronic lymphocytic leukaemia seemed certainly more vulnerable to infections. However, as her blood picture has been normal for the past ten years it must be assumed that she possessed a normal amount

USES OF CHLORPROMAZINE IN MENTAL HOSPITAL PATIENTS

BY

J. LOMAS, M.B., D.P.M.

Assistant Psychiatrist, Springfield Hospital, London, S.W.17

of myeloid tissue, sufficient for a normal defence reaction. Her proneness to infections cannot therefore be explained by a lack of myeloid tissue. If one assumes that it has some connexion with the leukaemia one has to look for another explanation. It may be that the formation of antibodies was altered in some way, if it is assumed that these are formed by lymphocytes. However, this is unproved. Hickling and Sutcliffe (1928) report a case of pneumonia in chronic lymphocytic leukaemia in which they found a moderate amount of protective antibodies in the serum after recovery.

The question of a remission of leukaemic signs through intercurrent infections has been summed up by Wintrobe and Hasenbush (1939). They come to the conclusion that there is little evidence for this even in the literature. In the case here presented it does not seem that the frequent infections have contributed to the remission. The recovery has taken place throughout unaffected by the infections.

Summary

A case is presented of ten years' clinical and haematological recovery from chronic lymphocytic leukaemia.

The clinical history of the patient, with blood pictures extending over eleven years, is given.

The literature is reviewed and one similar and one doubtful case are quoted and discussed.

The present case is discussed as regards diagnosis, frequency of intercurrent infections, and the influence of infection on leukaemia.

It is a great pleasure to thank Dr. C. J. Young, head of the Pathological Department, Bradford Royal Infirmary, for his constant encouragement, without which this paper would not have been written, and for kindly going through the manuscript. He has also given me considerable help with the laboratory investigations and advice in the management of the patient. I also wish to thank Dr. F. E. Chester-Williams for treating the patient and for permission to quote details of the x-ray treatment.

The number of fatal accidents in the home is rising every year, according to the figures quoted by C. A. Boucher in the March issue of the *Monthly Bulletin of the Ministry of Health*. Whereas there were 4,904 fatal accidents in 1949, in 1953 there were 5,895. During the last ten years 57,413 people have died as a result of home accidents, and of these approximately 10,000 were children aged under 5; children under 5 and old people of over 65 accounted for four-fifths of the total figure, the peak risk period for a child being in the third year of life. Although 1953 saw a drop in the figures of children killed accidentally, the number of old people affected increased, about 60% of the accidents in this group being due to falls. It was hoped that the regulations introduced under the Heating Appliances (Fireguards) Act of 1952 would reduce the fatalities due to burns, but the provisional figures for 1954 indicate that the situation has worsened. The regulations apply only to heating appliances on sale and not to those already in the home. To counteract the large number of these fatal accidents the Home Safety Department of the Royal Society for the Prevention of Accidents has set up 70 local committees and hopes to set up more. A Home Safety Group has also been inaugurated, which will supply posters and propaganda.

Since its original use by Laborit and Huguenard (1951) in anaesthetic practice chlorpromazine hydrochloride ("largaetil") has found a steadily increasing application first in the anaesthetic sphere and later in psychiatry.

Courvoisier *et al.* (1953) have investigated the pharmacology of the drug in animals, and from the psychiatric standpoint its most important properties appear to be its depressant effect on central nervous and autonomic activity and its potentiation of narcotic and analgesic drugs.

Early investigation into the psychiatric uses of the drug by Delay and his collaborators, reported in a series of papers (see References), has subsequently been confirmed and enlarged upon by a number of workers on the Continent, particularly by Sigwald and Bouttier (1953a, 1953b), Staehelin and Kielholz (1953), Flügel (1953a), and more recently in this country by Anton-Stephens (1954). All authors are agreed that its most striking effect is its sedative action in all states of tension, agitation, or excitement of whatever origin, but that this sedative effect is entirely different from that produced by the barbiturates or other hypnotics in that the patient is able to take a normal interest in his environment and perform his ordinary duties without, except in the early stages, any undue sleepiness.

Even when a soporific state arises, the patient is as easily roused as from normal sleep and tends to fall asleep only if he has no external interests at the time. Furthermore, Flügel (1953b) has shown that there is no falling off in mental capacity as measured by psychological tests—in some cases there is even an increase—and that the E.E.G. is not altered in the same way as with ordinary hypnotics. This unique sedative action of the drug has been variously described as a "chemical leucotomy" (Delay and Deniker), "a harmonizing of the personality" (Flügel), and "a state of psychic indifference" (Anton-Stephens).

The drug has been used in a wide variety of psychiatric conditions, and some success has been reported in almost all these conditions, but the most generally accepted indications are excitements of all kinds (manic, schizophrenic, or organic), agitated depression, neurotic tension states, and drug intoxications. Opinion about its effect on chronic psychotic states is more divided, but these conditions have been less extensively investigated.

Chlorpromazine has been in use at Springfield Hospital since November, 1953, and between then and the end of July, 1954, just under 500 patients have received the drug for periods varying from a few days to six months.

This paper reports the findings on the 205 patients (55 male and 150 female) who received treatment between November, 1953, and the end of March, 1954.

Selection of Material and Assessment of Results

The earliest cases treated were seriously disturbed chronic psychotics, but as the efficacy of the drug became more apparent the field of application steadily widened to include every type of case catered for by a large mental hospital.

Acute and chronic disturbed psychotics, however, are by far the largest class of patients in the series.

Patients whose treatment had to be stopped for any reason before they had received it for a week, and the few who had E.C.T. concurrently, are excluded from the results, otherwise the series includes all patients starting treatment during the stated period.

Results were assessed either when treatment was stopped or, in cases in which treatment was prolonged, at a time not less than eight weeks after the start.

The following criteria of improvement were used:

1. Not improved.—Slight or no change either in symptoms or in behaviour.
2. Slightly improved.—Decrease in symptoms and disappearance of gross behaviour disturbance.
3. Moderately improved.—Improvement in adjustment at hospital level or to the outside world at a dependent level, as shown by taking an interest in environment and in ward social activities and employability within the hospital.
4. Much improved.—Improved in adjustment to the outside world at an independent level, as shown by increase in initiative, reliability, and responsibility.
5. Recovered.—Symptom-free, with insight and capacity for adjustment to the outside world at the same level extant before the breakdown.

Where there was any doubt about the correct assessment the less favourable was chosen.

Dosage and Management of Cases

The early cases received a commencing daily dosage of 25 mg. t.d.s. intramuscularly, increasing to 50 mg. t.d.s. after the first three days. At the end of a week they were given the same dose orally. Despite reports that the drug is fully and rapidly absorbed from the intestinal tract, it was soon realized that a larger oral dose was required to produce the same effect. The oral dose was therefore increased to 75 mg. t.d.s. Later the intramuscular route was abandoned except in those who were too resistive to take drugs readily by mouth, as there seemed no special advantage in starting treatment by injection. This, however, is contrary to the findings of most other workers, who advocate starting treatment by injection except in very mild cases. Subsequent attempts to confirm the finding that treatment is more effectively initiated by intramuscular injection have failed to reveal any advantage. Improvement when it occurred was gradual whether the drug was administered orally or by injection, and the dramatic effects produced in the first 24 hours that are quoted by most authors were absent in this series.

Although there were many individual variations, the most generally adopted scheme of dosage in the later cases was to give 50 mg. t.d.s. orally in the first week, 75 mg. t.d.s. in the second week, and 100 mg. t.d.s. in the third and subsequent weeks. Very few patients failed to tolerate this dosage, and these were mainly among the neurotics and mildly disturbed psychotics.

Some patients received higher dosages than 300 mg. daily, but in general the impression gained was that most patients who improved with the drug did so on 150 mg. daily. Of those who failed to improve on 150 mg. a large number improved when the dose was increased to 225 mg. daily, and of those who still failed to improve at this level a few did so on 300 mg. Little further improvement could be expected with higher doses.

The more disturbed and chronic psychotic patients both tolerated higher dosages and required more drug to produce betterment. Improvement was noticed in some cases within a few days of starting treatment but in others not for several weeks. In only one case did improvement start after the patient had been on treatment for more than two months, and in the great majority of cases the maximum benefits of the drug had been achieved in three months. Treatment was therefore not abandoned as useless in under two months and was not as a rule prolonged beyond three. It was

terminated abruptly without any withdrawal effects being noticed in any case.

Almost all cases treated were ambulant from the start, the only exceptions being those whose mental state necessitated a period in bed, and all elderly people or those with cardiovascular dysfunction. Although a few patients complained of slight giddiness, particularly during the first few days of treatment or immediately following an increase in dosage, no marked hypotensive effects were observed except in those with arteriosclerosis or some other cardiovascular disease and in one other case.

In the early cases all sedatives were withdrawn and only later prescribed with great caution owing to the possible risk of potentiation. Experience, however, showed that this risk was negligible in normal dosage, most patients not only tolerating but also at first requiring whatever sedatives they had been having before the start of chlorpromazine treatment. The potentiating effect of chlorpromazine was noticeable only in those in whom continual narcosis was produced, when it was possible to do so with much smaller doses of barbiturates in association with chlorpromazine than would have been possible with barbiturates alone.

Unless, therefore, individual needs suggested some modification, it was customary to treat ambulant patients with an initial dosage of 150 mg. daily; to increase this to 300 mg. in the course of three weeks; and to maintain it at this level for three months, when treatment was abruptly terminated. But as opinion about the most suitable dosage and duration of treatment was changing throughout the period under review there is no doubt it will continue to evolve in the light of further experience.

Results

Table I shows the results in the different diagnostic groups in 196 cases. The remaining nine patients died while under treatment. They were all elderly patients and seriously ill physically before chlorpromazine was started. None were

expected to live. The cause of death, which was in each case ascertained by post-mortem examination, was pulmonary embolus from femoral thrombosis in one case, and in the rest either bronchopneumonia or the cardiovascular changes associated with senility. It was not thought that chlorpromazine could in any way be incriminated.

Schizophrenics comprise the largest single group, and a sufficient number have been treated to form a rather more definite impression of the value of the drug than in any other diagnostic group. But although 136 cases have been treated, no very definite prognostic criteria have emerged, both remarkable successes and equally unexpected failures being quite common. In the more acutely disturbed patients, the drug has a quieting effect in a few days, but the dramatic change described by other authors within 24 hours has not been noticeable in this series. In fact, where excitement has been intense it has invariably been necessary to give barbiturates in large doses in addition to chlorpromazine. It is, however, in just these acutely disturbed patients that the prognosis in schizophrenia is best, and it is doubtful whether chlorpromazine in any way improves

the outlook, although it is certainly a very effective sedative when used either alone or in conjunction with barbiturates.

On the other hand, in schizophrenics of poor prognosis—that is, in chronic cases and in the paranoid group—the value of the drug is much less ambiguous. Of the 136 schizophrenics treated, 55 had been in hospital continuously for two years or longer; their average age was 41 ± 1.8 years and the average stay in hospital prior to treatment 8.5 ± 0.9 years. All of them were seriously disturbed patients, but in this extremely unpromising group the following results were obtained: much improved, 2 (4%); moderately improved, 15 (27%); slightly improved, 21 (38%); not improved, 17 (31%).

The two patients who were much improved had both been in hospital for four years and both had previously had insulin, E.C.T., and prefrontal leucotomy without any improvement at all. They were both very difficult turbulent patients. One of them has now been out of hospital for three months and is earning her living, and the other is expecting to leave shortly.

The effect of the drug in these cases is somewhat similar to that of leucotomy but without its disadvantages. There is first a stage which Anton-Stephens well describes as one of psychic indifference in which delusions and hallucinations persist but no longer have the same emotional significance, and consequently there is considerable improvement in behaviour. Later the delusions and hallucinations themselves fade and in some few patients an unexpected degree of insight has developed.

In some patients the effects are clearly symptomatic only, as relapse occurred shortly after withdrawing the drug. But, although the long-term results of chlorpromazine treatment are as yet unknown, immediate relapse is surprisingly rare even in chronic patients if the drug is not withdrawn too soon. And improvement, once started, often continues for many weeks after the drug has been discontinued. It is felt, therefore, that an important effect of chlorpromazine is to make possible the rehabilitation of patients who were formerly too disturbed for this to be accomplished. In this respect it can again be compared to leucotomy.

In endogenous depression the results shown in Table I are unimpressive. This can largely be attributed to the fact that patients who failed to respond quickly to chlorpromazine were taken off the drug and given E.C.T. It is therefore possible that if treatment had been prolonged results would have been better. In general it was felt that E.C.T. is a more effective treatment for depression than chlorpromazine. On the other hand, in two cases of chronic retarded depression of nearly two years' duration which had either failed to respond or had responded but briefly to E.C.T., given on more than one occasion in the past, the results were excellent, a far more satisfactory remission being achieved with chlorpromazine, and one which has so far lasted in the first instance for four months, and in the second for two. Chlorpromazine may therefore prove a useful line of treatment in cases of depression which fail to respond to E.C.T.

In the 16 patients suffering from organic dementia improvement was largely symptomatic and relapse was frequent when treatment was stopped.

The findings in neurotic patients were in agreement with those of other workers in suggesting that states of anxiety or emotional tension were the most likely to respond to chlorpromazine. On the other hand, one chronic hysteric, whose principal complaint was irritation of the ear, completely lost her symptom. That this was a direct response to chlorpromazine and not due to suggestion was demonstrated by substituting identical neutral tablets, unknown to the patient, when her symptoms returned, to disappear once more when chlorpromazine treatment was resumed.

Psychopathic states behaved in a similar way to neuroses, the best results occurring when there was considerable associated anxiety. In one class of patients, the aggressive psychopaths, chlorpromazine appeared definitely to be con-

traindicated. Not only did it not produce any improvement, but it often increased the tendency to explosive outbursts of violence. While the number of cases in the series is too few to be more than suggestive, this experience has been repeated in cases treated subsequently.

Of the seven cases of mania and hypomania treated, only one was better than moderately improved. This man, who recovered, was the only case of acute manic excitement treated, and the effect of chlorpromazine was very impressive. Barbiturates had controlled his excitement only very ineffectively and he had developed pneumonia, so that both his physical and his mental conditions were causing grave concern. Within 48 hours of starting chlorpromazine he was overactive and euphoric, but was co-operating well and was no longer a nursing problem of any sort. The other six cases were all chronic hypomanics, and a good hospital adjustment was the best that could be achieved.

All patients were classified as acute, subacute, or chronic cases, according to the time they had been in hospital before treatment was started. Those who had been in less than six months were regarded as acute cases, from six months to two years as subacute, and over two years as chronic. This method of classification has the merit of being unambiguous. On the other hand, it does not take into account previous breakdowns, or the duration of the illness prior to admission. As information on this score was too often missing, it was felt to be the most satisfactory classification in the circumstances, but it is obviously biased towards the acute end of the scale.

In general, most of the acute cases were receiving chlorpromazine as the first line of treatment, the subacute group had recently failed to respond to some other form of therapy, and the chronic group had already received all appropriate treatment for their condition without improvement. There was no difference in the average age of the three groups, which was just over 40, nor in the dosage they received, and the mean durations of illness were 6 weeks, 13 months, and 9 years respectively.

Table II shows the results.

TABLE II.—Results Analysed According to Duration of Stay in Hospital Before Treatment

Time in Hospital Before Treatment	Recovered		Much Improved		Moderately Improved		Slightly Improved		Not Improved		Total No. of Cases
	No.	%	No.	%	No.	%	No.	%	No.	%	
1-6 months	9	10	20	21	23	25	19	20	22	24	93
6-24 "	—	—	5	13	15	39	6	16	12	32	38
Over 2 years	—	—	2	3	15	23	24	37	24	37	65
Total	9	5	27	14	53	27	49	25	58	29	196

As might be expected, the best results were achieved in the acute cases. But there are too many imponderables concerned in assessing the results in acute psychiatric cases for any definite assertions to be made about a new line of treatment unless carefully controlled trials are made, and this the present survey does not pretend to be. The preliminary impression gained is that chlorpromazine has a part to play in the treatment of acute psychiatric conditions of all sorts, but the detailed indications for its use remain to be worked out. In the subacute group, the part played by extraneous factors in any improvement produced becomes less important, and in the chronic cases any change can even more certainly be attributed to the drug. It is in these two groups that the value of chlorpromazine is felt to be beyond doubt.

It will be noted that 37 out of the 103 subacute and chronic patients (36%) reached a level of good hospital adjustment or better. All the patients in these two groups were previously making a poor adjustment and the great majority were seriously disturbed.

The indications for chlorpromazine have been considered by most authorities to be largely symptomatic—that is, in

states of excitement, agitation, or emotional tension. All patients were classified, therefore, according to their psychomotor state. In the overactive group were classed excited, aggressive, or emotionally unstable schizophrenics, manics, agitated depressives and seniles, and anxious neurotics, while the inhibited group contained catatonic stupors and detached schizophrenics, retarded depressives, and apathetic neurotics. Detached schizophrenics who became periodically impulsive were placed in a separate category.

The results shown in Table III are somewhat surprising. Although more patients recovered in the overactive group and more inhibited patients did not improve, if the recovered

TABLE III.—Results Analysed According to Psychomotor State

Psychomotor State	Recovered		Much Improved		Moderately Improved		Slightly Improved		Not Improved		Total No. of Cases
	No.	%	No.	%	No.	%	No.	%	No.	%	
Overactive	8	6	17	13	31	25	35	28	35	28	126
Inhibited	1	2	9	17	15	29	6	12	21	40	52
Inhibited with impulsive outbursts	—	—	1	6	7	39	8	44	2	11	18
Total	9	5	27	14	53	27	49	25	58	29	196

and much improved are grouped together on the one hand and the slightly improved and not improved on the other, the results are almost identical in both inhibited and overactive patients. This suggests that some revision is needed in the conception of chlorpromazine as being mainly a symptomatic treatment for excited states.

Chlorpromazine and Leucotomy

The effects of chlorpromazine have often been compared to those of leucotomy. It might therefore be supposed that patients in whom leucotomy had failed would equally fail to respond to chlorpromazine, and, conversely, that chlorpromazine might prove a useful prognostic indicator for leucotomy. Neither of these suppositions is borne out by the results in this series.

The results in 28 patients in the series who had previously been leucotomized were as follows: much improved, 3 (11%); moderately improved, 6 (21%); slightly improved, 11 (39%); not improved, 8 (29%). These results do not vary significantly from those in the series as a whole, and lend further support to the view that chlorpromazine can be of value in prognostically poor cases.

On the other hand, four patients who failed to respond in any way to chlorpromazine have made a very good immediate response to leucotomy, though it remains to be seen whether this will be maintained.

Side-Effects and Toxic Reactions

The various side-effects and toxic reactions recorded in the literature were noted in this series, but, as their occurrence in a much larger number of cases is the subject of a separate communication, no details are mentioned here.

Summary and Conclusions

The results in 205 patients treated with chlorpromazine are examined.

A tentative scheme of dosage and duration of treatment is discussed. It is not felt that the intramuscular route offers any advantages over the oral.

Results in the different diagnostic categories suggest that chlorpromazine may play a useful part in the treatment of acute states of excitement of all sorts, in neurotics in whom tension or anxiety is a prominent symptom, and in some depressive patients in whom E.C.T. has proved ineffective.

The most striking results, however, were obtained in chronic psychotic patients in whom the prognosis would

normally be very bad. It enabled a few of these patients to be discharged and many more to make a good hospital adjustment.

In chronic patients it was felt that the chief part played by chlorpromazine was to make possible the rehabilitation of those in whom this was formerly impossible and that, while in some relapse occurred immediately treatment was stopped, in others improvement still continued.

There seemed to be little difference between its effect on overactive and inhibited patients.

As good results were found after leucotomy as in other chronic patients.

I wish to thank Messrs. May & Baker for kindly making supplies of chlorpromazine available for this trial; Dr. Robert Forgan, of May & Baker, for his very valuable help and advice; and Dr. H. C. Becle, medical superintendent of Springfield Hospital, for much helpful criticism in the preparation of this paper.

CHLORPROMAZINE IN TREATMENT OF ELDERLY PSYCHOTIC WOMEN

BY

C. P. SEAGER, M.B., B.Ch., D.P.M.

Registrar, Bristol Mental Hospitals

One of the difficult nursing problems in a mental hospital concerns the group of elderly long-stay patients who suffer from periods of restlessness, confusion, and disorientation or who are continually in a state of agitation, with stereotyped speech and activity. The Board of Control (1954) stated that, "on January 1, 1953, 28.8% of the mental hospital population were over the age of 65 and two-thirds of these were women."

A related problem is the shortage of nursing staff, owing to which large wards of noisy, difficult patients have to be in the care of too few nurses, or patients have to be left at night with inadequate supervision. It is hoped to show that chlorpromazine ("largactil") may play a part in the solution of these problems.

Since interest in the psychiatric use of chlorpromazine was roused by Sigwald and Bouttier (1953), who summarize the literature, and by Ey and Bérard (1952), who used it as a method of prolonged sleep treatment (*cure de sommeil*) in psychiatric patients, various authors in this country have published series of cases suggesting its value when tension and agitation predominate—Anton-Stephens (1954) on psychiatric patients with varying diagnoses, Garmany *et al.* (1954) in psychoneurosis, Elkes and Elkes (1954) in psychosis, and Howell *et al.* (1954) in geriatrics.

The present series is a group of elderly psychotic women with varying diagnoses but having in common

the fact that they became nursing problems because they were noisy, abusive, violent, and destructive, or required constant attention for feeding and dressing.

Case Material

Forty-eight women aged from 58 to 87 were chosen, all being nursing problems to a varying degree. Many had been in hospital for several years, but some had been recently admitted with diagnoses of senile dementia. Table I shows the age grouping and the diagnoses.

TABLE I.—Age Grouping and Diagnoses

Age	No.	Diagnoses	No.
58-60	1	Schizophrenia (including paranoia paraphrenia)	13
60-70	18	Agitated depression	6
71-80	22	Dementia (all organic causes)	29
Over 80	7		
Total	48	Total	48

Two of the patients were later withdrawn from the trial—one because she developed jaundice, and the other because she fell and sustained a fractured femur.

Method

These 48 patients were divided into two groups: the parenteral Group P (22 patients), beginning treatment by injection, and the oral Group O (26 patients), receiving oral treatment only.

Group P.—Eleven of these patients were given a course of 50 mg. of chlorpromazine thrice daily by injection for one week, followed by 50 mg. thrice daily by mouth for three weeks. At the same time the other 11 patients received one week's treatment with an equivalent volume of inert control injection followed by three weeks' treatment with inert tablets. At the time of the experiment no one knew into which half of the group each patient fell. At the end of the first four weeks the two half groups were reversed, so that those receiving chlorpromazine now received control tablets while those on control tablets received chlorpromazine. For reasons discussed later, it was felt that patients should not receive further parenteral therapy, and oral therapy alone was used in the second month.

Group O.—This group originally consisted of 26 patients, half of whom began treatment with chlorpromazine, 25 mg. thrice daily for three days, then 50 mg. thrice daily for ten days, and 75 mg. thrice daily for two weeks. It was from this half of the group that the two cases had to be withdrawn. The other half received corresponding numbers of control tablets, and after a month the two halves of the group were reversed in a manner similar to that described above.

Summary of Results

Table II shows the number of patients in each group falling into categories of improvement. Three degrees of improvement were considered:

- + Some improvement: somewhat less agitated and restless; able to sleep without sedative.
- ++ Definite improvement: more rational and talkative; less restless; not so disturbed by delusions.
- +++ Marked improvement: able to look after herself, whereas she had been unable to do so hitherto; spontaneous conversation; could take part in social activities.

Dealing first with Group P, and taking the two treatment subgroups together and the two control subgroups together—that is, A1 and B2, also A2 and B1 (see Table II)—and grouping the results as either improved or not improved, we get $\chi^2 = 17.8$ and $P \leq 0.001$. The difference between the treatment and the control groups was highly significant. Similarly, in Group O $\chi^2 = 16.3$ and $P \leq 0.001$ —again highly significant.

TABLE II.—Number of Patients Falling into Various Categories of Improvement

	Group P				Group O			
	Improvement			No Change or Relapse	Improvement			No Change or Relapse
	+	++	+++		+	++	+++	
1st month:								
Treatment (A1)	4	5	2	0	2	2	3	4
Control (B1)	1	0	0	10	3	2	0	8
2nd month:								
Now control (A2)	3	0	0	8	2	1	0	8
Now treatment (B2)	2	3	2	4	8	2	0	1

The two patients who were withdrawn were in subgroup A1 of Group O.

It is necessary to differentiate clinically between those patients who improved on treatment and relapsed when receiving control tablets and those who improved when receiving control tablets or in whom no change took place. Combining Groups O and P, patients were found to fall into six further groups (Table III). It will be seen that 28 (60.9%) cases showed some degree of improvement with chlorpromazine, while if group 3 is added the figure is 33 (71.7%).

TABLE III.—Number of Patients in Each Category of Improvement

Group	No. of Patients
1 Improved on treatment. Relapsed on control	12
2 No change on control. Improved on treatment	16
3 Improved on treatment. Maintained on control	5
4 Improved on control. Maintained on treatment	4
5 Improved on treatment. Improved more on control	1
6 No change on control or on treatment	8
Total	46

Note: Group 3 probably corresponds to group 1, but where the effect of treatment was prolonged into the control period.

When assessed according to diagnosis, there was no significant difference between the groups.

Comment on the Series

It was very noticeable that patients on treatment looked ill, with pinched, drawn faces, and pallor, though there was no subjective complaint.

Cases of pyrexia and tachycardia were much more frequent in the group receiving parenteral therapy. When an inflammatory area developed at the injection site, this was associated with pyrexia (four cases), but five more cases had temperatures of 100–103° F. (37.8–39.4° C.) (axillary), usually lasting four or five days and subsiding without other medication and without discontinuing the drug. Only two of the Group O cases had temperatures during the period of treatment.

TABLE IV.—Liver-function Tests on Patient who Became Jaundiced

Date	Van den Bergh Direct	Serum Bilirubin mg. 100 ml.	Ser. Alk. Phosphat. Units	Thym. Turb. Units	Blood Urea mg. 100 ml.	Protein (g.%)			
						Total	Alb.	Glob.	A/G Ratio
8.9	+	4.6	55.1	3.0	30	6.66	3.77	2.89	1.3:1
15.9	—	1.8	—	—	—	—	—	—	—
24.9	—	1.5	—	—	—	—	—	—	—
27.9	—	0.97	45.7	4.0	32	6.86	3.46	3.40	1.02:1
11.10	—	1.2	39.4	0.7	36	7.9	5.3	2.6	2.04:1

One case of jaundice has so far occurred. This first appeared 21 days after the beginning of treatment, and was preceded by two days' pyrexia to 102° F. (38.9° C.). The patient had received a total of 2,700 mg. of chlorpromazine at that time. It was noticed that her skin appeared yellow before the conjunctivae. A bradycardia down to 40 a minute developed, and persisted for three weeks. Urine was dark, but stools were not noticeably pale. Liver-function tests on this patient are shown in Table IV.

The following report is that of another patient who received chlorpromazine, developed jaundice, and then

recovered. Some weeks later she died of bronchopneumonia, an illness believed to have been quite unconnected with the jaundice.

A married woman aged 79 was admitted to a geriatric ward, where a diagnosis of senile dementia was made and she was given chlorpromazine both orally and parenterally. After 32 days, and after receiving a total dosage of 3,875 mg. in two courses separated by ten days, she developed jaundice. This occurred on the fourth day of the second course, when only 750 mg. of chlorpromazine had been given; treatment was discontinued. The jaundice subsided in two weeks. She was admitted to this hospital two months later, dying two weeks after admission. The cause of death, bronchopneumonia and pulmonary embolus, was confirmed at necropsy. Section of the liver showed nothing specific except moderate fatty changes and patchy lymphocytic infiltration in the portal areas.

Drowsiness, sometimes accompanied by a subjective giddiness, occurred in 11 cases. It usually passed off after the first two weeks, and in itself was not a serious complication. It was probably responsible, however, for the case of fractured neck of the femur. In elderly patients, in whom the risk of fracture is already present, the unsteadiness or drowsiness may well lead to a fall. This patient fell about one and a half hours after receiving her tablets. All patients were put to bed—though not all could be kept there—for an hour after receiving treatment, and this one fell soon after getting up.

Senile patients often become noisy, confused, and deluded after fractures, and chlorpromazine has been found very useful in such cases. It is noteworthy that, in the two cases in which fractures have occurred in elderly patients who were on chlorpromazine at the time, the common agitated, confused state did not develop. One of these has just been described, and the second case occurred while electroplexy was being given as well as chlorpromazine.

Other mild side-effects were dryness of the mouth, abdominal pain and diarrhoea, polyuria, and rashes. These responded to simple medication and did not warrant discontinuation of treatment.

Discussion

These results show that chlorpromazine has been effective in improving the general behaviour of a group of elderly psychotic women, though this improvement was not uniformly good. Most of them became more manageable, with few noisy outbursts or demonstrations of violence, and were able to feed and dress themselves. While several cases showed striking improvement, no patient in this group was considered fit for discharge, although two were going out with relatives for week-ends. Several patients have become employable, and have been able to take part in the social activities of the ward, the cinema, and coach rides.

It is necessary to compare these results with those which could be obtained using other forms of treatment at present available. Firstly, of course, these patients were chosen from those who had not responded adequately to other forms of sedation—all had been receiving large and frequent doses of paraldehyde or barbiturates, while several had had maintenance electroplexy. When they were included in the series and had this sedation stopped, many of them became very noisy and difficult; these patients were subsequently found to be having control tablets. Sedation by paraldehyde, barbiturates, or bromides suffers from the disadvantage that large doses are needed for long periods, and, even if the drugs are varied, problems of tolerance, habituation, drug rashes, and bromism arise. The patients are drowsy and confused, and unable to look after themselves, whereas after the first two weeks on chlorpromazine drowsiness usually passes off and the sedative effect seems to continue. After the drug has been discontinued the effect persists for a period varying from two to six weeks, and thus it may be possible to give periodic courses instead of continuous treatment. There seems to be no indication for routine parenteral therapy, even for a short introductory period, unless there is an urgent need to quiet a confused or agitated patient.

Adequate dosage is usually 150–200 mg. in divided doses daily, and the last dose should be given fairly late in the evening so as to ensure a good night's sleep.

I would like to stress the value of chlorpromazine in the treatment of restlessness following fractures in elderly patients. This is rapidly controlled, so that adequate operative and splinting technique may be carried out. It is in this type of case that the intramuscular route should be used, at least for the first few days. It is important to realize that in elderly patients, with the risk of fracture, use of the drug may be an additional hazard: it is little consolation to know that it is effective in the treatment of the condition it has helped to cause. Thus patients must be encouraged to rest for some considerable time after they have received their tablet—one to two hours if possible—and the dosage should be regulated so that the minimum is given to produce a therapeutic effect.

The question of the occurrence of jaundice is one of great importance. In this series there has been only one case (2%)—in fact, it is the only case that has occurred in this hospital, where at least 80 patients have received reasonably long courses of not less than 150 mg. of chlorpromazine daily. Until the action of the drug in the liver has been fully demonstrated, I feel that one should discontinue treatment while there is any sign of liver damage, and I would be reluctant to use it unless it was urgently indicated, in spite of the finding in the section of liver, which showed no evidence of permanent damage that could be attributed to the chlorpromazine. It is noted that in the other case described, where the patient died, there had been a pause in treatment, and jaundice recurred after treatment was renewed. The possibility of a sensitizing effect must be considered, especially as many psychotic patients, unless under careful observation, may not take all the tablets given and therefore dosage with the drug may only be intermittent.

It is difficult to understand why a demented patient should improve when taking chlorpromazine when she does not do so with other sedative drugs such as paraldehyde. The response is probably due to reduction in tension and response to hallucinations without alteration in the basic dementia. Thus, although the misinterpretations still occur, they are no longer charged with the same degree of tension and the patient can spare time to deal with her immediate surroundings. Sedative drugs merely damp down the cerebral response as a whole, while chlorpromazine acts selectively in a manner similar to the operation of leucotomy, for which reason it has been called the "chemical leucotomy." The possibility of its use as a therapeutic test for leucotomy, even if its effects do not persist, must be investigated.

The question of whether chlorpromazine can restore a chronic mental hospital patient to a condition of health sufficient to enable him or her to be nursed at home or in a home for the aged must also be considered. The patients described here were cases of extreme difficulty, and several of them have improved a great deal, though not enough for discharge. Experience with these, and with less difficult patients in the hospital, suggests that this drug may prove of much value for those patients who are still at home but tend to wander round the house at night and keep the rest of the family awake, or who are somewhat preoccupied with hypochondriacal symptoms. If this is so, it will go some way towards solving the problem of shortage of bed-space and of nursing staff in mental hospitals.

Summary

In a controlled experiment, where each patient acted as her own control, 46 elderly psychotic women were treated with chlorpromazine ("largactil"), and in 33 (71.7%) cases there was some degree of improvement. Two serious complications, jaundice and fractured femur, were considered, but were not thought to preclude the use of the drug as an aid in the nursing of the difficult patient.

I wish to thank Dr. R. E. Hemphill, medical superintendent, Bristol Mental Hospitals, for permission to use these cases; Dr. D. F. Early for his guidance and encouragement in preparing this paper; Dr. K. R. L. Hall for his help with the statistics; and Dr. W. Sandry for the report on the liver section. I also wish to thank the nursing staff, dispenser, and laboratory staff for their unfailing assistance, and Messrs. May & Baker for supplying the largactil and the corresponding control tablets and injections.

L. CANICOLA INFECTION TREATED BY PENICILLIN

BY

J. CROOKS, M.B., F.R.F.P.S.

Medical Registrar, Western Infirmary, Glasgow

AND

W. BLAIR, M.C., M.B., Ch.B., D.P.H.

General Practitioner

Human infection with *Leptospira canicola* is infrequently recorded in this country although the organism is widely distributed in the canine population. Thus Stuart (1946) has shown that 25 to 40% of dogs in Glasgow are infected with the organism, and Broom and MacIntyre (1948) found similar figures in London. In dogs the organism produces a pyelonephritis, following which the animals may excrete the organisms in the urine for several months (Stuart, 1946).

The literature has been admirably reviewed by Broom (1951). He believes the infectivity to be low, since it is usual to find that only those in a household who have nursed an infected dog and who have cleaned up its dejecta are liable to contract the disease. Although the routes of infection are not known with certainty, the entry would appear to be through intact or broken skin, mucous membranes of the upper respiratory tract, or the conjunctivae. Bathing in contaminated water is a not uncommonly reported mode of infection.

The clinical features are those of an influenza-like illness of sudden onset, with signs of meningeal irritation appearing early in the illness in about two-thirds of cases (Alston, 1949).

We report two further cases arising in Glasgow. One of these was a laboratory infection, and it was possible to estimate the incubation period. Both were successfully treated with penicillin.

Case 1

Five days before admission to hospital a housewife aged 52 was suddenly taken ill with severe pains in the legs and paraesthesia from the knees to the ankles. On the second day of the illness she began to complain of severe throbbing frontal headache and pain in the neck. On the following day the pains and paraesthesia in her legs disappeared and were replaced by severe backache. On the fourth day of the illness persistent nausea, retching, and vomiting began, associated with an erythematous rash on her legs.

On admission to hospital she was found to be a flushed, rather drowsy woman with a pyrexia of 100° F. (37.8° C.). Discrete erythematous macules were present on the front of both legs, with a pin-point erythema over most of her

back. The edge of the liver was palpable, as was the tip of the spleen. Slight neck rigidity was demonstrable. There was no jaundice. The total white blood count was 12,500 per c.mm. (85% polymorphs, 8% lymphocytes, 4% monocytes, 2% eosinophils). The E.S.R. (Westergren) was 40 mm. in the first hour. The urine showed no abnormality.

On lumbar puncture clear fluid was obtained at a pressure of 180 mm. of water. A pleocytosis of 584 cells per c.mm. (86% lymphocytes, 9% monocytes, 5% polymorphs) was present. The chemistry of the fluid showed: protein, 45 mg. per 100 ml.; sugar, 67 mg. per 100 ml.; and chloride, 725 mg. per 100 ml. No organisms were found microscopically or on broth culture.

During the two weeks preceding her illness the patient had been nursing a sick dog, and in view of this the veterinary surgeon who had been treating the dog was consulted. He stated that the dog had been suffering from a renal infection, and, whilst he had no bacteriological evidence of *L. canicola* infection, he thought this a likely diagnosis in view of the frequency of such infection among dogs in Glasgow.

In the light of this opinion, a provisional diagnosis of "canicola fever" was made, and, after blood specimens had been obtained for diagnostic purposes, treatment was instituted with crystalline penicillin, given intramuscularly in doses of 250,000 units six-hourly. This was begun one hour after admission—that is, on the fifth day of illness—and continued until the fourteenth day.

Within 24 hours there was relief of symptoms, and, after 48 hours, apparent clinical cure (see Chart).

Bacteriology.—The organism was not obtained on blood culture using ordinary media nor on guinea-pig inoculation, but serological tests confirmed the diagnosis in both the patient (Table I) and her dog, the latter's serum agglutinating *L. canicola* to a titre greater than 1/30,000. The same tests made on members of the patient's household, who had been in contact with the dog, were negative.

The patient was dismissed symptom-free two weeks after admission. A lumbar puncture carried out just before discharge showed a clear fluid under a pressure of 50 mm. of

TABLE I.—Results of Serum Agglutination Tests in Two Cases of *Leptospira canicola*

Day of Disease:	Case 1					Case 2				
	5th	13th	23rd	50th	72nd	8th	19th	24th	44th	
Reciprocals of titres with:										
<i>L. canicola</i>	0	1,000	10,000	1,000	1,000	Neg.	Neg.	1,000	1,000	
<i>L. icterohaemorrhagiae</i>	0	0	10	0	0	..	..	100	30	

water and containing 17 lymphocytes per c.mm. The chemistry of the fluid was normal. The patient showed no evidence of relapse after six months' observation.

Case 2

A lecturer in veterinary medicine aged 33 was suddenly taken ill with headache, shivering, and backache. On the second day of the illness the headache became much more severe and he vomited repeatedly. On this day he was seen at home by one of us, when the only findings were a pyrexia of 104° F. (40° C.), a tachycardia of 140 a minute, and some abdominal distension. There was no evidence of a meningeal reaction. He was treated expectantly with half-normal saline by mouth. On the third day of the illness he felt slightly better. The vomiting had stopped, though nausea, retching, and headache persisted. The temperature was now 102.6° F. (39.2° C.), but on the following morning the headache was again intense and retching severe. The temperature was now 104° F. (40° C.). The spleen was palpable three fingerbreadths below the left costal margin, and small pink macules 1 mm. in diameter were present on the skin of the abdomen. A specimen of blood was taken for broth culture. The white cell count was 7,400 per c.mm. (93% polymorphs, 6% lymphocytes, 1% monocytes). The urine contained albumin and a few erythrocytes. The E.S.R. (Westergren) was 40 mm. in the first hour.

At this point the patient was closely questioned about the possibility of having acquired any infection in the course of his work. He now remembered that seven days before the onset of the illness he had broken a tube containing a culture of *L. canicola* and in so doing had cut his finger. He had immediately washed the wound with a solution of penicillin.

It seemed probable that the patient was suffering from *L. canicola* infection, and after a further specimen of clotted blood had been removed for culture he was given one million units of crystalline penicillin intramuscularly. Two and a half hours after the injection he had a very severe reaction. He felt very ill, and on taking his temperature found it to be 104° F. (40° C.). Immediately afterwards a severe rigor occurred which lasted about eight minutes. He felt extremely weak and was unable to feel his own pulse. After an hour he began to feel better, and, whereas previously he had been extremely restless, he was now content to lie still. Five and a half hours after the first injection of penicillin he was given a second dose of one million units. By this time he felt better, though he still looked very ill and had a temperature of 105° F. (40.6° C.). Two and a half hours later there was a marked improvement in his condition. His temperature was now 99° F. (37.2° C.), and his headache less severe (see Chart).

By the following morning (fifth day of illness) his improvement was remarkable. He had slept soundly, his appetite had returned, and the headache was only slight. The temperature was normal and the urine contained only a faint trace of albumin. The spleen was still palpable three fingerbreadths below the left costal margin.

The patient then made an uninterrupted recovery, the headache vanishing after three more days and the spleen soon becoming impalpable. He had received one million units of penicillin three times daily from the fourth to the seventh day of illness inclusive and the same dose twice daily from the eighth to the tenth day.

Bacteriology.—No growth was obtained from the broth culture. The specimen of blood clot was inoculated on to special media, and after four days' incubation *L. canicola* was isolated. The findings of serological tests carried out are shown in Table I.

Discussion

Pyrexia of Unknown Origin and Lymphocytic Meningitis

The ubiquity of *L. canicola* in this country is such as to make infection with this organism a possibility in every case of obscure fever. The clinical features, apart from the high

proportion of cases of meningitis, are often indistinguishable from those of any septicaemia. The clue to the diagnosis lies in the history of contact with a sick dog.

That the leptospira may be the cause of a lymphocytic meningitis should also be borne in mind. Broom (1951) examined the sera of 642 cases of aseptic meningitis and found that 25 gave positive reactions for leptospirosis (17 *L. icterohaemorrhagiae*; 8 *L. canicola*). The report by the Virus Reference Laboratory, Colindale (1953), gives the following results of serological examination of cases of suspected virus infections of the central nervous system during 1949 and 1950.

Year	No. Tested	No. Positive for Leptospirosis
1949	130	10 (7.7%)
1950	196	8 (4.0%)

This report suggests that increasing awareness of leptospirosis may be responsible for the lower figure of 1950, since sera were often sent direct to Dr. J. C. Broom and bypassed Colindale.

Minkenhof (1948), Broom (1951), and Joe and Sangster (1951) all emphasized the necessity for distinguishing between the meningitis of leptospirosis and that of non-paralytic poliomyelitis. Indeed, Alston (1949) reported that two-thirds of the cases of *L. canicola* infection in man showed signs of meningeal irritation. Broom and Joe and Sangster pointed out that a raised E.S.R., which is usual in leptospirosis, may be useful in excluding poliomyelitis where the sedimentation rate is usually normal. The raised E.S.R. in Case 1 illustrates this point.

Incubation Period

Kelser and Schoening (1948) showed that the incubation period of *L. canicola* infection in hamsters was 6–10 days. The incubation period has not, however, previously been accurately determined in man. The unique circumstances of the mode of infection in Case 2 would appear to place it at about seven days.

Treatment with Penicillin

The recorded cases of human infection with *L. canicola* between 1946 and 1951 which were treated with penicillin are enumerated in Table II. The results do not appear

POLYAGGLUTINABILITY OF HUMAN RED BLOOD CELLS

BY

SANTOSH MITRA, M.B.

AND

PROBHAT CHOUDHURI, M.B.

Blood Bank, Chittaranjan Cancer Hospital, Calcutta

Amongst the abnormal agglutinations, polyagglutination is a rare phenomenon and few cases have been reported. It is a transitory agglutinability of red cells developed *in vivo* and characterized by the agglutination of cells by a proportion of normal sera independent of their group agglutinins. It is not connected with auto-agglutination.

In ABO blood grouping the so-called Landsteiner's law states that if an agglutinin is present in the red cells of a blood the corresponding agglutinin must be absent from the plasma, and if the agglutinin is absent the corresponding agglutinin must be present. The first part of this law is a logical outcome of the situation, for if both agglutinin and agglutinin were present the cells would be agglutinated (Wright, 1952), but in cases of polyagglutination this law cannot and does not stand. This factor is known to appear in some diseased states, though it has been recorded in some healthy individuals as well, but in both cases it is found to be transitory. Whether there is any influence of this polyagglutinability on the diseased process is not yet known. It is very difficult to understand what initiates this agglutinability of these cells and why the process of agglutination is inhibited *in vivo* but initiated *in vitro*.

It has been described that *in vitro* the infection in a sample of blood may change the cells in such a way that they are agglutinated by all sera (Hübener-Thomsen-Friedenreich phenomenon). Friedenreich has shown that filtrates of certain bacteria contain an enzyme which acts on human red cells, changing a latent antigen to an active one, which is known as Friedenreich's T-antigen (Race and Sanger, 1954).

Case Report

A married Hindu woman aged 30 was admitted to Chittaranjan Seva Sadan Hospital on December 28, 1953. She had had four children, but no history of miscarriage or abnormal labour. Her first baby died a few years after birth; the other three are all living and in good health. Her menstrual history was normal. The last menstrual period was September 25, 1953. She had never had any transfusion. On admission to hospital she complained of pain in the lower abdomen for 22 days, bleeding per vaginam for 22 days, and fever for two days.

On examination the patient was very anaemic. There was no jaundice. Her temperature was 102.6° F. (39.2° C.) (the high fever continued until death), pulse 140, respirations 20, blood pressure 110/80 mm. Hg. A blood count showed Hb, 36%; red cells, 2,160,000; white cells, 13,400 (polymorphs 80%, lymphocytes 12%, monocytes 8%). The urine was acid in reaction and showed no abnormality.

Pelvic abscess was diagnosed and posterior colpotomy was performed. A substance like anchovy sauce was found. Microscopical examination of this showed inflammatory cells but no malignant cells. As transfusion was advised, the serum and the washed cells (suspended in normal saline) were tested, but in spite of repeated efforts we could not determine the group. The patient was Rh-positive with

encouraging. The difficulty in assessing the value of penicillin therapy is common to all conditions which tend to natural cure. It is especially difficult when different doses have been used and treatment has begun at different stages of the disease. In the case of *L. canicola* infections a further factor must be taken into account. McIntyre and Stuart (1949) have shown that in dogs there is an invasive or septicaemic stage followed by a later stage where there is renal involvement. Dogs in the first stage all recovered after penicillin treatment, but there was a 50% mortality if the kidneys were involved. The ineffectiveness of penicillin in the renal stage of the infection is further suggested by McIntyre and Montgomery (1952) and Brunner and Meyer (1949), who have shown that the organism can be recovered from the renal tubules 14 months to two years after treatment.

The very rapid response to penicillin in high dosage in our two cases strongly suggests a therapeutic effect. It is to be noted that both were treated early and were probably mainly in the septicaemic stage, although Case 2 showed some albuminuria. The severe reaction shown by Case 2 was of Herxheimer type, and is further evidence of a lethal effect on the organisms. It is perhaps significant that the only other recorded case of rapid improvement after treatment with penicillin (Case 4 in Table II) also received large doses early in the disease.

Stagg and Leibovitz (1951) believe that chlortetracycline ("aureomycin") is an effective therapeutic agent in *L. canicola* infection. The evidence for this is inconclusive, since in their case 18 hours of treatment with penicillin in high dosage had preceded chlortetracycline. In experimental *L. canicola* infection in hamsters, Heilman (1945) found that the protective effect of penicillin was greater than that of streptomycin.

Since no other satisfactory treatment is known, it seems desirable to treat recognized examples of this disease with large doses of penicillin as early as possible after infection.

Summary

Two cases of human infection with *Leptospira canicola* are described.

L. canicola infection should be considered in the differential diagnosis of unexplained pyrexia or lymphocytic meningitis.

Evidence is produced to show that the incubation period of the disease is about seven days and that the early administration of penicillin in high dosage is an effective form of therapy.

We are grateful to Dr. L. D. W. Scott, under whose care Case 1 was treated, for permission to publish, and for his helpful advice. We are also indebted to Dr. T. Anderson and Professor E. J. Wayne for their help in the preparation of this article and to Dr. J. C. J. Ives for his assistance in the bacteriological investigations.

C and D and negative with E antigen. The Kahn test was negative. The patient's cells were tested against α and β sera (Table I). The cells were agglutinated by both the sera, indicating Group AB, but when the serum of the patient was also matched against known cells A cells were agglutinated but there was no reaction with B cells (Table I), indicating Group B.

TABLE I

α Serum and patient's cells	..	+++ (agglutination)
β " " "	..	+++ " "
A cells " " serum	..	+++ " "
B " " "	..	--- (no agglutination)

As the need for blood transfusion was urgent, and as no definite group could be determined, we tried to cross-match with 10 Group O bloods, 4 Group AB bloods, 10 Group B bloods, and 12 Group A bloods. The results are shown in Table II. All these tests were done repeatedly and in dilutions of 1:4, 1:8, 1:16, 1:32, but without any change of results either at room or at refrigerator (4 to 6° C.) temperature.

TABLE II

	Group O		Group AB		Group B		Group A	
	Serum	Cell	Serum	Cell	Serum	Cell	Serum	Cell
Patient's cells	+++	---	+++	+++	+++	---	+++	+++
" serum	---	---	---	---	---	---	---	---

+, Agglutination. —, No agglutination.

The above grouping and cross-matchings were also done by the test-tube method at 37° C., but the results were the same as with the slide method. The serum and clotted blood of the patient were left in the refrigerator for more than one month at 4 to 6° C. and all the tests were repeated, but no change was detected. On all occasions her own serum did not agglutinate with her own red cells. The possibility of contamination can be excluded, as we performed all the tests immediately after the blood was withdrawn. The patient died on January 18, 1954.

Discussion

The first case of polyagglutinability was reported by Levine and Katzin (1938). They found that the red cells (Group O) of patients suffering from pneumococcus type I infection treated with sulphonamide and serum agglutinated with 15% normal sera independent of group. This peculiarity disappeared four months after recovery. Gaffney and Sachs (1943) reported two cases, of which one occurred in a patient with congenital syphilis and the other in a healthy adult. In both cases they found polyagglutination and concluded that both bloods were of Group O subjects.

Levine and Katzin's patient was also of Group O. In the first case of Gaffney and Sachs the titre of polyagglutinability went on increasing from 47 to 100%, in their second case it increased to 73%, and in both cases the cells and serum of patients agglutinated with both α and β serum and A and B cells respectively, but the cells failed to agglutinate at 37° C., thereby giving the correct grouping of the patient—that is, O. In neither case was there autoagglutination either at refrigerator or at room temperature. In all three cases this polyagglutinability was transitory and disappeared within four to six months.

In our case cells agglutinated with α and β serum and serum agglutinated with A cells but failed to agglutinate B cells and never agglutinated their own. We are thus inclined to describe the phenomenon here as polyagglutinability instead of panagglutinability.

Gaffney and Sachs found that the sera which agglutinated the cells of the patients at room temperature (20 to 25° C.) did not agglutinate at 37° C. This question does not arise in our country, because our room temperature is always around 37° C. In our case repetition of the tests in different dilutions and at our room temperature (34 to 37° C.) and at

refrigerator temperature (4 to 6° C.) did not show any alteration in any way. This type of agglutination gives a false idea about the grouping of patients.

The cross-match report (Table II) gives a peculiar result, and no definite conclusion could be reached; in order to come to a conclusion we made a back calculation to suggest that the patient was possibly of Group B.

Observations of different authors at different times suggest that panagglutination is due to bacterial contamination. Schiff *et al.* (quoted by Gaffney and Sachs, 1943) produced panagglutinability of cells artificially by bacterial contamination, in which the red blood cells did not agglutinate with their own serum and thus the difference was only one of degree.

Though the existence of a relationship of cold agglutination with polyagglutination was suggested by different authors, our case did not show any such relationship, as we got the same result in different temperatures, including that of the room.

The actual pathogenesis of polyagglutination is far from certain, but we have already mentioned that the T-antigen is responsible for some such abnormal agglutination as is described by Friedenreich and supported by Henningsen, Holländer, Van Loghem, Van der Hart, and Heier (Race and Sanger, 1954). In our case the patient was dangerously ill and ultimately died of the disease; it seems possible that bacteria were in some way responsible.

It is evident from the above that previous authors got agglutination at room temperature but not at 37° C., but we found the same result at room temperature, at the refrigerator temperature, and at 37° C. incubation. As our patient was seriously ill, it seems that the degree of bacteraemia or septicaemia might play some part in the phenomenon by transforming the latent T-antigen of cells into an active one. Further experimental work is necessary before any conclusion can be reached.

Summary

Polyagglutinability observed in a case of pelvic abscess with septicaemia is described and the relevant available literature reviewed.

The similarity between polyagglutinability and panagglutinability is observed and discussed.

The fact that such a case brings out the problem of correct grouping has been stressed.

T-antigen seems to have an aetiological bearing in such cases.

We wish to express our appreciation to Dr. A. E. Mourant, director, Lister Institute, London; Dr. R. Dutta-Choudhuri, pathologist, Chittaranjan Cancer Hospital; and Dr. Swadesh Basu, visiting surgeon, Chittaranjan Seva Sadan Hospital for Women. We thank Dr. Subodh Mitra, director, Chittaranjan Cancer Hospital, for his interest and help in this study.

An unusual case is described in the latest (1954) annual report of the Medical and Dental Defence Union of Scotland Ltd. "A National Service candidate, aged 18, was referred by the examining board to an ear, nose, and throat specialist for an opinion. The latter, on examining the candidate when referred to him, undertook to wash out the candidate's antrum, a procedure to which the candidate's father objected, as having been done on a minor (or infant) without the parent's consent. While the claim was not pressed, the consultant was advised that he had been in error in his zeal, as he was entitled to do nothing more than furnish a report to the medical examiners who had referred the candidate."

VARICOCELES OF THE ROUND LIGAMENT IN PREGNANCY, SIMULATING INGUINAL HERNIAE

BY

J. S. TOMKINSON, M.B., F.R.C.S., M.R.C.O.G.

Assistant Obstetric and Gynaecological Surgeon, Guy's Hospital; Obstetric Surgeon, Queen Charlotte's Maternity Hospital

AND

W. R. WINTERTON, M.B., F.R.C.S., F.R.C.O.G.

Obstetric and Gynaecological Surgeon, Middlesex Hospital; Surgeon, Hospital for Women, Soho Square; Obstetric Surgeon, Queen Charlotte's Maternity Hospital

It is worthy of note that swellings in the groin appearing for the first time in pregnancy do not seem to have attracted the attention of obstetricians and general surgeons. The similarity between femoral hernia and saphena varix is well recognized, but the likeness between a varicocele of the round ligament of the uterus appearing in the groin in pregnancy and an inguinal hernia appears to have been overlooked. A scrutiny of 16 standard textbooks in obstetrics, of 15 standard textbooks in general and operative surgery, North American and British, failed to reveal any comment. Textbooks on diseases of the vulva gave no information, and of the standard works on varicose veins only one made any reference to the subject, and then not specifically mentioning pregnancy: Verovitz (1941) states that "varices of the round ligament are often mistaken for an inguinal hernia." We believe we are describing a not uncommon condition which has been overlooked by clinicians, which is usually misdiagnosed, and which is omitted from the textbook literature.

The not infrequent occurrence of swellings in the groin, appearing for the first time in pregnancy and subsiding during the puerperium, had been noticed by us for some years. Although almost indistinguishable from an inguinal hernia on clinical examination, there seemed to be good reason to think that they were in reality varicoceles of the round ligament. Case 2, described below, stimulated our interest, so that medical officers in the antenatal clinics at Queen Charlotte's Maternity Hospital were asked to refer to us cases of "lumps in the groin." In a 12-weeks period 12 such patients were found and were followed through their pregnancy, labour, and post-natal period.

Case 1

This patient, aged 36, developed varicose veins of both legs during her first pregnancy in 1936. The veins subsided after delivery, returning during her next pregnancy, in 1951. During this second pregnancy lumps appeared in both groins, were diagnosed as herniae, and operation was advised. This advice was not taken.

She attended an antenatal clinic at Queen Charlotte's Maternity Hospital on July 27, 1953, in the 10th week of her third pregnancy, with a letter from her general practitioner referring her because of the history of inguinal herniae appearing in the previous pregnancy. On examination at that time the pregnancy was confirmed, notice being taken that varicose veins were present in both legs (including the upper thighs) and both labia majora. No mass could be produced in either groin, but a note was made that varicoceles of the groins were likely in view of the past history.

The following notes were made during the remainder of the pregnancy, the labour, and the puerperium. August 27: Swelling in right groin present (Fig. 1) diagnosed as a varicocele. September 24: Swelling in both groins, aching at the end of the day. A dragging sensation and aching in the groins continued until delivery. March 5, 1954: Spontaneous

Fig. 1.—Case 1. Photograph taken at 14th week (August 27, 1953), showing a swelling in the right groin.

Fig. 2.—Case 1. Photograph taken eight weeks after delivery (May 3, 1954).

vertex delivery; total duration of labour, 2 hours 25 minutes. March 12: Varicose veins improved, slight lump present in each groin. April 8: Very little swelling present in groins. May 3: No swelling present in either groin (Fig. 2).

Case 2

A patient, aged 27, pregnant for the first time, was booked for delivery at Queen Charlotte's Maternity Hospital, the expected date of delivery being February 16, 1953. Until October 6, 1952, no abnormality was detected, but on that attendance at the clinic the patient complained of a lump in the left groin; she was referred to an obstetric consultant, who diagnosed a left inguinal hernia, suggesting no active treatment. On January 1 varicose veins of the vulva were first noted.

At 9.40 a.m. on February 16 there was a spontaneous vertex delivery of a living female infant after a labour lasting 9 hours 50 minutes.

During the forenoon of the 17th the patient complained of pain in the right lower abdomen. On examination a tender mass was present in the right groin, measuring 1½ in. by 1 in. (3.8 by 2.5 cm.), irreducible, and diagnosed as a right inguinal hernia. At 5.30 p.m. the mass was unchanged, with normal bowel sounds. The opinion of a general surgeon was obtained, and at 9.30 p.m. he operated, the

provisional diagnosis being an irreducible right inguinal hernia. Under general anaesthesia a right oblique inguinal incision was made, dividing the right external oblique aponeurosis. This exposed the mass, which was found to be a collection of thrombosed vessels in the substance of the round ligament. This was divided, excised, and ligated at the internal abdominal ring. A small hernial sac was found to be empty; it was transfixed and excised. The inguinal canal was closed by suture of the conjoint tendon to the inguinal ligament. The post-operative recovery was uneventful, the patient leaving hospital on March 2. On April 14 healing of the right groin was perfect, and there was no evidence of a left inguinal mass.

It was thought that the "left inguinal hernia" in this case was a varicocele of the round ligament which subsided after the pregnancy, whilst a smaller varicocele of the right round ligament which was not discovered during pregnancy became thrombosed immediately after delivery, probably owing to the alteration in the size of the uterus producing a circulatory disturbance; both varicoceles were in association with varicose veins of the vulva.

Discussion

We believe that nearly all groin tumours first appearing in pregnancy are due to varicosities of the round ligament, which at first sight simulate an inguinal hernia. While in 2 out of the 12 cases under review there was little evidence of varicose veins, apart from the varicocele of the groin, in the remaining 10 varicosities of the vulva, with or without similar lesions of the thigh, were present, often to a gross degree. In seven patients a diagnosis of inguinal hernia was made when the mass was first seen, before being referred to us, and in one case operation had been advised.

It does not appear likely that a hernia of the inguinal region should make its first appearance during pregnancy, for, although there is an increase in intra-abdominal pressure, most of the structures which would fill the hernial sac (with the exception of free fluid) are kept out of the way by the bulk of the pregnant uterus and broad ligament. Some authorities (Berkeley *et al.*, 1938; Baird, 1950) state that pre-existing herniae frequently disappear during the later months of pregnancy, "the reason being that the enlarging uterus pushes the intestines away from the inguinal ring and presently blocks access to them" (Berkeley *et al.*, 1938). Strangulated inguinal herniae are extremely rare in the later months, and, in fact, Gaudier (1894) states that a strangulated inguinal hernia and pregnancy are incompatible. Although it is generally agreed that known pre-existing herniae tend to be temporarily cured during pregnancy, this series of 12 cases of swellings in the inguinal region first appearing in pregnancy was collected in the short space of 12 weeks. It is known that early in pregnancy, in the first trimester, there is a great increase in the vascularity of the pelvis, and varicose veins of the lower extremity may appear or worsen before the size of the uterus is likely to affect the venous return. The veins of the round ligament form an anastomosis with those of the vulva, and will join in any generalized varicosity—thus a varicocele of the round ligament is formed.

Clinical Features.—The clinical features of varicoceles of the round ligament are similar to those of an inguinal hernia. The patient complains of a lump and an aching feeling in the groin. The situation is identical, since both veins and hernial sac accompany the round ligament in the inguinal canal. Both swellings disappear on lying down and reappear on standing, though a varicocele may return more gradually than a hernia and is a little less circumscribed. A varicocele is of course dull on percussion and more closely resembles a hernia containing omentum than one containing bowel. The signs and symptoms of both conditions are therefore very similar, and it is only possible to make a diagnosis by the fact that in the case of the varicocele the swelling appears for the first time during pregnancy. The absence of varicose veins elsewhere does not exclude the diagnosis of a varicocele of the round

ligament. Thrombosis of the varicose veins is a complication which still further increases the resemblance between an inguinal hernia and varicocele of the round ligament, and is described in Case 2. This complication produces a firm, tender, irreducible swelling simulating a strangulated inguinal hernia, and a differential diagnosis becomes an urgent necessity, in view of the entirely different treatments required.

Treatment.—No active therapy has been found necessary in the patients we have seen. Suggestions to operate during pregnancy indicate that the probable aetiology of the lesion has not been appreciated. It is not necessary to commit a patient to bed rest because of the condition, although it is known that this occurred in a patient elsewhere, not in our series, in the belief that an inguinal hernia was present. A truss may, by giving support, add to the comfort of the patient. Reassurance, with a simple explanation of the temporary nature of the lump during pregnancy, and the recommendation of the usual supportive measures for the relief of vulval and leg varicose veins, is all that has been found necessary.

We wish to express our thanks to members of the clinical staff of Queen Charlotte's Maternity Hospital for helping to collect the cases, and to Mr. Bailey, of Queen Charlotte's and Chelsea Hospital photographic department, for the photographs.

THE SYMMETRICAL FORM OF STATUS BONNEVIE-ULLRICH (TURNER'S SYNDROME)

BY

J. B. BARLOW, M.B., B.Ch.

AND

S. E. LEVIN, M.B., B.Ch.

Department of Paediatrics, Baragwanath Hospital,
Johannesburg

In 1930 Ullrich reported a case of multiple congenital anomalies in an 8-year-old girl that was typical of a syndrome since known on the Continent as the symmetrical form of status Bonnevie-Ullrich. This child was of short stature, had a webbed neck (pterygium colli), an increased carrying angle of the arms (cubitus valgus), hypoplastic nipples, a highly arched palate, drooping angles of the mouth, hyperflexibility of the shoulder-joints, and irregular short nails of the hands and feet. The upper eyelids were prominent and heavy, giving the impression of bilateral ptosis. The ears were closely attached to the side of the head. At birth there had been a marked pitting oedema of the nuchal region and the extremities. The oedema, "congenital lymph-angiectatic oedema," disappeared during the second year of life.

Ullrich (1949) observed that this syndrome is identical with Turner's syndrome and the syndrome of ovarian agenesis, which have since been described and discussed in the English language literature by authors evidently unaware of his original report. It is apparent, however, that, whereas Ullrich (1930) described the congenital anomalies in great detail, it was the endocrinological aspects which aroused most interest in the American

and British literature. It is our purpose to present a typical case of this syndrome occurring in an African infant.

Case Report

A 3-week-old Bantu female was first seen on April 8, 1953. The mother complained that the infant had been "swollen" since birth.

Physical Examination.—**Head:** The circumference of the head was 14 in. (35 cm.). There was marked pitting oedema of the scalp, especially over the occipital region. Some oedema was present round the eyes, and the epicanthic folds were prominent. The bridge of the nose was flattened and somewhat broad. The corners of the mouth were drooping and the palate was highly arched. The upper parts of the ears were bound to the margin of the scalp. The superficial scalp veins were unusually conspicuous and large. The cranial nerves appeared normal. **Neck:** There were broad loose folds of skin over the postero-lateral aspects of the neck (pterygium colli). The occipital hair-line was low. **Chest:** The skin over the whole of the back was loose (cutis laxa). The chest was somewhat broad in shape. The nipples were hypoplastic, being pin-point in size. The heart and lungs were clinically and radiologically normal. **Abdomen:** The tone of the abdominal musculature was normal. A small umbilical hernia was present. **Extremities:** There

Photograph showing pitting oedema of the extremities.

was marked pitting oedema of the extremities (see Fig.). The nails of the fourth and fifth toes of the left foot and the fifth toe of the right foot were absent. The remainder of the nails of the hands and feet were spoon-shaped. There was a laxity of all the joints of the limbs, and the elbow-joints could be passively placed into a marked degree of cubitus valgus. **Genitalia:** The external genitalia appeared normal.

Investigations.—The urine was normal. Haemoglobin, 13 g. per 100 ml.; blood urea, 10 mg. per 100 ml.; serum proteins, 6.8 g. per 100 ml. (albumin 3 g., globulin 3.8 g.); thymol turbidity test, 1 unit; thymol flocculation, Takata-Ara, and colloidal red tests were negative; serum sodium, 350 mg. per 100 ml. X-ray plates of the spine, skull, and extremities showed no skeletal abnormalities. The mother's Wassermann reaction was negative.

Examination of Family.—The parents and the two other siblings were examined clinically and radiologically. The upper parts of the ears of the father and the two children were closely attached to the scalp margin, but no other abnormality was observed.

Progress.—When the child had been in hospital for one month she developed gastro-enteritis, which lasted for three days. During this period the oedema disappeared completely and recurred only when the diarrhoea and vomiting had stopped. She was discharged six weeks after this. When seen again, at the age of 6 months, the child was in

good health and mental development appeared to be normal. The circumorbital and nuchal oedema had disappeared, but pitting oedema of the extremities was still prominent.

Discussion

Turner (1938), unaware of Ullrich's report, described a triad characterized by webbing of the neck, cubitus valgus, and infantilism which he had observed in seven adult females. Numerous similar cases have since been reported by others (Sharpey-Schafer, 1941; Albright *et al.*, 1942; Varney *et al.*, 1942; Wilkins and Fleischmann, 1944; Lissner *et al.*, 1947; Del Castillo *et al.*, 1947; Dorff *et al.*, 1947; Jackson, 1950; Jackson and Sougin-Mibashan, 1953). Congenital anomalies observed by these authors, in addition to the webbed neck, cubitus valgus, and short stature emphasized by Turner, included the low hair-line at the nape of the neck, dystrophies of the ears, "shield" chest, arched palate, scoliosis of the spine, and coarctation of the aorta. Cases in a few females under the age of puberty were also recognized (Goldberg *et al.*, 1947; Silver, 1951; Cutler and Silver, 1953; Jackson and Sougin-Mibashan, 1953; Vulliamy, 1953).

Some authors have apparently avoided the term "Turner's syndrome"—firstly, because Turner (1938) considered that the sexual infantilism was of pituitary rather than gonadal origin, and, secondly, because congenital webbed neck or cubitus valgus was not invariably present. However, the term "syndrome of ovarian agenesis" is even more unsatisfactory, as the condition has been observed, though less commonly, in males (Flavell, 1943; Dorff *et al.*, 1948; McCullagh, 1948; Greenblatt and Nieburgs, 1948; Reforzo-Membrives *et al.*, 1949; Sohval, 1951; Cunningham and Harley, 1951; James, 1952; Sougin-Mibashan and Jackson, 1953; Mackenzie, 1953). It is possible that the term "Bonnevie-Ullrich-Turner syndrome," as suggested by James (1952), would do most to clarify the present somewhat disjointed situation and combine the contributions to the subject from both the Continental and the English language literature.

Our patient has shown virtually all the salient features of the syndrome as listed by Ullrich (1949). This author emphasized the frequency with which the "congenital lymph-angiectatic oedema" occurs, and considered the formation of this subcutaneous fluid during prenatal life to be the main aetiological factor in the various congenital anomalies seen. In over a hundred patients reported in the English language literature, however, we have found reference to oedema in only two case reports. Silver (1951) stated that the feet of his patient, aged 2 years and 8 months, were described as having been "swollen" at birth; and Vulliamy (1953), in his report of an 8-year-old girl, described "unexplained oedema of hands and feet at birth, persisting in the feet for the first three years." Pitting oedema was a very prominent feature in our patient, and was, in fact, the reason that the mother sought medical advice. It is difficult to understand how, if it were present, such a conspicuous abnormality could have been so frequently overlooked. Ullrich (1949), however, stated that the swelling disappears during the first two years of life. As our patient is the first under the age of 2 years whose case is described in the English literature, this may well explain why oedema has so seldom been mentioned.

No definite hereditary factor has yet been discovered. Unfortunately we were able to trace only our patient's immediate relatives, but were impressed by the complete attachment of the upper parts of the ears to the scalp margin in the father and the two other siblings. This particular anomaly was seen by Sharpey-Schafer (1941) in his patient; it is apparent to a moderate degree in the photograph of the male patient of Sougin-Mibashan and Jackson (1953), and is well marked in the male African reported by Mackenzie (1953). Whether this ear anomaly represents a very mild form of the syndrome in the relatives of our patient it is at present impossible to determine, but it was considered distinct enough to merit being put on record.

ADDENDUM.—Since this paper was written a case of this syndrome associated with hypertrophic pyloric stenosis has been recognized in a 2-months-old infant (Keay and Lewis, 1954). These authors, however, described the oedema of the extremities in their patient as non-pitting in character.

We are indebted to Dr. J. D. Allen, superintendent of the Baragwanath Hospital, for permission to publish this report. We wish to thank Dr. E. Kahn, under whom the patient was admitted, for his encouragement and advice.

Medical Memoranda

"Primary Myxoedema" in a Man of 30

Myxoedema was first described by Gull (1874) when he wrote "On a Cretenoid State Supervening in Adult Life in Women." It was Ord in 1878 who first used the term "myxoedema" to describe these cases of hypothyroidism. It is well known that myxoedema generally occurs in middle-aged and elderly women. Myxoedema in young males is uncommon, and so far as can be ascertained is either due to "pituitary myxoedema" as described by Means *et al.* (1940) or present as a true myxoedema following total thyroidectomy. It is therefore most unusual to find a case of "primary myxoedema" in a man of 30.

FIG. 1. Photograph taken on October 23, 1953. FIG. 2. Photograph taken on November 28, 1953.

CASE REPORT

A gardener aged 30 was first seen in consultation in October, 1953. He complained of a rash on the hands and forearms which was due to a plant-contact eczema. His

general appearance was most striking, as shown in Fig. 1. On further questioning he admitted to the following symptoms: (1) the gradual onset during the past two years of increasing weariness, which was now extreme towards the end of the day; (2) increase in weight; (3) a preference for hot weather and a feeling of the cold "right through him"; (4) a deepening of his voice and a slowing and hesitant speech; (5) a drying of the skin—"he had not sweated for months"; and (6) his hair was becoming coarse and lifeless.

On examination there were no physical abnormalities apart from a bradycardia of 50. The serum cholesterol was 400 mg. per 100 ml. and the blood urea 67 mg. per 100 ml. of serum. Examination of the urine showed: sp. gr. 1009, sugar, nil; albumin, slight trace; no casts or red blood cells. X-ray examination of the pituitary fossa was normal.

Treatment with L-thyroxine sodium 0.1 mg. daily for a week, then 0.1 mg. twice a day, was started on October 23. Improvement was most dramatic, both in his appearance as shown in Fig. 2, taken five weeks after Fig. 1, and in the blood chemistry as shown in Fig. 3, the serum cholesterol and the blood urea returning to normal within twenty-eight days.

He felt perfectly fit and all his symptoms had disappeared. His voice was now normal, he could sweat, his hair was improving in texture, he had lost weight, and he was no longer weary.

COMMENT

This record is of particular interest as it describes a case of "primary myxoedema" in a young man which responded dramatically to a relatively small dose of thyroxine and showed a fall, not only of the serum cholesterol as would be expected, but also of the blood urea. The fall in the blood urea was presumably due to the increased metabolism. Or could it have been due to a clearing of "cholesterol-clogged" arterioles in the kidneys?

I am grateful to Dr. C. A. K. Bird, of Macclesfield Hospital, for his advice and help with the blood chemistry in this case.

Ventricular Tachycardia following Exercise in a Case of Angina Pectoris

It is felt that the following case is interesting enough to be placed on record.

CASE REPORT

A man aged 46 attended the out-patient department giving a history typical of angina pectoris of four months' duration. The attacks had never occurred before this, had on no occasion lasted longer than 10 minutes, and had never been severe enough to cause absence from work. Apart from "pleurisy" 10 years previously, no history of any past

illness was obtained. He worked as a light machinist at a lathe in a nearby factory. He was married and had a family of four sons. No familial history of any ailments was obtained.

FIG. 1.—Standard leads taken at 11 a.m. Normal.

FIG. 2.—Standard leads taken at 11.15 a.m. The tracings show ventricular complexes which vary in size and which are deformed, the appearances being those of ventricular tachycardia or ? flutter. Rate 330 a minute.

FIG. 3.—Standard leads taken at 2.15 p.m. Normal.

Little of significance was found in the various systems, but examination of the cardiovascular system revealed: pulse, 70, regular, good volume and tone, arterial wall normal; blood pressure 150/100; apex beat displaced slightly downwards and outwards; a soft systolic murmur audible over the apex. Fundi: early silver wiring and tortuosity of the vessels.

Investigations.—Hb, 110%; white cells, 9,000; E.S.R., 19 mm./hour. W.R. and Kahn test negative. Urine normal. Chest x-ray examination showed no active disease in the lung fields; slight tenting of the right diaphragm was due to a minimal adhesion; the heart shadow was normal. Electrocardiograms were taken (1) before exercise (Fig. 1); (2) after exercise which caused a typical attack of retrosternal pain with sweating and coldness; the symptoms were relieved by inhalations of amyl nitrite (Fig. 2); and (3) 3½ hours after exercise (Fig. 3).

Trinitrin tablets for individual attacks, and quinidine sulphate, 6 gr. (0.4 g.) three times daily, have been given since. Up to the time of writing the patient managed fairly well, although he still had occasional tightness of the chest.

COMMENT

Schwartz (1942) describes three phases in the production of ventricular fibrillation—ventricular tachycardia proceeding to multifocal ectopic beats and eventual establishment of ventricular fibrillation. The ectopic beat prior to the run of tachycardia (initial premature beat) bears a constant relationship to the preceding ventricular complex, and all such beats appear to be identical in form and direction.

Runs of ventricular tachycardia are thought to originate from an irritable ventricular focus, and are the precursor of fibrillation.

Wetherbee *et al.* (1952) published tracings showing ventricular tachycardia following quinidine therapy in six cases of auricular fibrillation. Schwartz *et al.* (1953) showed tracings of transient ventricular fibrillation following quinidine therapy in cases of atrioventricular dissociation. A case of complete heart block described by Gresham (1952) gave rise to a series of electrocardiograms showing, at first, runs of ventricular tachycardia but, terminally, evidence of ventricular flutter and fibrillation.

The case described would appear to be in the first phase described by Schwartz in the production of ventricular fibrillation, and it is interesting to postulate an irritable ventricular focus arising from recurring relative ischaemia of a patch of ventricular musculature.

I wish to express my sincere thanks to Dr. Robert Mowbray for his constant help and permission to publish this case. I would also like to thank both the secretarial staff and members of the E.E.G. department, Dryburn Hospital, for their valuable assistance.

ROBERT BRUCE, M.B., B.S.

Grafting of Finger-nails

The restoration by grafting of lost or congenitally absent finger-nails is a subject upon which very little has been written. After carrying out a series of experiments it may be of interest to record that in suitable cases either the whole or part of the toe-nail can be transferred to the finger or thumb.

Apart from the disfigurement associated with absence of a nail, there is often a considerable reduction in function in the finger-tip. The normal nail acts as a support to the highly sensitive pulp, and without this counter-pressure the finer qualities of tactile appreciation are blurred. In the index finger or thumb this may be a very real disability in fine work.

The example shown here is the hand of a girl aged 8 in whom the middle finger showed congenital absence of a nail associated with brachydactyly (fusion of the distal and middle phalanges). Part of the great toe-nail with its

Restoration of middle finger-nail by free grafting of part of a toe-nail. One year after operation.

germinal matrix was implanted on the finger, and one year after the operation is seen growing normally. The donor toe-nail has also regenerated and causes her no discomfort.

Plastic and Oral Surgery Centre, Basingstoke.

Reviews

TROPICAL ARCHITECTURE

Conference on Tropical Architecture, 1953. A report of the Proceedings of the Conference held at University College, London, March, 1953. (Pp. 144; illustrated. 32s.) London: George Allen and Unwin, Ltd. 1954.

The problems presented by tropical architecture are as numerous and as varied as is the scene in tropical towns, packed as they are with innumerable forms of life and activity. The demand for a place in the jostling life of these towns is increasing, for, as Mr. C. Y. Carstairs states in an admirable introduction to this publication, one of the results of public order and better preventive and curative medicine latterly introduced into the Tropics has been a steep rise in population, and people unable to find a living on the land are crowding to the towns. "The expanding populations of the world cannot be fed unless more food is produced more efficiently by fewer farmers and peasants." Thus thousands are "extruded from an agricultural economy which no longer needs them." A tremendous social problem is being treated and must be tackled by promoting industrial development and planned housing schemes if the squalor of disorderly, insanitary, shanty-town slums is to be avoided. At this conference these and related problems were discussed, and the many subjects dealt with included the tropical aspects of planning, indoor climate and thermal comfort, style in architecture, traditional and modern building materials and construction, new building techniques, building with timber, and architectural education and training. On all these there are excellent papers which will be of interest, not only to architects and town planners, but to sociologists, educationists, and medical men. Professor Crowden reviews physiological principles underlying thermal comfort in the Tropics—a subject of importance to all who dwell in such regions, and one of which he has made a special study. Application of these principles to architecture has been attended by very good results.

Since the war several new towns and townships have been built, and already considerable experience in modern methods of construction and planning has been obtained and is here discussed. Problems very different from those encountered in temperate regions have had to be faced; thus the green open spaces so pleasant in temperate regions, and in tropical countries in which there is a high rainfall, in an arid climate become barren and dusty and are then used as public latrine areas or rubbish dumps. Underdeveloped regions often being synonymous with poor regions, financial stringency is usual, and much thought and ingenuity have been directed towards development of economical methods of ventilation, protection from dust storms, and making the best use of sunlight and breezes. A possible criticism of the conference is that insufficient attention appears to have been devoted to discussing and to encouraging research in domestic drainage, sewage disposal, and those aspects of building designed to limit fly-borne and intestinal infections. These remain one of the major sources of disability in the Tropics.

The book throughout is illustrated by numerous excellent and very informative photographs and diagrams. It can be strongly recommended, and is of the greatest importance to all concerned with the welfare of tropical peoples.

A. W. WOODRUFF.

CHILD GROWTH AND DEVELOPMENT

Growth and Development of Children. By Ernest H. Watson, M.D., and George H. Lowrey, M.D. Second edition. (Pp. 296; illustrated. 53s.) Chicago and London: The Yearbook Publishers Inc. 1954.

This is a second edition of a book the first edition of which has fully established its worth and has found its place in the reference libraries of teaching schools and on the shelves of paediatricians. In this edition the authors have

introduced changes in the chapter on physical growth and a new and valuable chapter on the growth and development of the face, jaws, and teeth, and on tooth eruption and malocclusion. The book gives a useful summary of knowledge on physical growth, including the development of organs and bones, with a brief account of nutrition, the development of behaviour, and the role of the endocrine glands.

The numerous references, totalling almost 300, are a particularly useful feature of the book, but it is regrettable that they refer almost entirely (in 96% of cases) to American work, to the exclusion of important work done in this country and elsewhere.

It is unfortunate that the book contains virtually no discussion of the normal variations which occur in development. For instance, on page 132 it is stated without reservation that in the normal child the anterior fontanelle is obliterated on palpation between 10 and 16 months of age. This is true of the majority of normal children, but not by any means of all. The doctor who is worried because a fontanelle is open at 18 months, or because the skull circumference is greater than the average, or because a child is smaller than the average in weight or height, or because a child is later than usual in walking, will receive no help in these pages in deciding whether his patient is normal or otherwise. It is hoped that the next edition will remedy this defect and attempt to draw some distinction between what is average and what is normal. The index, furthermore, should be improved.

This is hardly a book for the expert who has a special interest in any of the various aspects of development which it discusses, for the subject is such a wide one that it inevitably deals superficially with each item; but it does give an excellent bird's-eye view of development as a whole, and as such it will be valuable for almost all doctors who are concerned with the care of children, whether paediatrician, school medical officer, child welfare officer, or family doctor.

R. S. ILLINGWORTH.

CONGENITAL HEART DISEASE

Congenital Heart Disease: An Illustrated Diagnostic Approach. By Henry S. Kaplan, M.D., and Saul J. Robinson, M.D. (Pp. 126+xii; illustrated. £5.) New York, Toronto, London: McGraw-Hill Book Company, Ltd. 1954.

This book is yet another addition to the fairly numerous "atlases" of congenital heart disease that have appeared from several countries during the last few years. Its authors are respectively Professor of Radiology and Assistant Professor of Paediatrics at Stanford University School of Medicine, San Francisco.

It consists of two sections: the first is a presentation of the clinical features of various diagnostic procedures used in congenital heart disease, and the second a radiological atlas. The first section is in general excellent, the material being presented clearly and concisely; the atlas portion is well arranged, with drawings superimposed upon the cardiac shadow to demonstrate the position of the chambers and great vessels. The idea is good, but the angiocardiograms on which the atlas is based are of very poor quality and quite unconvincing; most show a merely formless opacity, much below the standards expected to-day. The aortograms of aortic coarctation are, for instance, just dreadful, whereas it is possible to show the lesion clearly and unequivocally. There is similarly no real demonstration of the lesions in Fallot's tetralogy or in pulmonary valve stenosis.

Like its fellow-atlases, this book is of approximately quarto size—a habit that seems to have grown upon us. It is an awkward size for handling, reading, and storing on the shelf. There seems no reason why a smaller and more convenient size could not be used.

The publishers state that it is intended primarily for the general practitioner and medical student. Its whole format is very suitable for direct, concise student teaching, and in this it succeeds admirably. The expert will find but little

in it for him. For students the price seems rather high, although the abundant illustrations make a high price inevitable. They will have to rely upon borrowing it from a library.

RUSSELL BROCK.

A SELFLESS SURGEON

The Scalpel, the Sword: The Story of Dr. Norman Bethune. By Sydney Gordon and Ted Allan. (Pp. 271+xv; illustrated. 16s.) London: Robert Hale Ltd. 1954.

Dr. Norman Bethune was born of pious Presbyterian parents at Gravenhurst in Ontario in 1890. By dint of working during vacations as a waiter or lumberjack he was able to study medicine at a university. Before he was qualified he served in the first world war as a stretcher-bearer in a Canadian field ambulance. He was wounded at Ypres, and on being invalided home obtained his medical degree and then served as surgeon-lieutenant in the British Navy. When the war was over he came to London and took the F.R.C.S. After marrying a young Scots lady of good family he returned to the New World and settled in practice in Detroit, where he gained a surgical reputation at the local hospital. He was then laid low by pulmonary tuberculosis, and while in a sanatorium read the writings of Dr. E. Alexander. He thereupon "stormed into the administrative building" and insisted that an artificial pneumothorax should be performed upon himself. This was done and he speedily got well. After his recovery he worked with Archibald, the famous thoracic surgical pioneer, and himself soon achieved success in that branch of surgery. He and his wife were divorced, but remained friendly.

Bethune was impetuous and irascible. He was impatient, and sometimes angry, with those who did not share his views. He had within him the missionary zeal, but not the doctrinal beliefs, of his godly parents. He became disgusted with ordinary practice and thought a State service was needed. He became a Communist, and, consenting to act as surgeon to the Spanish Republican Forces, did good work in arranging a transfusion service. Then he toured America and lectured in order to obtain funds for the Spanish cause. Finally, in 1938, he went to China to organize the surgical arrangements for the guerrilla Communist Forces. After almost two years of incredibly hard and self-sacrificing work he died of septicaemia in 1939 at the early age of 49.

The first part of this book deals with Bethune's early life and work in Spain; it is rather diffuse, and, while it may be attractive to a lay reader, is likely to be irritating to the medically qualified because of its melodramatic style and the unusual values it puts upon medical attainments and things in general. The second part, which deals with Bethune's experiences in China, is more restrained, and gives many extracts from his own writings penned in China. We see him here as a competent, selfless, hard-working surgeon who was absolutely devoted to his patients. On several occasions he continued operating, with scanty assistance and poor equipment, for two days continuously. His improvisations, his method of operating near the front line, his remarkable use of blood transfusion under the most difficult circumstances, stamp him as a pioneer. Dr. Richard Brown said of him: "Norman Bethune boasted that he was a Communist. I say he was a saint of God." To the reviewer the second part of the book was a delight and compensated for the rather turgid style of the first part.

ZACHARY COPE.

NATIONAL INSURANCE IN AUSTRIA

Praxis der Begutachtung. By Simon Mayr. Foreword by Lorenz Böhler. (Pp. 73+xi; illustrated. D.M.20.) Vienna, Bonn: For Medizinische Wissenschaften by Wilhelm Maudrich. 1954.

This little volume, for the title of which there is no English equivalent, presents an accurate and succinct description of National Insurance in Austria. Written by a consultant of

the great Hospital for Accidents in Vienna, and with a foreword by Professor Böhler himself, it carries unquestioned authority. It deserves the close study of all those, whether medical men or administrators, who have to deal with both health and accident insurance in this country.

Professor Böhler points out the immense importance of accuracy in both diagnosis and prognosis in insurance, the necessity for special training and experience in those who undertake the work, and the lamentable results which may follow if a mistake is made. Dr. Mayr, who was himself a general practitioner before he became consultant to the Accident Clinic, stresses the importance of an appreciation of these problems in general practice and of early recognition of conditions which may at this stage be easily corrected.

The first section describes the general organization of the clinic, which deals with some 50,000 cases each year, and gives an account of the provisions for compensation by the State. The second section, occupying two-thirds of the book, considers in detail all the conditions which may arise as the result of accidents to any part of the body. It is well illustrated and typical cases are clearly described. It concludes with a series of diagrams of possible injuries to the fingers, with a note in each case of the accepted percentage disability, which might well be adopted by our own Ministry of National Insurance and which would be of great assistance to both medical and appeal tribunals.

HENRY SOUTTAR.

A MYCOLOGICAL ATLAS

Practical Mycology: Manual for Identification of Fungi. By Sigmund Funder. (Pp. 146; illustrated. No price.) Oslo: Broeggers Boktrykkeris Forlag. 1954.

This little book, fairly described as a manual for the identification of fungi, is proffered as an introduction to mycology for beginners. It is in fact a mycological atlas comprising a large collection of excellent line drawings illustrating the characteristic microscopic morphology of various genera of fungi, with the minimum of textual description.

A short introductory section deals briefly with the fundamentals of mycology, the basis of classification, and elementary laboratory methods. The major part of the book, consisting of drawings of microscopical preparations designed as an aid in the identification of the fungi, is divided into three sections. The largest of these deals with fungi of general interest, the other two being devoted respectively to fungi of importance to the plant pathologist and those of medical interest; to the last section is appended a useful dichotomous key to the human mycoses. A schematic classification of 122 genera of the *Thallophyta* and a short glossary of mycological terms complete the volume.

As a textbook this work is wanting in balance. The admirable collection of plates for the identification of fungi will prove valuable to those with a basic knowledge of mycology, but to the beginner it is not an adequate introduction.

J. T. DUNCAN.

ATHEROSCLEROSIS

Experimental Atherosclerosis. By Louis N. Katz, M.D., and Jeremiah Stamler, M.D. (Pp. 375; illustrated. 75s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

It is remarkable how much information is gathered together, reassembled, and presented in logical sequence in this relatively short book of 291 reading pages. Appended are 713 references complete with titles. The authors have collected a vast amount of sifted evidence, to which they themselves have contributed in no small measure, in support of their proposition that altered cholesterol-lipid-lipoprotein metabolism plays a key role in human atherogenesis. The book is necessarily concise, well written, and therefore easily read, suitably illustrated to clarify the text, and full of detailed fact. It is strongly recommended to all workers in this important field, and will surely prove a milestone, if not a half-way house, on the road to full understanding of atherosclerosis and its consequences.

LONDON

SATURDAY APRIL 9 1955

NORADRENALINE

In 1946 the work of U. S. von Euler¹ drew attention to this very close relation of adrenaline. A substance which by its properties was indistinguishable from noradrenaline was found in the spleen, the heart, and the nerves of the sympathetic chain, and, when Tullar² separated the optical isomers of the synthetic compound, it was finally identified as L-noradrenaline. Von Euler put forward the view that noradrenaline was the chemical transmitter of sympathetic nerve impulses, and was in 1949 shown to be correct by Peart,³ who demonstrated that noradrenaline was liberated in the blood when the sympathetic nerves to the spleen of the cat were stimulated.

Noradrenaline has been used clinically to restore the blood pressure in various conditions, for which purpose it is superior to adrenaline primarily because noradrenaline does not accelerate the heart. This is the consequence of its greater pressor effect, which causes by reflex action an increased vagal tone. The greater pressor action of noradrenaline is explained by the fact that it constricts the vessels in the muscles as well as those in the skin and viscera, whereas adrenaline dilates those in the muscles. The properties of noradrenaline therefore enable it to be given by an intravenous drip so that its effect is always under control and can be increased or diminished at will. So readily indeed does the blood pressure respond to an increase or a decrease in the rate of inflow of noradrenaline that, when it is given, a constant watch on the blood pressure must be kept. The other precaution is that, once an infusion of noradrenaline has been started, it should not be terminated abruptly, since the blood pressure may then fall. This is because noradrenaline, like adrenaline, depresses the transmission through the sympathetic ganglia of the impulses which maintain vascular tone, and before the infusion of noradrenaline is finally stopped the trans-

mission must be given time to recover. Noradrenaline infusions have been used to maintain the blood pressure during the operation of removing an adrenal medullary tumour and also in the treatment of shock following cardiac infarction. Shirley Smith and Guz⁴ described its use in six patients in whom the systolic blood pressure had fallen to levels between 45 and 80 mm. and who seemed about to die. In each there was prompt clinical improvement, and, though two who had had previous infarctions died within three and four days, the others recovered well, and the lives of three were saved by the treatment.

The current interest in noradrenaline concerns the purpose of its release from the adrenal gland. Vogt⁵ has determined the presence of noradrenaline in the plasma of the adrenal vein of the cat, when the gland has been denervated previously. She found a mean secretion of 34 m μ g. of noradrenaline per minute, compared with 21 of adrenaline. In the normally innervated gland Duner⁶ has found that about three times as much noradrenaline is secreted. What is the purpose of this secretion? Does noradrenaline have a special function of its own, or is this simply the overflow of noradrenaline which is synthesized but cannot be stored? The work of West and his colleagues⁷ has shown that in foetal and neonatal life noradrenaline greatly predominates both in the rabbit and in man and that very little adrenaline is present. Later the position is reversed. Hence, ontogenetically, adrenaline seems to replace noradrenaline, and therefore phylogenetically adrenaline can be regarded as a more efficient form of noradrenaline. In the blue whale there is very little adrenaline. Since Bülbring⁸ has shown that noradrenaline is the precursor of adrenaline, the noradrenaline found in the adrenal vein may be the secretion of an unwanted product.

Comparisons between the amounts of noradrenaline and adrenaline in the adrenal vein during rest and activity have shown that the relative amounts change. Thus von Brücke and his colleagues⁹ found that the percentage of adrenaline was raised by stimulating areas in the hypothalamus. Von Euler and Folkow¹⁰ likewise found that the percentage of adrenaline was much greater following stimulation of the central end of the sciatic nerve or of the brachial plexus than it was when the carotid arteries were clamped. Finally, Folkow and von Euler¹¹ have published evidence that the proportion of the two substances in the adrenal vein can be modified by stimulating different points in the hypothalamus. Stimulation of one point caused a rise in the output of noradrenaline without raising the output of adrenaline, while stimulation of a different point caused a rise in the output of adrenaline and little or no effect on that of noradrenaline.

They conclude that in the adrenal medulla there are separate cells for producing adrenaline and noradrenaline and that these are innervated by separate fibres with a different hypothalamic representation.

Eränkö¹² has used histochemical methods which reveal brightly fluorescing cell groups in the adrenal medulla; and he has shown that, when different species are examined, the percentage of the medulla occupied by fluorescing cells is very similar to the percentage of noradrenaline in the mixture of the two amines. To establish the connexion between fluorescing cells and noradrenaline more securely, Eränkö adopted the following ingenious procedure. He cut serial sections of fresh frozen glands of the cat and the hamster. Alternate sections were examined histologically for the distribution of the fluorescing islets, and the other sections were freeze-dried. He then picked out of these freeze-dried sections the pieces which the histological examination had shown to contain many fluorescent islets, and found them to contain more noradrenaline than the pieces from the same section which contained fewer fluorescing cells. Eränkö also tested the effect of injecting rats with insulin and with nicotine. He found that insulin caused a selective depletion of adrenaline and a disappearance of the chromaffin reaction from all but some cells which form islets similar to the fluorescing islets. The fluorescence of these islets was not affected by insulin. This observation agrees with the previous evidence that in insulin hypoglycaemia there is a predominant release of adrenaline. On the other hand, when Eränkö injected nicotine there was a selective loss of noradrenaline and a disappearance of fluorescing and chromaffin material from the islet cells. These observations, made possible by the methods worked out in the Department of Pharmacology in Edinburgh, constitute an important advance in our knowledge of the physiology of the adrenal medulla.

CASTRATION OF SEX OFFENDERS

Castration has been used as a form of treatment or punishment for sex offenders since at least 1500 B.C., and continues to arouse controversy. Some consider it to be a barbaric and primitive custom; its modern advocates can claim that the real effects are rarely studied impartially and that it offers an alternative to years of imprisonment. Surprisingly little is known about the effect of castration on normal human males. Castration before puberty leads to serious diminution in sexual responsiveness, but when performed after puberty the only certainty is that the effects are very variable. Beech¹ points out that "the literature is replete with references to complete retention of sexual function in individuals who have been castrated for

many years," but that nevertheless the human male usually experiences a gradual loss of mating ability. Kinsey² questions whether this gradual loss is not largely due to the effects of advancing age, which his own studies have revealed in detail for the first time, since many of the reports do not give the age of the castrates. Most reports have failed to give detailed information, perhaps because the truth is hard to come by. Lange³ found that victims of accidental castration exaggerated the ill effects in order to obtain financial compensation, and Stürup⁴ that castrated sex offenders are apt to boast about their potency, at least for a time. However, some types of medical treatment have been found effective even when their rationale is rather suspect, and this may be so of castration. The cautious programme carried out at the Herstedvester psychopathic prison in Denmark is much more fully described than others and deserves careful study.⁴⁻⁶

Danish law permits treatment in a special institution of sexually abnormal and other offenders who are not certifiable as psychotic or mentally defective but are not amenable to punishment. The detention is for an indefinite period. Sex offenders, selected after careful study, may be offered the opportunity of volunteering for castration; if so, they are usually released in about six months, although they remain under supervision of the institution. Some 190 offenders were castrated in the ten years after the treatment became legal in 1935. Few are said to resent or to regret it afterwards, and some who establish themselves socially are pleased with the results. Any judgment of the effects is made difficult by the low rate of recidivism of sex crimes and the great variety of offences and of personality in the offenders. In a 10-year survey of over 3,000 sex offenders in Denmark⁶ the rate of recidivism for sex offenders in general was 16.8%. Except in incest cases 70-80% of the recidivism is homologous (the same sex offence). The highest rates of recidivism are for exhibitionism (32.4%), indecent assaults on boys (27.9%), and rape (22.3%). Analysed by personality, if the cause of any sex offence was considered to be "psychopathy," the recidivism was 37.6%, and, if "sexual abnormality," was 61.1%. Castration is never carried out for social convenience or security alone, but only in cases of severe but non-certifiable mental abnormality virtually untreatable by other means, and when the offences have been serious and the prognosis is bad. Thus 13.8% of men convicted of rape were castrated, 14.3% of those

committing indecent assault on boys, but only 2% of the much larger numbers committing indecent assaults on women and girls, for whom the prognosis is much better. Among 500 criminals admitted to Herstedvester before 1948, 199 were sex offenders (apparently about 2.5% of all sex offenders). Of these, 175 have been released, 117 after castration and 58 without castration; 15 are dead or in mental hospitals; 9 are still detained. Of the 117 castrated and released, only 5 have again committed a sex offence in a period of 4-10 years. Of the 58 who were released without being castrated, 25 again committed the same kind of offence. Seventeen of these later consented to be castrated and were released; so far they have not been convicted of further offences. Thus a total of 134 have been released after castration, with a homologous recidivism of 3.7%. Perhaps the most interesting feature is that all the 5 men who committed a sex offence after castration were homosexuals who associated with boys. Thus the recidivism for castrated heterosexuals was nil, but was about 10% for the 49 homosexuals who were castrated. The homosexual's attitude to castration may be more complex, and his opportunity for legitimate expression more limited, though homosexual activity between adults is not an offence in Denmark. The castrated and non-castrated groups, however, are not strictly comparable, since there is a natural tendency to risk releasing the minor offenders, such as exhibitionists, and to detain—sometimes for 10-15 years—men convicted of rape who refuse castration.

In Britain there are probably few advocates for the castration of sex offenders; and the Danish results, impressive as they are, do not suggest that castration offers such a sound solution to the problem of treating these people that we should re-examine the basis of our reluctance to use it. Nevertheless the more frequent passing of sentences of up to fourteen years' preventive detention may stimulate a humanitarian demand for some alternative to imprisonment. The production of reversible castration by means of oestrogens, perhaps implanted, might be worth studying.

PURE RED-CELL ANAEMIA

Marrow hypoplasia or aplasia is now known to affect haemopoiesis in more than one way. In what might be called typical aplastic anaemia the hypoplasia affects the formation of leucocytes and platelets as well as red cells and gives rise to pancytopenia in the peripheral blood. Less commonly, the formation of red cells is seriously affected and leads to a profound reticulocytopenia, although the production of leucocytes and platelets continues normally or almost normally. This latter type of anaemia—pure red-cell anaemia¹—gives rise to several

distinct clinical entities. The first of these is a chronic anaemia in infants—congenital hypoplastic anaemia² or erythropoiesis imperfecta.³ The second is an acquired chronic anaemia in adults—sometimes apparently associated with tumours of the thymus.⁴⁻⁵ And thirdly a temporary condition occurs occasionally in the course of congenital haemolytic anaemias⁶⁻⁸ and rarely in autoimmune acquired haemolytic anaemia⁹⁻¹⁰ or in previously healthy children.⁷

Pure red-cell anaemia of infants is usually diagnosed in the first year of life, though the infant may appear healthy at birth. Anaemia is the sole symptom and the children develop normally as a rule. The most striking pathological feature is the virtual or perhaps complete absence from the marrow of the nucleated precursors of the red cells. Nothing certain is known of the cause of the disorder. Recently, however, K. I. Altman and G. Miller¹¹ have demonstrated anthranilic acid in the urine of several children suffering from pure red-cell anaemia; this suggests an abnormality in tryptophan metabolism, but the link between the abnormality and the anaemia remains obscure. Periodic transfusion is usually necessary, and the outlook for the patient is rather grave. Even so, spontaneous cure or substantial improvement has been reported. Some of these children have been treated with A.C.T.H. or cortisone, or by splenectomy, or both. The results seem unpredictable and usually unsatisfactory.^{3, 12}

It is uncertain what relationship there is, if any, between the pure red-cell anaemia of infancy and typical aplastic anaemia leading to pancytopenia. Moderate degrees of leucopenia have been observed in children who otherwise would seem to belong to the group of pure red-cell anaemia.¹³ A further complication is the finding of peripheral reticulocytopenia (with normal leucocytes and platelets) in children whose marrows show normal or even increased numbers of erythroblasts instead of the expected hypoplasia. In these patients arrest of maturation rather than red-cell aplasia seems to be the cause of the anaemia.¹⁴

Pure red-cell anaemia in adults is a rare disease, and the pathogenesis is uncertain. In at least nine patients a tumour of the thymus (usually a benign thymoma) has been associated with the anaemia; some but not all of the patients have had myasthenia gravis.⁴⁻⁵ The case histories recently reported by Drs. J. N. M. Chalmers and K. Boheimer in this *Journal*¹⁵ are particularly interesting. The first patient developed temporary remissions following, respectively, thymectomy and splenectomy, and later went into apparent permanent remission after

receiving a course of A.C.T.H.; the second patient responded similarly to A.C.T.H. after thymectomy and splenectomy, which in themselves had conferred little or no benefit. Two other patients referred to by Chalmers and Boheimer responded to thymectomy (without splenectomy or A.C.T.H. therapy), but in neither of the patients of Ross and co-workers⁵ was the operation successful. Chalmers and Boheimer suggest that the anaemia may be brought about by an inhibitor of erythropoiesis, formed in lymphoid tissue, and that thymectomy may be successful, depending upon the degree of interference with erythropoiesis. In Chalmers and Boheimer's own patients, on this hypothesis, removal of the spleen as well as the thymus did not remove sufficient lymphoid tissue for erythropoiesis to proceed; only after subsequent A.C.T.H. therapy, which perhaps caused a further depression of lymphoid tissue, did erythropoiesis take place normally. In those cases, too, in which a similar type of anaemia has occurred with no evidence of a thymic tumour remission has followed splenectomy with or without subsequent A.C.T.H. or cortisone therapy.¹⁵ Finally, it should be mentioned that patients suffering from pure red-cell anaemia have been recorded as responding to riboflavine¹⁶ and cobalt.^{17, 18}

The concept of inhibition of erythropoiesis resulting from hyperplasia of lymphoid tissue is especially interesting. The spleen had often been thought capable of inhibiting haemopoiesis; usually, however, the result of "hypersplenism" is pancytopenia. The case reported by G. Eisemann and W. Dameshek,¹⁹ in which red-cell hypoplasia associated with an auto-immune haemolytic anaemia disappeared following splenectomy, might be looked upon as an example of a more specific type of hypersplenic activity.

SEASONAL INCIDENCE OF PEPTIC ULCER

It has long been a clinical impression that the symptoms of gastric and duodenal ulcers are exacerbated in the spring and autumn. If they are, the fact is of considerable theoretical interest, for it may provide a clue to the aetiology of two conditions which at present elude us. Few objective data support the impression, and they are not altogether consistent. The subject is reviewed by A. C. Ivy, M. I. Grossman, and W. H. Bachrach.¹⁹ Data for the month of onset of pain, haemorrhage, perforation, and death all show a decreased incidence in summer and a sharply increased incidence in the late autumn or winter. Most data have been obtained from the northern hemisphere, but the same rhythm has also been shown to exist—so far as symptoms are concerned—in the southern hemisphere.²⁰ Some data suggest that there may also be an increase of activity in the spring, but the evidence for this is not striking. In fact, R. A. Jamieson,²¹ who studied the distribution of nearly 8,000 cases of acute perforation treated in the three main Glasgow hospitals, found that throughout this period

of the year the incidence was remarkably constant. A partial explanation of these differences may perhaps be found in the grouping together of cases of gastric and duodenal ulcer. According to R. S. Boles and M. P. Westerman,²² who have recently reported on 320 cases of peptic ulcer admitted for haemorrhage to the Philadelphia General Hospital over the five years 1949-53, the peak months for gastric ulcer admissions were between January and June, with a lower incidence in the late summer and the autumn; while duodenal ulcer admissions showed two peaks of incidence, one in March and the other in November, with a minimum in July. Boles and Westerman suggest that the pattern for duodenal ulcer may be related to changes of temperature—the peaks of incidence occurring in the months in which the extent of the change between the beginning and end of the month is the greatest. They also suggest—though they provide no data in support—that haemorrhage may be precipitated by changes in barometric pressure. The correlation shown between temperature change and incidence of haemorrhage is undoubtedly close over the latter half of the year, but it is much less striking during the first six months, and, if their explanation were to be accepted, it would be necessary to postulate some additional factor responsible for the relatively high incidence in the middle of the winter. Other explanations put forward in the past are that the activity of an ulcer may be stimulated by upper respiratory infections or by the ingestion of vegetables which are subject to seasonal fluctuation in their supply. These suggestions, though stimulating to research, are based on very little factual data, and it may well prove that Jamieson was right in concluding that, so far as perforations are concerned, the decrease in incidence between mid-July and October is due to the physical rest associated with holidays and comparable to the reduced incidence characteristic of Sundays and Mondays and of the early hours of the morning.

THIS YEAR'S BILL

An increase of some £25m. in the total cost of the Health Service in 1955-6 had already been foreshadowed in the Vote on Account published a few weeks ago. The detailed estimates¹ that have now appeared show how the increase is distributed among the different branches of the Service.

The interesting thing is that each main branch shows an increase of some sort, though where the cost is partly offset by patients' payments—in the pharmaceutical, dental, and supplementary ophthalmic services—the net increases, after allowing for these payments, look insignificant against a background of £462m. being spent on the Service as a whole. But, small as they are, they give the impression that the effect of the charges has to a certain extent worked itself out. The gross cost of dental treatment is still well below the peak it reached in the early years of the Health Service—when dentists' fees were higher. But at £35½m. (reduced by charges to patients to £27½m.) it has climbed some way from the

¹ Civil Estimates for the Year Ending March 31, 1956, Class V. H.M.S.O., 6s.

low level it fell to when the charges were first introduced. A similar trend can be observed in the cost of the ophthalmic service. As regards the pharmaceutical service, a year ago the estimate (for 1954-5) was much the same as for the previous year, and there seemed some hope that a combination of charges and exhortations to doctors to prescribe economically had stabilized the cost of this service, which had gone up inexorably since 1948. But in the event a supplementary estimate of some £2m. was needed in the course of the year, and this year's estimate, though only slightly higher at £55m. gross (and £47½m. net), is £7m. higher than the estimate for the year when the shilling charge was introduced.

In all these cases the rise in the estimates reflects a bigger demand by the public rather than a rise in the cost of providing the Service, though drugs are certainly no cheaper. So far as the hospitals are concerned, the increase in the estimated advances to boards is largely accounted for by higher salaries and wages and other maintenance costs. The recent award to nurses was estimated to cost over £4m. a year, and in this instance there are expected to be more staff to pay, for 8,000 more nurses and midwives are now being employed than a year ago. The number of consultant and other medical staff, on the other hand, is roughly the same. On the whole, however, this year's estimated rise of nearly £20m. in the cost of maintaining the hospitals is due to the higher cost of the existing service rather than to any noticeable expansion. That will not come until the new hospital building programme, announced earlier this year to start in 1956-7, has been completed. But long before that the Guillebaud committee on the cost of the Health Service will have reported, and—just possibly—some change in the method of financing the hospitals may have been introduced.

CEREBRAL BASIS OF MEMORY

The relationship of mind and brain remains as firmly established and its exact nature as obscure as in the days of the Hippocratic school. The question has been of perennial interest to neurologists, and within the last few decades they have been able to throw light on the more limited problem of which parts of the brain especially influence consciousness. While Pavlov's view of the cerebral cortex as an analyser and therefore an essential organ for fine discriminatory consciousness remains unassailed, recent interest has focused on the neural background of the more crude diffuse "awareness" that must lie behind discrimination. The occurrence of pathological sleep in man in encephalitis lethargica with lesions shown to be maximal in the hypothalamic region, and later Hess's¹ production of sleep by electrical stimulation of limited sites in the diencephalon of animals, both directed attention to subcortical structures. The late Sir Hugh Cairns, in his Victor Horsley lecture,²

reviewed the evidence, from his own considerable experience, for a causal connexion between disturbances of consciousness and lesions of the brain stem and diencephalon. He concluded that such lesions could produce "severe disturbance of consciousness which arises without any direct involvement of the cortex or cortico-spinal pathways," and suggested that the reticular formation was an important part of the anatomical background for this.

Cairns's interest in this field has been maintained by his colleagues in the Oxford Medical School, and Williams and Pennybacker³ have made a valuable study of disturbance of memory in patients with brain tumours involving the floor and sides of the third ventricle. All of their four cases showed a Korsakov type of memory defect—amnesia with confabulation (that is, answering questions and recounting experiences without regard to actual happenings). In one the relation of symptoms to the function of third ventricular grey matter seemed particularly well established, because a cystic tumour which pressed on these structures was present: when the pressure was relieved by evacuation of the cyst symptoms subsided, only to recur as the cyst again filled up. The authors provide convincing collateral evidence that the memory disturbances were not associated with other and more diffuse cerebral lesions or with such factors as raised intracranial pressure. The quality of the memory defects was of special interest. Usually they were accompanied by some reduction in responsiveness and alertness, though the general dementia seen in other cerebral lesions was not present. But the striking feature was the confabulation and pseudo-reminiscence produced by attempts at recalling memories: it was almost as if the content of memory was still there but that its orderly arrangement and temporal sequence were at fault. In this sense the disturbances seem to follow the diffuse rather than discriminatory pattern of other subcortical lesions. A study⁴ of the mental disturbances in tuberculous meningitis is also concerned with defects of memory. In some patients such defects were prominent, consisting especially of "an inability to organize past events in correct temporal sequence"; and in these cases also the inflammatory process directly involved the floor of the third ventricle. The authors are cautious in connecting the two observations, but their evidence for a causal relation seems convincing and confirmatory of other work.

SUCROSURIA

Not so long ago "marasmus" was a term used to cover ignorance about the reasons why certain infants did not thrive after birth. Modern diagnostic methods, in particular chromatography, have shown that these infants may suffer from serious metabolic disorders, and it should be accepted that any child with obscure wasting requires urgent and specialized investigation. In this way, for example, Moncrieff and Wilkinson¹—writing in a special number of *Acta Paediatrica* in honour of Professor A. Wallgren's 65th birthday—have recently discovered sucrose in the urine of three such

¹ *Acta paediat. (Uppsala)*, 1954, 43, Suppl. 100, p. 495.

patients. Sucrose is a disaccharide which, unlike other common sugars, does not reduce alkaline copper reagents. It is rapidly split by hydrolysis in the intestine—probably by a combined action of gastric juice and succus entericus—into its component sugars, glucose and fructose, which pass quickly to the liver. If sucrose escapes hydrolysis it enters the tissue fluids, where it behaves as an inert substance and is excreted by the kidneys. Because of its rapid absorption this particular sugar is often used in the treatment of hypoglycaemia. Its presence in the urine has occasionally been reported in patients with gastro-intestinal and pancreatic disorders.

Studies by paper chromatography show that most sugars are excreted in small quantities in the urine of infants. In Moncrieff and Wilkinson's cases, however, abnormal amounts of fructose, lactose, and sucrose appeared after milk feeds (which contain lactose and sucrose). A single dose of sucrose increased the abnormality. When various combinations of dietary sugars were fed to the infants it was possible to recover individual sugars from the urine provided that sucrose and lactose were present in the diet. Moncrieff and Wilkinson are not yet able to say what is the nature of the defect in carbohydrate metabolism in their patients. Attempts to measure the activity of succus entericus were not wholly successful, but the fact that fructose was excreted after a dose of sucrose suggests that splitting takes place in the intestine. There must, however, be very rapid absorption before hydrolysis is complete, and it is significant that both sucrose and lactose are disaccharides, which perhaps compete with each other for hydrolysis. More will be learned about the utilization, storage, and excretion of sugars when further cases of this abnormality are detected. All three infants suffered from mental defect and hiatus hernia in addition to the sucrosuria. It is not clear whether these are associated congenital lesions or whether they are closely related to the sucrosuria. Necropsy in one infant showed developmental abnormalities in the brain, and it is difficult to imagine a relationship between an oesophageal lesion and abnormal sugar metabolism. On the other hand, galactosaemia is known to result in mental retardation. The fact that two infants died and the third is mentally and physically backward makes it unnecessary to stress the need for early detection of this interesting new metabolic error.

ELECTRICAL ACTIVITY OF THE UTERUS IN LABOUR

During the last few years interest has been shown in the recording of the electrical activity of the human uterus during labour.¹⁻³ In a recent paper C. M. Steer⁴ has reviewed his findings in 556 parturient women in whom recordings were made with his electro-hysterograph (E.H.G.). The value of this review is enhanced by the fact that the E.H.G. findings were not allowed to influence the management of any case, nor were they used to classify a labour as normal or abnormal. The E.H.G. is a device employing three pairs of elec-

trodes placed on the abdominal wall so that one pair lies over the right uterine cornu, another correspondingly on the left, and the third over the midline of the fundus. The location, duration, frequency, and amplitude of the electrical waves can thus be recorded. The waves are present only during uterine contractions, whether of true or false labour at or before term, and between contractions there is a relatively smooth tracing in which the electrocardiogram can usually be seen. The wave of electrical activity begins simultaneously with the mechanical contraction, some 10-20 seconds before pain is appreciated: the electrical wave and the pain end simultaneously, at which time relaxation begins, to become complete in a further 15-30 seconds. In normal labour the frequency of the waves is ½-2 cycles per minute, while the amplitude varies from 50 to 500 microvolts in direct proportion to the clinical strength of the uterine contractions.

Steer considered in particular detail 51 labours, all but two in primigravidae, in which a clinical diagnosis of uterine inertia was made. Such a diagnosis was based on the failure of the cervix progressively to dilate, with the strength and frequency of contractions remaining unchanged or becoming weaker. The eventual duration of labour varied from 15 to 120 hours with a mean and median of 35 hours. The significant finding by E.H.G. was the absence of electrical activity during contractions in five of these 51 women. Two of the five were treated with pitocin by intravenous drip, while in the other three only sedative and supportive measures were employed; but in all five cervical dilatation never progressed beyond two fingerbreadths, and caesarean section was required. In Steer's opinion these are cases of true primary uterine inertia, and he remarks, as others have done, that this is a rare condition. In the remaining 46 women electrical activity was present, and Steer regards these as cases of slow but basically normal labour, in which stimulation with pitocin is nearly always effective. He notes, however, that disproportion was present in over one-third of these 46 cases. The importance of such coexistence of disproportion and inertia, an association which again has been remarked by others, lies in the fact that stimulation with pitocin may succeed in overcoming minor disproportion and effecting vaginal delivery, but only at the cost of damage to the foetus.

The electro-hysterograph can thus serve to distinguish between the more common slow normal labour and the rarer true inertia which represents some basic disturbance of uterine muscle activity. Such a distinction can also be made by observing the results of stimulation with pitocin, but without the same absolute safety. The nature of true inertia is still unexplained. The uterine muscle contracts but does not provide sufficient force for progressive labour, and Steer concludes by suggesting that the fault may lie either in the contractile apparatus within the uterine muscle fibre or in the transmission of the impulse to contract.

EMERGENCIES IN GENERAL PRACTICE

DIABETIC AND INSULIN COMA

BY

J. D. N. NABARRO, M.D., M.R.C.P.

Assistant Physician, the Middlesex Hospital

The treatment of severe diabetes mellitus involves the use of one or more of the many insulin preparations now available and the prescription of a suitable diet. There is an increasing tendency for the routine management of these patients to be undertaken in special hospital out-patient clinics, partly because in some cases it is difficult and time-consuming, and partly because the help of dietitians and other ancillary workers may be required. The general practitioner is apt to see his diabetic patients only if some emergency arises, such as an intercurrent infection or the development of ketosis or severe hypoglycaemia. When this happens, lack of familiarity with the patient's diabetic condition makes his task much harder.

Diabetic Coma and Pre-coma

It is now generally accepted that diabetics fall broadly into two groups—those who are underweight and those who are overweight when the condition is recognized. It seems likely that in the first type insulin-lack is the underlying cause, whereas in the second type insulin is still being produced by the pancreas in approximately normal amounts. Both groups have a high blood sugar with glycosuria and polyuria, but those suffering from insulin lack tend, in addition, to produce an excess of ketone bodies unless adequate replacement therapy is given. If these ketone bodies are being formed so fast that they accumulate in the blood, the patient may be said to be in a state of diabetic ketosis, and unless treatment is given will deteriorate, first becoming drowsy and finally unconscious. Coma resulting from severe diabetic ketosis is fortunately rarely seen nowadays, and the practitioner is concerned with recognizing the condition in the pre-coma stage, which in itself is to be regarded as a medical emergency.

Severe diabetic ketosis or diabetic pre-coma is usually defined on a biochemical basis (carbon dioxide combining power less than 20 vols.%), but on clinical assessment it may be said to be present when, following a period of severe diabetic imbalance, there is evidence of dehydration and the patient's breath smells strongly of acetone. In this condition there is a heavy glycosuria and in almost all cases ketone bodies are present in sufficient concentration to give a positive ferric chloride reaction.

Patients with recently developed diabetes rarely reach the stage of severe ketosis before seeking medical advice. Known diabetics may go into ketosis because the dose of insulin prescribed for them is inadequate or because their syringe is defective and they are not getting the full amount. Much more commonly it follows a sudden increase of insulin requirement produced by an intercurrent infection, usually of the upper respiratory or gastro-intestinal tract. Occasionally an emotional upset increases the insulin requirement enough to lead to diabetic ketosis.

Recognition of Severe Diabetic Ketosis

Severe diabetic ketosis does not develop in a matter of hours: with very few exceptions the patient will give a history of thirst, polyuria, and nocturia for several days. As the ketosis becomes more severe, appetite is lost and increasing nausea is followed in many cases by vomiting. Intense thirst persists until consciousness is lost. Some patients, when they lose their appetite or start to vomit,

reduce or omit their insulin injections—a step that still further aggravates their condition. Constipation is the rule and is occasionally associated with severe abdominal pain suggestive of an acute attack of appendicitis or some other surgical emergency. In a few cases the acidotic respiration is very striking and the patient's chief complaint is of breathlessness or dyspnoea.

A history of increasing thirst and polyuria followed by nausea and vomiting in a diabetic patient should warn the practitioner of the possibility of diabetic ketosis. The most important findings on physical examination are signs of dehydration—a dry red tongue, inelastic skin, and often a reduction of blood pressure. The breathing is usually very deep and may be rapid. The breath smells strongly of acetone.

Examination of the urine is of great importance, and, unless the patient is unconscious or severe dehydration and hypotension have led to impairment of renal function, there is seldom any difficulty in obtaining a specimen. This should first be tested for sugar. There is no longer any need to use Benedict's solution or to boil the urine in a test-tube over a spirit flame. The "clinitest" tablet method has been shown to be accurate and reliable and is much more convenient for use in the patient's home. If the urine contains less than 2% sugar it is extremely unlikely that the patient is in diabetic ketosis. An approximate quantitative assessment of the percentage of sugar in the urine is obtained from the colour chart provided with the tablets. Corresponding colours obtained with Benedict's test, using 0.5 ml. urine and 5 ml. reagent, are as follows:

	Clinitest Colour	Benedict Colour
0%	Blue	Blue
1%	Yellow-green	Cloudy green
1%	Yellow-brown	Yellow
2% or more	Orange	Red

If there is a heavy glycosuria the urine should next be tested for ketones: a number of methods are available. The sodium nitroprusside or Rothera test is extremely sensitive and in practically all cases of severe diabetic ketosis it is very strongly positive. The ferric chloride test is much less sensitive and a true positive result indicates a gross ketonuria and the presence of a severe degree of ketosis. Unfortunately, however, salicylate medication leads to a false-positive reaction in the ferric chloride test and it is not uncommon for patients, feeling unwell on account of their unbalanced diabetes, to take a couple of aspirins. Methods are available for distinguishing the false-positive from the true-positive ferric chloride reaction, but these involve boiling the urine for 10 minutes and are not really suitable for use in the patient's home. Recently a tablet modification of the Rothera test has been introduced and has greatly simplified the detection of significant degrees of ketonuria. When using the "acetest" tablet a ++ or +++ reaction indicates marked ketonuria, corresponding to a true-positive ferric chloride reaction. It must be emphasized that the colour given by the acetest tablet is much weaker than that of the original Rothera test, and any patient giving a ++ or +++ result on the chart provided with the tablets should be considered to have severe diabetic ketosis and to be in urgent need of treatment.

Diagnostic Difficulties

A number of conditions have been incorrectly diagnosed as diabetic ketosis: salicylate poisoning, meningococcal meningitis, and subarachnoid haemorrhage may be quoted

as examples. Such errors are rare and may be avoided by careful consideration of the clinical features and critical assessment of the results of the urine tests. There are two situations, however, which more often give rise to difficulty.

Obese diabetics, seriously ill with cerebral or coronary thrombosis, often develop some degree of starvation ketosis. The presence of ketonuria in a drowsy or comatose diabetic may lead to the diagnosis of diabetic ketosis being made. Obese diabetics, however, do not lack insulin and are not liable to develop true diabetic ketosis. The differentiation between true diabetic ketosis and starvation ketosis occurring in a seriously ill obese diabetic is of some prognostic importance. Diabetic ketosis usually responds dramatically to suitable treatment, whereas large doses of insulin are unlikely to help the obese diabetic.

Severe diabetic ketosis may on very rare occasions be present without ketonuria. Failure to excrete the ketones is the result of secondary impairment of renal function. These patients always have oliguria. The clinical features and especially the strong smell of acetone in the breath should point to the correct diagnosis.

Prevention of Diabetic Ketosis

The practitioner is particularly concerned with the prevention of ketosis in a diabetic patient who develops an intercurrent infection. Not only must he treat the infection as intensively as possible but also ensure strict control of the diabetes. These patients should be instructed to test their urine before each meal, or, if they are not taking food, at least four times a day. If the intercurrent illness is severe, long-acting insulins (globin, protamine zinc, or insulin zinc suspension) should be discontinued and regular doses of soluble insulin given instead. One-third of the previous total dose should be given six-hourly; when calculating the dose to be taken the practitioner should ask to see both the insulin bottle and the syringe and verify the usual dose taken. This is necessary because patients often refer to marks on the syringe as units, and as most syringes are graduated for single-strength insulin, whereas that usually used is double or quadruple strength, confusion can easily arise.

If the urine tests continue to show 2% or more of sugar the insulin dose should be increased by about 10% every six hours until the urine sugar falls to 0.5% or less. When the urine is sugar-free, the insulin dose should be reduced. If the patient is unable to take food, glucose drinks should be given at a rate of about 10 g. of glucose hourly (10 g. glucose=approximately one level tablespoonful of glucose powder). If there is severe vomiting insulin should still be given based on the results of the urine tests, but if the urine sugar falls below 2% while there is a heavy ketonuria (++ or +++ with acetest tablets) parenteral therapy is indicated and the patient should, if possible, be sent into hospital. If the intercurrent infection is only mild the patient's usual insulin may be continued, but if there is 2% of sugar in the early morning urine the dose should be increased by 10% (patients using protamine zinc insulin alone or insulin zinc suspension should increase the dose by 20%) and further tests taken before each meal. If 2% glycosuria continues an additional small dose of soluble insulin should be given before meals and at bedtime.

The method of control outlined for these patients is only applicable if the renal threshold for glucose is normal. Some diabetics have an abnormally low threshold and pass sugar in the urine, sometimes up to 2%, while their blood sugar is in the normal range. Patients soon discover if they have this abnormality, and know that for them a sugar-free urine is a warning of impending hypoglycaemia. In these cases the best indication that an increase of insulin dose is needed is the presence of thirst and polyuria, but, if the intercurrent infection is at all severe, blood-sugar estimations are likely to be needed and admission to hospital should be advised.

Emergency Treatment of Severe Diabetic Ketosis

Severe diabetic ketosis requires hospital treatment, and this is essential if there is dehydration associated with nausea or vomiting. Furthermore, experience has shown that a delay of even a few hours may influence the ultimate outcome, therefore the practitioner should initiate treatment before leaving the patient's home. Every practitioner should have a supply of soluble insulin (80 units per ml. strength) and of sterile ampoules of 50% glucose solution, so that he can take them on any emergency call to a diabetic patient. In severe diabetic ketosis soluble insulin in large doses is required, and if the practitioner is certain of the diagnosis he should give 50 to 100 units by deep intramuscular injection. A dose of 100 units is to be regarded as the standard for a case of severe ketosis with dehydration, nausea, and vomiting, but if the patient is a previously undiagnosed diabetic or a child the dose should not exceed 50 units.

In less severe cases without any nausea or vomiting, treatment can, when necessary, be undertaken at home. If the patient is an adult and a known diabetic, treatment should be started with a dose of 50 units of soluble insulin. At the same time fruit-flavoured saline drinks should be ordered (2.7 g. of salt—about half of a level teaspoonful of table salt—in a pint (570 ml.) of water) and given at the rate of one to two pints (half to one litre) every three hours. After the first three hours glucose should be added to the drinks, about 50 g. spread over each three-hour period. Urine tests should be made every three hours and the insulin dose repeated if the urine still contains more than 2% sugar. If the patient is unable to produce a urine specimen after three hours, it suggests that the blood sugar has been reduced to the normal range and that in consequence the glycosuria and polyuria are controlled; the next insulin dose should therefore be omitted. As the glycosuria decreases, glucose and insulin in smaller doses should be continued until the ketonuria is abolished. If the patient is responding satisfactorily to treatment a reduction of the ketonuria should be apparent by the sixth hour; if this has not been achieved or if there has been vomiting at any time in the course of treatment it is probably advisable to send the patient into hospital. The principal steps to be taken in the management of patients with diabetic ketosis treated at home are given in the following table:

Treatment of Diabetic Ketosis at Home

Note: This is not suitable for patients who are nauseated or vomiting.

On making the diagnosis give 50 units of soluble insulin intramuscularly and start fruit-flavoured saline drinks.

At 3 hours:

Obtain a urine specimen and test for sugar and ketones.

If urine sugar 2% give 50 units of insulin

" " " 1% " 32 " " "

" " " 0.5% " 16 " " "

" " sugar-free or if no specimen obtainable omit insulin

Add glucose to saline drinks—50 g. every three hours

At 6 hours:

Obtain and test urine specimen

Repeat insulin as at three hours

Continue glucose-saline drinks. If glycosuria is 0.5% or less, milk and light diet may be started

If there has been no improvement in the patient's condition and ketonuria, transfer to hospital is advisable

If the ketosis has been precipitated by an intercurrent infection immediate steps should be taken to treat the infection.

Hypoglycaemic or Insulin Coma

Although "insulin reactions" or mild hypoglycaemic attacks are quite common in diabetics taking insulin, severe episodes leading to coma are relatively rare. The commonest causes of insulin reactions are unusual exercise, missed and delayed meals, or a sudden alteration in the insulin requirement. The reactions resulting from physical exertion may be somewhat misleading in patients taking long-acting insulins, because, instead of occurring during or immediately after the

exercise, they tend to be delayed and to come on during the night or even the next day. Reactions due to a sudden alteration of insulin requirement may occur after an illness in which the insulin dose has had to be increased. When the patient is convalescent and resumes normal activity the insulin requirement often falls rapidly and it is difficult to judge the dose required.

Recognition of Hypoglycaemic Coma

Patients on soluble insulin usually have adequate warning that their blood sugar is falling dangerously low. Blurring of vision, slurring of speech, unsteadiness of gait, sweating, or a sense of unreality all draw attention to the need for glucose or other easily assimilated carbohydrate food. Patients using long-acting insulins may have insulin reactions following this pattern, but in some cases there may be loss of consciousness without any of the warning signs; in others the patient becomes disorientated and violent so that he fails to appreciate the situation and may refuse to take a glucose drink. Another danger with the hypoglycaemic attacks of the long-acting insulins is that they tend to come on during the night. When this happens a severe attack will result in the patient being found to be unrouseable in the morning. Mild nocturnal hypoglycaemia often leads to unpleasant nightmares, and the patient wakes the next morning drowsy, and with a headache which may be relieved by breakfast or persist through the day.

When the blood sugar falls to an unusually low level during a hypoglycaemic attack, typical epileptic convulsions may occur. In older patients with cerebral vascular disease Jacksonian fits and hemiplegia may result from mild hypoglycaemia.

Hypoglycaemic coma compared to diabetic coma is a condition of rapid onset. The patient is seen going about his business and apparently quite well, and then half an hour later he is found unconscious; or he goes to bed normal in the evening and the next morning he cannot be roused. Further details about the case are of value in making the correct diagnosis. It is helpful to know that the patient is a diabetic taking insulin—for this reason all diabetics who take insulin should carry a card giving the details. Secondly, a knowledge of the patient's meals and activities may give a clue to the diagnosis, whether at the time the attack came on the patient was late for a meal or whether there had been some unusual physical exertion.

On examination there is usually a striking absence of physical signs. The patient, unless actually having an epileptic convulsion, appears to be sleeping quietly, breathing normally, well hydrated but pale, and sometimes sweating. In severe attacks the plantar responses may be extensor and in older patients there may be signs of a hemiplegia. Urine examination is of little value; the presence of urine in the bladder containing 2% sugar does not exclude hypoglycaemic coma, because the urine may have been secreted before the blood sugar fell, or the patient may have a low renal threshold. In some cases a trace of acetone may also be present.

Emergency Treatment of Hypoglycaemic Coma

Hypoglycaemia is a dangerous condition. If the nutrition of the brain is seriously affected, recovery may be delayed or never occur; after a severe episode of hypoglycaemia the patient may be dull and retarded for several months, and permanent mental defect has been described in children after repeated attacks. Immediate treatment is needed, and the best way to restore the blood sugar in an unconscious patient is to give an intravenous injection of 40 ml. of 50% glucose solution. In most cases the patient will rouse after this has been given, but after a severe attack it may be 24 hours or more before consciousness is regained. If the patient fails to respond to intravenous glucose, arrangements should be made for transfer to hospital so that continuous intravenous therapy can be given. If the patient does respond, glucose drinks should be given by mouth; this is particularly important if the attack is due to a long-acting insulin, because

the patient can easily slip back into hypoglycaemic coma. A dose of 50 g. of glucose should be given at once in about 300 ml. of fruit juice, followed by a further 50 g. an hour later, or, better still, if the patient is able to take it, a normal meal.

Some of the most severe attacks have occurred when a patient found in coma due to hypoglycaemia has been incorrectly diagnosed as being in diabetic coma and given a large dose of soluble insulin. The differentiation between these two types of coma is seldom difficult—hypoglycaemia comes on rapidly or overnight, the patient is not dehydrated, and there is no smell of acetone in the breath. Coma due to diabetic ketosis follows several days of severe thirst and polyuria, and the patient is drowsy for 12 hours or more before consciousness is lost, dehydration is marked, and the breath smells strongly of acetone. If the practitioner is in any doubt, an injection of 50% glucose solution should be given; this will lead to an immediate improvement in nearly all cases of hypoglycaemia, whereas if the case is really one of diabetic coma little or no harm will result.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

ADVANCES IN CARDIOVASCULAR SURGERY

REPORT OF AN INTERNATIONAL SYMPOSIUM AT THE HENRY FORD HOSPITAL, DETROIT, MARCH 17-19

[FROM A SPECIAL CORRESPONDENT]

The outstanding contribution to this symposium was that of WALTON LILLEHEI (Minneapolis). Earlier in the programme a panel had discussed the diagnosis and treatment of congenital pulmonary stenosis, during which WILLIS POTTS (Chicago) and HELEN TAUSSIG (Baltimore) described their vast experience with the indirect or shunt operations and Sir RUSSELL BROCK (London) strongly advocated direct surgery in the form of either pulmonary valvotomy or infundibular resection; the latter even went so far as to state that in the future the treatment of the tetralogy of Fallot would be a direct operation during which each of the congenital malformations would be corrected. It was Lillehei who showed that such an operation is now a reality. He reported the results of 30 operations on patients using a controlled cross-circulation technique which allows the surgeon to open the heart widely and gives plenty of time for carefully performed intracardiac procedures under direct vision.

Septal Defects

Lillehei had confirmed the work of Andraeson that both venae cavae can be clamped for 20 to 30 minutes provided the azygos venous flow continues, which means that no great quantity of blood need be provided by an external circulation to maintain life. In his technique the donor's (usually the mother) superficial femoral artery is cannulated and the blood passed through a small pump to the patient's aorta via the subclavian artery, the flow being reinforced when necessary from a reservoir of oxygenated blood collected from the arteries of other donors. The blood is

then returned from the patient's venae cavae by a second pump to the veins of the donor. After the establishment of the cross-circulation both of the patient's venae cavae are clamped and the heart is opened. Lillehei reported that, using this technique, 22 interventricular septal defects had been closed with seven deaths, two patients with the tetralogy of Fallot had been treated by closure of the interventricular septal defect and resection of the infundibular stenosis with one death, and in six patients the abnormality of atrio-ventricularis communis had been corrected with three deaths; there had been no donor mortality; the oldest patient of his series had been a 14-year-old girl weighing 100 lb. (45 kg.), but Lillehei felt that the method could be used with success in adults.

The discussion on the treatment of interatrial septal defects included the description of diagnostic aids by both ANDREW MORROW (Bethesda) and CLARENCE CRAFOORD (Stockholm). The former stated that with a small shunt the oxygen differences between the two sides of the heart might vary only slightly from normal, but that if nitrous oxide was used as a test gas the differences were greater. Crafoord described a double balloon catheter which could be passed through the septal defect: inflation of the balloons could then be used either to estimate the size of the defect or to block the defect and study the changes which this produced. Various methods of closure were described; both CRAFOORD and TYGE SONDERGAARD (Aarhus) used a strong non-absorbable ligature which they passed round the defect, guiding the needle with a finger placed in the atrium. CHARLES BAILEY (Philadelphia) showed how he had modified his patch operation, which he introduced in 1952, and also how it was possible to treat an associated mitral stenosis by passing a finger through the defect before its closure. And GILBERT BLOUNT (Denver) stated that Henry Swan, using hypothermia, had closed 24 secundum defects by a direct suture under vision. There had been only two deaths in this group, and all but two of the closures were considered to be complete when tested at the follow-up.

Patent Ductus and Transposition of the Great Vessels

Other aspects of congenital heart disease which were discussed included atypical patent ductus arteriosus. ROBERT ZIEGLER (Detroit) felt that a patent ductus entering below a coarctation (infantile ductus) should be operated on at an early age with closure of the ductus and resection of the coarctation. FRANK GERBODE (San Francisco) described 12 children with a balanced ductus (pressures the same on each side) treated by operation, all of which still have evidence of pulmonary hypertension, while one adult with the same lesion had done well; he also mentioned that he had diagnosed by pressure readings at operation one case of ductus with a reversed flow; this he had left alone. WILLIAM MUSTARD (Toronto) stated that transposition of the great vessels was the leading cause of death in congenital heart disease in infancy. There were three possible operations: transposition of the veins, cross-grafting of the great arteries, and transposition of the great arteries, including the left coronary. He preferred the last, and had performed it with the aid of an extracorporeal circulation using a monkey lung as an oxygenator on 16 infants, but had no success as yet. CRAFOORD and EARLE KAY (Cleveland) described their modifications of these procedures, but, like Mustard, their results had so far been unsatisfactory.

Diagnostic Techniques

Diagnostic techniques were discussed by many of the participants, including JOHN LIND (Stockholm), who described his technique of performing selective angiocardiology with a synchronous electrocardiogram, and BENGT JONSSON (Stockholm), who stressed the danger of repeated injections of contrast medium at the same session. RICHARD BING (Birmingham, U.S.A.), in an outstanding contribution, described some of his experiences with cardiac catheterization aided by a new type of catheter which could be bent

in any direction by means of nylon threads to facilitate its passage through the heart. He had shown by coronary sinus catheterization that the relative contribution of carbohydrate and non-carbohydrate metabolism to the total myocardial oxygen consumption was in the range of only 24% for carbohydrate and 76% for non-carbohydrates such as fatty and amino-acids; and that in experimental coronary occlusion under hypothermia the metabolic effects of interruption of a coronary artery were much less severe than without hypothermia, probably owing to a reduction of enzyme activity.

REJANE HARVEY (New York) thought that it was logical to insist on the demonstration of raised pulmonary artery pressure by cardiac catheterization before advising mitral commissurotomy, in order to exclude those patients with myocardial insufficiency. OLGA HARING (Chicago) believed that in mitral stenosis of rheumatic origin there was always some regurgitation, and she used the electrokymogram of the left atrium to detect the degree of this regurgitation.

Mitral Valvular Disease

The treatment of mitral stenosis was discussed by a panel whose combined experience must have reached many thousands of operations. The main point which emerged was that technique and selection have now become standardized. On the other hand, the problem of mitral regurgitation, which was introduced by DWIGHT HARKEN (Boston), is still unsolved. He stated that the various baffle operations which he had introduced had proved unsatisfactory and that he was now trying to reduce the circumference of the annulus by open operation under hypothermia. ROBERT GLOVER (Philadelphia) was trying to do the same thing by inserting a purse-string suture around the valve, and four out of five cases had been improved by the operation. CHARLES BAILEY had now given up his pericardial flap operation and was using a piece of costal cartilage wrapped in pericardium in the hope of creating an adequate baffle. For aortic insufficiency he was passing a nylon suture around the valve ring in order to reduce its circumference.

Aortic Stenosis and Regurgitation

CHARLES BAILEY stated that he had performed 211 operations for aortic stenosis using the transventricular route, but that he now used a digital technique, the finger being inserted through a pouch of preserved homologous pericardium sewn to the aorta.

CHARLES HUFNAGEL (Washington) described his operation for aortic insufficiency using a leucite valve inserted into the upper descending aorta. He had operated on 80 patients with a hospital mortality of 20%. STANLEY SARNOFF (Bethesda) described the anaemia which usually develops during the first few weeks after this operation; it ceases spontaneously after this period, but has to be treated by transfusions of packed cells if relative coronary insufficiency and death were to be avoided.

Hypothermia

The panel on hypothermia which WILFRED BIGELOW (Toronto) conducted was divided into two groups: the majority, including DENTON COOLEY (Houston), HARRIS SHUMACKER (Indianapolis), and HENRY SWAN (Denver), favoured surface cooling, whilst Sir RUSSELL BROCK preferred veno-venous blood-stream cooling; all the participants favoured rapid rewarming. SWAN, in addition to the closure of atrial septal defects already mentioned, had used hypothermia on twelve patients with no deaths in whom he had operated on the pulmonary valve under direct vision. Another method of obtaining direct access to the heart was mentioned by CRAFOORD; using a complete extracorporeal circulation, he had resected a large myxoma of the auricle from a woman of 40, and she was alive and well one year later.

Aortic Aneurysms and Occlusive Disease

HENRY BAHNSON (Baltimore) reported that he had resected 26 aneurysms of the thoracic aorta, excluding coarctation aneurysms, with eight deaths, and COOLEY stated that he and MICHAEL DEBAKEY (Houston) had resected 101 abdominal aneurysms (17 of these had leaked prior to operation) with 18 deaths.

CHARLES ROB (London) gave the results of a follow-up of 93 homologous arterial transplants, the majority for occlusive arterial disease, inserted over a period of five years. He pointed out the good results which followed such surgery in the aorta, iliac, and some popliteal arteries, and the very careful selection which should be practised before a femoral transplant was inserted.

Blood Vessel Substitutes

This panel included ARTHUR BLAKEMORE (New York), who gave his views on plastic cloth. The most widely used material appeared to be orlon dipped in polyvinyl. ERIC NANSON (Saskatoon) was using nylon taffeta, which could be heat-sealed, thus making a seam unnecessary. In the field of homologous arterial transplantation OSCAR CREECH (Houston), HUFNAGEL, ROB, and EMERICK SZILAGYI (Detroit) used freeze-dried material. SZILAGYI had developed an outstanding method of sterilizing contaminated arteries with beta-propiolactone. CREECH and ROB were in agreement that the degree of ingrowth of recipient tissues was less than had been thought.

Just before the conclusion JAMES FRYFOGLE (Detroit) described a method of arterial suture using temporary split metal cuffs which may well revolutionize this branch of surgery. He stated that with this method he had transplanted the whole aortic arch of a dog in hypothermia time, with survival of the animal. It was a pity that time did not allow us to hear more from him.

Great credit is due to the organizers of this symposium, which was an outstanding success. The local members of the programme committee, Dr. ROBIN BUERKI, the executive director of the Henry Ford Hospital; Dr. CONRAD LAM, the symposium chairman; Dr. JOHN KEYES, the secretary; and Dr. EMERICK SZILAGYI and Dr. ROBERT ZIEGLER deserve the sincere thanks of all the participants. We understand that the proceedings of this symposium are to be published in book form by Saunders and Co. in about four months' time.

DOCTORS AND THE PRESS

An exploratory meeting between representatives of the Press organizations and the medical profession was held at B.M.A. House on March 29 (see *Journal*, March 12, p. 677) to discuss relations between the medical profession and the Press, particularly with reference to news from hospitals. Dr. H. Guy Dain (chairman of the Public Relations Committee of the B.M.A.) was in the chair, and the following attended:

Medical Representatives

Dr. E. A. Gregg, Chairman of Council, B.M.A.
Mr. L. Dougal Callander, Treasurer, B.M.A.

Dr. H. M. Cohen
Dr. F. Gray
Dr. D. F. Hutchinson
Mr. J. R. Nicholson-Laiely
Dr. A. Talbot Rogers
Dr. W. Woolley

Members of Public Relations
Committee, B.M.A.

Dr. Robert Forbes, Chairman of Central Ethical Committee, B.M.A.

Dr. J. G. M. Hamilton, Chairman of Journal Committee, B.M.A.

Sir Harold Boldero, Representative of Joint Consultants Committee.

Press Representatives

Sir Linton Andrews (General Council of the Press).
Mr. J. L. Palmer (Newspaper Society, also representing the Scottish Newspaper Proprietors' Association).
Mr. David Prosser (Guild of British Newspaper Editors).
Mr. Norman Robson (Newspaper Conference).
Mr. C. Webster (Scottish Daily Newspaper Society).
Mr. H. Gudenian (Periodical Proprietors' Association).
Mr. Edward Davies (Press Association).
Mr. Brian R. Roberts (Institute of Journalists).
Mr. H. J. Bradley (National Union of Journalists).
Mr. S. W. Rumsam (B.B.C., "Sound" Radio).
Mrs. Mary Adams (B.B.C., Television).

Mr. S. Heald represented the Ministry of Health as an observer. The Newspaper Proprietors' Association, which was to have sent an observer, was unavoidably prevented from doing so.

The meeting decided to establish a committee to examine the subject in detail and to formulate proposals for further consideration by the full meeting. The following were appointed to the committee:

Sir Linton Andrews	Dr. H. Guy Dain
Mr. H. J. Bradley	Sir Harold Boldero
Mr. H. Gudenian	Dr. R. Forbes
Mr. J. L. Palmer	Dr. F. Gray
Mr. David Prosser	Dr. J. G. M. Hamilton
Mr. Brian R. Roberts	Mr. J. R. Nicholson-Laiely
Mr. Norman Robson	Dr. A. Talbot Rogers
	Dr. W. Woolley

It was decided to invite the Newspaper Proprietors' Association to nominate a representative to the committee. The first meeting of the committee will be held on Wednesday, April 27.

Nova et Vetera**MEDICAL ART AND HISTORY IN EXETER**

Under the auspices of the Devon and Exeter Medico-Chirurgical Society a medical historical exhibition was opened on March 31 by Dr. J. W. Cook, F.R.S., Principal of the University College of the South-West. The exhibition is centred on the classics of medical literature from the library of the Cathedral Church of St. Peter, Exeter, and from the Exeter Medical Library; it also includes documents from the city archives relating to the ancient Exeter hospitals, and documents and portraits from the early years of the Royal Devon and Exeter Hospital. Thus it provides an introduction to medical history of interest alike to lay as well as to medical men and women. But more than this is attempted, and the exhibition gives emphasis to the beauties of sixteenth-century printing in Italy and the excellence of engraving up to the end of the eighteenth century.

Although to modern thought the idea of a provincial metropolis may be contradictory, it was quite otherwise up to the end of the eighteenth century. Then the city played a dominant part in the life of the south-west of England. It was the focal point of religious and social affairs, of government, industry, and commerce, and it provided leaders in medicine. In the early nineteenth century it had its own medical school. The Church has played an important part in medical history, as is to be seen from the possession by Exeter Cathedral of many of the more important classics of medical literature up to the early part of the eighteenth century. These include a fourteenth-century manuscript copy of John of Gaddesden's *Rosa Anglica* and an incunabulum of Celsus. Hippocrates, Galen, Manardus, John of Vigo, Vesalius, Eustachius, Paré, Fabricius, Spigelius, Harvey, Sydenham, and many others are represented. In the Exeter Medical Library the seventeenth, eighteenth, and early nineteenth century are particularly well covered. A very special attraction is the Vesalius *de Fabrica*, represented by a handsome copy of the great 1555 edition, the 400th anniversary of which is commemorated in the illustrated catalogue available. Among the City of Exeter's archives are documents relating to the foundation of the first hospital in the city, that of St. Mary

Magdalene in the twelfth century. It was first devoted to lepers, then to the scrofulous, and to-day, on a new site, is an almshouse. In addition the exhibition is showing a large Hunter collection, which also touches upon the work of the Hunterian disciples, including the eccentric genius John Sheldon, who worked for the last twenty years of his life in Exeter.

The Royal Devon and Exeter Hospital, many of whose portraits and early documents are on view, was founded in 1741 during the social revolution which saw the beginnings of several other notable provincial hospitals as well as most of the London teaching hospitals of to-day, apart from Bart's and St. Thomas's.

The exhibition has been organized by the president of the Devon and Exeter Medico-Chirurgical Society, Mr. Norman Capener, and is open throughout the month of April from 1.30 to 5.30 p.m. daily.

Reports of Societies**LOCAL MEDICAL SOCIETIES****Liverpool Medical Institution**

The value of "C-reactive protein" as a sensitive test for activity in rheumatic fever and tuberculosis was discussed in a contribution to the Institution on March 24 by Dr. S. E. KEIDAN, lecturer in child health at Liverpool. In 1930, he said, during investigations of the chemical and immunological properties of pneumococci, Tillet and Francis had isolated a polysaccharide (Fraction C) from the bacterial body which was found to form a precipitate with the serum of patients suffering from various infective illnesses. Precipitation occurred only during the acute phase of the illness and could no longer be demonstrated after recovery. In 1943 Löfstrom independently reported the occurrence in human serum of a substance which caused capsular swelling and agglutination of pneumococci. The substance was found only in the serum of patients in the acute stages of various bacterial diseases or with conditions characterized by tissue destruction. It was later suggested that this substance was identical with the precipitin for C-polysaccharide which had been previously described. This precipitin, C-reactive protein, was eventually separated from serum and obtained in crystalline form. It proved highly antigenic to rabbits, and the antiserum produced is a sensitive test for its presence in serum.

Clinical studies in rheumatic fever, continued Dr. Keidan, had shown that the detection of C-reactive protein in the serum is both the most consistently positive laboratory index of rheumatic activity and the most sensitive. The test is, however, non-specific, and may be positive in myocardial infarction and malignant disease as well as in the presence of any inflammatory process. His own studies, using rabbit antiserum, had been done on 70 children with a variety of illnesses. In 16 cases of rheumatic fever, 11 with polyarthritis gave positive tests, 2 cases with chorea and carditis gave positive tests, and 3 cases of pure chorea gave one negative, later becoming positive, and 2 weak positive. Four suspected cases gave negative results in 3 cases and positive in the other; none of them developed further evidence of the disease. One child in congestive failure had a very low sedimentation rate but a strongly positive test for C-reactive protein. Fifteen cases of tuberculosis were studied. Five out of six patients with primary infections gave positive tests, and in the one who was negative there was doubt about the activity of the disease. Two cases of meningeal and two of miliary tuberculosis were positive. Two cases of pleural effusion were negative, one later becoming weakly positive. Of two cases of post-primary disease, one was negative and one positive. Tests in children suffering from other infections were usually positive. In 32 newborn babies, 28 gave negative tests, and the four who were positive were found to be unwell, either with infection or with a history of anoxia at birth.

It was suggested that C-reactive protein might be an antibody precursor, and that its persistence in rheumatic fever might be due to an inherited or acquired failure to synthesize a particular type of antibody against haemolytic streptococcal infection.

Manchester Medical Society

Twenty-three babies out of every 10,000 born alive require general surgical operations in the first month of life, according to figures given by Mr. A. JOLLEYS, a Manchester paediatric surgeon, in a contribution to the Section of Surgery on March 8. Most of the congenital malformations from which these babies suffer are remediable. In intestinal and oesophageal surgery both practical experience and the results of experimental work suggested the value of simple end-to-end anastomosis with one layer of unabsorbable sutures. The early diagnosis of many of these malformations was of paramount importance, and it was essential to carry out a routine examination of the child at birth.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Ban on Heroin

SIR,—Your annotation (*Journal*, July 25, 1953, p. 196) on the omission of heroin from the *British Pharmacopoeia* suggested that this should be a precedent for Government authorities to make the use of the drug illegal. I protested in a subsequent letter (*Journal*, August 8, 1953, p. 338) to you, but my voice was of one crying in the wilderness. With sinister failure to seek the views of the profession as a whole, the Government has now decided to implement the recommendation of the Economic and Social Council of the United Nations regarding the manufacture and use of heroin. After the expiry of the current licences for the general manufacture and import of heroin under the Dangerous Drugs Act, small quantities will be manufactured in this country for scientific purposes only and the import of the drug will not be permitted. The full implication of this astonishing move is certainly not grasped by the majority of practitioners. It is nothing more or less than direct interference with our liberty to prescribe for patients what we think is best for them.

The ban on heroin is being imposed not in response to any demand for such action in Great Britain, but solely as the result of political pressure from foreign countries, notably the U.S.A. and the World Health Organization. The United States has a vast problem of drug addiction, and has since 1925 forbidden the manufacture or importation of heroin. The result could have been foreseen. Addiction is still rife there because the cost of the drug has rocketed. This provides the stimulus for the black marketeer to take any risk to spread the heroin habit. The lessons of prohibition and opium control have been as seed fallen on stony ground.

Pain, the most clamant of all symptoms, must be relieved. Have our legislators been advised that morphine causes severe vomiting in 10% of patients, or that pethidine, a drug of addiction, is less reliable than heroin, and is also frequently emetic in action? Have the medical advisers, who are presumably behind this move, forgotten that codeine, except in constipating and highly depressant doses, may not ameliorate the cough of tracheitis? The fact is there is no complete substitute for heroin. Our D.D.A. is a highly effective agent to discourage addiction. This governmental ban will inflict untold hardship on a multitude of patients in a futile attempt to save foreign decadents from addiction.

Clinical practice must be kept free from political interference. The views of the royal colleges and general practitioners should always be sought on matters of this kind. Let us not view meekly the sacrifice of freedom on the altar of woolly humanism.—I am, etc.,

London, W.1.

A. H. DOUTHWAITE.

Chicken-pox Quarantine

SIR,—Dr. M. Curwen (*Journal*, March 19, p. 727) asks the pertinent question: "Is it really necessary to exclude children with chicken-pox from school?" Certainly, in junior schools, it could be argued that it would be more logical to take steps to spread chicken-pox rather than attempt to control it. Chicken-pox is such a prevalent disease that few, if any, of us can hope to escape exposure to infection during life. Whereas an attack experienced during early school life is likely to be mild and to occur at a time of least inconvenience, an attack later in life tends to be more severe and to occur at an inopportune moment, interfering with important events such as examinations and big sporting occasions, a good topical example being this year's Cambridge boat race crew.

I think that Dr. Curwen is right in suggesting that very many children are excluded from school for an unnecessarily long period on account of this relatively trivial disease. There is very little, if any, evidence that cases of chicken-pox remain infectious for longer than five or six days after the appearance of the rash. During this period most patients are suffering clinically from the disease and are better resting at home, even if not in bed. At the end of a week, however, if the clinical condition permits, I see no reason why patients should not return to work and children to school. The present policy of waiting until each and every scab has separated before release from isolation is far too rigid, and, as Dr. Curwen has indicated, gives rise to a lot of unnecessary absence from school and to parental frustration. In special circumstances, such as the admission of a case to a paediatric unit, it may be advisable to play for absolute safety and wait until every scab has separated, but the vast majority of cases could be released from isolation much sooner, and a period of one week from the appearance of the rash would, in my view, be quite adequate.—I am, etc.,

Oxford.

J. F. WARIN.

SIR,—Dr. M. Curwen (*Journal*, March 19, p. 727) recommends the ignoring of all precautionary treatment in an attack of chicken-pox. I venture to suggest that there is one very important and sometimes dangerous complication, the onset of which would be made all the easier by such procedure—namely, acute nephritis. One of the worst cases I ever saw of this disease was during the later stages of an attack of chicken-pox in a child whose parents had either overlooked or had ignored the attack and had allowed the child to lead a normal life.—I am, etc.,

Southsea.

M. ASTON KEY.

Natural Childbirth

SIR,—My letter on the subject of natural childbirth (*Journal*, February 19, p. 475) was deliberately provocative; I set out to try to rock the boat. Unfortunately prejudice and immature reasoning have tended to distort the argument. May I therefore clarify some points? (1) I did not condemn preparation for childbearing, only "special training"; of course we all prepare our mothers in one way or another. It is over-elaboration in teaching and training that I see as a danger. Even Dr. Anthony Ryle (*Journal*, March 19, p. 725) admits that there may be a case for simplifying and shortening. (2) My main attack was on training for the second stage of labour. All my experience and reasoning rebel against this practice. On the question of the first stage and relaxation exercises I left an open verdict. (3) I do not disapprove the quest for painless childbirth—quite the reverse. I am afraid Dr. Ryle, and possibly others,

misunderstood the phrase where I was praising the pioneer work (thinking particularly of Dr. Grantly Dick Read) which weaned women away from demanding painless labour by artificial means. Twilight sleep, unnecessary forceps delivery, and even caesarean section were demanded by some women not so very long ago to save them from pain in labour. (4) The extravagance to which I was alluding was the tendency for local authorities and other bodies to appoint special personnel, often without full midwifery knowledge, to run clinics to train women for childbirth. I believe that all teaching should be given by the doctor, midwife, or hospital team who are going to look after the same woman in labour. Is Dr. Ryle putting the clock back or using false considerations of economy when he teaches his patients himself? (5) There is a danger that, either from inexperience or from too great enthusiasm for one particular facet, we lose sight of the fact that with modern improvements in labour management, even without all the palaver beforehand, women on the whole are having satisfactory confinements. Patients have recently been heard to say that books and classes make it all seem so much more complicated than it really is. (6) In a process with such a high rate of normality we must assess our results by focusing attention not on the successful cases but on the failures. Unfortunately the less successful tend to keep quiet, overshadowed by a feeling of frustration and inadequacy, while the successful ones are only too ready to applaud, particularly when it has been instilled in them that their own skill has played so large a part. Would that more Mrs. Constance Lynns (*Journal*, April 2, p. 851) came forward and that the Mrs. Honor Kennys (*Journal*, March 26, p. 785) would reason out that it is no praise of any method if it takes a previous confinement and a physiotherapist standing over them to achieve a satisfactory second birth. (7) My plea is that the way should be left open to allow of trial of a variety of methods and that we should not be too ready to accept or to publicize that any particular regime is right in its entirety. Knowledge of childbirth, like knowledge about sex, should be instilled gradually during the process of growing up. Only "topping up" would then be required when the time came.

It seems by implication that my experience to form an opinion on this problem has been doubted. To Dr. Grantly Dick Read (*Journal*, March 5, p. 604) I would say that I base my views on 18 years of private obstetric practice with complete and personal care of some 900 women, the majority of whom achieved normal birth, as well as on my observation in consultant practice. To Mrs. Kenny I would say that I, too, am a mother (of four), but I believe that personal experience should not be given undue weight. From the midwife's point of view I can only speak through having been very closely associated with them for many years. It is certainly not my finding that their instructions to women in labour are of little or no avail. With experience they give very few, because they learn that nature directs the process better than they can if allowed to do so.

Finally, I will not accept Dr. Ryle's suggestion that "civilized social beings" are beyond hope of natural childbirth. Some, it seems, would nearly go so far as to imply that women require psychiatric treatment before being able to achieve their natural heritage of bearing children. Please let us keep our sense of proportion and help women to take childbearing in their stride, regarding it as a normal, natural, and not unduly difficult process.—I am, etc.,

Hove.

CONSTANCE L. BEYNON.

Environmental Factors in Cervical Cancer

SIR,—Dr. Ernest L. Wynder's paper (*Journal*, March 26, p. 743) made very interesting reading. In particular, I would commend his statement that international co-operation is of importance in achieving "more conclusive results than can be obtained from any one country alone." Among U.S.A. Negroes he found the rate of cervical cancer "high," the age of first coitus "early," and circumcision state and penile hygiene "poor." May I suggest that this important

research be extended elsewhere? For example, figures from Nigeria, where the Ibos—of pure Negro stock—have a 100% male circumcision rate, may go further to elucidate the place of epidemiology in the investigation of cervical carcinoma.—I am, etc.,

Glasgow, C.3.

W. I. B. ONUIGBO.

Hypodermic Injection Technique

SIR,—Dr. L. P. Lockhart (*Journal*, February 12, p. 415) rightly calls attention to the danger of injections being given without first withdrawing the plunger of the syringe. But, passing from the dangers to the discomfort of injections, may I mention a simple way of reducing the pain caused by injections? Needless to say, the smaller and sharper the needle the less the pain, but a satisfactory needle is only one of the secrets of semi-painless injections; the other and more important is this.

When about to give the injection let the needle of the loaded syringe rest lightly on the skin so that the patient, although conscious of its touch, is unaware of its sharpness; *continue to hold it thus for five to ten seconds*, and then suddenly, and as quickly as possible, pierce the skin to the necessary depth. With this technique many babies being immunized against diphtheria neither cry nor register pain, and many adults with previous experience of receiving injections have remarked, "That was the most painless injection I have ever had."

I think the explanation for the relative freedom from pain when injections are given in this way is that the stimuli of touch and pain are thereby separated. It was Pavlov, I believe, who stated that the brain cannot react to more than one stimulus at one time. A slap may cause one to jump, and momentarily one is uncertain whether the slap was a painful or painless touch. When, however, the touch is accompanied by pain (as in the case of an injection) the perception of pain seems to dominate that of touch, and the stimuli of pain and touch are both recorded by the brain as pain. The pain therefore becomes magnified. On the other hand, when a stationary object has been gently touching the skin for a period, one ceases to be conscious of it—for example, as in the case of the clothes one wears. By dissociating touch from pain and adopting the simple technique mentioned, scores of thousands of injections every day could be made relatively painless.—I am, etc.,

Reading.

K. D. SALZMANN.

Dermatomyositis

SIR,—The case described by Dr. Hillas G. Smith (*Journal*, March 26, p. 770) does not appear to me to be that of dermatomyositis. The diagnosis seems to have been made on the increased creatine output in the urine, together with "skin and muscle involvement."

The skin and muscle involvement appears to be that of painful erythema and swelling over painful joints and muscles, following a history of severe tonsillitis. Acute dermatomyositis usually starts as an acute febrile illness resembling influenza, with shivering attacks, hyperpyrexia, and general muscle aching, but no joint involvements. The face is involved first, with erythema and swelling—the infra-orbital swelling being marked and persistent. The patches of erythema are diffuse and not confined to joint areas. The patient complains that he cannot carry out certain movements, not because his joints are painful but that he just cannot do it—i.e., his muscle power is lost.—I am, etc.,

Bradford.

ALLAN BIGHAM.

Grants for New Hospitals

SIR,—Dr. J. M. Alston (*Journal*, March 26, p. 789) has misread my letter (*Journal*, March 5, p. 600) on the subject of grants for new hospitals. I did not advocate the patching up of old hospitals (indeed, I have worked for too long in such places), nor did I object to the building of new hospitals. I cited specific examples of a situation in the North-west Metropolitan Region, where I advocated new buildings for some of the old hospitals in addition to, or even instead of, some of the proposed new hospitals. I am, of course, well

aware of the fact that, even with the latest proposals from the Ministry, we shall be doing only a fraction of the hospital building which was taking place immediately prior to the war. This being so, it is surely all the more important to re-examine the present building programme, and to ensure that the needs of the public will be properly and economically satisfied. In many instances it will prove much easier to rebuild old hospitals (in part or in whole) rather than to build new ones and then be faced with additional staffing problems and overhead expenses.

I stated in my last letter that local medical opinion had not so far been consulted. I have since been informed that the Management Committee in the area concerned has also not been consulted. This is surely a curious and deplorable state of affairs, and I feel certain Dr. Alston will agree that the gentleman from Savile Row does not always know best.—I am, etc.,

Radlett, Herts.

R. S. MURLEY.

Post-maturity and Asphyxia

SIR,—Dr. E. Robert Rees (*Journal*, March 19, p. 723) draws attention to a danger which is, I am sure, not generally recognized among midwives, or perhaps even among some doctors. I refer to the fact that in some cases of post-maturity the placenta has diminished in efficiency and the oxygen supply to the foetus is only just enough to maintain its life. The placental circulation is interrupted during a prolonged second stage contraction and asphyxia may well result. How often has one seen or read of large, healthy-looking post-mature boys born after a prolonged labour but unfortunately dead on arrival. The nurse's satisfaction at having maintained an intact peritoneum is a very poor compensation for this misfortune.

One remedy is of course an episiotomy done without delay, and followed by forceps if necessary. I should also like to stress that the use of gas-and-air analgesia may very well be enough to turn the scale against the child's survival. The medical certificate of fitness for gas and air refers only to the mother, and is given at a time when post-maturity has not entered the picture. I do not know whether this is pointed out to midwives in their gas-and-air training, but very much doubt it. I also think that local authorities issuing these sets should consider the fact that in certain circumstances they are potentially lethal weapons.—I am, etc.,

Shipley.

HENRY S. RUSSELL.

Post-puerperal Recurrent Depression

SIR,—I have read with interest Dr. A. B. Hegarty's paper on post-puerperal recurrent depression (*Journal*, March 12, p. 637). Any paper which draws attention to the fact that premenstrual symptoms are common, often severe, rarely treated, and usually curable is to be welcomed. But I fail to see in what respect the condition he mentions differs from the premenstrual syndrome which has so often been described, most fully by Dr. Dalton and myself. He quotes previous mention by Hemphill and by Rees, but dismisses their statements as "the passing remarks of writers who were dealing with a different theme." The rest of the extensive "literature" is left out altogether, except for a brief mention of the work of Stieglitz and Kimble and of Bickers and Woods.

Why "a different theme"? It would appear that the right of Dr. Hegarty's syndrome to a separate existence rests upon his selection of patients who, in addition to the main complaint of ovulatory or premenstrual mental disturbance, have a pyknic build, have suffered from puerperal depression, and have irregular menses. On this principle medical literature would soon be overburdened with syndromes. If one looked for them one could probably collect a number of cases of a most interesting and hitherto undescribed condition of acute appendicitis occurring in blonde women with ingrowing toe-nails whose husbands are heavy smokers (will Dr. Horace Joules please note?).

I do not propose to examine again the case records of the 84 patients described by Dr. Dalton and myself, but I feel quite sure that many of them were pyknic, many of them had irregular menses, and some of them had had puerperal depression. Many of them had flat feet, too.—I am, etc.,

London, W.1.

Adrenocortical Activity and Puerperal Depressive States

SIR,—In his enlightening article (*Journal*, February 26, p. 495) Dr. R. I. S. Bayliss has revealed some interesting data on the blood levels of 17-hydroxycorticosteroids during pregnancy and the puerperium. It appears that the high mean level of 24 µg. per 100 ml. blood occurring during the last month of pregnancy falls rapidly after parturition, reaching a normal value by the eighth post-partum day.

It is now well known that the sense of well-being and elation experienced by many patients receiving A.C.T.H. is liable to give place to a temporary depressive phase when the drug is withdrawn. It might be, therefore, that the mental depression so common in women during the second week of the puerperium is associated with the relatively sudden fall in circulating corticosteroids which Dr. Bayliss describes. If this is so, then the more severe case of puerperal depression, showing obvious deterioration, might be tided over this critical period by the administration of gradually diminishing doses of A.C.T.H.—I am, etc.,

Leeds, 2.

K. A. EXLEY.

Manipulation and Low Back Pain

SIR,—Drs. Anthony B. Coyer and Ian H. M. Curwen (*Journal*, March 19, p. 705) have compared the treatment of low back pain by manipulation with treatment by bed rest and simple analgesics. In assessing their results they have analysed all the 76 patients treated by manipulation, but only 60 of the 76 patients who were advised to go to bed and take simple analgesics. The reason for the exclusion of these 16 patients is that they "did not carry out instructions or did not report for assessment." No information is given about the results in these 16 patients, and if it is assumed that all of them did well the apparent differences between the two treatment groups will largely disappear. It is a great pity that no information is provided about the discarded 16 patients, since their exclusion destroys the value of what would otherwise have been an interesting study.—I am, etc.,

Manchester.

J. H. KELLGREN.

Pre-employment Examinations

SIR,—The Chief Inspector of Factories in his Annual Report for 1953 refers to the fact that the number of first examinations for employment under the Factories Act (269,379) was larger than the number of subsequent examinations (218,367), whereas the reverse would be expected. A probable explanation lies in the fact that several "first" examinations are done in respect of some young persons, as, if they move from the area of one A.F.D. to that of another, form 71 (card for the use of A.F.D.) does not follow them. Indeed, it may happen that it does not follow from job to job even within the area of one A.F.D., since a new card is prepared by the employer for the first examination at the place of the new employment. The A.F.D. will use this, and if he files the cards by factories the duplication will not come to light.

The reasons for refusal of certificates of fitness, which the Chief Inspector lists in table L1 of his report, may not present an accurate picture of the health of young persons seeking factory employment, since many applicants are seen by a works medical officer before being taken on. Thus the A.F.D. to a factory which has its own medical officer is likely to have a very small number of rejections. Where the works doctors is also the A.F.D. the number will be nil.

Of course, an unsuccessful applicant can always try his luck elsewhere, and if he is again unlucky his particular defect will be twice recorded.—I am, etc.,

Wrexham, near Bristol.

Clinical Board Meetings

SIR,—I have recently returned from 14 months in North America, most of which was spent in one fairly typical city hospital in the U.S.A. There was one particular feature which does not seem to be generally known here and which I think should be widely adopted in the hospitals in this country. I refer to the so-called board meetings which are a regular feature in nearly all American hospitals. The commoner boards are the tumour boards, the pathological boards, the endocrine boards, etc. The great benefit of these boards might be clarified if I were to mention how one example, the tumour board, worked.

To its weekly meeting came physicians, surgeons, gynaecologists, pathologists, the radiotherapist, the radiologist, and any other interested consultants, as well as the housemen. Interesting and perplexing tumour cases were presented. Someone familiar with the case, usually the consultant or his houseman, would give the relevant history, physical findings, and results of investigations. The patient would then be examined by those at the meeting. A discussion would follow, directed by the chairman of the board, on the diagnosis, treatment, and prognosis of the case. A healthy sign was the frequency of open disagreement and the sympathetic attention paid to the opinion of the lowliest houseman. The board would finally advise the course of treatment, but the consultant whose case it was was in no way obliged to follow the recommendation of the board, though he nearly always did so. The end of the meeting was devoted to follow-up cases previously presented, with reports of progress.

I feel that the institution of boards of this nature would be of material benefit to British doctors and to the patients they aim to serve.—I am, etc.,

London, N.18.

MICHAEL C. LATHAM.

Anticholinergic Drugs for Peptic Ulcer

SIR,—The final paragraph of the leading article (*Journal*, March 19, p. 711) calls for comment. Is not the appreciation of "brand-new treatments" by patients often short-lived? The "brand-new" description will often convey to them a major advance in therapy, leading to high hopes and ultimate disillusionment. It may give patients the impression that the doctor is doing his best for them, and help to satisfy the emotional dependence which the chronically ill are apt to develop with regard to their doctor. But surely we should encourage as many as possible to develop a courageous understanding of their ailment, and discourage the hypochondriasis which so frequently results from over-treatment. We should also remember we are doctors, not salesmen, whether public money is involved or not.—I am, etc.,

Barton-on-Humber, Lincs.

S. H. F. HOWARD.

Bolus Obstruction

SIR,—Having read reports of small bowel obstruction resulting from the impaction of a variety of undigested foodstuffs (*Journal*, December 18, 1954, p. 1484, and November 27, 1954, p. 1301) we would like to record our recent experience in the management of a patient with small-bowel ileus where the impacting bolus consisted of undigested meat.

Recently a female of 67 years was admitted to Hammersmith Hospital complaining of central abdominal pain and vomiting of eleven hours' duration. The onset was abrupt, and the vomiting was associated with bouts of colicky pain. Clinical examination revealed an elderly edentulous patient having obvious attacks of intestinal colic accompanied by vomiting and with a soft non-tender abdomen. No mass was palpable and no evidence

of the cause of the obstruction could be found. It was decided to observe her overnight, during which time a piece of undigested meat 3 cm. by 2 cm. by 1 cm. was discovered in the vomit. Further questioning revealed that 12 hours prior to the onset of symptoms the patient had eaten a meal of sheep's heart and sausages which she had not masticated properly because of ill-fitting dentures. A tentative diagnosis of bolus obstruction was made, and, as the clinical signs of unrelieved obstruction persisted, laparotomy was performed. This revealed a firm rubbery bolus impacted in the terminal ileum about 90 cm. from the ileo-caecal valve. The ileum above this point was dilated and congested. The mass was with difficulty milked into the caecum and the patient made an uneventful recovery. Small pieces of meat but no bolus were recovered from the stools post-operatively.

In a review of 178 cases of bolus obstruction, Ward-McQuaid¹ found no case of obstruction from this cause. But from our experience in this case it is clear that to the long list of possible ingredients of an impacting food bolus we must now add incompletely masticated meat.

We are grateful to Mr. M. R. Ewing, F.R.C.S., for advice and permission to record this case.—We are, etc.,

G. E. ALLIN.

Additional Drawer for the Boyle's Machine

SIR,—I find that at the start of an operating session the essential anaesthetic accessories—laryngoscope, Magill's forceps, mouth gag, etc.—are neatly laid out on the top shelf of the anaesthetic machine, but in a short time the maintenance of this state of neatness, however desirable, becomes something of a nuisance.

In an attempt to obviate this difficulty I designed the drawer unit illustrated for the B.O.C. Boyle's apparatus. This unit fulfils two important criteria: (1) An unobstructed top shelf is provided. (2) There is adequate additional storage space for the essential anaesthetic accessories just at the anaesthetist's hand.

The unit, which was made by Mr. Young, of the Belfast City Hospital Works Department, consists of a wooden box-like structure which has a washable plastic top, and contains a drawer of the greatest possible size—that is, 15½ × 13 × 2 in. (40 × 32.6 × 5.1 cm.). It is fitted in place of the original glass top shelf of the Boyle's apparatus and occupies the space between the upper structural frame and the under surface of the surrounding guard rail. This latter

forms a lip around the edge of the new top shelf. In use the drawer has been found to be large enough to hold the laryngoscope, mouth gag, Magill's forceps, airways, connectors, lubricating jelly, cylinder key, etc., and has been proved to be of great practical value.

I wish to thank Dr. James Sutcliffe and Mr. J. Poots for the photograph.—I am, etc.,

Newtownards, N. Ireland.

J. A. MCNEILLY.

Fluoridation of Public Water Supplies

SIR,—In their letter (*Journal*, March 26, p. 789) Drs. H. M. Sinclair and Dagmar Wilson, in a kind reference to me, mention a visit I made to an Oxfordshire village at Dr. Wilson's invitation to see and verify some of her cases of fluorotic teeth in the early days of her investigation.

Dr. Wilson has done an immense amount of work on this subject and I have done nothing since 1933, for lack of the necessary laboratory experience. I feel, therefore, some reluctance to offer criticism. I did, however, have the advantage at that time of having been able to examine in detail the teeth of a whole series of Maldon school-children, including all the age groups up to 16, and the further advantage of familiarity, as a dentist, with teeth in general, and I am sure that Dr. Wilson will not mind my correcting her implication that I verified all her findings. There was, among the fairly mild cases of fluorotic teeth, one apparently marked one showing dense brown staining which on closer examination we discarded because the stain proved to be superficial and could be removed, though with difficulty.

This incident is only of significance in connexion with the possibility mentioned by others that occasional cases can occur closely resembling mottling whose aetiology is in doubt. I have recently been shown another such case by Mr. Howell, of the Royal Dental Hospital: this was a variety of congenital amelogenesis imperfecta, and the stain was not removable.—I am, etc.,

London, W.1.

N. J. AINSWORTH.

SIR,—My interest in this subject has recently been aroused not only by the correspondence in the *Journal*, but also by being asked by a patient, who apparently resides in one of the proposed "experimental areas," whether an increase in her fluoride intake would be injurious to her health. So far the evidence as to whether there is any risk of physical disease by adding 1 p.p.m. of fluoride to the water supply is most controversial. No mention, however, has been made of the possible psychological effect on a nervous patient who is forced by a medical officer not known to her, or by a committee of laymen, to increase her consumption of fluorides.

Surely some method of ensuring an adequate intake of fluoride in children up to the age of 14 years could be devised and the general practitioner allowed to advise his patients, to the best of his judgment and ability, about the taking of this potentially lethal substance.—I am, etc.,

Bangor.

EYNON VAUGHAN.

Hydrocortisone Ointment in the Eczemas

SIR,—I was extremely interested to read in Dr. R. Church's paper (*Journal*, February 26, p. 517) and your annotation (p. 530) on the use of topical hydrocortisone in various dermatoses confirmation of my own limited experience with this type of therapy. It would seem evident that sufficient trials have now been carried out to evaluate the worth of this new therapeutic agent, and to establish that there are no dangers attached to its use.

Skin conditions, I find, make up a large proportion of one's general practice, and many of these prove quite intractable to the treatments readily available to G.P.s. Consequently, with the long-term and diverse treatments one has recourse to, these cases may tend to cost the N.H.S. large but "hidden" sums. One imagines that the only reason hydrocortisone ointment is not freely available is one of cost; but if this new agent will control symptoms, and

perhaps cure much more quickly, then surely it will prove to be more economical, if not cheaper, on a weight-for-weight basis than tar and zinc ointments. When can we in general practice hope to be free to prescribe this valuable addition to our pharmacopoeia?—I am, etc.,

Manchester.

S. EDEN.

Treatment of Pulmonary Tuberculosis

SIR,—Regarding any tuberculous infection and its effects, there are, since Koch's epoch-making discovery in 1882, many well-known factors. Of these, weight of infection, site, virulence of the organism, natural resistance of the host, allergy, and acquired immunity are the time-honoured "big five." Time was when the relative significance of these factors, *inter se*, largely dominated the whole clinical course of a tuberculous patient's illness. By and large good general health and greater natural resistance went hand in hand, so that the poorer-class patient had a greater chance of dying—but even here there were exceptions, particularly where the soil was virgin. There is much evidence that mortality and morbidity from tuberculosis are declining, but it is at once clear that, depending only on better social standards and the like, it would be a long time indeed before the disease became epidemiologically insignificant.

Fortunately, the "big five" above mentioned are no longer supremely important. Though one would be hesitant to say they now merely jutted up as rocks in a sea of new discoveries, nevertheless the old horizon has been shattered. Following hard on the discovery and development of antibiotics and chemotherapy and the ever-rising standards of anaesthesia came the increasing significance of thoracic surgery in tuberculosis. As the old horizon fell away, new vistas hitherto undreamed of—unless by the prescient—were opened up. And it is now not hard to understand why the patient's attitude to tuberculosis is being transformed. The *mens sana* is being established.

I cannot, in any degree, bear out Dr. J. F. Brailsford's sanguine remarks (*Journal*, March 12, p. 665) regarding current trends in the treatment of pulmonary tuberculosis. "Pleasant" is hardly a suitable adjective for any surgical operation—despite the advances in anaesthesia—and mutilating, in a sense, it can be. But pleasant it is indeed to find that those of our patients who have been transferred for surgical treatment return to continue their convalescence renewed not only in body but obviously in mind also. Here it is apposite to make a few additional observations. In the majority of our cases major operation has been performed under infiltration analgesia, yet terror, anguish, and psychological upheaval are absent. Most of these patients return—some quite soon—to self-supporting employment. The recurrence of positive sputum is rare. Hospitalization has been considerably reduced—especially now, as waiting-lists shrink. Further, the grossly swollen waiting-lists until recent times surely bear witness to the inadequacies of the past. Treatment may have been "most pleasant and enjoyable," but, despite any amount of honest endeavour, it had gross limitations. In assessing any method the results are all-important.

It is surely timely now to express the hope that when the reservoir of chronic infection has been effectively drained by the thoracic surgeon, and those unfortunates who developed their disease too early to be redeemed by chemotherapy, etc., are no more, then the family doctor with the facilities which are at his disposal will ensure that tuberculosis never gets beyond the earlier stages at which, in modern times, it can be adequately dealt with in the home.—I am, etc.,

Stornoway.

EWEN A. CAMERON.

The National Formulary, 1955

SIR,—Dr. T. W. G. Kinnear (*Journal*, March 19, p. 725) can hardly expect his criticism of my letter (*Journal*, February 26, p. 541) on the *National Formulary* to be taken as anything but a leg-pull, but, seeing you have published it, may I reiterate that, though we all wish prescribing to

be sensible and honest, the use of these adjectives in your leading article (*Journal*, February 12, p. 402) did imply that those who disagreed with the writer were not sensible or honest—which is, I think, untrue and certainly regrettable. If Dr. Kinnear had read your leading article he should have noticed that you used the term "ammonia and senega mixture" which I repeated, and which, incidentally, was more correct for my purpose, for many variants of this mixture have been used throughout the years.

I am sorry Dr. Kinnear cannot see my point about tablets, but although the new *National Formulary* does in one case prescribe a quarter of a tablet to be used—against which I protested, as one cannot expect many mothers to divide a tablet into reasonably equal quarters—the variations in dosage from infancy to adult life can seldom be properly graded with tablets, whereas they can with mixtures: and the variations between thirds, quarters, fifths, etc., of a tablet are much greater than those of the household teaspoon, etc. The point of mentioning economy was that it is, unfortunately, not uncommon to order 100 tablets and patients can easily carry them—and often leave many unused—but few doctors would order the equivalent 40 oz. or Winchester quarts for their patients to take away.

Similarly about "overburdening" the prescriber. In a mixture there are rightly main ingredients and adjuvants or modifiers. To get the same effect—which is a correct therapeutic aim—one would have to order a number of tablets or remember the name of the innumerable combinations which are quite justifiably being offered. It is no secret that the pundits condemn these, as Professor Dunlop did the comparatively simple "drinamyl" at Glasgow last year; though, to my knowledge, if the question had been handed to one of the other members of the panel he would have said it was a most valuable tablet. When we get this acute difference of opinion between the academic and the G.P. or even the consultant, it is inevitable that opinions on the content as well as the format of the *Formulary* should also differ widely. Few would criticize it more strongly than I could, but as it is it remains an honest effort to meet many differing requirements, and it is up to each doctor to use as much of it as he can; and when he disagrees he will be safe in thinking charitably that there has been some valid reason for the apparent oddity.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Psychical Phenomena in Epilepsy and the Psychoses

SIR,—The article by Drs. Shafica Karagulla and E. Elizabeth Robertson (*Journal*, March 26, p. 748) expresses views with which many will be in sympathy. I feel the response of epileptic patients to drug treatment is an interesting corollary to the writers' opinions. Some anti-convulsants alleviate the mental symptoms somewhat, but they only do so in patients showing affective disorders. The more psychotic the thought content and behaviour, the less benefit there is likely to be derived from such drugs. Any change of mood is largely masked by these symptoms, whereas many patients with merely neurotic reactions improve dramatically.

The drug I have in mind particularly is primidone ("mysoline"), and these results were noted when it was first used in the epileptic wards of Long Grove Hospital, Epsom, in 1952.—I am, etc.,

Croydon.

DAVID J. ADDERLEY.

Treatment of Vaginal Discharges

SIR,—As a taxpayer I feel the waste in the large quantities of expensive proprietary preparations which are issued to National Health patients for the treatment of vaginal discharges. As one who often sees the end-results of these cases, I deplore the frequent results of giving pessaries in quantity and without supervision.

The trouble begins, I think, with the well-meaning traveller who claims that his firm have found the cure for

the trichomonas or monilial infections, if not both. The preparation is conveniently packed up as a month's supply of pessaries or medicament (jelly or cream) and all prescribable on the E.C.10. Alas, in that month how much harm can be done. First, the preparation may be excellent, and fulfil all the claims, but in that case a small supply would have sufficed for cure. Secondly, as frequently happens, especially with sulphonamide and acetarsol preparations, the trichomonas and other infecting organisms are quickly destroyed, leaving the vagina clear for the monilia, which seems to flourish on the pessary debris, particularly those with a carbohydrate base. If this has been allowed to go on for long, the result may be a monilial infection which nothing will cure.

I feel that if only some cheap and simple glycerin or lactic acid pessaries could be ordered, to use alternating with the more patent and costly preparations, the results would be so much better. I have recently been prescribing a pessary of phenylmercuric dinaphthylmethane disulphonate with 2% lactic acid. This is a step in the right direction, as it is a combined preparation and easy to order and use. I have found it markedly more successful than the same preparation without the lactic acid.—I am, etc.,

London, S.W.4.

ELIZABETH GOURLAY.

Medical Numismatics

SIR,—Although I personally can throw no light upon "Dr. Eady," I can at least add one more token to Dr. G. E. B. Payne's collection (*Journal*, March 19, p. 729).

This professional token, or more properly jetton, dates from about 1850 and was lent to me by Dr. Thomas Marmion on the occasion of the opening of the new Battersea Varicose Ulcer Clinic. Issued by John Mappin, Surgical and Deformity Instrument Maker of Newhall Street, Birmingham, it shows on the reverse side the sites of the various circumferential measurements necessary when making an elastic stocking.

Dr. Marmion tells me that these tokens of the late nineteenth century were not necessarily sanctioned by the Crown as legal tender, but nevertheless they often circulated locally and were redeemed by the originator for legal money. Thus John Mappin's token, if traded in another shop in the same street, is likely to have been accepted with the same alacrity as a farthing.—I am, etc.,

London, W.1.

STANLEY RIVLIN.

The "Nape Naevus"

SIR,—The communication of Dr. F. Parkes Weber (*Journal*, March 19, p. 726) on the Sturge-Weber-Kalischer syndrome prompts us to record our observations of a condition we have come to term the "nape naevus." This abnormality consists of a cutaneous capillary haemangioma ("port-wine stain") in the region of the hair line posteriorly. The naevus may extend below the hair line, usually in a roughly triangular shape overlapping both sides of the spine, or it may be of irregular delineation and perhaps composed of separately spaced components. In some instances the naevus was confined to the area below the hair line while in others it extended upwards over the occipital region and occasionally was only visible, with careful observation, on separating the hair.

Our interest was aroused by the finding of a naevus in this situation in two patients who suffered from epileptic seizures and who demonstrated intracranial calcification of the type seen in the Sturge-Weber-Kalischer syndrome. Subsequently we came to regard the nape naevus as a concomitant of neurofibromatosis, but when our observations

were extended to include a routine search of the skin hidden by the hair above the nape of the neck we became impressed by the frequency of its existence. In view of this high incidence of the nape naevus in patients not suffering from epilepsy or neurofibromatosis it is difficult to consider it as a component confined to any one particular syndrome. Some patients with the nape naevus also displayed similar naevi in other parts of the body, and, unless looked for carefully, these could readily be missed. Lastly a hereditary aspect of the nape naevus was demonstrated in several subjects. A member of the staff, for example, was able to trace its presence through three generations, the naevus in all those affected being in the nape of the neck. In one example of the nape naevus associated with fits and intracranial calcification, examination of the father showed a very extensive naevus covering almost the whole of the right side of the head but hidden from view by the hair.—We are, etc.,

Burnley, Lancs.

Haemorrhagic Disease of Newborn

SIR,—In 1951 one of us (I. K.), with a colleague,¹ recorded the occurrence of haemorrhagic disease of the newborn presenting as a unilateral proptosis; two cases were reported with complete recovery. We now wish to record a further example of this syndrome with post-mortem confirmation of the haemorrhage situated in the orbital fossa behind the eyeball. This newborn infant died of atelectasis and also had a proptosis of the right eye. Necropsy revealed the cause of the proptosed eye as being due to a haemorrhage in the orbital fossa pushing the eyeball forward.—We are, etc.,

Exchange Transfusion in Haemolytic Disease of the Newborn

SIR,—We have read with very great interest and benefit the excellent paper on the above subject by Drs. William Walker and G. A. Neligan (*Journal*, March 19, p. 681), and from our small experience in the Ronswood Hospital unit find ourselves in complete agreement with them on many points. We have, however, found that, in spite of the most careful maintenance and the use of silicone fluid, syringes do tend to stick from time to time. We have found that the simplest solution to this problem is to have half a dozen syringes in our emergency exchange transfusion set. We have found that as many as six may be required during the course of an exchange of 500 to 600 ml.—We are, etc.,

J. A. CHALMERS.
C. J. THORNBERRY.

Worcester.

Treatment of Coughs

SIR,—The whole trend of your leading article (*Journal*, March 12, p. 651) is that the treatment of cough should be by sedative cough mixtures; you apply this especially to patients who "seek advice about a cough which has persisted for more than a short time" and whom you consider it "clearly desirable to examine carefully." Sir, in general practice we rarely prescribe for coughs of even short duration without careful examination; serious acute disease may frequently only have been present for a short time and the patient still ambulant when he first consults us, but I will not dwell on that now since I have not access to the paper concerned, on the experiment of giving three grains of codeine to suppress cough, though I should scarcely like to repeat it.

When I first joined the wartime R.A.M.C. my regular colonel quoted to me an old regulation of the Service which, so he said, laid down "Mist. expect. sed. will be prescribed for not more

than two days; after that mist. expect. stim. will be prescribed." I regret the clinical interference, but I still think this was good advice and probably saved many lives and much invalidism; patients have frequently come to me with persistent minor bronchial catarrh treated for too long with sedative mixtures and very quickly relieved with pot. iod., and pot. iod. only. I have seen a fellow patient in hospital dying of Gee's linctus every four hours. From a personal point of view I have frequently obtained great relief with a single dose of pot. iod., though a similar effect may be obtained by the ingestion of large quantities of hot tea—embarrassing if one is short of breath, and not always convenient to work or sleep. I believe antispasmodics, very valuable in moderation, can have the same deleterious effect as sedatives when given in excess, since I suspect "normal spasm" may have some physiological action in extruding the sputum.

I agree that in severe advanced chronic bronchitis pot. iod. is of little or no value, but I suggest that sedative mixtures are dangerous to these patients when lack of sleep at night outweighs their disadvantages. At least pot. iod. does little harm if the patient likes a cough bottle, and one can ring the changes on hot fluids, postural coughing, inhalations, antispasmodics, local heat, and antibiotics—anything but sedative cough mixtures. It should be remembered that many patients given a relatively strong linctus will take too much unless very specifically warned. Anyone can suppress most coughs, just as anyone can suppress most pains with opiates, but this would hardly be regarded as the practice of medicine. You appear highly optimistic in regarding a clinical trial of linctuses in cough—a subjective symptom unless one lives with the patient—as easy. I feel it would be neither easy nor particularly useful. Further research into the mode of action of potassium iodide in troublesome but not advanced bronchial catarrh and in asthma, and search for new and more effective sputum liquefiers, would be more helpful.

Sir, only a strong sedative could control my indignation and I make no apology for my views, those of one of the 10,000 or so G.P.s who have been treating "cough" every day for 16 years, in other words "cough specialists." I hold no brief for senega, ammonia, liquorice, chloroform, squill, syrup of Virginian prune, or any of the other deleterious substances sometimes advocated. Let others defend them.—I am, etc.,

Amble, Northumberland.

R. P. ROBERTSON.

Cancer Education

Sir,—The paper by Drs. J. Walter and E. C. Atkinson (*Journal*, March 12, p. 627) describing an early cancer detection and educational scheme in general practice reveals that, of 1,482 presumably healthy list patients, no fewer than 837 (56%) accepted an offered free medical examination, the purpose of which was to detect early cancer. The fact that one new case of (metastasizing) cancer was discovered is noteworthy, but the really interesting feature of this experiment is the amazingly high number of volunteers, which in itself conflicts with the theory that many people are afraid of cancer detection.

Hull, a city of 300,000 inhabitants, has been taken over by the cancer educationalists as a suitable experimental centre and we are constantly bombarded with British Empire Cancer Campaign lectures and leaflets on the subject. Also, we can listen to recorded cancer talks by merely dialling a number on the local telephone system, and, since these talks are given in serial fashion, we have the opportunity to apply to the Marie Curie Memorial Foundation for the scripts of any previous talk we may have missed. The Kingston-upon-Hull Corporation has now entered into the spirit of things with a huge notice in the local newspaper telling the "facts." To an intelligent man with an interest in the subject, the collected facts are really a series of warnings. He is urged to watch for ulcers and lumps in skin, lip, mouth, and throat, etc.; he is told to watch his stools and urine for blood; to watch out for hoarseness and dysphagia. The ladies are advised to search their breasts for lumps (not more than once every 3 months) and to keep a careful watch on their menstrual cycles. And, of course, if ever in doubt we are all urged to consult our doctor.

Your leading article on this subject (p. 652) states that there is need for some cancer education of the public, having satisfied yourselves that the main criticisms against it—that surgeries would be crowded with worried people and that

cancerphobia would be created—are disproved by the experiment in cancer education carried out by Dr. Ralston Paterson and co-workers.¹ Such an assumption is surely premature. The huge business concern did not become huge after its first few advertisements; nor was the enormous incidence of bowel sickness created by the initial advertisements for purgatives. In any case, the Ralston Paterson experiment was carefully controlled and confined itself to certain neoplasms (breast excepted) almost certainly readily curable in the very early stages of the disease. Here in Hull we have propaganda directed against certain neoplasms extremely difficult to cure at any stage of the disease—bladder and oesophagus, for example. For that matter, what is an early neoplasm? Duration of lump is not by any means necessarily tied to stage of disease. Breast, so popular with the educationalist, is notorious in this respect. Even the better-behaved neoplasms, such as cervix, are often advanced and quite incurable in spite of a short history of bleeding and vice versa. What about those unfortunate women who are told to feel their mastitic breasts? It is difficult enough for the experienced clinician to make a diagnosis readily, without biopsy. Once the public do start taking notice it would be most unfortunate if any doctor were to miss an early cancer after the patient has presented it on a plate, so to speak. All such patients will be pushed on to the hospital consultant, who would not dare to turn away any lump, however innocent, without biopsy or local excision.

Is it really necessary? Is there any reason to suppose that doctors to-day die less frequently of this disease than do other professional groups? The V.D. campaign during the war was well worth while for the very reason that quick cure could be offered the patient in practically every case; but in the present state of our knowledge cancer education, on any large scale, is merely putting the cart before the horse.—I am, etc.,

Hull.

Neon Lighting in Hospitals

Sir,—I would like to support the plea of Dr. W. B. Bacon (*Journal*, March 12, p. 666) for the abolition of neon lighting in anaesthetic and recovery rooms and operating theatres. With this form of illumination it is quite impossible to detect minor degrees of cyanosis, despite the asseverations of the manufacturers to the contrary. I already know of an anaesthetic death from unrecognized anoxia in a patient undergoing herniotomy under spinal analgesia.

The introduction of strip lighting in modern hospitals is an unfortunate example of a tendency which is becoming all too common in medicine: the assumption that because a thing is new it must be good.—I am, etc.,

London, W.1.

MASSEY DAWKINS.

Doctors' Visits and Coronary Infarction

Sir,—There have been an article and a letter lately in the *Journal* (February 5, p. 318, and February 26, p. 539) about patients suffering from coronary infarction dying shortly after being seen by the doctor. Your correspondent seems to think that this occurrence is more or less confined to hospital in-patients. However, it can also happen when visiting a patient in his home, as an experience of mine testifies.

I was asked to see a man who had been rather ill in the night with chest pains and attacks of dyspnoea. These symptoms undoubtedly were due to coronary insufficiency. In all probability he had a coronary infarction. There was a history of "bad heart" for years, made worse by chronic bronchitis. Also he had been suffering from hypertensive symptoms. His age was approximately 68 years. He was much better on the following morning when I called to see him. There are two points worth noting which I think are

more important than any details of clinical examination—that is, the fact that he was deaf and I had to shout to make him hear, also the fact that I questioned his self-diagnosis of "bad heart." His wife thought that he was rather upset by my questioning his diagnosis. Also she seemed to think that I need not have shouted quite so loudly. At all events I learned later that the patient, although quite comfortable when I left the house, died a few minutes later. I also learned subsequently that the deceased was a sensitive type of person rather easily upset.

In future I shall speak softly to all patients, whether deaf or not. Also I think it is as well to agree with any opinions that they may express.—I am, etc.,

M. B. BARRY.

Melanoma and Pregnancy

Sir,—Dr. H. Stewart's statement (*Journal*, March 12, p. 647) that "no reference is found to the effect of pregnancy on the growth of a melanoma" calls for comment. Pack and Scharnagel¹ have suggested that "every prenatal examination of the mother should include a survey of her pigmented moles, and those subject to irritation, as well as any situated on the genitals or feet, should be removed and histologically examined." Cunningham² writes that, because of the unusual rapidity with which melanomata grow and metastasize in pregnancy, prime consideration must be given to prophylaxis. The stimulant is, of course, the melanocyte-stimulating or melanophore-expanding hormone of the pituitary, the secretion of which, according to Lerner *et al.*,³ increases progressively from the eighth or ninth week until term, after which it reverts to normal in a few days. Nevertheless, therapeutic abortion is said to have no effect in checking the growth of melanomata.

The melanophore-expanding hormone is also responsible for the enlargement of lentigines or for the appearance of new ones in some patients receiving treatment with corticotrophin. It seems clear therefore that hormonal influences are of the greatest importance in the activation of melanomata, as witness the benignity of these lesions before puberty.—I am, etc.,

London, W.1.

POINTS FROM LETTERS

Chilblains

Dr. W. M. GRAY (Culter, Aberdeenshire) writes: Your annotation (*Journal*, March 5, p. 592) prompts me to send the following prescription, my use of which is purely empirical. In every case in which I have prescribed it the results have been very satisfactory and the patient has been relieved of the sores (open) and pain and discomfort. . . . I copied the prescription from the *British Medical Journal* many years ago and it has done all it claimed. Perhaps it may improve the circulation and is so simple: pot. cit. 15 gr. (1 g.), sod. bicarb. 10 gr. (0.65 g.), inf. gent. 2 dr. (7 ml.); 2 dr. (7 ml.) three times a day to be taken at very beginning of itching or other symptom.

Night Cramps

Colonel P. F. CHAPMAN (Taynuilt, Argyll) writes: I was interested in the annotation on night cramps (*Journal*, March 12, p. 653), having myself been a sufferer. I was surprised to find no mention made of what I have found in my own case, and in that of others to whom I have recommended it, an infallible preventive and cure. It is to take a few mouthfuls of strong salt and water before turning in at night. My last meal often consists of porridge, and I find by oversalting this the same end is attained. . . . I have found myself, as pointed out in your annotation, that night cramps occur after heavy exercise such as marching and drill, or now, in my own case, after a long day's walking over the hill after game. This method of prevention and cure is a very simple one, and I feel sure will prove efficacious in a very large number of cases. The administration of saline either by the mouth or into the blood is now routine in cases of heat stroke.

Obituary

H. M. J. PERRY, C.B., O.B.E., F.R.C.P.

The death of Major-General Marrian Perry occurred at his home at Walton-on-Thames, where he had been living in retirement for some years, on March 23, 12 days after his 71st birthday.

Henry Marrian Joseph Perry was born at Cork on March 11, 1884, and was educated at Queen's College (now University College), Cork, qualifying L.R.C.P.&S.I. in 1906. Commissioned in the R.A.M.C. in the following year, he served in China as a young man, but had returned to home service well before the outbreak of the first world war in 1914. He went to France with the original British Expeditionary Force and was made prisoner of war during the early period of hostilities.

It was after repatriation that Perry began his career as an Army pathologist, and he finished his war service with a rising reputation. At the end of the war Leishman began his reorganization of the Army pathological services, and, recognizing Perry's great ability, posted him to the Royal Army Medical College, Millbank, where he was to spend so many years of his professional life, and where he was appointed professor of pathology in 1922. In 1926 he was seconded to the Foreign Office to serve as director of the Egyptian public health laboratory service, with his headquarters in the Cairo central laboratory. It was a responsible post with quite wide terms of reference, and Perry proved to be a good choice.

In 1930 he returned to the Army to take up a further period as professor at Millbank, and later was promoted to hold the combined appointment of professor and director of pathology, a post he continued to hold until the second year of the second world war, after which he retired from the Army and gradually gave up professional work altogether. For his services in the first world war Perry was appointed O.B.E. in 1919, by which time he had attained the rank of major, and for his work at Millbank he was appointed C.B. in 1937. Promoted full colonel in 1934, he became major-general in the following year. He was an Honorary Surgeon to the King from 1933 to 1940, and he was elected F.R.C.P. in 1941. He is survived by his widow, formerly Miss Mary E. Brewer, whom he married in 1912 and to whom we extend our sympathy.

We are indebted to Lieutenant-Colonel H. J. BENSTED for the following appreciation: Perry will best be remembered by senior and retired officers of the R.A.M.C. for his pathology and bacteriology lectures in the junior and senior courses of instruction at Millbank, but those who worked closely with him knew him for a most painstaking technician and a reliable bench worker. He took a great deal of trouble over everything that he set out to do. In order to make himself certain of delivering without notes an unhesitating and word-perfect lecture, he used to learn

[Lalayeite

his carefully prepared script and then declaim it silently as he walked round and round the lake of St. James's Park. These efforts were not wasted, for his lectures were very widely appreciated. Perry had a strong personality, but he also had a good deal of charm and could carry a committee without obvious effort. He was quick to see the importance of any scientific development that might be of importance to the health of the Army, and the encouragement that he gave to the investigations that led to the improvement of the Army T.A.B. vaccine and the introduction of active immunization against tetanus are witness to this. Perry was always well served, but the development of the Army pathological services in the second world war owed much to his own foresight and organizing ability.

R. G. LADKIN, M.B.E., B.M., D.P.H.

The sudden death from poliomyelitis of Dr. R. G. Ladkin on March 14 at the age of 36 has cut short a career of the highest promise and deprived Uganda of the services of an outstanding medical officer. To those privileged to know him he will be remembered as the ideal Colonial medical officer. Able, resourceful, adaptable, he seemed to be filled with boundless energy and was always willing and co-operative, and interested in every aspect of medical work in East Africa and in many fields outside medicine. He had a vivid personality, and was that forceful, formidable man, a truly realist Christian idealist. He knew only too well the frustrations and difficulties of medical work in Africa, the immense problems, the meagre resources, but he never let them daunt or deter him, and he flung himself cheerfully and selflessly into the task of improving the life and health of the African people of Uganda.

Ronald Greaves Ladkin was born on January 13, 1919, and was educated at Kingsbridge Grammar School and at Exeter College, Oxford, where he was Stapledon Scholar and Devon Scholar, taking the B.M., B.Ch. degrees in 1942. After a period as house-physician at the Radcliffe Infirmary he entered the Colonial Medical Service in 1943 and spent some years in the more remote districts of Uganda before being posted to Kampala, where he taught anatomy in the medical school of Makerere College and carried out much surgery at Mulago Hospital. He became interested in genito-urinary surgery, and this led him to a special study of venereology, which in turn led him towards public health. He took his D.P.H. in 1948 and visited Trinidad to study venereal disease control. On his return to Uganda he was given the medical charge of Mengo District and later of the Province of Buganda. This included the peri-urban African areas around Kampala, in whose problems he became deeply interested and of which he gained a vast knowledge. This post entailed much safari work, at which he was an expert and in which he took great pleasure. His clinical acumen, which he retained to the full, led him to the discovery that the so-called pygmies of the Mabira Forest were in fact pathological dwarfs. It also caused him to institute an improved system of dispensary returns so that he was able to analyse the causes of African morbidity. All the information he collected and the knowledge he gained were generously shared with his clinical colleagues: he lectured to medical students, and frequently spoke at meetings and conferences of the British Medical Association in Uganda. This willingness to help others is gratefully remembered, and it is a sad blow that the frequent concluding remark—"Ask Ron Ladkin—he's sure to know"—will never again

elicit his generous help. One of his greatest assets was his knowledge and understanding of the African mind and his ability to persuade Africans to co-operate with him. In part this was because they recognized his curative skill and were the more willing to accept his advice on prevention. His work in Buganda led to great improvements in many fields of public health and attracted the attention of medical visitors from other countries. His colleagues watched his activities with admiration and respect, and his appointment as M.B.E. in 1952 for his work in Buganda gave them much pleasure.

Ronald Ladkin had become more and more convinced of the necessity for health education in Africa, and he took up this problem with his usual enthusiasm, using many new techniques of his own devising. His success in this field was so outstanding that he was transferred to medical headquarters at Entebbe, where a new post, that of senior medical officer in charge of health education, was created for him, and his sphere was widened to include the whole Protectorate. In this capacity he travelled ever more widely. He spent much time and worked very hard in detailed planning and had interested many different bodies in this task. All his plans, which were coming to fruition when his untimely death took place, will go forward as he would wish, but his zeal and energy will be sorely missed and years will pass before another medical man can gain the detailed knowledge of the health problems, especially of the peri-urban areas, which Ladkin possessed.

Just as his official life was full, happy, and rewarding, so was his unofficial. He was active in the affairs of the Red Cross. He was a founder and past president of the Uganda Mountain Club, and spent many happy hours climbing and exploring, especially in the Ruwenzori mountains. He enjoyed playing cricket and would cheerfully hurl down fast balls for long spells under the hot African sun. Shortly after going to Kampala he married a nursing sister of the Colonial Nursing Service. His home life was ideally happy, and his wife ably supported all his work. Everywhere they went they set themselves to create a beautiful garden ablaze with colour. He lies under the green grass and the blue skies of Entebbe within sight of Lake Victoria. Uganda and his colleagues there have lost a great servant and friend they could ill afford to lose. The sympathy of all their friends goes to his widow and three young children in their great loss.—J. N. P. D.

F. H. SCOTSON, M.B., F.R.C.S.

Mr. F. H. Scotson, one of Manchester's leading surgeons, died on March 23 at the age of 55.

Born on January 28, 1900, at Manchester, where his father, Dr. F. C. Scotson, was a well-known general practitioner, Frederick Hector Scotson was educated at Manchester Grammar School and at Manchester University. He had a distinguished record as a medical student and was awarded numerous prizes and distinctions, including the Bradley Memorial Scholarship in surgery and the graduate prize in medicine. In 1922, in his 23rd year, he obtained medical degrees from both the Manchester and London universities, being awarded honours in his final examination at Manchester. In the following year he took the London Conjoint diploma, and in 1924 passed the final examination for the F.R.C.S., but, being under age at the time, did not qualify to receive the diploma until the following year. After graduation he was appointed house-surgeon at Manchester Royal Infirmary, the first of a long series of

appointments to that hospital: he was resident surgical officer from 1927 to 1929 and later surgical officer to out-patients and surgical tutor. During this period he took the opportunity to visit some of the American clinics. In 1930 he was appointed honorary surgeon to the Manchester Northern Hospital and to the Manchester Victoria Memorial Jewish Hospital, and a few years later he became consultant surgeon to the Crumpsall Hospital.

Scotson was a general surgeon with his chief interest in the surgery of the abdomen. He published a number of papers in this and other journals and spared no pains to keep abreast of current surgical ideas. He was a keen and good teacher and for the past seven years had been a lecturer and examiner in surgery in Manchester University. At the time of his death he was president of the section of surgery of the Manchester Medical Society and was to have given his presidential address on the subject of peptic ulceration. He was a past president of the Middleton and North Manchester Medical Society and a former vice-president of the Manchester Pathological Society. He was twice married: first, in 1928, to Annie M. Bradbury, who died in 1940, and second, in 1942, to Leila M. B. O'Connell, who survives him, together with her son and the two sons and one daughter of his first marriage.

R. L. H. writes: F. H. Scotson was an excellent technician and a shrewd clinician. In addition, he was always extremely kind to and thoughtful of his patients. He led a very active professional life, for besides a heavy hospital programme he had an extensive private practice. His friends had told him he was working far too hard, and unfortunately their prophecy proved true, for the constant nervous strain under which he was working precipitated a breakdown which never satisfactorily cleared up. A remarkably tolerant man, he had, in addition to his professional ability, many endearing personal qualities. His natural friendliness was apparent to all, and as "Scottie" he will be remembered and his loss mourned by all his colleagues in Manchester. His patients have lost not only a good surgeon but a friend.

Dr. NEIL McLEAN died on March 14 at Ryde, Isle of Wight, where he had been in practice for the past eight years. A native of Skye, Neil McLean was born in 1898, and he graduated M.B., Ch.B. at Glasgow University in 1924, after seeing active service with the Cameron Highlanders in France, the Balkans, and Russia in the first world war. At the university he was a well-known shinty player, gaining his blue. He joined the Colonial Medical Service in 1926, and served in Kenya for twenty years, retiring as senior medical officer in 1946 after a severe illness.

P. R. writes: Neil McLean did valuable work in Kenya, especially in sleeping sickness research, for which he was awarded the North Persian Forces Memorial Medal in 1931, an award given for the best piece of original work in tropical medicine for the year. For a time he was stationed in the Masai Reserve, and when he was posted elsewhere the Masai tribe offered the Government a large number of their precious cattle to have him back again, probably a unique tribute to a doctor and an index of the affection with which natives of all the Kenya tribes regarded him—an affection shared by the European population, officials and settlers alike. Neil will long be remembered by all who knew him, and their sympathy goes out to his wife and three daughters. In 1935 he married Miss G. Davidson, of Whitley Bay, who proved a constant support and strength to him. His was a lovable personality, and his cheerfulness and courage in adversity won the admiration of his friends. I can see him now sitting with his microscope at a camp table under a thorn tree on the shore of the Nyanza, talking Luo to his

patients with a strong Gaelic accent, or, dressed in an old kilt, fishing from a boat in Broadford Bay, singing quaint Gaelic airs. Though greatly incapacitated by cardiac trouble, he took up practice in Ryde in 1947, where he continued, making a brave fight against declining health, until his death at the early age of 56.

Medical Notes in Parliament

Radioactive Contamination Report

Mr. ARTHUR HENDERSON (Rowley Regis and Tipton, Lab.) asked the Prime Minister on March 29 if he would publish a White Paper containing all available facts and information, together with the report from British scientists, on the effects of continuing radioactive contamination of the world's atmosphere.

Sir WINSTON CHURCHILL stated that the Government had already invited the Medical Research Council to review the existing scientific information on the medical aspects of nuclear radiation and to prepare a report. The report would cover the medical aspects of nuclear radiation, including the genetic aspects. It would review existing scientific information and set forth the most up-to-date information and the latest research results available. The report would be laid as a White Paper.

London Atmosphere Measurements

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Parliamentary Secretary to the Ministry of Works (as representing the Lord President of the Council) on what evidence his estimate was based that there was no significant increase in the radioactive content of London's atmosphere during recent years. Mr. J. R. BEVINS told him that it was based on measurements made in London periodically since 1947. Dr. STROSS said that M.P.s who went to the Chester Beatty Research Institute, as members of the Parliamentary and Scientific Association, were informed that the radioactive contamination of the London atmosphere was 10 times as high now as when measurements first began, and was 300 times the normal during the great fog of 1952. Was that taken into account, could it be checked, and would it not be significant? Mr. BEVINS replied that he had checked the statement in Dr. Stross's pamphlet that the radioactivity had increased 10 times. There must have been a misunderstanding during the visit to the Institute, because he was assured that the increase in radioactivity since 1947 had been negligible. It was true that the measurements that were taken were very limited, and the evidence was not conclusive in its present form. Nevertheless, he would like to refute the statement that there had been a large increase in radioactivity. Dr. STROSS asked him to check that point with the Chester Beatty Institute, and make certain that the facts given to those who were present were as he had stated. Mr. BEVINS said that the Lord-President had checked with the Institute. The Institute denied that the statement was made, and said that if such a statement were made there had been a misunderstanding on one side or the other.

Hospital Workers' Protection

Mr. S. SWINGLER (Newcastle-under-Lyme, Lab.) asked the Minister of Health on March 28 what regulations he had issued about the protection of hospital workers using radioactive substances and about the disposal of radioactive waste in hospitals. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, said that it was the normal practice of hospitals in the Health Service to observe the recommendations of the British X-ray and Radium Protection Committee about protection and working conditions in x-ray and radium departments. This code of practice was, however, in some

respects out of date, and the Minister hoped to bring into operation shortly a revised code approved by the Radioactive Substances Advisory Committee which included a section governing the disposal of radioactive waste.

Charges Against M.R.C. Denied

Mr. PETER FREEMAN (Newport, Lab.) asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, whether he was aware that a number of cases had recently been brought to the courts of cat-stealing on a large scale and that several people had been convicted for this offence; that these cats had been stolen for sale to medical research laboratories, as admitted in court; that the cost of the defence and the fines had in some cases been paid by the M.R.C. and that they had employed the same counsel in most of the cases; what authority existed for the payment of such expenses out of public funds; how much had been spent on each of these cases in the last six months; and what action he proposed to prevent a recurrence of such incidents. Mr. BEVINS, replying on March 29, stated that he was glad to have the opportunity of stating, quite unequivocally, that there was no truth whatever in the hon. Member's allegations against the M.R.C. Mr. FREEMAN said that further inquiries should be made. Counsel who defended these cases was known to have made a voluntary statement that the fines and costs had been paid either by the M.R.C. or one of its members. This was confirmed by a Mr. Taylor, of Rectory Square, London, E.1, who supplied over 100 cats a week—most of which had been stolen—to the M.R.C. The same counsel was employed to defend Mr. Taylor, and had been employed on repeated occasions. Some brothers named Bailey were recently ordered to pay £170 in fines and costs, and they had admitted that in that case the cats stolen had been sent direct to the M.R.C. Mr. BEVINS said that the Lord President of the Council had been into the matter with meticulous care, and was satisfied that none of the suggestions in the question was based on evidence. The barrister whose name was supplied to him had had no contacts of any sort with the M.R.C. As for statements made in court, defendants sometimes told the truth and sometimes they did not. Mr. FREEMAN gave notice that he would raise the matter again.

Doctors' Telephones

Mr. D. WALKER-SMITH (Hertford, Con.) asked the Minister of Health on March 28 whether he would seek powers to ensure that general practitioners in the Health Service should be available to their patients on the telephone. Mr. IAIN MACLEOD replied "No," but added that, without prejudging any entirely exceptional case, it seemed quite clear to him as a general matter of common sense that a doctor providing general medical services was not in a proper position to fulfil his obligations to visit his patients when their condition so required if he did not make reasonable arrangements for them to communicate with him by telephone.

Foreign Patients in Hospitals

Mr. A. HURD (Newbury, Con.) asked if the Minister of Health would make a sample check of admissions to hospitals to show the numbers of patients who were not ordinarily resident in the United Kingdom, and to find out how many had come here with the purpose of obtaining free hospital treatment. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replied on March 28 that the Minister was not satisfied that the information obtained would be of sufficient value to justify the very considerable work which would be involved.

Progress in Leprosy Treatment

Mr. W. TEELING (Brighton, Pavilion, Con.) on March 30 asked the Secretary of State for the Colonies how many leper hospitals there were in the Colonies, where they were, and in what Colonies lepers were refused permission, even when suitably accompanied, to visit towns away from the

leper centres. Mr. H. HOPKINSON, the Minister of State, Colonial Office, stated that there was an institution for the treatment of leprosy in every Colony in which the disease was endemic, either in leprosy hospitals, out-patient departments of general hospitals, or in separate settlements or villages. Contact with the general public in the case of patients under treatment was related to the risk of infection in each case. Mr. TEELING said that recent discoveries had led those studying the disease to consider that it was no longer necessary to have completely isolated settlements. Would the Minister make sure that the Colonial Office was keeping that in mind? Mr. HOPKINSON said he entirely agreed. Many of the new drugs had made it possible to treat an increasing number of cases as out-patients, to allow patients in institutions to go home for short periods, or to discharge them altogether.

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked if we may take it that it is now accepted that leprosy is not a dangerously infectious or contagious disease, and that free movement does not necessarily bring danger to the community. Mr. HOPKINSON replied "Yes." The danger depended on the specific case, but in a general way people still retained a serious dread of the disease. Only education on the effects of modern drugs and so on would eradicate that fear.

Mr. TEELING also asked how many lepers were on the leper station near Fiji; what had been the expenditure on this leper island over the last five years, year by year; and how many of the lepers there were European, Fijian, and Indian, respectively. Mr. HOPKINSON informed him that there were 634 patients in the Fiji Leprosy Hospital at Makongai. Expenditure in Fijian pounds was 51,000 in 1949, 55,000 in 1950, 58,000 in 1951, 69,000 in 1952, and 64,000 in 1953. Three of the lepers were Europeans, 139 Fijians, and 193 Indians. Mr. TEELING asked if it would be possible to bring those people back into Fiji and Suva. The leper island was far away, and the lepers felt completely cut off. Mr. HOPKINSON said he would refer the suggestion to the Governor of Fiji. He added in answer to Mr. T. L. IREMONGER (Ilford, North, Con.) that Gilbertese, Samoans, Cook Islanders, and others were also treated in the colony. Generous help had been given to the hospital from the New Zealand Leper Trust Board and others.

Blood Tests for Motorists

Mr. S. P. VIANI (Willesden, West, Lab.) asked the Minister of Transport on March 30 whether he was aware that a majority of the public were in favour of the imposition of a blood test for motorists involved in serious accidents; and if he would give consideration to the introduction of legislation to enable such tests to be carried out in the future. Sir F. MEDLICOTT (Norfolk, Central, Nat. Lib. and Con.) asked if, in view of the recent substantial increase in the number of deaths and injuries on the roads, the Minister would make legislative provision for the imposition of a blood test on all drivers of motor vehicles involved in accidents causing death or serious injury. Mr. JOHN BOYD-CARPENTER, answering them both, said that he had no evidence either to confirm or to reject the assertion made by Mr. Viani. Research was being carried out jointly by the Medical Research Council and the Road Research Laboratory to find out, under laboratory conditions, how precisely measured quantities of alcohol affected driving performance and whether such effect could be satisfactorily assessed. He hoped their report would be available this year.

Mr. VIANI said that his question was based on evidence provided by a recent Gallup poll conducted by the *News-Chronicle*. Sir F. MEDLICOTT said the reliability of this test had been largely proved—which provoked cries of dissent—and it would be a much more satisfactory way of ascertaining the condition of drivers than the present tests of conduct. Mr. BOYD-CARPENTER said that he would rather await the conclusions of the Road Research Laboratory tests. Mr. R. R. STOKES (Ipswich, Lab.) said that most M.P.s

would fail to pass such a test immediately after lunch, and it bore no relation whatever to the condition of the driver.

Doctors' Lists.—The average number of patients on doctors' lists on July 1, 1954, was 2,219 in England and 2,077 in Wales. In July, 1951, the numbers were 2,391 and 2,348 respectively.

Cortisone Products.—The Minister of Health is not yet in a position to make cortisone products available on prescription by general practitioners.

Medico-Legal

£2,000 DAMAGES FOR SILICOSIS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On March 25, 1955, a majority of the First Division of the Scottish Court of Session upheld an award by Lord Wheatley to John Harkness Wardlaw of £2,000 damages. Wardlaw had sued his employers, Bonnington Castings, Ltd., for damages for lung injuries sustained through inhaling silica dust during his employment as a steel dresser from January, 1942, until May, 1950, when he was found to be suffering from pneumoconiosis. It was Wardlaw's job to operate a pneumatic hammer in the dressing shop to remove steel rags from castings.

Wardlaw's case was that his pneumoconiosis was caused by a breach of duty by his employers to take reasonable care for his safety, among other things by failing to provide employees in the dressing shop with masks or respirators to intercept the dust, and that such masks were a simple and inexpensive precaution which was frequently adopted in the foundry industry.

Lord Carmont, dismissing the appeal, said it would not do for the employers to say that it was much more likely that the disease was contracted through work at a hammer close to the source of dust rather than from breathing the air of a shop which was generally contaminated. Even if most of his inhalations took place near the source of dust, a minority of inhalations from the general atmosphere of the shop needlessly contaminated through breakdown of the extractors might well have contributed a quota of dust to Wardlaw's lungs and so helped to produce the disease. The evidence did not show that in 1950 a mask or respirator was in common use, but the employers had failed to show that silica dust from sources other than the hammer had played no part in causing the disease.

Lord Russell, agreeing with Lord Carmont, said that, having anxiously considered the evidence, he was of opinion that the employers had not discharged the onus resting on them.

The Lord President, Lord Clyde, would have allowed the appeal. In his dissenting judgment he said that, although an effective mask would have prevented the inhalation of the particles of silica dust loosened from the surface of the casting by the hammering operation, the evidence showed that in 1950, in spite of considerable research and effort by Government and departmental committees, no such respirator or mask existed. In his view the evidence did not show that the breakdown in ventilation had any causal connexion with Wardlaw's disease, and Wardlaw had failed to discharge the onus that it had. In his view the ventilation breakdown had been the employer's only breach of duty, and it was not shown that its effects had caused the disease.

SURGEON WINS FEE CLAIM

Judge W. H. Paton gave judgment for an orthopaedic surgeon at Bristol County Court on March 28 against a woman dancing teacher who alleged that the surgeon had forced her to walk on a broken ankle. The judge said he could not accept her story and entirely exonerated the surgeon. The judgment, with costs, was given to

¹ *Scotsman*, March 26, 1955.

Mr. Kenneth H. Pridie, of Clifton, Bristol, on his claim for £48 6s. for his professional services rendered to 56-year-old Mrs. Mary Ellen Boss, of Bristol. A counter-claim by Mrs. Boss for damages for alleged negligence was dismissed.

Mrs. Boss, a dancing instructress, said she broke her ankle in October, 1949, and Mr. Pridie set it in plaster. The next month she went to his surgery. He took her sticks away from her and insisted that she was only suffering from nerves. He told her to walk the length of the room to the x-ray table. She said that Mr. Pridie told her friend and partner, Miss Hilda Walker, who was with her at the time, to go home for Mrs. Boss's other shoe, so that she could walk home. "He removed the plaster and manipulated my foot, with great pain to me, and said my ankle was perfect," and that she would dance as well as ever she did. Mr. Pridie went outside, but then rushed in and said, "Don't put that foot to the ground. If you do you will be a cripple for life." Mrs. Boss said she replied, "You are too late. You have made me walk already." She said she went home in an ambulance.

Mr. Kenneth Pridie, a consulting orthopaedic surgeon to several hospitals, said that before ever he saw Mrs. Boss he examined the radiographs which had been taken at Bristol Royal Infirmary. He realized that she had a very severe fracture of the ankle, which was bound to produce a permanent disability whatever treatment she had. He gave her an injection into the ankle and a sedative, manipulated the bones, and put on a plaster. Dealing with the events at his surgery in November, 1949, Mr. Pridie said he sent Miss Walker for the shoe before he had examined Mrs. Boss, but when he did so he found that the ankle was unstable. It was not until five years later that he first knew it was being alleged that he had compelled Mrs. Boss to walk on the ankle. He had no complaint from her that day about anything. She was very emotional and he did his best to comfort her.

Judge Paton, giving judgment, pointed out that Mr. Pridie eventually performed an operation on Mrs. Boss. It was very difficult, he said, to believe that a person who had really been treated as she says she had been treated by Mr. Pridie would have allowed him to go on treating her. It has never been suggested that she even considered anybody else doing it. He was quite unable to accept her story. No doubt she became extremely despondent and upset, and had persuaded herself that she was badly treated by Mr. Pridie. The judge was completely satisfied that, so far as Mr. Pridie was concerned, there was nothing in his conduct of this case with which he should reproach himself.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Mr. Pridie.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on February 26 the degree of D.M. was conferred on J. F. D. Frazer and A. L. Turnbull.

Dr. E. M. Vaughan Williams has been elected to an Official Fellowship at Hertford College.

In Congregation on March 8 the appointment of Dr. D. St. C. Roberts as a Clinical Tutor in Ophthalmology from April 1, 1955, to September 30, 1957, was approved.

James Learmonth Gowan (Lincoln College) has been elected to the Philip Walker Studentship in Pathology for two years from October 1, 1955.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of College held on February 1, with the President, Sir Stanley Davidson, in the chair, the following were elected Members of the College:

G. J. Summers, A. Muir, D. P. Puri, L. E. Wynter, S. Bell, A. K. Black, M. B. Morris, J. A. Kay, I. M. Cuthill, D. C. Peiris, T. S. Kalyanani, P. S. Macfarlane, H. M. P. Perera, F. V. Edrington, D. M. Chakraborty, V. Srinivasan, P. M. Hewlett, G. F. Trobridge, B. Kaplan, E. D. Myers, M. S. Karve, H. S. Wong, T. A. Cunningham, D. C. Sen, F. O. Simpson, C. G. Caro.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 19 (No. 11) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

STILLBIRTHS ..	197	18	27			201	15	29		

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were more prevalent in England and Wales during the week ending March 19, and the rises in the number of notifications included 3,697 for measles, from 25,321 to 29,018, 409 for dysentery, from 1,407 to 1,816, 59 for scarlet fever, from 780 to 839, and 43 for whooping-cough, from 1,881 to 1,924.

The largest rises in the incidence of measles were 1,059 in London, from 2,626 to 3,685, 365 in Yorkshire West Riding, from 3,737 to 4,102, 364 in Middlesex, from 1,047 to 1,411, 313 in Surrey, from 986 to 1,299, 263 in Northumberland, from 709 to 972, 250 in Warwickshire, from 2,120 to 2,370, 218 in Kent, from 988 to 1,206, 180 in Essex, from 1,905 to 2,085, 178 in Durham, from 808 to 986, 176 in Glamorgan-shire, from 167 to 343, 174 in Derbyshire, from 879 to 1,053, 146 in Southampton County, from 156 to 302, 141 in Lancashire, from 2,123 to 2,264, and 105 in Staffordshire, from 878 to 983, and the only large fall was 100 in Lincolnshire, from 477 to 377. The only variation of any size in the trends of scarlet fever was a rise of 47 in Yorkshire West Riding, from 57 to 104. The largest fluctuation in the returns of whooping-cough was a decrease of 30 in Cheshire, from 62 to 32. 10 cases of diphtheria were notified, being 1 more than in the preceding week. Areas with multiple cases of diphtheria were Plymouth C.B. 3, Liverpool C.B. 2, Birmingham C.B. 2.

13 cases of acute poliomyelitis were notified, and these were 1 more for both paralytic and non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 5 (Batley M.B. 2), Warwickshire 2 (Birmingham C.B. 2), and London 2 (Hackney 2).

For the eleventh consecutive week a rise has been recorded in the incidence of dysentery, and the number of notifications during the week reached a new record level, being 144 above the previous highest level recorded in 1951. The largest centres of infection during the week were Lancashire 700 (Blackpool C.B. 286, Oldham C.B. 86, Blackburn C.B. 69, Manchester C.B. 69, Liverpool C.B. 49, Chadderton U.D. 33, Middleton M.B. 18, Salford C.B. 15, Lytham St. Anne's M.B. 15, Royton U.D. 14, Failsworth U.D. 10), London 195 (Hackney 103, Shoreditch 33, Islington 14, Stepney 11), Durham 156 (Sedgefield R.D. 56, Felling U.D. 23, South Shields C.B. 15, Gateshead C.B. 11), Northumberland 114 (Newcastle-upon-Tyne C.B. 30, Morpeth M.B. 24, Whitley Bay M.B. 23), Yorkshire West Riding 94 (Leeds C.B. 37, Huddersfield C.B. 21, Sheffield C.B. 11), Leicestershire 90 (Leicester C.B. 62, Melton Mowbray U.D. 13), Norfolk 70 (Norwich C.B. 55), Cheshire 52 (Stockport C.B. 33), Northamptonshire 44 (Northampton C.B. 23, Kettering M.B. 14), Lincolnshire 41 (Scunthorpe M.B. 36), Surrey 39 (Farnham U.D. 26), Yorkshire North Riding 30 (Middlesbrough C.B. 24), and Glamorganshire 25 (Swansea C.B. 12).

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in February was 119, compared with 108 (revised figure) in the previous month and 114 in February, 1954.

The numbers of cases of industrial diseases in the United Kingdom reported during February, 1955, were as follows: lead-poisoning 6, compressed air illness 3, epitheliomatous ulceration 18, chrome ulceration 27; total 54. There were no deaths.—*Ministry of Labour Gazette*, March, 1955.

Medical News

Wellcome and Carlsberg Foundations.—At the Apothecaries Hall on April 4 the Wellcome Trustees and directors of the Wellcome Foundation, Ltd., entertained at dinner the members of the Carlsberg Foundation and the management of the Carlsberg Breweries of Copenhagen. Sir HENRY DALE, O.M., F.R.S., chairman of the Wellcome Trustees, presided, in the presence of a distinguished company of guests. The link between the two Foundations is that for all practical purposes their constitution and aims are identical. Both were created with the object of using for philanthropic purposes the whole of the profits of a continuing industrial concern. The Carlsberg Foundation is the senior and came into being in the 1880's following the founding of the Carlsberg Breweries by the late J. C. Jacobsen and their extension by his son. They left the ownership of their breweries to an independent foundation consisting of five eminent Danish citizens appointed by the Royal Danish Academy of Arts and Sciences, whose responsibility it is to apply the profits from the breweries to scientific research and the promotion of the arts, for the benefit of the Danish nation.

Scottish Orthopaedic Council.—On March 21 the Scottish Orthopaedic Council agreed to dissolve. In a statement after the meeting it was pointed out that orthopaedic services were now firmly established in all five regions of Scotland, and therefore the work for which the council was formed has been accomplished. Since its inception in 1942 the council, as the channel through which grants from the Lord Nuffield Fund for Cripples were distributed in Scotland, has disbursed over £24,000 to assist with orthopaedic clinics, educational establishments for crippled children, and other aids for cripples in Scotland. In addition the Nuffield Trustees have made grants amounting to £26,500 for hospital developments at Philipshill, Busby, and Princess Margaret Rose Hospital in Edinburgh. A balance of £17,000, earmarked for orthopaedic developments in Scotland, is to be used for the construction of occupational therapy and workshop departments at the proposed spinal injuries unit at Edenhall, Musselburgh, and to extend the residential training establishment for severely handicapped girls at Anton House, Broughty Ferry.

Kirk Duncanson Fellowship.—The council of the Royal College of Physicians of Edinburgh invites applications for a Kirk Duncanson Research Fellowship of the value of £600 for two years from October 1, 1955. Applicants should submit details of their proposed research and the place where it will be done to the Secretary of the Royal College of Physicians of Edinburgh, 9, Queen Street, Edinburgh 2, before May 7.

Royal Flying Doctor Service.—The QUEEN has honoured Australia's Flying Doctor Service by granting permission for it to be known in future as the "Royal Flying Doctor Service of Australia." An account of the service, given by

Dr. ALLAN VICKERS, the service's senior medical officer, was printed in the *Journal* last year (June 19, p. 1436).

Instruments for Users of Radio-isotopes.—The Scientific Instrument Manufacturers' Association of Great Britain has published a catalogue to help the user of radioactive isotopes in selecting electronic equipment to suit his special needs. The first copy of the catalogue, which is called "Radio Isotope Instrumentation and Accessories," was presented to Sir JOHN COCKCROFT, F.R.S., at a ceremony in London on March 30. Details are given in the catalogue about apparatus for radioactive assay and radiation monitoring and other equipment such as isotope containers and isotope-handling apparatus. Last year, according to figures supplied by the Atomic Energy Research Establishment at Harwell, there were 9,692 orders for radio-isotopes for use in Britain, of which over half came from hospitals, while 6,694 orders were received from abroad. The comparable figures for 1948 were 1,379 and 35. The catalogue may be obtained from the Scientific Instrument Manufacturers' Association, 20, Queen Anne Street, London, W.1.

COMING EVENTS

Westhill Hospital, Dartford.—Postgraduate course for general practitioners, every Thursday afternoon at 2.30 p.m. from April 14 to June 23. Inquiries to Dr. J. C. HOGARTH, Westhill Hospital, Dartford.

Wessex Rahere Club.—Spring dinner on April 30 at the Royal Clarence Hotel, Exeter. Details from Mr. A. DAUNT BATEMAN, 11, The Circus, Bath.

Christian Medical Fellowship.—Two house-parties have been arranged: May 6-9, at the Belsfield Hotel, Bowness, Windermere; and May 20-23 at Linden Hall Hydro, Bournemouth. Details from the Secretary of the Fellowship, 39, Bedford Square, London, W.C.1.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 39, No. 4) is now available. The contents include:

SOME OBSERVATIONS ON THE WATER-DRINKING TEST IN GLAUCOMATOUS AND NON-GLAUCOMATOUS SUBJECTS. D. Campbell.
INFLUENCE OF LOCAL ASCORBIC ACID CONCENTRATION ON COLLAGENOUS TISSUE HEALING IN THE CORNEA. T. A. S. Boyd.
THE PRESSURE IN THE CANAL OF SCHLEMM. E. S. Perkins.
VASCULAR SUPPLY OF THE OPTIC PATHWAY. II. FURTHER STUDIES BY MICROARTERIOGRAPHY OF THE OPTIC NERVE. J. François, A. Neetens, and J. M. Collette.
OPHTHALMOLOGICAL COMPLICATIONS OF MULTIPLE MYELOMATOSIS. E. Clarke.
CLINICAL REPORT ON THE RESULTS OF FIFTY CASES OF ROUTINE DACRYOCYSTORHINOSTOMY. G. J. Romanes.
MULTIPLE ISLANDS OF RETINOBLASTOMA. A STUDY OF THEIR INCIDENCE RATE AND THE TIME SPAN OF THEIR APPEARANCE. H. B. Stallard.
CORNEAL INFECTIONS AFTER CORTISONE THERAPY. Y. Mitsui and J. Hanabusa.
OCULAR MANIFESTATIONS IN A CASE OF HAEMORRHAGE INTO THE FOURTH VENTRICLE. M. Sengupta.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, April 12

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Sir Clement Price Thomas: Resection for Pulmonary Tuberculosis; 6.30 p.m., Professor F. A. R. Stammers: Complications of Gastrectomy.

Wednesday, April 13

HARVEIAN SOCIETY OF LONDON.—8.15 p.m., Sir Adolphe Abrahams, Sir Arthur Porritt, and Dr. Roger Bannister: Medical Aspects of Athletics.
●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Sir Russell Brock: Some Aspects of the Surgical Treatment of Mitral Stenosis; 6.30 p.m., Professor A. M. Boyd: Management of Phlebitis and its Complications.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. A. I. G. McLaughlin: Incidence and Prevention of Dust Diseases in British Industry (illustrated).

Thursday, April 14

BASINGSTOKE PLASTIC CENTRE MEDICAL SOCIETY.—At Rooksdown House (Park Fawcett Hospital), Basingstoke, Hants, 7.30 p.m., Professor R. H. S. Thompson: Skin Enzyme Problems in Burns; Dr. W. J. H. Butterfield: Abnormal Carbohydrate Metabolism in Burns; Dr. P. A. Gorer: Serology of Tissue Transfer; Mr. Douglas M. Jackson: Early Primary Surgery with the Use of Homografts; Dr. J. P. Bull: Early Electrolyte and Fluid Balances.

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, 5 p.m., Dr. H. Fergie Woods: Sciatica; Dr. N. J. Pratt: Analysis of 100 Consecutive Homoeopathic Prescriptions.
INSTITUTE OF PSYCHIATRY.—5.30 p.m., inaugural lecture by Professor H. Mollwain: Maudsley, Mott and Mann on the Chemical Physiology and Pathology of the Mind.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. Norman Capener: Hip Joint—Surgical Approaches and Procedures; 6.30 p.m., Mr. V. H. Riddell: Toxic Goitre.

Friday, April 15

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, The University, Liverpool, 11 a.m. (Saturday, April 16, 11.15 a.m.), joint meeting with Association of Clinical Biochemists.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical meeting for general practitioners. Mr. W. S. McKenzie: Surgical Treatment of Deafness.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Professor Lambert Rogers: Carotid Aneurysms; 6.30 p.m., Mr. J. N. Barron: Skin Grafting for the General Surgeon.

Saturday, April 16

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—10.30 a.m., symposium: Tuberculosis and Other Diseases of the Chest.

APPOINTMENTS

DAVIDSON-LAMB, WILLIAM, M.C., M.B., Ch.B., D.P.H., Deputy County Medical Officer of Health and Deputy Principal School Medical Officer, Gloucestershire County Council.

DEWAR, JOHN, M.B., Ch.B., D.P.H., County Medical Officer of Health, Joint County Council of Moray and Nairn.

GIBSON, JANE ISABELLA, M.B., Ch.B., Consultant Pathologist, Birkenhead and North Wirral Hospital Group (Liverpool Regional Hospital Board).

IRWIN, DAVID, M.B., Ch.B., D.P.M., Deputy Medical Superintendent, St. George's Hospital, Morpeth, Northumberland.

MASON, RICHARD MICHAEL, D.M., M.R.C.P., Consultant Physician to Department of Physical Medicine, The London Hospital, Whitechapel, E.

RAINSFORD, C. R. C., M.D., D.P.H., D.T.M., Medical Officer of Health, Braintree and Bocking and Witham Urban District Councils, and the Braintree and Dunmow Rural District Councils, and Assistant County Medical Officer, Essex.

REID, EDWARD NEIL, M.B., Ch.B., D.P.H., Medical Officer of Health, Kilsyth, Stirlingshire.

RICHCESTER, MARIE-JOYCE, L.R.C.P.&S.Ed., Assistant Medical Officer of Health (Midwifery and Child Welfare), Blackpool.

RICHARDS, NORMAN A., M.D., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist to the Stafford Group of Hospitals.

SHEMLIT, PHILIP, M.B., F.R.C.S., Surgical Consultant, The Military Hospital, Tidworth.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—Joan M. Waterfall, M.B., Ch.B., D.A., Primary F.F.A.R.C.S., temporary Senior Anaesthetic Registrar at Frenchay Hospital, Bristol; Mary F. West, M.B., B.S., D.A. (Part I), Anaesthetic Registrar at Southmead Hospital, Bristol; G. P. Jolly, M.B., B.Chir., M.R.C.O.G., D.O.Bst.R.C.O.G., Registrar in Obstetrics and Gynaecology at Southmead Hospital, Bristol; Angela D. Fuller, M.B., B.Chir., D.C.H., Paediatric Registrar at Southmead Hospital, Bristol; J. S. Knutzen, M.B., Ch.B., Ear, Nose, and Throat Registrar to the Bath Group of Hospitals; M. J. Gallagher, M.B., B.S., F.R.C.S., Orthopaedic Registrar at Princess Elizabeth Orthopaedic Hospital, Exeter; T. L. Schofield, Ch.M., F.R.C.S., Consultant Surgeon to Bath Clinical Area.

UNIVERSITY COLLEGE HOSPITAL OF THE WEST INDIES.—Dinah J. Hony, M.B., B.S., Registrar in Anaesthetics; Ruth Porter, M.B., Ch.B., D.C.H., Medical Registrar.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Hetherington.—On March 25, 1955, to Monica, wife of Dr. A. W. Hetherington, Redcote, Rainham, Essex, a daughter—Jane Mary.

DEATHS

Dunn.—On March 30, 1955, at 62, Cecil Street, Hillhead, Glasgow, James Churchill Dunn, D.S.O., M.C., D.C.M., M.D., D.P.H.

Mann.—On March 29, 1955, at Drummie House, Letham, Angus, David Mann, M.B., F.R.C.S.Ed.

Nicoll.—On March 17, 1955, at Womersley, Surrey, James Thomson Bell Nicoll, M.B., Ch.B., aged 55.

Pank.—On March 13, 1955, at Market Rasen, Lincs, Harold William Pank, M.R.C.S., L.R.C.P., aged 80.

Petrie.—On March 17, 1955, at Chertsey Hospital, George Ford Petrie, M.D., of Woking, Surrey, late of Elstree, Herts.

Roe.—On March 17, 1955, at 20, Billing Road, Northampton, Robert Bradley Roe, M.R.C.S., L.R.C.P.

Scott.—On March 22, 1955, at the Hostel of St. Luke, London, Agnes Catherine Scott, C.B.E., ½ B., of Cleves, France Lynch, Stroud, Glos, aged 79.

Sharp.—On March 18, 1955, Alexander Sharp, C.B., C.M.G.T.D., F.R.C.S.Ed., Colonel, A.M.S., retired.

Thomas.—On March 21, 1955, at Addenbrooke's Hospital, Cambridge, John Glyndor Treharne Thomas, M.C., M.R.C.S., L.R.C.P., D.P.M., of 353, Hills Road, Cambridge, aged 62.

Thorp.—On March 16, 1955, at Bafford Cottage, Charlton Kings, Cheltenham, Glos, Henry Thorp, M.Sc., M.B., Ch.B., formerly of Lymm, Cheshire.

Wallis.—On March 16, 1955, William Evershed Wallis, M.B., B.Ch., of Oakhurst, East Grinstead, Sussex, aged 71.

Woodward.—On March 22, 1955, at Coventry, Herbert Croker Sperling Woodward, M.B., B.C., of Kingston Bagpuize, Abingdon, Berks, aged 86.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Wet Clothes

Q.—What, in healthy people, are the disadvantages of getting wet, and staying in wet clothes? How is the picture modified by atmospheric temperature, relative humidity, amount of clothing, and regular use of soap and hot water in washing? Primitive people, even the malnourished, appear to get wet and stay wet for long periods without discomfort or subsequent ill effect.

A.—Presumably the questioner is thinking of the old advice: "You must get those wet clothes off before you catch your death of cold." It is doubtful if wearing wet clothes ever gave anyone a cold; but when the outer garments are wet there is evaporation from them and the surface temperature of the outside clothing will fall below that of the surrounding air, possibly to the wet-bulb temperature. The temperature gradient from the skin to the outer surface of the clothing is therefore increased; at the same time the replacement of the insulating air between the fibres of the cloth by non-insulating water will decrease the thermal insulation of the clothing. These two factors together cause a man in wet clothing to lose heat more rapidly to the environment than a man in dry clothes. Skin temperature and later even body temperature may fall. It has been said that when the body temperature does fall there is diminished local resistance to infection, especially in the nasopharyngeal tract (although experimental work has failed to confirm this). To this extent, therefore, wearing wet clothing might contribute to catching a cold, but the cold infection has got to be there to be caught.

Atmospheric temperature and humidity have an effect inasmuch as these two factors govern the wet-bulb temperature. For physical reasons the surface temperature of the wet clothing can never fall below the wet-bulb temperature, and the higher the humidity the nearer does the wet-bulb temperature approach the atmospheric dry-bulb temperature. At high humidities therefore the skin surface gradient is less affected than at low humidities.

The more clothing worn, within limits, the warmer the skin, so long as the clothing is dry. If this clothing suddenly becomes soaked and so loses all its insulation the thermal gradient from the skin to the surface of the clothes will be very steep and heat loss will be rapid. When very little clothing is worn the skin temperature may be almost the same in the clothed as in the unclothed areas, and wetting the clothing will then make very little difference.

The regular use of soap and water, according to O'Brien,¹ predisposes to prickly heat and allied skin conditions, as it removes the natural fats of the skin. As prickly heat and intertrigo are more likely to develop in damp areas of skin, it is possible a well-washed individual might suffer more in this respect if he had to live in wet clothes than one of the "great unwashed." The questioner may also be thinking of the value of grease as thermal insulation. It has been found experimentally, however, that in immersion experiments the minimum thickness of grease on the skin which will have any effect on the rate of cooling is 1.8 mm. This represents 2.7 litres of grease for an average-sized man—and a mighty long time between baths.

I doubt if primitive men are any better able to withstand the purely physical effect of wearing wet clothes than are others; but they may be better prepared to put up with the discomfort, as they may have no alternative. On the other hand, a primitive man may be wearing fewer

clothes, with the advantage already noted, or he may even take all his clothes off. Once clothes are wet right through their insulation value is almost nil, and a naked man is actually better off, as the area from which evaporation can take place may be 25% less. The really important thing here is knowing what to do when one's clothes do get wet. The old Scots shepherds were said to turn their plaids wet side in when the rain stopped; in this way they stopped excessive evaporation and consequent cooling. Changing wet socks for dry socks, even though the boots are still wet, restores the insulating power of the sock and is also a great comfort; it is both physically and physiologically justified.

Ringworm

Q.—In treating a case of ringworm affecting the groins, axillae, and toes, should the fungicide be applied widely to all areas showing scaling (such as between the toes) irrespective of whether inflammation is present or not? What disinfection of clothes and bedding is advised? How should the bathroom floor (made of wood) be disinfected?

A.—Fungicide should be applied to all areas where there is scaling.

Bed linen is disinfected by the usual process of washing, and most types of underclothing can be boiled. The feet of socks or stockings are probably best sterilized by soaking in lysol or some similar disinfectant before they are washed.

For the disinfection of a wooden floor, scrubbing with soap and water would probably be efficient.

Dangers of Adrenaline During Prostatectomy

Q.—What is the risk of injecting adrenaline into the prostatic bed prior to performing a prostatectomy? Would you consider 1.5 ml. adrenaline (1 in 1,000) diluted with 40 ml. of saline to be a small, medium, or a large dose? General anaesthesia is used, but trichlorethylene, cyclopropane, and chloroform are avoided.

A.—There is some risk that in injecting adrenaline solution into the prostatic bed some or all of it might get into the circulation. If this did happen 1.5 ml. of adrenaline would be a large dose for anybody. Little is gained by making the dilution of adrenaline intended for vasoconstriction much stronger than 1 in 100,000. If the whole 40 ml. of solution is to be injected, the required dilution is obtained by mixing 0.5 ml. of adrenaline in 50 ml. saline. Few genito-urinary surgeons require this volume for the purpose described. Usually a few ml. only of the solution is injected into two or three points in the prostatic capsule. In these circumstances the stronger solution mentioned in the question may be used, since the dose of adrenaline would then be kept to about 0.5 ml., a reasonably safe dose.

The risk of sudden death due to adrenaline is present with any form of anaesthetic; it is probably increased in the case of the three anaesthetic agents mentioned in the question.

Hitch-hiking to Australia

Q.—Two patients of mine are shortly hitch-hiking to Australia via Yugoslavia, Greece, Turkey, Syria, Iraq, India, Pakistan, Singapore, Burma, and Indonesia. Can you please tell me what inoculations and vaccinations they should have before starting on this journey? Can you also tell me what antimalarial drug is advised, in what doses, and during what part of the journey should this be taken? Are any other health precautions advised?

A.—Travellers are required by international law to be vaccinated against smallpox, and must be in possession of a valid international certificate of vaccination. As these particular travellers are going through India and Pakistan they

should also be vaccinated against cholera; this, too, is legally required as a condition of entry into these countries. Although vaccination against the enteric group of fevers is not required by law, it is advisable to have this done. There is no special order in which the above vaccinations should be carried out. Vaccination against yellow fever is legally required of those travelling to tropical Africa or America, and it is recommended that this be done at least four days before smallpox vaccination if this is also required.

The most effective antimalarial prophylactics are proguanil in doses of 100 mg. daily and chloroquine in doses of 300 mg. (base) weekly. It would be advisable to start taking the prophylactic on reaching the Mediterranean littoral and to continue thereafter throughout the journey and for three weeks after entering the non-malarial region at the end of the journey.

Among other health precautions the most important is the use of safe water supplies, and if safety cannot be guaranteed water should be boiled. Salads and other uncooked foods should be avoided. A valuable book, designed for the lay reader and dealing with general health problems in the Tropics, is *Health and Disease in the Tropics*, by Charles Wilcocks, published by Oxford University Press, price 15s. The Ross Institute, c/o London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, also issue a pamphlet entitled "Notes on the Preservation of Personal Health in Warm Climates."

Constant Sexual Urge in an Old Man

Q.—I have a patient in his late eighties with a moderately enlarged prostate who is tormented with an almost constant sexual urge. He is impotent. Frequency of micturition is the only other symptom. Would oestrogen therapy help?

A.—Although it is possible that stilboestrol in a dose of 5 mg. daily might diminish the sexual urge, it is unlikely to do so if erections do not occur. Probably the best treatment would be prostatectomy if the other symptoms justify it.

Hairy Tongue

Q.—During the last six months in this practice I have seen an increasing number of hairy tongues, with and without glossitis. Some have been present for only a few days or months, others for years or even for life. (a) Are several clinical types of hairy tongues recognized? (b) What is their cause? (c) Has there been a recent increase in the incidence of the condition?

A.—There are probably at least four types of black hairy tongues with differing aetiologies: (1) congenital and familial, when the condition is present from birth and is sometimes known as ichthyosis of the tongue; (2) parasitic, when it is due to various micro-organisms (yeasts, particularly *Candida albicans*, actinomycetes, and microbacilli); (3) the result of chemical irritants, such as toothpaste, mouthwashes, and disinfectants; (4) following the local or systemic use of antibiotics, particularly chlortetracycline ("aureomycin").

It is difficult to say whether there has been an increase in the incidence of the condition in recent years, because we see only a small proportion of those afflicted with this benign malady. The literature and personal experience suggest that there has been an increase in the incidence of hairy tongue, and that antibiotics, particularly those of the tetracycline group, are responsible for this increase, as many patients develop the condition towards the end of, or shortly after, a course of one of these drugs.

Lozenges containing antibiotics are more likely to produce black tongues, and they have also followed the use of an ointment containing chlortetracycline on the lips.

A number of cases arise spontaneously, and recently studies of the tongue with Wood's light have shown that the flora of the dorsum of the tongue may change very rapidly in the apparently normal, healthy mouth, so that it

is not surprising that occasionally a brown tongue follows this spontaneous change in the flora. With increasing use of mouthwashes, antibiotic drugs, toothpastes containing various chemicals, and the like, it is probable that the condition will be more frequently met with in the future.

Cigarette Stains on the Fingers

Q.—How can one take off nicotine stains from hands and mouth of heavy cigarette-smokers, without irritation to the skin? Attempts with hydrogen peroxide, up to 20%, and 10% sodium hypochlorite solution have been only partially successful.

A.—It is presumed that these stains are caused not only by nicotine but by tar as well, though I have no precise information on this point. The stains can be removed comparatively easily with pumice stone, and it is probably better to do this periodically than to make frequent applications of strong chemicals to the skin. However, the use of a cigarette holder will prevent most of this staining.

NOTES AND COMMENTS

Thiourea.—Dr. J. H. PETERS (Atlanta, U.S.A.) writes: In answering a question regarding thiourea ("Any Questions?" November 13, 1954, p. 1179), it is stated that the compound had been administered in 1-2 g. daily doses and was abandoned in favour of "more active . . . compounds" and because it was unpleasant to take and imparted an odour to the breath. Actually, thiourea has been used successfully for therapy of hyperthyroidism, administered in quite low (70-280 mg. per day) doses, displays relatively little toxicity, and is pleasant to take.^{1,2,3,4} The authors of these investigations reported halitosis only when the drug was given intravenously. Actually the early abandonment of thiourea in favour of other goitrogens was due to a combination of factors. One was that early investigators did set dosages too high and experienced the difficulties mentioned in your answer. In the meantime, the introduction of propylthiouracil, and later of aminothiazole, proved to be so successful that thiourea, which may actually be less toxic than either, has been ignored. I pass this information to you lest readers might consider using the compound in excessive doses in cases not tolerating other goitrogens.

Restoring natural rhythm

Senna is a neuro-muscular stimulant of peristalsis and produces a good imitation of normal defaecation. Such a physiological effect is of great value in restoring natural rhythm.

Through the production of Senokot, the first stable, standardised preparation of senna, the full therapeutic activity of the drug has been made available and its re-educative effect demonstrated.

NOTES ON CANADIAN MEDICAL HISTORY

BY

H. E. MacDERMOT, M.D., F.R.C.P.(C.)

Montreal

A short paper on the history of Canadian Medicine of necessity will be highly selective. I have therefore chosen to deal with a few of its earlier aspects only.

It is natural to date the development of medicine in Canada from the time of the French settlements in the seventeenth century, but the North American Indians had their own medical knowledge, and there is much in it to interest us. Several well-known vegetable drugs, such as sarsaparilla, jalap, cinchona, and guaiacum were native to North America and were used by the aborigines. One writer even gives the Thompson Indians credit for employing organo-therapy in their use of beavers' testicles for pain; and undoubtedly some tribes realized the value of an infusion of spruce tips in scurvy. Jacques Cartier learnt this from them to good effect. However, their medical knowledge in general is chiefly of ethnological interest.

The Early Practitioners

From the little that is known of the first medical men to arrive in the country, they seem with a few exceptions to have been barber surgeons and apothecaries. They came in the first instance with Champlain on his voyages to Acadia and Quebec, and later with the troops and colonists for New France. By the beginning of 1700 it is said that about 96 people practising medicine were scattered along the shores of the St. Lawrence up to Montreal. Many of these can have been little better than charlatans.

Two names, however, deserve attention. One is Michel Sarrazin (1659-1734), who came out in 1685 as surgeon and later was made chief surgeon to the troops in Quebec. He returned to France to take his degree in medicine, and then returned to settle in Canada, being named royal physician. His practice extended over an area which would have been large even with modern methods of transportation, and there were the added dangers of travelling between Quebec and Montreal. Still, he managed to carry on a great deal of botanical and zoological work, which he reported to l'Académie Royale des Sciences, of which he had been made a corresponding member in the same year (1699) in which Sir Isaac Newton had been admitted. He made a collection of over 200 plants and sent them back to Paris. Tournefort, of the Jardin Royal, forerunner of Linnaeus, named the pitcher plant (*Sarracenia purpurea*) after Sarrazin. He was the first to put the production of maple syrup on a commercial basis and to describe the blueberry. His work on Canadian fauna was extensive and unequalled; he described the beaver, the porcupine,

and the muskrat, which he dissected, but when he came to examine the skunk he failed, because, in his own words, "it had a frightful smell, capable of making a whole canton desert." In his latter days, however, he fell on bad times: he lost all his money and died a pauper.

Jean François Gaultier (1708-56) was his successor as royal physician, and a worthy one. He too did outstanding work in botany, natural history, and entomology. His name is enshrined in the wintergreen plant, *Gaultheria procumbens*.

Otherwise, men of mark did not begin to appear until the early nineteenth century. They will be mentioned later.

In Ontario, then called Upper Canada, settlements began considerably later. The Treaty of Versailles in 1783 saw the migration of a large number of so-called United Empire Loyalists from across the border. Few medical men came with them to Upper Canada, the explanation apparently being that physicians in the American colonies were not forced out of the country as much as in the case of the other professions. It is probable, too, that the rigours of pioneering life were too severe: as was said, the pioneer physician needed the constitution of a horse and the clothing of an Arctic explorer.

There were not more than 40 qualified men in the province as late as 1815. Quacks flourished. An appeal is found in a Kingston newspaper against quacks "who, without one ray of science, presume to thrust the created into the presence of the Creator."

But gradually better men came in, chiefly retired regimental surgeons, and Boards were set up to control practice, as had been done in Lower Canada (Quebec). Amongst the earliest names of importance are those of James MacAulay; William Baldwin, who laid out the present Spadina Avenue of Toronto as the approach to his summer home "Spadina"; the eccentric "Tiger" Dunlop, whose unusual last will and testament is frequently quoted; and, perhaps most notable of all, Dr. Christopher Widmer. A born leader, Widmer initiated the building of the Toronto General Hospital and was early interested in medical education. He was termed the Father of Surgery in Upper Canada. His name was associated with every medical enterprise, and his energy, ability, and foresight made him a dominating figure till his death in 1858.

Of 260 doctors whose biographies appear in Canniff's *History of the Medical Profession in Upper Canada*

from 1783-1850, 70 were graduates of Scottish universities, 43 of English, 28 of Irish, and 40 of American. Thirty-nine had their training wholly or in part under the system of apprenticeship.

The eastern provinces of Nova Scotia, New Brunswick, and Prince Edward Island were so distinct from Upper and Lower Canada that their early history is quite a separate chapter. They seem to have had no shortage of physicians, as was the case in Ontario. Some were French, but the majority were English, and with the founding of Halifax in 1749 several medical men came into the country. The old churchyards in Halifax have many records of medical interest. One tombstone to two young brothers who died of diphtheria bears the following commentary: "Stranger; whether has the disease or medical omission clad meast in their last claiht?"

From 1775 to 1800 there was, as in Upper Canada, a large influx of the United Empire Loyalists, but in this case they were accompanied by many physicians. Nathaniel Perkins, one of the first to practise varicella in Boston; W. J. Almon; and the Hon. John Halliburton were all prominent men. The name of Abraham Gesner is outstanding. A native of Nova Scotia, he had studied under Abernethy and Astley Cooper. His work in geology and natural history was notable. He discovered coal oil, inventing the word "kerosene" for it. His old refinery still exists, and is owned by the Standard Oil Company.

In the West there were pioneer doctors with the fur-trading establishments as early as 1814. Dr. (Sir) John Schultz built the first house in Winnipeg. He later became the Lieutenant-Governor of Manitoba, and in welcoming the Canadian Medical Association at one of its early meetings in the West (Banff) exhorted them to "pause and reflect for a moment that they were where for economic purposes Canada was widest, and no longer a mere arable strip on the banks of the St. Lawrence."

In the North-West Territories, which comprised what is now Alberta and Saskatchewan, there were occasional medical men with explorers and fur-trading settlements. Dr. J. Richardson, with Sir John Franklin in his overland journey to the Polar sea, makes a reference to Edmonton in 1820 (it had been founded in 1795 as a fur-trading centre) as having much goitre, and Dr. W. B. Cheadle treated patients there on his transcontinental journey.

With the formation of the Northwest Mounted Police (the "Mounties") in 1873 a regular succession of surgeons began, the first being Dr. George Kittson. Dr. R. G. Brett (1851-1929), Ontario born, helped to found the Manitoba Medical College, then moved to Alberta and became a leading medico-political figure. He established the sanatorium at Banff.

The building of the Canadian Pacific Railway (finished in 1885) brought yet more medical men into the country, and by 1889, the year in which the Canadian Medical Association held its meeting in Banff, there were 33 physicians registered in the N.W.T.

There is no difficulty in naming the pioneer doctor in British Columbia. This was Dr. John S. Helmcken (1825-1920), a graduate of London, who came to British Columbia in 1850, as surgeon to the Hudson's Bay Company. At one period he described himself as "the leading practitioner from San Francisco to the North Pole, and from Asia to the Red River of the north." This

was easily accounted for, as he was then the only practitioner within those limits. He filled a large place in the medical and political life of British Columbia, and his house in Victoria is preserved as a museum. He was one of the delegates to Ottawa from the province to support terms of union with Canada.

Medical Teaching

As the better type of men increased medical boards were set up for the control of medical practice (in Lower Canada in 1788; Upper Canada in 1795; Nova Scotia in 1828), but these had little control over the large numbers of unlicensed practitioners. Often these latter were the only form of practitioner available under pioneering conditions. There was no medical teaching in the country, as would be expected. The Canadian medical student had either to be satisfied with the training of an apprentice or else go abroad at great expense.

At this very early stage of development a well-organized medical school was formed in Montreal in association with a general hospital to provide clinical teaching. The teachers—four Edinburgh graduates—were the staff of the Montreal General Hospital, founded in 1819, and their school, which was opened in 1823, was at first called the Montreal Medical Institution. In 1829, however, the school agreed to become the Medical Faculty of McGill University, thereby gaining the right to confer degrees, whilst enabling the University to begin active operation as required by the terms of its foundation.

This school owed its formation to the desire of its four founders to raise the professional standards in Canada. The names of the four founders were John Stephenson, A. F. Holmes, William Robertson, and William Caldwell. They were men, of strong personalities. Caldwell had fought a duel over some derogatory comments on the first proposal to build the hospital. Holmes became the first dean of McGill Medical Faculty, but was no more influential than the more reserved Robertson. Stephenson apparently was the *vis a tergo* in the organization of the school. As a student he had the distinction of being the first to be operated on by Roux, of Paris, for cleft-palate, and his Edinburgh graduation thesis *De velosynthesi* is still preserved in the Osler Library at McGill.

These men left their mark on the school by their transmission of the Edinburgh tradition of clinical teaching in the wards. This school has the longest uninterrupted record of bedside teaching in North America*; it was what attracted Osler to McGill.

The first attempt to form a medical school in Ontario was made by Dr. John Rolph in 1824. Rolph was at once a politician, which got him into a great deal of trouble; a member of the Bar, which probably helped him out of trouble to some extent; and a well-trained surgeon. He had studied under Astley Cooper and had great attainments as a lecturer. He became involved in the rebellion of 1837, fled to the States with a price on his head, and was finally pardoned in 1843, when he came back to Toronto and began his school again. He gathered good men around him, notably Dr. Joseph Workman (1805-94), who probably had more brilliant mental powers than Rolph himself. Rolph's school was eventually taken into the University of Toronto in 1887. There were two other private medical schools in Toronto for a time which also merged with the University.

Even when they became medical faculties of universities the older medical institutions remained largely independent for many years, making their own appointments and controlling their own finances. The right to grant medical

*Clinical teaching at the bedside had been carried on at the Pennsylvania Hospital in 1756, but it was interrupted by the War of Independence and was not resumed in the Edinburgh tradition until Osler went to Philadelphia in 1884. Macphail rightly speaks of "two faint streams from Edinburgh across the Atlantic, one to Philadelphia and one to Montreal." ("Sources of Modern Medicine," *Canad. med. Ass. J.*, 1933, 28, 239).

degrees, however, was always retained by the universities. This discouraged the formation of weak and undesirable institutions.

The following is a list of the Canadian Medical Schools in geographical order from east to west:

Established Canadian Medical Schools

	Founded as a Medical Faculty or School in
Dalhousie University, Halifax, N.S.	1868
Université Laval, Quebec City	1853
Université de Montréal, Montreal, Que.	1843
McGill University, Montreal, Que.	1823
University of Ottawa, Ottawa, Ont.	1945
Queen's University, Kingston, Ont.	1854
University of Toronto, Toronto, Ont.	1844
University of Western Ontario, London, Ont.	1881
University of Manitoba, Winnipeg, Man.	1883
University of Saskatchewan, Saskatoon, Sask.	1926
University of Alberta, Edmonton, Alta.	1913
University of British Columbia, Vancouver, B.C.	1950

Up to 1914 those seeking postgraduate training still turned almost wholly to British and Continental centres, French-speaking doctors in particular going to Paris. The first world war checked this severely. The second war ended it altogether as regards the Continent. The great expansion in hospitals and research centres in the U.S., but also in Canada in such institutions as the Montreal Neurological Institute and the Banting and Best Institute in Toronto, has reversed the direction of postgraduate migration.

No university degree in medicine of itself confers the right to practise in Canada. Each province retains the control of licensure within its boundaries. Some schools require their students to register with their home province before beginning their course. Even this registration, however, only gives the right to practise in that particular province.

There were many years of discussion before the provinces agreed on a uniform registration which would permit of Dominion-wide practice. This was one of the first objectives of the Canadian Medical Association when it was formed in 1867, but it was only achieved in 1912 by the persistence and statesmanship of Dr. (Sir) Thomas Roddick (1846-1923) after his election to the Federal legislature.

A Newfoundlander by birth, Roddick had early shown his outstanding capacities. It was he who first brought Lister's methods convincingly before the profession in 1877.* In 1885 he was put in charge of the medical services in the Riel Rebellion in Saskatchewan, work which required not only organizing ability but unusual physical endurance, for which his powerful physique was well prepared. His real genius, however, lay in the patience and imperturbability by which he was able finally to harmonize apparently irreconcilable views and to persuade men to rise above provincialism. Roddick evolved the Canada Medical Act (the "Roddick Bill"), by which a medical register under a Dominion Medical Council was set up. Those passing an examination set by the Council were to obtain the right to register for practice in any province without further examination, on complying with the regulations pertaining thereto. Thus the right of the provinces to control their licensure was not disturbed, whilst it did away with the

*Sir Thomas was the first medical man outside of the British Isles to be chosen as President of the B.M.A. This was on the occasion of the first visit of the B.M.A. to Canada in 1897.

necessity for taking separate examinations for each province to which a man might wish to go.

In the carrying out of this Dominion registration certain complicating factors have arisen in late years, chiefly relating to the large numbers of medical men from other countries seeking to practise in Canada. But there has been no change in the general tenor of the legislation.

Newfoundland

The union of Newfoundland with Canada (1949) is too recent for the inclusion of its medical history in this sketch. It may be said, however, that the first colonists to reach Newfoundland (1610) had no medical men with them. The comment by Guy, the leader of the expedition, after ten months in Newfoundland, was that only four had died during the winter, and in his opinion "all of them if they had as good will to work as they had good stomachs to their victuals would long since have been recovered."

The first medical men came with a French military force in 1662, and military surgeons came and went with the various expeditions. Dr. William Carson, an Edinburgh graduate, has left a name for his fearlessness in urging reform in the government of the island, and was chiefly instrumental in having the first hospital for civilians built in St. John's in 1813. Before that, two military hospitals existed (one for infectious disease), but they were almost exclusively for the soldiers of the garrison.

Hospitals

The first hospitals in Canada were built in the stormy years of the French settlements in the seventeenth century at Quebec and Montreal, and later at Three Rivers. The oldest is the Hôtel-Dieu of Quebec, begun about 1641, but suffering many vicissitudes from attacks by the Indians.

The Hôtel-Dieu of Montreal was built first in 1644, and was due entirely to the courage and ability of Mlle. Jeanne Mance. She had no training as a nurse, but devoted herself to the care of the sick of the small colony. The hospital suffered much from

poverty. It was burnt down three times. In 1861 it was moved uptown from its site in the business section, and has become greatly enlarged and completely modernized.

The oldest English hospital in Canada is the Montreal General Hospital. It was founded in 1819 and its original building was erected in 1822. It arose as a direct result of the rapid growth of Montreal, and of the floods of immigrants arriving in Canada in the post-Napoleonic period. It was a teaching hospital from the beginning, as already mentioned, and for about 60 years was the only English hospital in the city. Osler studied in its wards and later was one of its physicians. Much of the material for his original *Textbook of Medicine* was drawn from his experience in its wards and necropsy room. The hospital is now being transferred to a more suitable site uptown.

The Royal Victoria Hospital, the second teaching hospital to appear in Montreal, was opened in 1892, and immediately began to build up a first-class staff. In the last 50 years there has been a tremendous expansion in hospitals in the city and province.

In Toronto (first called York) the Toronto General Hospital was built in 1820, but was taken over by the Provincial Government for parliament buildings in 1824,

Sir Thomas Roddick.

L'Hôtel-Dieu de Québec in 1816. The walls date from 1696.

and was not used as a hospital until 1829. The T.G.H. has seen many changes and difficulties before becoming the present very large and modern institution (1,418 beds).

Toronto can claim the honour of having established the first hospital for children in the Sick Children's Hospital. Beginning in small rented quarters in 1875, it has gradually been built up into an institution of international reputation.

It was in the Department of Physiology of the University of Toronto that Banting and Best did their original work on insulin in 1921. The Banting and Best Department of Medical Research was established by the Board of Governors of the University as the result of a special grant made by the province of Ontario in 1923.

Medical Journals in Canada

The first Canadian medical journal, *Le Journal de Médecine de Québec*, was published in Quebec in 1826 by a young French doctor, F. X. Tessier. It had both French and English papers, and was well conceived; but it was much too far ahead of the medical strength of the country, and ceased in 1828.

It was 1844 before the appearance of the next journal, the *Montreal Medical Gazette*. Although it lasted for only a little more than a year, it was the beginning of a series of publications which managed to maintain medical journalism in various guises until some degree of permanence was attained. It was as difficult then as it always has been to find men both capable of editing and willing to make the necessary sacrifices. Two men stand out in the early years.

Dr. Archibald Hall, of Montreal, started the *British-American Journal of Medical and Physical Science* in 1845, and for eight years waged a losing battle against a small circulation and lack of funds. But he produced a first-class journal, which reflects his championship of high standards, his courage and dignity, and his absolute certainty that he was always in the right. He strongly reproved the profession for failing to support him even after a second venture later on; but he seems to have been too dictatorial, too bitter, and too easily irritated to carry on a journal successfully.

In contrast there was Dr. John Fulton, of Toronto, who edited *Canada Lancet* (1868-1922)—first called the *Dominion Medical Journal* (1868-9)—from 1872 to 1887, and drew high praise from Osler for his publication. It was successful because he was methodical and business-like, even if it

lacked the fire which warmed the pages of Hall's journal. As Osler said, Fulton learned the lesson "that success cometh neither from the east nor from the west, nor yet from the south, but is found in close attention to the everyday details of life, no matter how trivial."

Several French journals have been produced. *L'Union Médicale*, begun in 1872, has the record for the longest uninterrupted publication under one title. But the *Canadian Medical Association Journal* has an older lineage. Its progenitor was the *Canada Medical Journal and Monthly Record of Medical and Surgical Science*, which first appeared in 1864. The two editors, George Fenwick and G. W. Campbell, parted company in 1872, owing to "personal differences," and each then carried on a journal of his own under slightly different names. Campbell's journal, the *Canada Medical Record*, was very much his own affair, and ceased with his death in 1904.

But Fenwick learned the wisdom of teamwork and was able to attract to the staff of the *Canada Medical and Surgical Journal* the best men in the Montreal profession. Under the later title of the *Montreal Medical Journal* it reached great heights in the journalistic field, especially under the editorship of Andrew Macphail, who exploited to the full his clear and pungent style. In 1910 the proprietors of the journal agreed, in the interests of organized medicine, that it should become the *Canadian Medical Association Journal*, along with the *Maritime Medical News*, a Halifax publication. The difficulties which beset the journal in the war years are mentioned later; it need only be added that its editorship was undertaken in 1921 by Dr. A. D. Blackader (1843-1932), as Macphail had resigned on account of ill-health. Dr. Blackader, who was then in his seventies, gave himself wholeheartedly to the work of building up the journal, and when he resigned in 1930 he had placed it on a solid foundation.

A total of 72 periodicals have appeared in Canada in the course of 128 years. At present there are 18, including provincial Bulletins and undergraduate publications. Medical journals are not now undertaken with the apparent light-heartedness of last century. The economic implications are too severe, and advertising support is indispensable in almost every instance.

The Canadian Medical Association

The desire to organize the profession in Canada arose several years before the time was ripe for carrying it out. In 1844 Dr. Joseph Painchaud, of Quebec, suggested the

The Montreal General Hospital as it was when Osler was a student there.

formation of a "Medical Fund or Association" whose main object was to be a charitable one. The *Montreal Medical Gazette* (the earliest Montreal medical journal) at once proposed to widen the scope of the Association to include the dissemination of medical information and to obtain representation of its wants in legislation. The two medical societies of Toronto and Montreal then combined in developing the movement, with Dr. F. Badgley, of Montreal, as one of the most active leaders.

However, friction developed between the medical societies and the so-called "districts," and the movement failed utterly. Another attempt four years later began in a better spirit, but lacked organization enough to get beyond the first meeting. The wonder is that these efforts were made at all. Communications were difficult, and the number who realized the value of organization was very small. The eastern provinces were not approached in the matter at all.

The third attempt followed on, though it was not directly the result of, the political union of the Canadian provinces in 1867. Dr. William Marsden, of the Quebec Medical Society, who had taken part in the earlier abortive attempts, was now the first to realize, or at any rate to act on, the more favourable prospects for medical organization which would arise from confederation. He was further stimulated by a visit he had paid that year to a meeting of the American Medical Association, as delegate from the College of Physicians and Surgeons of Quebec, bringing back reports of what was being proposed in regard to education and licensure.

His report was taken up by the Quebec Medical Society, and a committee, composed of Drs. J. A. Sewell, William Marsden, R. H. Russell, P. D. Tessier, L. J. A. Simard, F. H. A. Larue, and H. Blanchet, drew up an appeal to all members of the profession in Canada (now nearly 3,000) to meet in Quebec for the organization of an Association. The chief object named was that of medical legislation.

This time there was no hesitation. On October 9, 1867, 167 medical men met in Quebec, including representatives from Upper and Lower Canada, as well as from Nova Scotia and New Brunswick, and the organization of the Association was successfully completed, with Dr. (Sir) Charles Tupper as president.

The first annual meeting was held in Montreal, again under the presidency of Dr. Tupper, of whom Osler has said that he was a brilliant example of success of the doctor in politics, although "he never really served two masters—he was a politician first and a practitioner only when stranded by the exigencies of party." The value of his experience to the Association in its formative years was inestimable. His physical attributes were remarkable. He lived to the age of 94 and actually "stumped the country" for his party in his 80th year, and successfully, too. And yet he had been ready at the age of 59 to give up all activities, as he was believed then to have Bright's disease. His case was mentioned by Osler in his paper "On the Advantages of a Trace of Albumen and a Few Tube Casts in the Urine of Men above 50 Years of Age" (*N.Y. Med. J.*, 1901, 74, 949).

It should be added that Dr. Marsden, who was rightly called the Father of the Association, refused nomination

Sir Charles Tupper in 1891.

Dr. Palmer Howard, outstanding in the early days of the C.M.A.

even as vice-president. Extremely retiring in disposition, he preferred to work without recognition, but did accept the presidency in 1873.

The Association immediately began to discuss the problem of medical education and licensure. The first proposal favoured an Act similar to the Medical Act of Great Britain, setting up a general council of medical education for registration. No other subject occupied more of the time of the Association in its early years, and none gave rise to more frustration. In 1874 it was dropped altogether, by common consent, fully vindicating the reflection of Dr. Joseph Workman, of Toronto, that "our greatest, and alas, too palpable want is Union—honest, earnest, self-sacrificing Union—and our next great want is prudence."

The other subjects dealt with at the first meeting were those of statistics and hygiene, and the formulation of a code of ethics. It was only in the third year that a programme of scientific papers was presented. In the tenth year the scientific proceedings were published in printed form; the secretary of the publications committee that year was William Osler.

The Association took some credit to itself for its continuous representations to the Government on the necessity for centralizing the control of public health. Its records show an appreciation of the Government's action in finally establishing a Department of Public Health in 1919.

It is of interest that a proposal was made in 1876 in favour of uniting the Canadian and American Medical Associations. After due consideration, however, and the expression of most cordial feelings on both sides, it was decided to let the matter drop, and merely to continue to exchange courtesies by sending delegates to each other's meetings.

The Association has had its difficult periods. At the end of the first 25 years, for example, interest in it seems to have sunk very low, even to the point of a suggestion in 1893 that it should disband. Membership was small, and only a faithful few carried on the work, notably men like LeBaron Botsford, of St. John, N.B., E. M. Hodder, W. H. Hingston, H. S. Birkett, Joseph Workman, R. P. Howard, F. N. G. Starr, and Alex McPhedran.

Then it gained new life, and in 1910 an Association journal was begun with Dr. (Sir) Andrew Macphail as editor. But just as the journal was getting well under way the war broke out. The editorial staff went overseas on active service, along with a good many contributors, and only the devotion of one or two unofficial editors, notably Dr. Maude Abbott, kept the journal going, whilst the Association itself had great difficulty in carrying on. No

meetings were held in 1915 and 1916, and by the end of the war the financial position of the Association was extremely bad.

The turning-point came at the annual meeting in Halifax in 1921. It was realized then that reorganization was essential. The various provincial organizations had not been brought closely enough into relationship with the Association, and the finances needed immediate attention. A full-time secretary was appointed in the person of Dr. T. C. Routley, a bond issue was raised, and once more the Association began to expand. Within a few years it had paid off the bond issue and was showing the vigour and growth which has brought it to its present stature.

The Association has continued not only to deal with the profession's educational and economic problems, but to concern itself with social and political developments. Post-graduate lectures were first organized in 1925, and were carried on throughout Canada for seven years, with the help of generous grants from the Sun Life Assurance Company. A Department of Hospital Service, also aided by this company, was carried on for 20 years.

Health insurance has probably occupied the attention of the Association more continuously than has any other subject. The principle of insurance against the cost of illness has received the support of the Association, particularly through the medium of prepaid medical care plans.

The first proposals to establish a Royal College of Physicians and Surgeons of Canada were made at the annual meeting in Vancouver in 1920, the primary object being to stimulate study and postgraduate work in medicine and surgery. The idea gradually matured, and the College was finally incorporated by Act of Parliament in 1929. Once launched, the College became an entirely independent organization.

Inspection and accreditation of hospitals is one of the later activities of the Association. This work had previously been done in Canada by the American College of Surgeons, and on their withdrawal from this particular field the Association initiated plans for the necessary machinery to carry it on. To Dr. E. K. Lyon, of Leamington, Ont., is due most of the credit for focusing attention on the importance of this phase of hospital life and of eventually bringing into being the Commission to deal with it. The C.M.A. contributes the major part of the very heavy cost of this work. Formation of a College of General Practice originated within the Association some five years ago, and the College came into being last year, with a full-time secretary. There has been an encouraging response to this movement, but of course it is still at a very early stage of development.

There is little information on the growth and physical development of Indian children, according to the latest annual report of the Nutrition Research Laboratories at Coonoor. However, a start has been made. Workers at the Coonoor Laboratories first analysed data in the literature on 46,000 boys from various parts of India, and from this prepared growth curves for them. Then a homogeneous group of about 2,000 boys were examined from around Coonoor, and their growth curve was found to correspond closely to that derived for India as a whole. But, what is more interesting, these curves were found to parallel, though at a slightly lower level, recent growth curves for British and American boys. The report poses the question of the influence of nutrition in producing the lower growth progression found in the Indian children.

TREATMENT OF POLYCYTHAEMIA WITH RADIOACTIVE PHOSPHORUS

BY

J. B. HARMAN, F.R.C.P.

Physician

P. L. de V. HART, M.R.C.P.

Formerly Senior Registrar

AND

E. M. LEDLIE, M.B., B.S., D.M.R.

Clinical Research Radiotherapist

The Royal Marsden Hospital

Polycythaemia was first treated by radioactive phosphorus (P^{32}) in 1940 by Lawrence, who has reported 201 cases dealt with since that time (Lawrence *et al.*, 1953). Two reports have already been made in this country, comprising 20 cases (Bodley Scott, 1953) and 27 cases (Abbatt *et al.*, 1954). P^{32} was used in the Royal Marsden Hospital at the end of 1948, and 48 cases have been treated since then. Our purpose is to draw attention to the benefits that may be expected and to comment on certain features of the symptomatology and course.

Radioactive phosphorus is prepared by the irradiation of pure sulphur, and is obtained as a solution of orthophosphoric acid. It has a half-life of 14.3 days, but excretion of part of the administered dose in the urine reduces its effective half-life in the body to about 10 days.

When P^{32} is administered the phosphorus participates in the general biochemical reactions of the body. A large amount is incorporated into those cells in which proliferation is most active, because this is where the turnover of phosphorus is greatest. One of the most active tissues in this respect is the bone marrow, and this activity is increased when there is marrow hyperplasia as in polycythaemia or leukaemia. The injection of radioactive phosphorus therefore provides a method of irradiating the overactive haemopoietic tissues more selectively than can be done with external irradiation.

Dosage

The patient is admitted to hospital. The P^{32} is injected intravenously as a solution of sodium phosphate. There are no side-effects and no irradiation reactions have been observed, even following the administration of the maximum dose. After the P^{32} has been given, the urine is collected and its radioactivity measured. The patient is discharged from hospital when the excretion has reached a safe level (100 mC in 24 hours), which in practice means two to three days after the injection.

Two methods of P^{32} dosage have been employed. At first all patients were treated by a "split" dose—that is, two injections of P^{32} at an interval of about two months. Subsequently it was thought that a single injection would probably be sufficient for some patients, and both methods are now used according to the severity of the disease. The split dosage was used for 28 patients, with an interval of 6-12 weeks between the injections. The dose was usually 5 mC followed by 4 mC. The smallest amount given in the two injections was 6 mC and the largest 12 mC. A single injection was given to 16 patients as the first treatment. The dose varied between 4 and 7 mC, according to the severity of the symptoms and haematological findings. The single dose is more convenient, and, since there is no obvious difference

in the results, it is used whenever possible, and almost always in the treatment of relapse. Further treatments are usually required every one or two years throughout the duration of the polycythaemia. The largest total amount of P^{32} given to one patient to date is 36 mC.

The inhibition of the bone marrow persists in most cases for a year or more. But the effect on the circulating red-cell mass, and hence on the symptoms, becomes apparent only gradually, in the course of two to three months. If this period of gradual improvement is added to the period of gradual worsening before treatment is again worth while, it may be found that a patient who needs treatment once a year is properly controlled for only two-thirds of the time. In order to shorten the period of improvement we have done a massive venesection at the same time as injecting P^{32} on 48 occasions when the patient has had a notably high red-cell mass. This is made possible only by a simultaneous infusion of a plasma substitute to prevent shock and heparinization to keep the blood flowing. By this means it is possible to bring the haemoglobin down to a normal figure in one operation. The most that has been removed is 5 litres, replaced by 3.6 litres of dextran: the haemoglobin fell from 155% to 94%. It has been found best to reduce the haemoglobin to slightly below normal, since the excretion of plasma substitute in the next 48 hours usually causes it to rise again by about 10%. The replacement should be a half to one litre less than the quantity withdrawn; a rise of pulse rate shows that insufficient plasma substitute is being replaced. It is advisable to keep the patient in bed for a day and forbid solid food, lest fainting or nausea occur.

Present Series

The distribution by age and sex is shown in Table I. It is very difficult to determine the age at which polycythaemia develops, since for a time there may be no symptoms, and

TABLE I.—Age When First Seen at the Royal Marsden Hospital

Age:	30-39	40-49	50-59	60-69	70-79	80+	Total
Male	3	5	8	5	2	1	24
Female	1	4	3	10	5	1	24
Total	4	9	11	15	7	2	48

even when they occur they are often too mild to send the patient to a doctor. For example, a woman first diagnosed at the age of 39 said she had had symptoms since adolescence, and it was clear that her symptoms were due to polycythaemia. Perusal of the histories suggests that the disease was present for an average of four to five years before it was diagnosed.

The frequency of the various symptoms is shown in Table II.

TABLE II.—Main Symptoms of Above 48 Cases

	Cases	%
High colour	48	100
Haemorrhagic phenomena	27	56
Dyspepsia: all cases	17	35
cases with D.U. on x-ray film	6	12
Splenic pain	14	29
Pruritus	17	35
Thrombosis: venous	8	17
arterial	9	19
Dyspnoea, headache, dizziness, etc.	10	21
Ulceration, chronic sepsis, or gangrene	9	19

The high colour is most evident on the face, but is here an unreliable diagnostic guide. It is best to examine the conjunctivae, tongue, nail-beds, and especially the palms of the hands, in which high colour is at least as reliable a guide as an isolated blood count. A complaint of red eyes was not uncommon, and a few patients had been treated for "conjunctivitis" over many months; but soreness was present in only one case. Telangiectases were common on the cheeks. The heightened colour has a distinct purplish tinge, which is, in fact, the natural colour of concentrated oxyhaemoglobin and is not necessarily due to the presence of reduced haemoglobin.

Thromboses and haemorrhages were both common. Arterial thromboses were found in those sites where their occurrence is most easily detected—that is, in the retina, internal capsule, pons, and the coronary, femoral, and popliteal arteries. Venous thromboses were common in the legs. Haemorrhages occur from the nose, upper and lower gastro-intestinal tract, ruptured varicose veins, gums, and as ecchymoses. Prolonged bleeding is also apt to occur after dental extractions and operations. Both thromboses and haemorrhages might occur at the same time, with a normal or high platelet count and no demonstrable abnormality of coagulation or prothrombin generation. It is probable that the haemorrhages are due to some capillary abnormality.

Dyspepsia had the usual characteristics of peptic ulcer, and a duodenal ulcer was demonstrated in 6 of the 17 dyspeptics. Pruritus was usually generalized and always worse in the palms and soles; it is aggravated by a hot bath. Chilblains, ulceration, sepsis, and partial gangrene of the toes were common and occurred in cases with apparently normal vessels. Other symptoms commonly complained of were dyspnoea, faintness, palpitations, headache, thumping in the head, dizziness, fatigue, lethargy, and a congested feeling in the face and head. Splenic pain was due either to infarction or to the weight of the tumour. The spleen was definitely enlarged in 27 of our cases and was below the umbilicus in 9.

Haematology

The most reliable measures of red-cell concentration both at the Royal Marsden Hospital and elsewhere have been the haemoglobin or packed cell volume. The red blood cell count has commonly been extremely variable and unreliable, which is probably due to the difficulty of homogenizing samples properly. No patients were regarded as polycythaemic unless the readings were well above normal—for example, Hb, 130%; P.C.V., 60%; R.B.C., 7,000,000. As is well known, there is usually an increase of polymorphs, with a few metamyelocytes, and less often of platelets. These associated changes are best seen in marrow puncture or biopsy.

Blood Volume

The ordinary methods of haematology measure the concentration of red cells or haemoglobin, and in polycythaemia the concentration is of course raised. The essential pathological change, however, is an increase in the red cell mass, and this can be deduced from measures of concentration only if it is known that the plasma volume remains constant. It would therefore be desirable to have simple and accurate methods of measuring both the red-cell mass and the plasma volume that could be used in clinical medicine. Unfortunately, the measurement of blood volume is attended by considerable theoretical and practical difficulties. Until recently the usual method was to measure the plasma volume by dye dilution and to deduce the red-cell mass from the haematocrit. Radioactive tagged protein fractions of normal plasma can now be used. The plasma volume, however, is not a constant quantity, because water passes in and out of the capillaries in various states of body activity. The same applies to some extent to any substance used as a marker. Moreover, the venous haematocrit is not an accurate measure of the proportion of cells to fluid in the vascular system as a whole. The ratio of cells to fluid is different in arteries, capillaries, and veins, where the rate of flow is different, and the distribution in these compartments will also vary with differing states of body activity. It is, however, now possible to measure the red-cell mass directly by tagging cells with radioactive iron, phosphorus, or chromium. These measurements are simple and fairly accurate, and so the plasma volume is best deduced from the red-cell mass and haematocrit, using appropriate correction factors.

These observations may be sufficient to show why there is no wide and accurate knowledge of blood-volume changes in polycythaemia. It is generally thought that the plasma

volume tends to be unchanged or even to be diminished as the red-cell mass increases until high haematocrit levels (55% $\pm$) are reached (Mollison, 1951). Our limited observations show that this is usually true, though patients with high haematocrit levels (over 75%) may also have a low or normal plasma volume. Measures of the red-red concentration, by haematocrit or haemoglobin estimations, are therefore usually proportional to the red-cell mass, but this is not always the case. One of our patients has a greatly increased plasma volume, so that he is plethoric though not polycythaemic as ordinarily defined.

We have found that the chromium method is simple to use and consistent in its results, and we are now defining normality in this way. Patients with normal concentration may still retain a plethoric appearance of the face, eyes, and especially of the palms. This does not indicate a raised total blood volume, but is due to an irreversible dilatation of the skin venules.

Diagnosis

The long time that elapsed before some of our cases were diagnosed suggests that polycythaemia is not always readily detected—which is probably due to its rarity or to unfamiliarity with the symptoms.

Once polycythaemia has been recognized there appears to be little difficulty in distinguishing cases that are secondary to heart or lung disease. Doubts may exist where there is emphysema and no splenomegaly, but they are usually settled by the state of the bone marrow. A mistake was made in a man who had gout, nephritis, and multiple arterial abnormalities. Despite his normal marrow he was eventually treated with P^{32} 3 mC and venesection, which threw him into right heart failure. Cardiac catheterization showed that he had a persistent ductus with flow reversed owing to pulmonary hypertension.

Cases are not accepted for treatment unless they are actually polycythaemic when seen. In some cases the only evidence presented has been a raised red-cell count, which is fallacious. It is also just possible that long remissions may occur naturally or with conventional treatment—one man, a roving Irish labourer, had been treated for 13 years at six different hospitals with venesections and phenylhydrazine, but was quite normal for the year and a half that we observed him. Two other patients who undoubtedly had a marrow dysplasia were diagnosed for many years as cases of polycythaemia, which they may well have had; but they had none with us, and one became leukaemic and the other is probably developing myelofibrosis.

Course and Prognosis

The natural history of polycythaemia is probably not completely known. The disease is not common, its course is very long, and the sufferers have not previously been collected into special clinics. It is usually regarded as a disease of older persons that remains with them till they die or are killed by a stroke, which is the natural termination of the disease. This is true of most cases, but exceptions are common enough to deserve mention. The early age at which it may occur has been noted. The other exceptions are those that develop leukaemia or myelofibrosis.

Transition into myeloid leukaemia is not uncommon; the change from leukaemia to polycythaemia is rare but has occurred in our series. Others become anaemic owing to replacement of the bone marrow with reticulum cells or fibroblasts. Anaemia may also be due to haemolysis, which can be stopped by splenectomy as in leukaemia and lymphadenoma. In some cases the erythropoietic tissue is not confined to the bone marrow, but is found in the liver and spleen, and may even form sizable discrete tumours elsewhere which erode bone. The production of polymorphs and platelets is usually both increased and abnormal, and in

some the platelet level is so high that the diagnosis of essential thrombocythaemia might have been made with equal justification.

Observations of this sort have made it impossible to maintain concepts of polycythaemia, leukaemia, myelofibrosis, and so on as separate diseases, though the terms are retained for convenience. The present tendency is to regard them as possible manifestations or phases of a neoplastic disease that affects primitive mesenchyme cells. Although polycythaemia may be but a phase, it is clearly one that is both stable and benign, so that once patients enter into it they are likely to remain in it for the rest of their lives.

These considerations have some bearing on treatment, especially with radiation. Radiation can play a part in the causation of both leukaemia and marrow aplasia. Can it be held responsible for the leukaemia and myelosclerotic terminations of polycythaemia? Leukaemia is known to supervene without radiation therapy, and it has been estimated that its frequency is no greater after P^{32} (Lawrence *et al.*, 1953; Stroebel, 1954). One of our cases became leukaemic, and another is probably going that way. The evidence for myelosclerosis is less certain because of its rarity. But cases certainly occurred before the advent of P^{32} , and the replacement of erythroid tissue by reticulum and fibrous tissue, such as occurs with myelosclerosis, has not been seen after radiation aplasia. One of our cases developed myelosclerosis and another probably did.

Another point is that though P^{32} is indicated in the polycythaemic phase it may be harmful in another. Leukaemia usually develops quite suddenly, and there is no difficulty in detecting its onset. In contrast, the patients who are developing myelosclerosis appear at first to be in a satisfactory remission lasting a year or so. Eventually the blood count sinks below normal and they die despite transfusions. We have been somewhat uneasy about five of our patients whose remissions have lasted more than two years. But two with the longest remissions, over three and over four years each, have now become polycythaemic again. It appears that a fall below the normal haemoglobin is the ominous feature, not the length of remission.

Effect of Treatment

The objects of treatment are to prevent disastrous vascular accidents in the central nervous system and to relieve the patient of annoying symptoms.

Our own observations are not sufficient to prove that major thromboses have been prevented, though none has occurred since treatment. Stroebel (1954) has shown from a ten-year study of 241 cases that the expectation of life is increased with treatment. Most symptoms are completely relieved when the blood count is controlled. This applies particularly to ulceration and sepsis of the toes, haemorrhagic phenomena, the various "congested" feelings, and splenic pain and enlargement. Pruritus has sometimes proved resistant. Dyspepsia has seemed to be improved, except where ulcers were present. In general all patients are better and most are symptomatically normal. Those who have had other forms of treatment are quite certain that P^{32} is both more effective and much more convenient despite the occasional admission to hospital that is required.

Most symptoms that are continuous, such as facial congestion, headache, dyspnoea, ulceration, and gangrene, are clearly due to the increased blood volume, since they are immediately relieved by an exchange venesection. Pruritus is diminished, but seldom completely, and tends to persist in the palms, especially after a hot bath. It is probably caused in part by the irreversible dilatation of the skin venules. We can draw no conclusions about haemorrhagic episodes, thromboses, and dyspepsia because they are too inconstant. The spleen diminishes slowly only when the P^{32} has had time to act. It became impalpable in 10 of the 27 cases in which it was enlarged.

Commentary on Cases

Group I: Observed for More than One Year.—(A) *Successfully treated* (29 cases). Of these, 17 have had more than one treatment. The average length of remission was nearly two years. The longest was four and a half years and the shortest nine months. Of the 12 cases which have had only one treatment the longest remission is three and a half years. (B) *Inadequately treated* (5 cases). Two of these were young men with severe and resistant polycythaemia. One has received 36 mC of P^{32} in four years and the other 17 mC in four and a half years. Possibly this dosage was unnecessarily cautious. Two were elderly women who had difficulty in attending regularly. The last was a man of 49 in whom remissions have been short and incomplete for over three years. Although his haemoglobin is now normal he still has a large spleen and a raised blood volume.

Group II: Observed for Less than One Year (7 cases).—These cases look like doing well, though it is too soon to be certain.

Group III: Dead (4 cases).—(1) Female aged 63 with over 10 years' history. Between 1949 and 1953 she was given 20 mC of P^{32} in three episodes with good remissions. After the last she gradually became anaemic and died from acute myeloid leukaemia. (2) Male aged 42. Severe polycythaemia was treated with 13 mC of P^{32} . A year later the patient became anaemic and died, according to reports, from

myelosclerosis. (3) Male aged 66. Admitted to hospital with a cerebral thrombosis in 1947. Severe polycythaemia was diagnosed and he was treated by bath irradiation to the trunk (4.2 m.g.r.). In 1948 he was given 4 mC of P^{32} with no effect, and he died elsewhere four years later with polycythaemia. (4) Male aged 77. Diagnosed 1948. Given 7 mC of P^{32} in 1950. Remission for two years was followed by anaemia due to myelofibrosis and haemolysis, of which he died six months later.

Group IV: Insufficiently Followed Up (3 cases).—These patients attended too irregularly for any conclusion to be drawn about the effect of treatment.

Summary

A group of 48 patients treated with radioactive phosphorus is described. In severe cases the blood concentration was brought to normal by a massive venesection and simultaneous infusion of plasma substitute.

The presenting symptoms and general course of the disease are reviewed. Observation over a period of up to six years shows that the blood concentration can be kept at or near normal in most cases. When this is done symptoms are relieved. Relief may last from just under one year to over four years, with an average of just under two.

The haemoglobin chart of four illustrative cases. P means the injection of radiophosphorus and the figure in brackets is the dose in millicuries. V means a venesection; the figure is the amount in litres removed, a smaller amount of dextran being replaced.

Case I.—Good control. A woman now aged 68. She is sensitive to small doses of P^{32} (5 and 4 mC). Note that the fall to normal is quicker with venesection and P^{32} than with P^{32} alone. She was out of control in the winter of 1952-3. This is the only case in which the haemoglobin level fell below 100%.

Case II.—Bad control. A man now aged 38. Note the absence of visible effect of 9 mC of P^{32} in 1950. Haemoglobin brought to normal in 1951 by a large venesection, but continues to range around 130% despite subsequent treatments. Total dose of P^{32} was 36 mC and probably should have been more. Nevertheless he is much better for treatment.

Case III.—Good control. A woman now aged 70. Remission of over four years after 8.4 mC of P^{32} , which is the longest we have seen. Note that the haemoglobin did not fall below normal despite the long effect of P^{32} .

Case IV.—Good control. Man now aged 73. A very severe case, but easily treated. The haemoglobin has been kept normal for nearly six years. Note the sudden relapses in 1951 and 1953. The slow rise of haemoglobin in 1954 is of a different type. The small dose of P^{32} in 1950 was possibly unnecessary.

This treatment is quite the most effective and is the least disturbing to the patient.

We would like to thank Professor D. W. Smithers, of the Radiotherapy Department, and Professor W. V. Mayneord, of the Physics Department, and members of their staffs, for making this work possible. We are also grateful to numerous colleagues in this and other hospitals for referring cases to us, and in particular to Dr. P. E. T. Hancock. The earlier cases in the series were treated by Dr. R. J. Walton, to whom we acknowledge our debt.

PROTHROMBIN AND THE ONE-STAGE PROTHROMBIN TIME*

BY

ARMAND J. QUICK, Ph.D., M.D.

AND

CLARA V. HUSSEY, M.S.

(From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wisconsin)

The discovery that the prolonged prothrombin time of stored human plasma was caused by the disappearance of a clotting factor, hitherto unrecognized (Quick, 1943), made it clear that prothrombin activity depended on more than prothrombin itself and that the one-stage procedure could no longer be regarded unequivocally as a specific test for this constituent. When it was subsequently established that the plasma contained a second prothrombin accessory factor (Alexander *et al.*, 1952), the need for a reinterpretation of the test was further emphasized. It is the purpose of this paper to present pertinent experimental and clinical observations that should be helpful for the re-evaluation of the test, and for furnishing at least a partial answer to several basic questions concerning the prothrombin time.

Methods and Materials

Since the purpose of this study is a critical evaluation of the one-stage prothrombin time, it is necessary to limit discussion to results obtained by the original rigidly standardized method (Quick, 1938). Of particular importance is the source and preparation of the thromboplastic reagent. Rabbit brain carefully cleared of blood and blood vessels and dehydrated with acetone not only has a high and constant activity but is devoid of both stable and labile factors.

In this study blood was collected with a silicone-coated syringe and needle and kept in test-tubes similarly coated. All clotting tests were carried out in uncoated glass test-tubes at 37° C. unless otherwise stated.

Tricalcium-phosphate-treated Plasma.—By means of this adsorbent, prothrombin and stable factor are quantitatively removed, while labile factor and fibrinogen remain unaltered. Since rabbit plasma is exceedingly high in labile factor, it serves as a good source for this agent as well as for fibrinogen. The preparation of the tricalcium phosphate

reagent and the procedure for deprothrombinizing plasma have been described in detail (Quick, 1951). Plasma treated with tricalcium phosphate is designated as "Ca₃(PO₄)₂ plasma." Stable factor was prepared by the method of Duckert, Koller, and Matter (1953). In many experiments aged serum from normal blood served as the supply of this factor.

Serum Prothrombin Time.—The blood or plasma was clotted in a glass test-tube at 37° C., centrifuged 15 minutes after a solid clot had formed, and reincubated for an additional 45 minutes. The prothrombin time was carried out as follows: 0.1 ml. of fresh rabbit plasma deprothrombinized with Ca₃(PO₄)₂ was mixed with 0.1 ml. of 0.02 M CaCl₂ and 0.1 ml. of thromboplastin reagent (from rabbit brain). To this mixture 0.1 ml. of the serum was blown in and the clotting-time determined. In this procedure the deprothrombinized rabbit plasma supplies both fibrinogen and stable factor.

Three patients with true congenital hypoprothrombinaemia were available for this study. Two are brothers whose prothrombin times have remained 19 to 26 seconds for the past seven years. The third is a girl whose prothrombin time is 37 seconds. The patients have a normal concentration of labile factor and their prothrombin time is not shortened by stable factor. A patient with pure stable-factor deficiency was also utilized in this investigation. Her prothrombin time varies from 26 to 55 seconds, but is usually about 27 seconds. The addition of stable factor prepared according to Koller completely corrects the prothrombin time. A detailed study of these patients has recently been presented (Quick, Pisciotta, and Hussey, 1955).

For the sake of simplicity the terms "labile" and "stable" (factors) are employed. Labile factor may be considered to be synonymous with factor V or proaccelerin of Owren and ac-globulin of Seegers, while stable factor is probably the same as factor VII of Koller, proconvertin of Owren, S.P.C.A. of Alexander, stable prothrombin conversion factor of Owen, and co-thromboplastin of Mann.

Why is the Prothrombin Time Constant in Fresh Normal Plasma?

Few values of blood are as constant as the prothrombin time. It is consistently 12 seconds in normal subjects, in contrast to the wide variations of prothrombin concentration as measured by the two-stage method, which, according to Mann and his associates (1948), may vary from 244 to 452 units. While it is established that three agents—namely, prothrombin, and stable and labile factors—affect the prothrombin time, it remains to be determined which of these is specifically responsible for the 12-second value of normal blood. A rather convincing answer can be found from the results of Table I. It is to be noted that an excess of neither

TABLE I.—Effect on Prothrombin Time of Adding Excess Labile and Stable Factors to Normal Plasma and Plasma Deficient in These Accessory Agents

	Prothrombin Time (Seconds)		
	Original	With Excess	
		Labile Factor*	Stable Factor†
Normal plasma	12	12	11½
Stored plasma (labile factor deficient)‡	16	12	16
Plasma deficient in prothrombin	21	21	21
Plasma deficient in stable factor..	39	40	12

* To 0.1 ml. of plasma, 0.01 ml. of rabbit plasma deprothrombinized with Ca₃(PO₄)₂ was added.

† To 0.1 ml. of plasma, 0.01 ml. of aged serum prepared from normal blood was added.

‡ Stored in a silicone-coated test-tube for 24 hours at 4° C.

labile nor stable factor significantly shortens the prothrombin time of fresh normal plasma. After storage in a silicone-treated container for 24 hours, the prothrombin time is increased to 16 seconds. The addition of excess

labile factor in the form of deprothrombinized rabbit plasma corrects the prothrombin time to 12 seconds, whereas stable factor has no effect. The addition of labile factor does not correct the prolonged prothrombin time of plasma from a patient with congenital deficiency of stable factor, but a small quantity of aged serum, which has an excess of this factor, brings the value to exactly 12 seconds. Plasma with a prolonged prothrombin time due to a true deficiency of prothrombin is not corrected by an excess of either labile or stable factor.

These results clearly suggest that the concentration of prothrombin fixes the value of the prothrombin time, provided adequate amounts of labile and stable factors are present. Since excess of these accessory factors exerts a corrective effect only on those plasmas which lack the specific factor, it seems clear that a deficiency of any one is not compensated by an excess of the other two. The determinant of the prothrombin time is the component which decreases below a minimal critical level. In normal blood, labile and stable factors are in excess while prothrombin is the limited factor and, therefore, is the agent responsible for the prothrombin time. The constancy of the prothrombin time of fresh normal plasma can therefore be explained by assuming a fixed level of prothrombin.

Why Does the Prothrombin Time Change During Storage?

It is generally accepted that the increase of prothrombin time during storage is caused by a decrease of labile factor. Apparently, the rate of disappearance is related to the calcium-ion concentration, for it is much more when blood is mixed with one-ninth its volume of 0.1 M sodium oxalate or 0.2 M sodium citrate than with 0.1 M sodium citrate. The latter does not completely depress the concentration of ionized calcium and, as seen from the results recorded in Table II, no demonstrable amount of labile factor is lost in

TABLE II.—Changes in Prothrombin Activity of Normal, Prothrombin-deficient, and Stable-factor-deficient Blood During Storage

	Immediate	After 24 Hours' Storage	
		In Glass	In Silicone
Normal blood (9 volumes) and sodium oxalate 0.1 M (1 volume)	12	15	16
After adding labile factor ..	12	8	12
stable ..	11½	15	16

" " labile and stable factor ..	11½	9	12

24 hours. Significantly, with this anticoagulant no change in the prothrombin time occurs if the plasma is stored in a silicone-coated tube, but a marked decrease is observed when stored in glass. This rise in prothrombin activity can be explained either by an actual increase in prothrombin or by the generation of an accelerator. Irrespective of which explanation is correct, it is obvious that storage in glass increases prothrombin activity as measured by the one-stage test. Owing to the simultaneous decrease in labile factor, the increase in activity is usually masked. Thus the prothrombin time of oxalated plasma after 24 hours' storage in glass is 15 seconds, but when labile factor is added it decreases to 8 seconds. The plasma in the silicone-coated test-tube has nearly the same prolonged prothrombin time, but labile factor reduces it only to 12 seconds. This suggests that the generation of prothrombin activity is slower in silicone than in glass.

When oxalated plasma deficient in stable factor is stored the prothrombin time is further increased in both glass and silicone. If labile factor is added, a partial correction occurs, whereas the addition of stable factor caused no shortening. When both labile and stable factors are added the prothrombin time is reduced to 8 or 9 seconds. Plasma from a patient with true hypoprothrombinaemia likewise, when stored, exhibits a further prolongation of the prothrombin time which is partly corrected by the addition of labile factor. Stable factor has no corrective action.

From these results one may conclude that if the increase in the prothrombin activity of stored plasma is caused by the generation of an accelerator, it is produced independently of either labile or stable factors. It is significant that plasma which lacks prothrombin shows only a small increase in activity on storage and that neither stable nor labile factors bring the prothrombin time to normal. Two basic causes account for changes in the prothrombin time of stored plasma: the first is a loss of labile factor, the second is either an actual increase of prothrombin or the generation of an accelerator independent of either labile or stable factors. In the absence of labile factor the increase of this prothrombin activity is masked.

Why is the Prothrombin Time of Serum from Haemophilic or Thrombocytopenic Blood Shorter Than That of Plasma?

When plasma deprived of platelets by means of high centrifugation or obtained from subjects having thrombocytopenia or haemophilia is clotted in glass, the serum has a prothrombin time of 8 seconds provided the plasma is normal—that is, gives a value of 12 seconds (Table III). It is certain that the poor consumption of prothrombin explains in

TABLE III.—Prothrombin Time of Plasma and Its Corresponding Serum in Haemophilia and Thrombocytopenia

Type of Plasma	Platelet Count	Prothrombin Time		
		Of Plasma	Of Serum	Of Stored Plasma with Labile Factor Added
Haemophilic ..	300,000	Sec. 12	Sec. 8	Sec. 8
Thrombocytopenic ..	65,000	12	9½	8
Normal (highly centrifuged) ..	3,000	12	8	8
Hypoprothrombinaemic (congenital) ..	270,000	20	180+	16
Congenital hypoprothrombinaemia (highly centrifuged) ..	3,500	20	20	16
Stable factor deficient ..	250,000	27½	73	18½
"centrifuged" .. (highly)	3,000	27½	19	18½

part the short prothrombin time, but does not account for a value of 4 seconds less than that of the fresh plasma. Since the same decrease occurs in plasma stored in glass to which excess labile factor is added, one may conclude that a common mechanism is responsible for the increased prothrombin activity. As already stated, the most obvious explanation is either an actual increase in prothrombin or the generation of an accelerator.

When one compares the prothrombin time of the serum obtained from normal blood with that of blood from a patient with true hypoprothrombinaemia, one finds that the serum prothrombin becomes extremely prolonged in the latter and only to 20 seconds in the particular normal blood used in this experiment. When blood from the hypoprothrombinaemic patient is highly centrifuged and the resulting plasma clotted, the serum has about the same prothrombin time as the serum, thus suggesting that either little new prothrombin is formed or little accelerator is generated.

The results obtained on blood lacking stable factor are particularly interesting. With an adequate supply of platelets the consumption of prothrombin as measured by the serum prothrombin time is fairly high, indicating that

*This work was supported by a grant from the National Heart Institute, National Institutes of Health, United States Public Health Service.

deficiency of stable factor does not prevent normal utilization of prothrombin. When stable factor is added in determining the prothrombin time of the serum a value lowered to normal is obtained, thus showing that the serum does not contain adequate amounts of the factor to assure an accurate prothrombin time. Even more striking are the results when the stable-factor-deficient and platelet-poor plasma is clotted. The serum shows a prothrombin time less than that of the plasma but still markedly prolonged. The addition of stable factor brings the prothrombin time to 9 seconds. Since the addition of a fixed amount of stable factor corrects the prothrombin time of the fresh plasma from the patient with pure stable-factor deficiency to 12 seconds and the serum from the platelet-poor plasma to 9 seconds, it is obvious that these two values are not fixed by the stable factor. The results obtained on the serum from true hypoprothrombinæmic plasma suggest that the serum prothrombin time is closely related to the prothrombin concentration.

The answer to the question heading this discussion is: The prothrombin time of serum from haemophilic or thrombocytopenic blood is shorter than that of the corresponding plasma because almost no prothrombin is consumed and, in addition, there is formed either additional prothrombin or an accelerator independent of labile or stable factors.

Why is the Prothrombin Time of Blood of Newborn Babies Normal When Measured by the One-stage Method and Low by the Two-stage Procedure?

If it is possible to answer this question satisfactorily a real advance should be made in clearing the confusion concerning the interrelationship of prothrombin and accelerators. The original study of Brinkhous, Smith, and Warner (1937) established that the prothrombin is only about 30% as high in newborn as in adult blood. Equally as incontrovertible is the fact that the prothrombin time is 12 seconds in almost all newborn infants whose mothers had adequate amounts of vitamin K (Quick, Murat, Hussey, and Burgess, 1952). Warner, Brinkhous, and Smith (1939) explained this difference by postulating a change in convertibility of prothrombin. Later, the discovery of the labile and stable factors made it appear probable that these accessory factors might in some way be accountable for this striking discrepancy. The finding that the labile factor is normal in newborn blood (Quick, Flood, and Hussey, 1953; Owen and Hurn, 1953) eliminates this agent from consideration. The report of Loeliger and Koller (1952) that the stable factor is reduced in newborn blood clearly shows that it cannot be the agent that compensated for the lack of prothrombin and thereby normalizes the prothrombin time.

The results of a few simple experiments recorded in Table IV offer pertinent information. While the prothrombin time of newborn plasma is 12 seconds, which is the same as

TABLE IV.—Comparison of Prothrombin Activity in Adult and in Newborn Blood

	Prothrombin Time	
	Adult	Newborn
1. Fresh plasma	12 sec.	12 sec.
2. Stored plasma*	9 "	12 "
3. Serum from platelet-poor plasma	8 "	12 "
4. Plasma diluted with equal volume of saline	15 "	15 "
5. Plasma diluted with equal volume of $\text{Ca}_2(\text{PO}_4)_2$ -treated plasma	12 "	15 "

* In glass at 4° C. for 24 hours with 0.1 M sodium citrate.

that of adult plasma, it fails to show the characteristic shortening of the latter on storage. Likewise, the prothrombin time of serum prepared from platelet-poor newborn plasma is not 8 seconds, as is the serum from platelet-poor adult plasma, but is 12 seconds, which is the same as the original plasma.

Earlier it was pointed out that the increase in prothrombin activity of adult plasma on storage or in serum from platelet-poor plasma could be explained by postulating either an actual increase in prothrombin or by the evolution of an accelerator. From the results obtained on newborn plasma

it is clear why the first is the more likely explanation. According to the two-stage test, the prothrombin of newborn blood is only about one-third of that in adult blood. Since no evidence of an accelerator in newborn blood has been demonstrated, it seems quite plausible that the augmented prothrombin activity in adult blood is caused by an actual increase in prothrombin derived from an inactive precursor that may be designated as prothrombinogen. According to this hypothesis, newborn blood lacks this precursor, and this accounts for the low prothrombin obtained with the two-stage method. The one-stage method specifically measures active prothrombin and is unaffected by prothrombinogen.

Further support for the concept is obtained from the results of experiments 4 and 5 of Table IV. If either newborn or adult oxalated plasma is diluted with an equal volume of saline the prothrombin time is increased to 15 seconds. If, however, plasma treated with $\text{Ca}_2(\text{PO}_4)_2$ is used as the diluent, the prothrombin time of adult plasma remains 12 seconds, whereas that of the diluted newborn plasma is 15 seconds. Apparently, $\text{Ca}_2(\text{PO}_4)_2$ -treated plasma contains a factor which can convert inactive prothrombin to the active state. Since newborn plasma is devoid of prothrombinogen, the addition of the deprothrombinized plasma cannot increase the active prothrombin, and therefore the prothrombin time becomes prolonged to 15 seconds, the same as is obtained by dilution with saline.

To present the hypothesis in an easily comprehensible form one may visualize prothrombinogen as prothrombin kept inactive by an inhibitor, "X." On storage the inhibitor deteriorates, thus liberating prothrombin, which accounts for the increased prothrombin activity. Plasma treated with $\text{Ca}_2(\text{PO}_4)_2$ contains an agent which can activate prothrombinogen presumably by removing the inhibitor. If the factor be designated "Y" one can postulate an equilibrium according to the following equation:

This is undoubtedly an oversimplification, but the essential idea offers a logical answer to the four basic questions presented. It appears to be the Y factor which fixes the level of free prothrombin in human blood, and therefore it is the basic determinant of the prothrombin time. There is evidence that the concentration of this agent is determined by heredity. A family has been reported in which a mother and two of her children have a prothrombin time of 16 minutes, due presumably to a lower-fixed concentration of factor Y (Quick, Flood, and Hussey, 1953).

According to the present findings, the answer to this fourth question is: The newborn plasma has a normal prothrombin time because it has a normal concentration of free prothrombin, but it has a lower prothrombin as measured by the two-stage method because it is devoid of prothrombinogen. Its total prothrombin content which the latter test measures is much lower than in adult blood.

Relation of Haemorrhage to Prothrombin Time

In the early study of poisoning from spoiled sweet clover hay it was observed that a heart puncture caused fatal haemopericardium whenever the rabbit's prothrombin time was markedly prolonged (Quick, 1937). Later it was shown that a puncture caused fatal bleeding when the prothrombin time was 24 seconds or longer (Quick, Honorato, and Stefanini, 1948). Interestingly enough, these findings correspond remarkably well with human findings. Two boys who have a prothrombin time varying from 19 to 26 seconds due to congenital true hypoprothrombinæmia have a rather mild but distinct bleeding tendency. A girl of another family who has a more severe deficiency of prothrombin, with a prothrombin time of 35 seconds, has a much more severe bleeding condition. A woman aged 50 who has a prothrombin time which varies from 27 to 51 seconds due to a pure deficiency of stable factor has a rather mild bleeding history.

The exact relation of the prothrombin time to haemorrhage in the human is difficult to determine. In most types

of coagulation defect bleeding does not occur unless induced by trauma. Even a severe haemophilia with a clotting-time over one hour may have no bleeding episodes for long periods. Since the newborn infant with a normal prothrombin time but a low prothrombin as measured by the two-stage method can undergo surgery with impunity, one can conclude that the one-stage method is the more reliable in that it measures the fraction of prothrombin that apparently participates directly in haemostasis.

Discussion

A hypothesis has been offered to help answer four basic questions concerning the prothrombin time. The central idea is that the prothrombin in adult blood is present partly in the active form and partly as prothrombinogen. The one-stage method measures only the active prothrombin, while the two-stage test determines total prothrombin—that is, both the active and the inactive fractions. The early studies of Bordet (1919) already indicated the possibility of inactive prothrombin. He concluded that all of the prothrombin was in the precursor state, to which he gave the name proserozyme. The concept of Warner *et al.* (1939) of an altered convertibility of prothrombin is in accord with the basic concept provided one reinterprets convertibility. It is unlikely that the prothrombin molecule can have gradations of convertibility. There is a much greater probability that the convertibility follows the all-or-none law. It is either entirely non-convertible—that is, in an inactive state—or fully convertible, and the apparent convertibility actually is the ratio of free to total prothrombin. The higher the percentage of free prothrombin, the greater will appear to be the convertibility.

Whether the hypothesis is accepted or not, it must be recognized that the prothrombin time of plasma is easily altered by relatively simple factors such as contact with glass. Any modification of the original procedure is apt to measure something different from what is present in the plasma immediately after removal from the vein. Modifications designed to measure prothrombin specifically deserve particular scrutiny. Contrary to the claims that the prothrombin time is not a measure of prothrombin, it can be argued from the evidence presented in this paper that it is actually the only method which determines active prothrombin. It is to be emphasized that the one-stage and two-stage methods do not measure the same thing in human blood, and therefore there is no justification to use the two-stage procedure as the criterion to evaluate the one-stage test. Since deficiency of stable and labile factor can easily be detected and the test corrected accordingly, the one-stage method continues to remain the simplest and probably the most reliable means to determine prothrombin.

Summary

In this study evidence is offered to show that the constancy of the prothrombin time of fresh normal human plasma is due to the fixed concentration of active prothrombin. The increase of prothrombin activity during storage and during the clotting of haemophilic or platelet-poor plasma can be explained simply by the assumption that adult blood contains in addition to active prothrombin a high concentration of inactive prothrombin (prothrombinogen) which does not influence the one-stage method but is measured by the two-stage test. During storage or clotting the precursor is converted to active prothrombin, which in the hypoprothromboplasmic states is not consumed and therefore accumulates. Newborn blood contains a normal concentration of active prothrombin but is devoid of prothrombinogen, which accounts for the normal prothrombin time but the low prothrombin as measured by the two-stage test.

CARDIAC GLYCOSIDES IN THE TREATMENT OF CARDIOGENIC SHOCK

BY

RICHARD GORLIN, M.D.

Chief Medical Resident, Peter Bent Brigham Hospital,
1953-4

AND

EUGENE D. ROBIN, M.D.

Chief Medical Resident, Peter Bent Brigham Hospital,
1954-5

From the Medical Clinics, Peter Bent Brigham Hospital,
and the Department of Medicine, Harvard Medical
School

Myocardial infarction complicated by severe shock is usually attended by a mortality estimated as high as 93% (Rosenbaum and Levine, 1941). Numerous forms of therapy have been advocated for this serious complication, including vasopressor agents, transfusions, and cardiac glycosides (Hellerstein and Brofman, 1951). The use of the first two agents has been fairly well clarified in the past five years, but the role of cardiac glycosides, in the absence of overt or predominant congestive failure, is as yet unsettled.

Four cases are presented to illustrate the specific use of the cardiac glycosides in the treatment of cardiogenic shock, and in so doing to demonstrate survival from the usually lethal combination of pulmonary oedema and shock.

Case 1

A 60-year-old undigitalized hypertensive man entered hospital in shock. He had had a previous myocardial infarction four years prior to admission. He collapsed on the morning before admission and was found to be cold, sweaty, cyanotic, and unresponsive. No blood pressure was obtainable. There were bilateral moist rales up to the scapulae. An electrocardiogram showed an acute posterior myocardial infarction with bizarre arrhythmias, including ventricular tachycardia, ventricular bigeminy, and auricular flutter. He was given 50 mg. of procaine amide hydrochloride ("pro-nestyl") intravenously, with conversion to a normal sinus mechanism. Treatment with intravenous noradrenaline raised the blood pressure to 100/80, but he remained unresponsive and in clinical shock. Slowing of the infusion resulted in an immediate fall in blood pressure. He was then given 0.4 mg. of lanatoside C intravenously. Thirty minutes later the heart sounds became more distinct, and he was able to speak and recognize his family. Blood pressure was maintained without vasopressors. Signs of congestion virtually

disappeared. He was given another 0.4 mg. of lanatoside C and appeared to be doing well. Approximately one hour after this dose he suddenly died. A pre-terminal electrocardiogram showed ventricular fibrillation. Post-mortem examination showed a fresh posterior myocardial infarction and pulmonary congestion.

Comment.—Shock and coma responded specifically to lanatoside C. Blood pressure was maintained without vasopressors. Death may have been related to a digitalis-induced arrhythmia.

Case 2

A 49-year-old white woman with disseminated lupus erythematosus had been on cortisone, 75 mg. daily, and had had severe hypertension, congestive heart failure, and angina pectoris. She was maintained on digitalis, 0.1 g. daily, but this had been omitted two days before admission. Five hours before admission she developed left anterior chest pain followed by acute dyspnoea and cyanosis. On admission to hospital she was found to have rales to the apices and gurgling respirations. The blood pressure was 250/138, pulse 152, respirations 40. An electrocardiogram showed left ventricular hypertrophy and a possible anteroseptal myocardial infarction.

The patient was treated initially with morphine, 10 mg., atropine, tourniquets, and a 250-ml. venesection, with a fall in blood pressure to 110 systolic. Pressure was maintained at this minimum level with phenylephrine hydrochloride ("neosynephrine") intravenously in 5-15-mg. doses. When the blood pressure was at its peak of 110 systolic the pulmonary oedema became worse; however, when the blood pressure became less than 90 the pulmonary oedema lessened, but the patient became unresponsive. As the hours wore on she remained in coma and pulmonary oedema at all blood-pressure levels. The pulse rate was 135 and the blood pressure could not be maintained above 100 mm. Hg. At this time ouabain was given intravenously in divided doses of 0.05 mg., to a total of 0.15 mg. Forty-five minutes after initiation of this therapy three things occurred: the patient awakened and became alert, the blood pressure was easily maintained at any level on phenylephrine, and despite the blood pressure being maintained at about 120 to 130 mm. pulmonary oedema cleared.

Comment.—In this patient shock and coma were successfully treated with ouabain. Vasopressor action was aided and supported by digitalization.

Case 3

A 65-year-old widowed white woman had had a known hypertension of 160/100, angina pectoris, and probably myocardial infarctions for fourteen months before admission. Twenty-four hours before admission she developed severe substernal pain with radiation down the left arm and sweating. These disappeared only to recur four hours before admission, and were associated with progressively severe dyspnoea and later with orthopnoea and cyanosis. The patient entered the emergency ward, where her blood pressure was 190/110, pulse 150, and respirations 40. She was cyanotic, foaming at the mouth, the veins were full, and rales were heard to the apices. A diastolic gallop and pulsus alternans were present.

Oxygen, 15 mg. of morphine sulphate intravenously, and a 300-ml. phlebotomy was given. On this treatment respirations were noted to be less laboured. However, about half an hour later the blood pressure fell to 100/80 with disappearance of peripheral pulses and she lapsed into coma. She appeared to be in clinical shock at this time. Thereupon 0.2 mg. of ouabain was given intravenously. The pulse rate dropped from 150 to 120 in 15 minutes and the pulse became strong. The blood pressure rose to 125/80 and she awakened. Half an hour after the administration of ouabain she had transient multi-focal ventricular premature beats, treated successfully with 250 mg. of procaine amide hydrochloride intramuscularly. She gradually recovered. An electrocardiogram showed left ventricular hypertrophy and

an anteroseptal infarct of uncertain duration. The sedimentation rate, white blood count, and blood sugar rose early with a fall in all three after the first two weeks, substantiating the clinical impression of myocardial infarction.

Comment.—This patient with shock and pulmonary oedema responded dramatically to digitalization. The dramatic clinical improvement probably cannot be attributed to the fall in heart rate from 150 to 120 because in the absence of mitral stenosis such a rate is seldom critical. The equivocal electrocardiogram is probably caused by the two prior infarctions.

Case 4

A 68-year-old white woman had been having exertional dyspnoea, chest pain, and paroxysmal nocturnal dyspnoea for two months. She was brought to hospital unconscious and slightly cyanotic. The skin was clammy and cool; blood pressure 280/140; pulse rate 130; respiratory rate 32. She had not been digitalized. There were rales to the apices and the veins were full. An electrocardiogram showed an anteroseptal infarct and auricular flutter. She was treated with oxygen, 10 mg. of morphine sulphate, and venesection without effect. The blood pressure fell to 120/70 and the typical picture of shock developed. Then 0.125 mg. of ouabain was given intravenously; in 20 minutes she was awake, with clearing of her chest and stabilization of blood pressure at 160/80 and a heart rate of 110. She was discharged four weeks later.

Comment

Herrick (1912), in his classic article on the subject, recommended the routine use of digitalis in myocardial infarction. Within the last 25 years, however, clinicians have been hesitant to use digitalis in myocardial infarction because (1) the tolerance of the experimentally infarcted heart to digitalis is decreased (Travell *et al.*, 1938), and (2) both digitalis and myocardial infarction increase the likelihood of ventricular irritability and arrhythmia, and their effects may be additive in the same patient (Goodman and Gilman, 1941). In 1951 Askey gave digitalis to half of a group of 100 patients with proved myocardial infarction. He failed to show any increased incidence of arrhythmia or sudden death in the digitalis-treated group. In fact, Gilson and Schemm (1950) administered digitalis for its classical contraindication—namely, ventricular tachycardia—with salutary results in four patients.

There appears to be general agreement regarding the use of cardiac glycosides for frank congestive failure complicating cardiac infarction, but whether these agents have any role in treating the shock of cardiac origin is less certain. Goodman and Gilman (1941) take a strong position in opposing its use as follows: "Digitalis is contraindicated during the first few days following an acute coronary thrombosis. The clinical picture is usually one of shock rather than congestive heart failure, and digitalis, by further decreasing cardiac output, may make the patient worse."

Recent haemodynamic studies have contributed much to an understanding of this problem. Clinical shock implies that the blood pressure in the arterial tree is much less than normal. The level of the blood pressure depends on the height of systemic resistance—that is, vasoconstriction or dilatation—and the level of the cardiac output. Either the resistance or the cardiac output is low when there is shock. It is only in a small group of patients that a low systemic resistance is seen. G. Lee (personal communication) has demonstrated in some patients with the severe pain of an infarction that there may occur a marked muscle vasodilatation with a concomitant normal cardiac output and resulting fall in blood pressure. Most patients, however, show vasoconstriction with an increased systemic resistance and a decreased cardiac output (Freis *et al.*, 1952).

The lowered blood pressure indicates either inadequate, although increased, constriction or a greatly depressed cardiac output, out of proportion to homeostatic compensation. This decrease in output is related either directly to the myocardium itself or to poor venous return consequent

upon decreased venomotor and muscle pump activity. This latter is seen in nitrite syncope and spinal anaesthesia. However, this possibility seems less likely because shock often exists in the presence of an elevated venous pressure, and the simple restoration of venous pressure by either position in bed or intravenous infusion is not usually effective. The decreased output, then, is probably the direct result of a decreased myocardial contractility (Corday *et al.*, 1949) with the consequent immediately limited ability of the heart to do work following myocardial infarction. The ultimate response of the heart will, of course, depend on the size of the area of infarction and ischaemia, although small infarcts may in and of themselves initiate shock. The whole pattern is a vicious cycle in that the low perfusion pressure occasioned by the myocardium results in poor coronary inflow, with further myocardial ischaemia and hypodynamic myocardial contraction (Wiggers, 1923).

Why the systemic resistance is not maximally increased is not clearly understood. Whether there is a vasomotor paralysis with poor cerebral flow is not known, but in this regard cardiogenic shock is similar to traumatic shock. The first line of defence, then, is to further increase this systemic resistance and decrease the vascular bed to be perfused. The second line of defence is to increase the stroke work of the heart and hence perfusion pressure and minute output. Here has rested the controversy.

Harrison (1939) was among the first to call the shock of coronary thrombosis forward failure and thus semantically implicate the myocardium itself. Stead and Ebert (1942) reported six cases of myocardial infarction resulting in shock. One patient received ouabain and there was an increase in the blood pressure, although the patient subsequently died. Boyer (1944) stated that the shock and the pulmonary oedema syndromes were simply different stages of the same myocardial insult, and perhaps digitalis should be used in both conditions. Fink *et al.* (1953) described the cases of 10 patients in varying degrees of shock who had received lanatoside C. Their criterion for the use of this agent was an elevated venous pressure, suggesting that in such cases shock was myocardial in origin. In every case, despite the ultimate outcome, the blood pressure rose following digitalis administration while the venous pressure was variably affected. It is noteworthy that three of their patients had nearly normal venous pressure and still showed improvement in arterial blood pressure.

Lee (personal communication) demonstrated the fallacy of accepting normal venous pressure as an index of minimal right ventricular failure in patients with myocardial infarction. Although the venous pressure was normal, the gradient between veins and right atrium had disappeared and the right atrial pressure was higher than normal. Finally, studies by Sarnoff *et al.* (1954) have shown that the production of simple haemorrhagic shock in normal dogs results in elevation of left atrial pressure, while right atrial pressure is normal. These experimental observations fit well with the clinical fact that many patients with myocardial infarction have normal venous pressures, yet show pulmonary congestion first by x-ray examination and finally at necropsy (Friedberg, 1950).

Our own clinical reports support the above-presented evidence. The effect of the cardiac glycosides is not only to improve the stroke output of the heart but to increase its ability to deliver the blood against the increased peripheral resistance. The first patient demonstrated clearly that a normal arterial pressure could be maintained solely by digitalis. The second patient demonstrated that increased blood pressure could be delivered by the heart when digitalized optimally, and that this could be done without the production of pulmonary oedema. Similarly, shock was averted solely by the use of ouabain in two patients who had the combination of shock and pulmonary oedema. It is particularly noteworthy that all four patients had been in coma as well as shock; two received vasopressors without effect, yet came out of coma without change in blood pressure following cardiac glycoside, and one patient no longer

had pulmonary oedema yet maintained an increased arterial pressure. This suggested that cerebral and coronary blood flows were probably increased.

This is not to propose the standard use of the cardiac glycosides in myocardial infarction, but rather to re-emphasize that so-called cardiogenic shock is a manifestation of forward failure. Clinical methods of defining failure of the left ventricle are poor, and the right ventricle seldom manifests gross failure early in acute myocardial infarction. Finally, patients not previously in failure and with normal blood volumes may not develop massive right-sided congestion. Because overt evidence of failure is frequently absent, therapy in this type of shock is seldom aimed at the heart itself.

It is recommended that an orderly therapeutic problem might include the following: (1) morphine sulphate for pain; (2) position in bed for its effect on blood pressure and venous return; (3) phlebotomy for elevated venous pressure; (4) vasoconstrictor agents for increasing systemic resistance and arterial pressure; and (5) cardiac glycosides for increasing stroke work and with it cardiac output and arterial pressure. Each should be tried in additive succession—realizing the physiological contribution of each agent—that is, how digitalis may support the pressor response to phenylephrine hydrochloride as in Case 2. Digitalis is still a potentially dangerous drug and should be used only when the indications are clear cut. The dose is important in avoiding acute toxicity. We achieved therapeutic responses with 25-50% of the generally accepted effective dose of ouabain (Friedberg, 1950). The first patient may have died in a fashion temporally related to digitalis intoxication, and the third patient developed premature bigeminal beats thirty minutes after a remarkable therapeutic effect had been achieved. We recommend small doses of intravenous glycoside. Ouabain has not been a dangerous agent in our hands because we have used 0.05, 0.1, or 0.2 mg. as initial doses instead of the recommended 0.5 mg., and similar aliquots of other intravenous preparations.

Conclusions

Four patients, one in clinical shock and three with shock and pulmonary oedema, were treated primarily with a cardiac glycoside intravenously in small doses. All four patients showed remarkable clinical response, with a rise in blood pressure, decrease in pulmonary oedema, and dramatic clearing of coma. Three of the four ultimately survived. It is re-emphasized that the shock of myocardial infarction represents true myocardial failure and that the use of digitalis may be highly efficacious. When given, digitalis should be administered in doses fractionally 25-50% of the initial dose given to the average cardiac patient. In so doing many of the toxic complications may be avoided.

LYMPHANGIOGRAPHY

A TECHNIQUE FOR ITS CLINICAL USE IN THE LOWER LIMB

BY

J. B. KINMONTH, M.S., F.R.C.S.

Professor of Surgery, St. Thomas's Hospital

Director, Department of Radiology, St. Bartholomew's Hospital

Arteriography and phlebography have been used in clinical medicine since their development some twenty years ago. The early work with these techniques was done by dos Santos *et al.* in 1931, Moniz *et al.* (1932), and dos Santos (1938). A comparable method of studying the lymphatic circulation would be of obvious value, but its development has been delayed by technical difficulties. Lymph vessels, or at least normal ones, are much smaller than the arteries or veins used in angiography. They contain colourless lymph, which makes them difficult to see, and under normal circumstances they may be empty or nearly so, existing as potential spaces like the pleura or peritoneum (Kinmonth, 1952). Special methods have therefore been developed to make the lymph trunks visible to the naked eye at operation and opaque to x rays so that radiographs could be made to study their role in disease in man. Some of our findings have already been described (Kinmonth, 1951, 1952, 1954; Kinmonth and Taylor, 1954). This paper describes a method which has proved useful in practice and which embodies certain technical improvements. The general principle is that the lymph trunks are made visible to the naked eye by subcutaneous injection of a diffusible blue dye so that radio-opaque solution can be injected direct into them through a small needle.

Lymphangiography of the Leg and Thigh

(1) The diffusible dye patent blue* (also known as patent blue violet or patent blue V) is made up into an isotonic solution (11%) in distilled water and sterilized by autoclaving. About 2 to 2.5 ml. of this solution is injected subcutaneously between the toes, roughly 0.5 ml. into each web, which is massaged with gauze for about half a minute.

(2) The ankle-, knee-, and hip-joints are then passively moved repeatedly through their full range for five minutes. The dye, which permeates the lymph trunks soon after injection, is thus moved along them so that they are filled as far as the pelvis. In this dosage (up to 2.5 ml. for an adult) the dye is without toxic effects. It is, however, absorbed into the blood stream, and the patient soon becomes blue in colour. The anaesthetist and the nursing staff in the ward are warned of this. It is excreted in the urine, and the patient regains a normal complexion in about 24 hours. Severe oedema of the limb should be reduced so far as is possible by elevation and massage for a few days beforehand, because the flow of dye through the lymph trunks may be retarded if they are waterlogged by tissue fluid.

*Obtainable from G. T. Gurr, 36, New King's Road, London, S.W.6.

(3) A bloodless field is helpful in the next stage. This can be produced with a rubber bandage and air cuff, but a better way is to tilt the patient into a full Trendelenburg position so that the limb is sharply elevated.

(4) A transverse incision is made in the skin of the dorsum of the foot about 2 in. (5 cm.) proximal to the webs of the toes (Fig. 1). The lymph trunks run upwards in the line of the long axis of the foot, and it is sometimes possible to see them filled with the blue dye through the skin before the incision is begun. They lie very close to the skin, which is thin in this situation, and so the incision must be deepened by cautious light strokes of the scalpel.

Fig. 1.—Injection of diodone into a lymphatic (see description in text).

Small bleeding points are coagulated with the diathermy. Lymph trunks of normal size are just under 1 mm. in diameter. A length of some 5 or 6 mm. is exposed by gently pushing apart the edges of the incision with the scalpel. A clean exposure of the superficial aspect of the vessel is necessary, but its whole circumference must not be free or it may collapse and make injection impossible.

(5) At this stage it is helpful to distend the lymph trunk with dye. An assistant places a finger on the skin an inch (2.5 cm.) above the incision, and presses gently to obstruct the lymph trunk, and the surgeon massages the interdigital area so that the dye passes up and fills the exposed length. The exposed length of lymphatic is held as straight as possible by grasping the areolar tissue next to it in the distal part of the incision. All is now ready for the injection.

(6) The radio-opaque solution used is 70% diodone. The preparation known as "pyelosil" has given good results in our experiments. It has been kept warm until required, when a 10-ml. syringe is filled with it. A No. 18 hypodermic needle is firmly mounted on the syringe. This is the smallest needle of the standard sizes and its bore will just allow the viscous solution to pass. The needle point is introduced some 2 mm. into the lymph trunk and the piston tentatively advanced. If it is accurately placed, diodone enters and the vessel becomes white and transparent. If, however, the needle point lies in adventitia a bleb forms and the injection must be stopped and another attempt made, often in another reach of the lymphatic or in another vessel. If all is going well the injection is continued, the surgeon watching the needle-point and an assistant telling him of the progress of the piston along the barrel of the syringe. The diodone is injected as rapidly as the small bore of the needle will allow. The full 10 ml. is injected if possible, but sometimes rapid extravasation around the needle occurs before this and the injection is then stopped. Surprisingly good delineation is sometimes obtained with injections as small as 1 ml. Minor leakage of diodone around the needle during the injection is gently mopped up with cut pieces of gauze by an assistant, who takes care not to disturb the needle point.

(7) The needle is withdrawn when the injection is complete and the table immediately altered from the Trendelenburg to the horizontal position.

(8) The x-ray tube is moved into position and radiographs are made of the whole limb with as little delay as possible. The sooner they are made the better will be the definition, because the diodone starts to diffuse through the permeable walls of the lymphatics after a few minutes, giving rise to blurred outlines in the film. The films have been placed in position under the limb in the beginning so that no time is lost at this stage.

Radiological Technique

As with all radiographic procedures in operating theatres, radiography in these cases is carried out under certain difficulties. Examination is even more difficult when the thicker parts of the body such as the pelvis, abdomen, and thorax have to be radiographed.

Fig. 2.—Normal lymphangiogram: 6 ml. of 70% diodone was injected and the films were exposed one minute later.

Fig. 3.—Lymphangiogram in a patient with idiopathic lymphoedema: 10 ml. of 70% diodone was injected and the films were exposed one and a half minutes later.

Good definition and reasonable contrast are essential, as normal lymphatics are demonstrated as fine opaque filaments in the soft tissues.

It has been found advantageous to use non-screen film for the extremities and screened films for the thicker parts. Exposure times need not be as critical as in arteriography, as the flow of opaque medium through the lymphatics is comparatively slow, but immobilization is essential, and undue delay may result in blurred lymphatic outlines, due to seepage through the walls of the vessels.

The films or cassettes are placed in boxes, under the sterile towels, below the part to be examined and prior to the injection. Several non-screen films can be used if necessary, each protected from the other by lead-protected trays, the box being long enough to carry on each tray two 15 x 6-inch (38 x 15-cm.) films placed end to end. There is no appreciable gap between the end-to-end films, so that little of the lymphatic system is undemonstrated. Almost the whole length of a limb can be radiographed at one time

with a special type of tube arm which we use on these mobile units to give adequate focus-film distance. The trays are removed one by one from the distal end of the box as each exposure is made.

In general, it is unnecessary to take serial films of each area (such as are required in arteriography) unless more of the lymphatic system has to be filled by a further injection. It is of great advantage to have a wedge filter to compensate for the varying thickness of the lower limb, and the recent use of such an accessory, similar to that which we use in arteriography, has been of much value in improving the quality of the films. A difficulty may be to make interchange of the filter simple, as it is not always practicable to have the same mobile x-ray set available for this type of operating-theatre work.

A cassette and a fixed grid, usually in a cassette tunnel, are used for the successful demonstration of the inguinal glands and pelvic lymphatics, and the abdominal lymphatic channels have also been so demonstrated. As stated above, it is surprising how small quantities of opaque medium, such as 1-1.5 ml., give good delineation of the lymph vessels

when there is little sign of dilatation. If, however, gross dilatation and varicosity exist, a much larger quantity may be necessary to demonstrate all the ramifications of these vessels and to outline the more proximal lymph vessels in leg and arm. With care and co-operation much interesting information concerning the state of the lymphatic system can be gleaned by this type of examination.

For the limbs our technique has been as follows. Non-screen film: 65 kV, 65 mA; time, 2 seconds; distance, 48 in. (122 cm.).

For the thicker parts:—cassette and grid: 80 kV, 45-50 mA; time, 1.5 seconds; distance, 48 in. (122 cm.).

It is important that each new technique should be thoroughly supervised by a radiologist, as difficulties occur in operating theatres which may require special equipment, and discussion between surgeon and radiologist may be necessary to reconcile the problems with which each is faced, in order to evolve a satisfactory solution to the problem and obtain the best possible results.

Results

The method has been used to study lymph vessels in lymphoedema praecox, post-mastectomy oedema of the arm, post-phlebotic ulceration and oedema of the leg, congenital arteriovenous fistulae, and other diseases. Some of the findings have been reported elsewhere, and it is not proposed to give further details here, but instead to describe some examples illustrating the technique.

A normal lymphangiogram is shown in Fig. 2. The lymph trunks remain the same width in their course up the limb, unlike veins which become wider. Bifurcation occurs frequently, so that the trunks appear to multiply as they pass upwards. The ampullae of valves are often seen.

The lymphangiogram shown in Fig. 3 was taken from the leg of a patient with idiopathic lymphoedema (Fig. 4). The lymph vessels are tortuous and wide. There is both

Fig. 4.—Idiopathic lymphoedema. Lymphangiogram shown in Fig. 3. Operation gave considerable amelioration.

lateral and retrograde flow of the dye into other lymph vessels. These features are never seen in normal lymphatics.

We wish to thank Professor Sir James Paterson Ross and the other members of the Surgical Professorial Unit at St. Bartholomew's Hospital for their help and encouragement in developing this method.

THE DELLWOOD FIRE

BY

MARIAN E. COX, L.R.C.P.&S.I., D.C.H.

AND

R. A. RATCLIFF, M.D.

Assistant Paediatrician, Reading Area Hospitals

In the early morning of Easter Sunday, April 18, 1954, a fire occurred in the nursery of Dellwood Maternity Home, Reading, which resulted in the death of 13 newborn babies. Dellwood is a general-practitioner obstetric unit of 17 lying-in beds dealing with normal cases. The hospital staff serve in a consultant capacity. The building is about fifty years old and there have been a few structural alterations during the twenty-four years of its use as a maternity home. The nursery measures 20 by 12 ft. (6.1 by 3.6 metres), with two doors and two windows: the floor boards are of deal covered by linoleum.

The fire was caused by the flue of a hot-water boiler which in September, 1953, had been moved so that it ran beneath the floor of the nursery. It has been established by subsequent inquiry that the installation of the flue complied with the local building regulations, though the experts who assisted the Regional Board in their inquiry agreed that the regulations need overhauling. It seems likely that the fire began slowly, with much smouldering of wood over a large area of floor. This, the destructive distillation of soft wood and also of some linoleum, filled the room with thick smoke, until finally part of the floor caught alight and the flames spread to one of the cots. It is thought that the room may have been filled with smoke for between 20 and 30 minutes.

There were 15 babies in the nursery, the doors of which were closed, while the windows were kept slightly open. A gas fire was burning. A nursing staff of two were on duty and the nursery was visited at intervals during the night, the last visit before the fire being about 3.15 a.m. The fire was discovered by one of the sisters*

*Sister E. M. Holland was later decorated with the George Medal by Her Majesty the Queen.

at 4 a.m., and she immediately began to remove the babies from the room while help was being called. While removing the first babies she received considerable burns of face and arms and was in great distress from inhalation of smoke; she continued to bring them out one by one, and finally collapsed when the last one had been carried out. She was subsequently admitted to hospital.

One of us (R. A. R.) first saw the babies at 4.30 a.m. One whose cot had caught fire was dead following extensive burns involving the whole body, with some charring. Three others were transferred to the Battle Hospital at once and placed in oxygen boxes. One of these had some superficial burns of the face. All three were limp and pallid and in great respiratory distress. There was much clear viscid discharge from nose and eyes and complete nasal obstruction. The remaining 11 babies were in good general condition, but all were coughing a little and had some discharge from the nose and eyes. Their colour was generally good apart from slight occasional cyanosis produced by coughing attacks and interference with breathing by nasal obstruction. During the day there was some deterioration. Respiratory rates were rising, and in all cases cough had increased: a little clear yellow fluid was occasionally coughed up or aspirated. Scattered rales, in every case, became audible in the afternoon and evening. Oxygen boxes had by this time been obtained for all the cases.

That evening it was decided to clear a hospital ward and make special arrangements for nursing staff, and early on Monday morning all the surviving babies were transferred in oxygen boxes to the Royal Berkshire Hospital. An alarming increase in respiratory obstruction developed in all the cases, and on Monday evening it seemed unlikely that any of the babies would survive. The appearances were similar to those with which we are familiar in asphyxia due to hyaline membrane, with, in addition, signs of upper respiratory tract irritation: but these were strong infants several days old, and were making very forcible efforts to breathe, whereas in hyaline membrane asphyxia we are dealing usually with a shocked or feeble baby. Thus the characteristic contrast between struggling respiratory effort and poor breath sounds on auscultation was very striking.

Two of the babies began to improve after the third day and finally appear to have made a good recovery. There is no reason to suppose that these two suffered less exposure to the smoke than any of the others.

Treatment

All the babies were given oxygen, the first three being placed in oxygen boxes on admission to hospital, and the remainder (who at first stayed at Dellwood) being similarly treated later on the first day when chest signs were appearing and extra boxes had been obtained. Before this, some oxygen was given by tube and funnel or catheter when coughing attacks led to cyanosis. Mucous secretions were aspirated at intervals as needed, and 5% sulphacetamide was applied to the nose and eyes. Penicillin was given in all cases, starting on the morning of the first day with 100,000 units eight-hourly by injection. The dose was later reduced and given orally to the babies who survived. Humidification was maintained by electric steam-kettles.

At midday on Monday, the day after the fire, streptomycin (100 mg. eight-hourly) and cortisone (50 mg., then 25 mg. eight-hourly) were added to the treatment.

The babies were nursed with the foot of the cot raised and were kept for most of the time in a high concentration

of oxygen, with a flow of four to five litres a minute. The position was altered from side to side at two-hourly intervals and aspiration of the nose and pharynx was carried out by catheter and electric sucker very frequently. Temperature and respiratory rates were recorded at hourly, and later at two-hourly, intervals. Feeds, at first of glucose-saline and later of milk mixture, were given by oesophageal tube during the first 48 hours. Aspiration of the trachea was attempted in three cases without apparent benefit, and hardly any mucus was obtained by this method. Gastric oxygen was given to several babies *in extremis*, and in one of these it was noted that the colour improved and was maintained for about half an hour after all respiratory movement had ceased.

In those babies who survived the first 48 hours percussion drainage was attempted in addition to postural drainage and frequent changing of position. This seemed to produce some good results: mucus was coughed up and aeration seemed to have improved. In one baby (one of those who recovered) a large bronchial cast was aspirated from the nose on the sixth day, after one of these periods of percussion drainage.

Outline Course of Individual Cases

Case 1.—Male aged 6 hours. Died during fire. Extensive burns and charring.

Case 2.—Female aged 6 days. Superficial burns of face and chest and oedema of eyelids. Respiratory distress was apparent immediately, with severe coughing, grey cyanosis, and much mucous discharge from nose and eyes. Was transferred to Battle Hospital and placed in oxygen and steam, with frequent local treatment to nose and eyes. Penicillin powder applied to burns. Progressive deterioration throughout the day until death at 10.33 p.m. Survived 18½ hours.

Case 3.—Male aged 9 days. Very slight scorching of face. Respiratory distress and cyanosis from onset. Transferred to Battle Hospital and placed in oxygen box. Much greenish-yellow mucus was aspirated from nose and pharynx. Slight deterioration throughout day. Feeds of glucose-saline given by tube were retained. At midday trachea was aspirated but no mucus obtained. Condition became steadily worse during the night. Died at 4.55 a.m. on the second day. Survived 25 hours.

Case 4.—Female aged 2 days. Had seemed to be in good condition at first and during the first day. Onset of dyspnoea and cyanosis during early morning of Monday, with subsequent rapid deterioration. Died at 6.30 a.m. on the second day. Survived 26½ hours.

Case 5.—Female aged 4 days. Some cyanotic attacks with coughing on first day, but general condition was fairly good and feeds were retained well. Slowly increasing distress on second day as the respiratory rate rose. Died at 10.45 a.m. on the second day. Survived 31 hours.

Case 6.—Female aged 8 days. Condition seemed fairly good at first, but the respiratory rate rose to 60 during the first 24 hours, after which dyspnoea increased progressively. On account of the very great respiratory distress the trachea was aspirated on the second day on two occasions, but this produced no relief and very little mucus was obtained. Died at 6.10 p.m. on the second day. Survived 38 hours.

Case 7.—Male aged 3 days. Well, apart from slight cough during the first 12 hours. After this period similar course to Case 6. Strong baby, making violent respiratory efforts. Period of intermittent breathing preceded death at 6.30 p.m. on the second day. Survived 38½ hours.

Case 8.—Male aged 4 days. After some slight intermittent dyspnoea and cyanosis during the first 24 hours appeared to be improving. Much stained mucus had been aspirated from the pharynx. There was a rapid deteriora-

tion with increasing dyspnoea during the evening, and he died at 9.10 p.m. on the second day. Survived 41 hours.

Case 9.—Male aged 3 days. In good condition in early stages, symptoms gradually increasing after the first 24 hours. Died at 10 p.m. on the second day. Survived 42 hours.

Case 10.—Male aged 7 days. This baby showed early signs and was one of the three (with Cases 2 and 3) who were transferred to the Battle Hospital immediately after the fire. He had improved, respiratory rate had fallen, and feeds were retained satisfactorily. Cyanotic attacks and rising respiratory rate recurred during the night of Monday and became more severe in the early morning. One unsuccessful attempt was made to suck out the trachea. A period of several hours of marked head retraction preceded death at 4 a.m. on the third day. Survived 48 hours.

Case 11.—Female aged 6 days. This baby remained in fairly good general condition until 24 hours after the fire, respiratory rate remaining in the region of 40 a minute. There was very slight scorching of the face and one hand. Pyrexia with temperature 102° F. (38.9° C.) developed during the second night, and, following this, chest symptoms and signs increased until she died at 10.24 a.m. on the third day. Survived 54 hours.

Case 12.—Male aged 2 days. Gradual development of symptoms during the first 24 hours, after which there seemed to be a steady improvement. At 2 a.m. on Tuesday became hyperpyrexial: temperature 107° F. (41.7° C.). This subsided, but the baby did not improve further, and after repeated attacks of cyanosis and development of head retraction, died at 11 a.m. on the third day. Survived 55 hours.

Case 13.—Female aged 3 days. Course was very similar to the previous one, with pyrexia—temperature 104° F. (40° C.)—during the second night and final deterioration after early improvement. She died at 12.50 p.m. on the third day. Survived 57 hours.

Case 14.—Female aged 3 days. The early course was similar to previous cases, but there was some improvement in aeration during the third day and subsequently as mucus was coughed up and aspirated. Percussion drainage seemed to be increasingly effective, and on one occasion was followed by the production of a large cast. From the fifth day there was a steady improvement, though an x-ray film (Fig. 1) on the sixth day showed that extensive areas of collapse were present. Cortisone was reduced to 12.5 mg. eight-hourly on the fourth day, and stopped after a further 24 hours. Oxygen was gradually withdrawn and penicillin and streptomycin were stopped on the ninth day. On the eleventh day an x-ray film

FIG. 1.—Case 14. Chest film on sixth day of illness, showing extensive areas of collapse consolidation. Later films show complete clearing.

showed considerable clearing. There were several alarming cyanotic attacks at this late stage, but these were of brief duration. Breast-feeding was re-established, and she was discharged home fully breast-fed and symptom-free on May 5, 17 days after the fire. Subsequent x-ray films show clear lung fields.

Case 15.—Male aged 7 days. Course was parallel to that of Case 14, and this infant was fully breast-fed by his mother when he was discharged on May 5. Both mothers had been admitted to re-establish feeding as soon as the babies began to improve. As in Case 14, there were several brief but alarming cyanotic attacks during convalescence associated, it seemed, with the separation of bronchial casts. Some yellow staining of the skin in both these babies persisted until a few days before their discharge.

Pathology

Post-mortem examination of the respiratory tract was carried out initially by Dr. J. A. Hardy, police surgeon at Reading. Permission was given by the coroner for further investigation of the specimens to be undertaken, and accordingly one lung from each case excepting the first was made available for examination in the Department of Morbid Anatomy, Hospital for Sick Children, Great Ormond Street.

Naked-eye Appearances

The most striking changes were seen in the bronchial tree, where the formation of a membranous cast had occurred in each case. In Cases 2 and 3 this was still firmly

FIG. 2.—Cast of bronchial tree removed at necropsy. Black flecks of carbon are seen scattered throughout the specimen.

attached to the bronchial wall, and consisted of a thick layer of greenish-yellow material flecked with carbon. This replaced the normal shiny bronchial mucosa. A little yellow watery fluid was also present in the bronchial lumen. In those cases which survived longer, separation of this membrane from the bronchial wall had occurred. The cast now appeared as a firm tubular structure surrounded or indented by a quantity of sticky brownish mucoid material. Separation occurred initially in a patchy fashion so that only in those cases surviving longest was it

possible to extract a whole cast of the bronchial tree without leaving portions behind (Fig. 2). The extent of involvement of the large bronchi was similar in all cases, none of the main branches being entirely devoid of a membrane. In many cases secretion of mucus together with the resultant dislodgment and infolding of the cast had led to a severe degree of bronchial obstruction.

Involvement of the smaller bronchi and bronchioles was less constant, and in the gross specimen it was usually difficult to distinguish cast formation in air passages of this size from the bronchiolitis and adjacent bronchopneumonia which was subsequently shown histologically to have complicated several cases.

Congestion and oedema of the lung tissue was present in all the specimens, but was particularly noticeable in Cases 2, 3, and 4. Interstitial emphysema and oedema were also frequently seen, with resultant accentuation of the mosaic pattern produced on the pleural surface by the lobules.

Occasional large interstitial emphysematous bullae were also present. There were considerable areas of collapse and alveolar emphysema in all specimens, although the quantity of lung tissue involved in these changes varied somewhat from case to case. In most of the lungs collapse predominated over emphysema. All the specimens showed pleural

haemorrhage, varying in size from scarcely perceptible petechiae up to extensive haemorrhagic areas involving a considerable proportion of the pleural surface.

Histology

Examination of the larger bronchi showed that, while the greater part of the epithelium had been destroyed, not all areas were quite so severely affected, and in a few places the epithelium had been spared completely. This was particularly noticeable where relative protection had been afforded by mucosal folds, or near the ducts of mucous glands. In the less severely affected regions the epithelial cells had desquamated either singly or in clumps. The cytoplasm was swollen, homogeneous, and intensely eosinophilic, and the nuclei either showed degenerative changes or had disappeared. In the more severely affected parts individual cellular detail was less evident. The necrotic cells had fused together, replacing the epithelium by a densely eosinophilic membrane containing occasional nuclear remnants and patchy aggregations of carbon particles.

FIG. 3.—Destruction of bronchial epithelium with formation of a thick membranous cast. Cast contains carbon particles and is still attached to the bronchial wall. ($\times 90$.)

The bronchial walls were intensely congested and oedematous, and frequently haemorrhagic. Moderately numerous inflammatory cells were present in the cast and adjacent bronchial wall. These consisted of approximately equal numbers of polymorphs and mononuclear cells. At a later stage secretion of mucus from the underlying glands occurred, with resultant separation of the membrane from the bronchial wall. This process was barely starting in Cases 2 and 3, in which most of the cast was still attached (Fig. 3), but became progressively more advanced in those cases surviving longer, when large quantities of mucus could be seen lying between the cast and the bronchial wall. In some of the bronchi this led to complete occlusion of the lumen. Where separation had occurred the bronchi were sometimes devoid of a lining epithelium, although usually a few of the basal cells had been spared. No definite evidence of epithelial regeneration was seen in any of the specimens.

Cast formation in the bronchioles was very much less extensive, the majority being uninvolved in this process. In several cases there was acute bronchiolitis, which in Cases 2, 3, and 4 had progressed to well-developed bronchopneumonia. Cases 8, 10, and 11 showed very much earlier bronchopneumonic changes. This bronchiolitis was independent of the presence of bronchiolar casts, and was commonly seen where the latter was absent. The inflammatory exudate in the bronchiolar walls was very much more cellular than that seen in relation to the casts in the large bronchi.

The alveoli were congested and oedematous, and showed well-marked collapse and emphysema. In addition to the oedema fluid the alveoli contained carbon particles, small quantities of eosinophilic fibrillary material which gave negative stains for fibrin, and moderate numbers of mono-

nuclear cells, many of which were vacuolated. Occasional squames were present in some of the lungs, but no hyaline membrane was seen. The interstitial tissue was oedematous and often contained large air spaces (Fig. 4). There were numerous interstitial and intra-alveolar haemorrhages. The latter were not particularly extensive except in Case 5, in which large areas of the lung were involved, giving an appearance reminiscent of pulmonary infarction.

FIG. 4.—Interstitial emphysema, with large air spaces in interlobular septum. ($\times 55$.)

FIG. 5.—Droplets of lipid material (appearing black) within the alveoli. ($\times 200$.)

tions of painted wood and linoleum were distilled separately. In each case a brown oily distillate was obtained. No attempt was made to analyse this, but it was smeared on slides and subjected to the same staining procedure (Scharlach R) as the histological material. In the case of the distillate from the painted wood, small quantities of positively staining material were obtained, while in the case of the linoleum a considerable proportion of the distillate stained positively by this method. Thus it seemed reasonable to infer that the lipid material in the lungs had been inhaled in the smoke.

From the gross and microscopical appearances it was not possible to determine which cases had suffered the greatest exposure to the smoke, nor was it possible to correlate the severity of the bronchial lesion with the quantity of either carbon or lipid present.

Discussion

These 12 babies died as a result of progressive bronchial occlusion together with pulmonary oedema and infection. The first three babies to die showed less severe obstruction than the subsequent cases; little separation of the cast had occurred, but pulmonary oedema was much more pro-

nounced, and there was extensive bronchopneumonia. In the later cases pulmonary oedema and infection were less prominent features, but bronchial obstruction had become much more complete as a result of secretion of mucus and displacement of the membranes cast into the centre of the bronchial lumen.

The retention of such large quantities of mucus within the bronchial tree was due largely to two factors. Firstly, much of the mucus was trapped between the bronchial wall and the cast, and removal was often further impeded by the fact that adjacent parts of the cast were still adherent to the bronchial wall. Secondly, the removal of mucus was prevented by the destruction of most of the ciliated epithelium.

The formation of the bronchial cast was attributed to irritant substances present in the smoke to which the babies were exposed. Membranous bronchitis is a recognized, though fortunately uncommon, complication of some infections, notably diphtheria, and has also been reported following the inhalation of certain war gases (Winternitz, 1920), nitrous fumes (von Oettingen, 1941), and after exposure to atomic radiation (Liebow *et al.*, 1949). Lesions very similar to those described above were reported as occurring in some of the victims of the Coconut Grove fire.

There is every reason to believe that if the babies had survived the initial hazards of pulmonary oedema and infection, and the later period of bronchial obstruction, complete restoration of the bronchial epithelium might have occurred, regeneration proceeding from the surviving islands of epithelium in the mucosal folds and duct orifices (Wright, 1950).

If the course of events is reviewed in the light of subsequent investigations the most important question that arises is whether anything further could have been done to help these babies. Atropine might have been given in sufficient doses to diminish secretion. It might, however, also have made secretions more viscid and less likely to separate. Humidification by mist, perhaps with the addition of a detergent, might have been used, but this could have led to fatal increase in the already great amount of fluid in the lungs. Cortisone might perhaps have been given earlier and in larger doses; but in addition to diminishing exudative responses cortisone has other effects, including that of promoting fluid retention and possibly diminishing resistance to infection. More vigorous and intensive aspiration of the lower respiratory tract might have been attempted, including perhaps aspiration through tracheotomies, but such procedures in the newborn have their own risks and probably a high mortality. They might, however, have been effective in the babies who survived to the third day, when some of the casts were beginning to separate.

The simple measures which were attempted were carried out by ourselves and by the nursing staff. The latter, working in eight-hour shifts, showed skill and gentleness that were all that could be desired. Percussion drainage was at first performed by one of us, but later, too, this was taken on by the nursing staff in some cases.

A tragic event such as this should not perhaps be used as an argument for or against any system of care. The custom of putting all the babies into a nursery for the night so that the mothers can sleep undisturbed is a widespread one, and is particularly the rule in smaller maternity homes. Quite apart from the possibility of a disaster such as this, the system is, we think, a bad one, and we would repeat the opinion frequently given by paediatricians and obstetricians that the proper place for the normal newborn baby is in a cot close to the mother's bed.

Summary

An account is given of the Dellwood fire which caused the death of 13 newborn babies. Two babies survived and are now apparently normal. One baby was found dead. The others died within three days of the fire.

The symptoms were those of increasing respiratory distress, pyrexia, cough, and cyanotic attacks. Death was due to bronchopneumonia in the first 24 hours, or later to bronchial obstruction caused by casts consisting mainly of fused necrotic epithelial cells. The bronchial changes were due to inhalation of smoke.

Treatment included oxygen, chemotherapy, cortisone, percussion and postural drainage, and aspiration of mucus from the mouth and nasopharynx. Tracheal aspiration and gastric oxygen were used, but the results were disappointing. The question of possible alternative treatment is discussed.

Among the many who helped us during these babies' illness we would like especially to record our thanks to Dr. B. Schlesinger, Dr. D. Foskett, and Mr. E. Hunt Williams. Acknowledgments are due to Dr. J. A. Hardy, the police surgeon in Reading, who on H.M. Coroner's instructions carried out the post-mortem examinations. In later investigations valuable technical advice was received from Mr. L. C. Nickolls, Director of the Metropolitan Police Laboratory. Valuable help was received in the laboratory investigations from Dr. C. de Courcy and Mrs. A. Hopkins. We are also grateful to Dr. M. Bodian for assistance in the preparation of this paper, and to Mr. Derek Martin, of the Department of Medical Illustration, Great Ormond Street, for the photographs.

THE SOCIAL AND PSYCHOLOGICAL BACKGROUNDS OF TUBERCULOUS CHILDREN

BY

DINA ROSENBLUTH, B.A.

AND

JOHN BOWLBY, M.A., M.D.

Deputy Director, Tavistock Clinic

One of the projects undertaken by a research team investigating the effects on personality development of separation from the mother in early childhood was a follow-up of children who, because they had tuberculosis, had been separated from their mothers, and in a sanatorium, for a period during their first years of life (Bowlby, Ainsworth, Boston, and Rosenbluth, 1955). This required us to investigate the social background of these children, and the present study is a by-product of the main research. It gives some findings relating to the economic and housing conditions, the extent of family illness and disruption, and some of the psychological attitudes found among members of these families during the year 1950. Although we are aware that what is described will not be new to workers in the field of tuberculosis, our impression is that that knowledge exists in rather a fragmentary form.

The gross sample studied was obtained by extracting from the records of a sanatorium the record of every child admitted between birth and 4 years, between January 1, 1940, and November 30, 1948, inclusive. From this sample were eliminated children whose primary tuberculosis was complicated by bone or abdominal infection, those who had left the county of Middle-

sex, who had gone into the care of other institutions, or who had died, and those who were not yet of school age. The resulting sample consisted of 60 children—41 boys and 19 girls. They had all returned to their homes and were attending schools in the county. The present addresses of the children were traced with the help of the chest clinic and education authority records.

The need to make direct systematic inquiry of the families in which we were interested was recognized by the staffs of chest clinics, and in arranging the interviews it was of great help to be able to state that both the sanatorium and the local chest clinics were co-operating in the research. The warm welcome and readiness to talk which the psychiatric social worker met with in most families are believed to be a tribute to the sanatorium, which most families remembered with gratitude. Lack of co-operation was on each occasion related to reluctance to disclose an especially difficult or disturbed family situation.

The total sample of 60 children came from 57 families. Two families, containing three children, refused altogether to co-operate, and one of two siblings was in a residential school. The total number of families remaining is therefore 55, containing 56 children.

The average length of interviewing time was four to five hours, usually spread over two or three visits. The psychiatric social worker spent a little time at the beginning of the first interview explaining the purpose of the research. Once the family had agreed to co-operate she attempted to guide the interview so as to cover the main points on which information was sought. Where there was reluctance to give information this was not pressed for. On the other hand, the parents often talked at length about their problems, and in many cases revealed their attitudes to tuberculosis and to the tuberculosis service. It was thus, incidentally and unasked for, that much of our material was obtained.

Economic and Housing Conditions

The families were rated for economic and for housing conditions, each on a four-point scale. The rating "A" for economic conditions implies an income on which the family could manage fairly well and afford an annual holiday. The rating "B" implies an economic situation that is fairly adequate. The rating "C" implies a rather poor income, usually only one parent being at work, in an unskilled occupation, and the family finding it difficult to make ends meet; a summer holiday was out of the question, or possible only once in a while and at great sacrifice. The rating "D" implies that the families suffered real economic hardship. These were the families the mothers of which were widows and had to live on widows' pensions supplemented by a little earning of their own or by the National Assistance Board. The distribution of ratings is shown in Table I.

TABLE I.—*Economic Circumstances of 55 Families*

Rating	No. of Families
A: Comfortable	6
B: Fairly adequate	20
C: Poor	16
D: Economic hardship	13

Not infrequently the psychiatric social worker heard accounts of severe economic hardship in the parent's own childhood, and also during the pre-war or early war years, when the sample child was an infant. But with the great majority of the families the economic situation had taken a marked turn for the better in the post-war years. At the time of the inquiry the black spot was the 13 families rated "D"

which constitute one-quarter of the families concerned, and which were living on a bare subsistence level. Twelve of these families were existing on widows' pensions, and in the other the father had been ill for the past two years and the family lived on National Assistance money. It seemed that they could not afford all the food they should have, and the psychiatric social worker heard stories of children having to stay away from school on rainy days because they did not possess adequate clothing.

Most of the families lived in good, usually small, semi-detached suburban houses, often on council estates. The rating "A" for housing conditions indicates that the house was very good and there were sufficient rooms for the children to have their own bedrooms; rating "B" also implies good housing, but with the need for some sharing of bedrooms; rating "C" was given either where the house was in a poor condition or where, although the house was a reasonably good one, it was not large enough for the family; rating "D" implied that the house was in a poor condition and there was inadequate space. The distribution of ratings is shown in Table II.

TABLE II.—*Ratings of Housing Committee*

Rating	No. of Families
A: Very good	10
B: Good	24
C: Poor	15
D: Inadequate	6
	55

Of the six families living in inadequate housing conditions, one lived in a condemned house, three had only part of a house each with quite insufficient room for the family, and the two others lived in old-fashioned small houses where there was gross overcrowding.

Family Illness and Disruption

The extent to which there had been illness in the family with consequent disruption was very great. In the 55 families, only the children of 29 were living with both their parents in an intact family. The remaining 26 families (containing 27 children) were all disrupted, either through the death of one or other of the parents (in 22 families) or because the parents were separated (in 4 families).

In the great majority of cases this disruption was due to tuberculosis, either in the past or in the present. Nineteen parents and 8 siblings had died from the disease. Altogether infection or death from the illness had occurred in a parent or sibling in 33 of the families, leaving only 22 families in which the child studied was the only case. Table III presents the incidence of cases of tuberculosis in the families

TABLE III.—*Extent of Tuberculous Illness in the 55 Families*

	Both Parents	Father Only	Mother Only	One Sibling	More than one Sibling
Past tuberculosis	1	16	11	11	5
Death from tuberculosis	1	16	1	6	1
Present tuberculosis	—	—	9	2	—

other than the sample child. In addition to the deaths shown in this table, two fathers and three mothers had died of other causes.

Table IV shows the presumed source of the child's infection. It will be seen that about half the children were believed to have been infected by one of their parents.

TABLE IV.—*Contact Through Whom Child was Thought to Have Been Infected*

Contact	No. of Children
Father	18
Mother	11
Grandparents, uncle, or aunt	10
Neighbour	4
Contact unknown	13
	56

In addition to the 22 families which had been disrupted by death, four were not intact for reasons of illegitimacy (1), divorce (2), and separation (1).

Even among the 29 children who were living with both parents family life was not always normal. In two cases the parents had, since the child's birth, separated for a while, but had later decided to live together again. In one of these the ostensible cause for the separation had been father's dread of mother's tuberculous illness. There were four families in which the mother was ill with tuberculosis at the time of inquiry, and in several other cases the mothers were very preoccupied with their own health and worried in case they had tuberculosis. In two more families the fathers were ill, but the nature of the illness was not known to the psychiatric social worker. In a further eight families father, mother, or a sibling had had tuberculosis at one time or another, and family life had therefore been upset owing to the absence of a member in a sanatorium, with consequent anxiety about the health of other members of the family. This leaves a balance of only 13 families whose family life had been relatively undisturbed.

Attitudes and Feelings

In the course of the inquiry it became apparent what far-reaching and complex psychological repercussions were aroused by the existence of a tuberculous illness in a member of a family. Many parents spent a considerable time in discussing with us their fears for their own or their children's future health, or whether or not to tell the child about his having had tuberculosis in early childhood. As a result, much incidental light was thrown on the attitudes to the illness and on the ways these had influenced their relationship to their children and their neighbours. As these attitudes to tuberculosis were not the focus of interest, they were not systematically investigated and therefore there are gaps in our information. In the description which follows it is thus not possible to give accurate figures of the numbers of families concerned.

Fear of Tuberculosis

As was only to be expected in view of the extent of the illness and the number of deaths among these families, a conscious fear of it and its implications was very widespread. In a surprising number of cases (about one-fifth), however, the parents dealt with these anxieties by attempting to deny that there had been any tuberculous illness at all. The most striking was where a father, whose wife and son had both been in the sanatorium for considerable lengths of time, attempted to convince the psychiatric social worker that he had x-ray plates to prove that neither of them had had tuberculosis at all. He felt that there had been some plot to take his family away from him. (His wife had been infected by her mother, whom she had nursed until the mother had died of tuberculosis.) This man does not approve of his son going to the chest clinic now. He was clearly very paranoid, extremely suspicious, and willing to co-operate in the research only after the psychiatric social worker had explained that we were not really concerned with the reasons for the child's having had to go to hospital but only with his subsequent development.

Although this man's reactions were exceptional, similar attitudes in lesser degrees were present in quite a number of parents. There were cases where a mother or father had in the past refused to go to a doctor or into a sanatorium after the diagnosis had been made, staunchly denying that there was anything wrong with them. Some of them had died at home, and before doing so had infected their young child. One woman told the psychiatric social worker that it was almost a relief to her when her husband died, as she felt that that had saved the child's life, because he had refused to let the child be seen by a doctor. The father of one family and the mother in another were ill at home at the time of the investigation, afraid that they might

have tuberculosis, but protesting that there was nothing really wrong and that they did not think it was necessary to consult a doctor.

Several parents maintained that they did not know why their children had had to go to the sanatorium. Even where the hospital stay had been a very long one they insisted that it had probably been only for observation, not because the child had really been ill. This attempt to deny the illness was clearly bound up with a tremendous fear of it; in some cases both attitudes existed quite consciously side by side. One mother, who had herself on two occasions been in a sanatorium, and whose child had had tuberculosis too, was in a continuing and constant panic about this illness. She remarked several times during the interview, however, that she did not think that either she or her child had really been ill, and clung to the belief that no doctor had ever told her in so many words that either of them had actually had tuberculosis. At another time she said, however, that she did not suppose they would have been kept in hospital so long if they had not been ill.

The attempt to deny the illness because of so overwhelming a fear of it thus led, in a number of families, to a failure to take proper measures for prevention and treatment. These findings are consistent with those of Gore and Hartston (1953), who, reporting on the results of questioning more than a thousand mothers of young children, found that 69% of them thought that there are many people who are afraid to be examined in case they have tuberculosis.

In a number of families (again about one-fifth) the reaction was the opposite to denial, and took the form of constant hypochondriacal fears for the families' health even in the face of frequent reassurance by their doctors that there was now nothing wrong; their lives appeared to be permanently overshadowed by fears for the children's health. Some mothers were so worried about their own health that it was difficult to get them to talk about anything else. One woman in particular described in detail all the symptoms from which she was suffering, which were identical to the symptoms which her own mother had had just before she had died of tuberculosis. Her doctor had assured her that there was in fact nothing wrong with her, but she was still very afraid that she was ill, and was also constantly watching her children's health for the slightest signs of indisposition. She said that she would be reassured only if she had an x-ray examination, but that her doctor would not give her a letter for an examination at the chest clinic, and without it the chest clinic would not see her.

In some cases the children had caught their parents' fears. One 13-year-old girl was said to be constantly preoccupied with her health and was always weighing herself. This girl was afraid to go to bed at night and always found one excuse after another to put it off for as long as she could. Frequently, when her mother finally said she must be tired now, she would reply, "Who wants to go to bed? People die in bed." She was said to grind her teeth, to sleep-walk, and often to talk and shout out in her sleep. Another young girl was described as a "proper old woman" by her mother, always fussing about her health and demanding aspirins.

Parents' Feeling of Guilt

Even where there were no great fears for their own or their children's health a certain pampering and over-protectiveness towards the child who had been ill was fairly general. Although this attitude is a very natural and understandable one after the child's return from the sanatorium, it frequently continued and was still very pronounced at the time of the investigation, years after the child's complete restoration to health. In these cases it seemed connected with the mother's feeling of guilt and assumption of personal responsibility that the child should have been ill at all. In some few cases there might have been legitimate grounds for the mother's feelings that had she taken greater precautions the child might not have been

infected. One woman, for instance, said that she was entirely to blame for the child's illness because, when he was a toddler and his father was ill at home, she was on one occasion not quick enough in removing the father's eating utensils and found the child with the father's spoon in his mouth.

Even where there was no reason whatsoever to think that the parents were in fact responsible for the child's illness through any lack of precaution—for instance, where the contact through whom the child was infected was unknown—some mothers said that they somehow felt guilty that their child should have been ill. In other cases it appeared to the psychiatric social worker that the parents protested too much that the blame for the illness lay elsewhere (with the grandparents, neighbours, etc.), and it seemed that unconsciously they also felt it was their own fault.

This widespread feeling of guilt no doubt played its part in leading a majority of the mothers to an initial over-anxiety and overprotection of the child. However, such attitudes are almost inevitable in a mother after her child has been away from her for a long time and especially if he shows some of the emotional disturbances which commonly follow such separations. In consequence, in considering the subsequent relations of mother and child, it is not easy to determine how much is due to the mother's sense of guilt and how much to the child's disturbance following separation and to the mother's attempts to meet the disturbance.

Attitude of Overprotection

It seemed that some of the mothers soon realized that it was important that their child should be treated the same as his siblings and so should not feel that he was a special case. Other mothers said that only after a while did they realize, through bitter experience, that the child was harmed by this attitude of overprotection, of constant watchfulness and anxiety about his health. In these cases the children had reacted by considering themselves special cases, or else had rebelled and become difficult to manage. Some of these mothers were able gradually to relax and allow their children more independence, but in some cases difficulties persisted; the children continued to insist that they must have special treatment because they had been ill. Other parents were quite unable to overcome their constant over-anxiety, and seemed to be unaware that they might be harming the child by it.

Although the knowledge that tuberculosis is an infectious illness was general among the 55 families, there quite often persisted side by side with it the belief that it is a hereditary disease. In several families there was some discussion and a wish for reassurance that the children, who are at present all well and not in contact with any tuberculous person, would grow up healthy; in particular, anxiety was expressed that, because there had been tuberculosis in the father or mother's family, the children were likely later to fall ill too. No doubt because of the great frequency of cross-infection in families the belief that tuberculosis is hereditary dies hard. Gore and Hartston (1953) found it expressed by 43% of the mothers questioned.

Should Parents Tell?

At the same time, much more surprisingly, it seemed to be taken almost for granted among many families that psychological factors influence both the incidence and the course of the illness. In those cases where the parents raised the problem whether or not to tell their children that they had been ill in early childhood, one of the main arguments against it was that the child might later worry and thus again develop tuberculosis. One woman said of her husband that when he fell ill she felt that he did not stand much chance of recovery as he was such a worrier. Another family agreed to co-operate in the research only when they were reassured that the child would not, through the psychiatric worker, get to know that he had ever been

in a sanatorium; they were determined never to tell him, as if he were to know about it he would worry and therefore fall ill again. Another woman said that her sister had announced that, should she ever have tuberculosis, she would not be ill long; when subsequently she did fall ill she died within a few months. This same woman was also determined never to tell her daughter that she had been ill, again for fear that the girl might worry and thus inevitably fall ill again. Many similar remarks showed that there was a very general belief that there is a close interaction between psychological attitudes and the course of the illness.

These attempts to keep the illness a secret from the child were perhaps also another indication of the mother's unconscious feeling of guilt that the child should have been ill at all and of the fear that he would blame her for it. Another important factor, however, was that it was felt that having had tuberculosis was equivalent to "being branded for life," a phrase the psychiatric social worker heard several times. It was felt to imply both a social and a vocational stigma. There were fears whether the child later might have difficulties in finding employment if he knew, and therefore would have to tell, that he had once had tuberculosis. An adoptive mother of one of the children said that she had not disclosed the fact that the child had ever had tuberculosis even to a new general practitioner: "Why should I tell him—let him find out for himself."

Ostracism

In some families the attempt to keep the illness a secret from the neighbourhood had been the response to most painful experiences of ostracism and of consequent loneliness and isolation. The popular feeling that tuberculosis is a result of neglect, poverty, uncleanness, and therefore a very shameful disease, as well as the tremendous fear of infection, resulted in cases of what seem to have been really cruel behaviour. One boy, who was 6 years old on his return from the sanatorium and did not go to school until 18 months later when he was perfectly well, had found that at school no other child would play with him. He was shunned equally by the children in his street. He was told by the mother of a little girl in his school that he must not breathe in her face, and several children, at their parents' request, were not allowed to sit next to him. He also started at a Sunday school at about the same time, but two children told him that if he continued to go to Sunday school they would have to have the windows open all the time. The parents did not send him there after that. On his eighth birthday his mother invited some children to tea, but none came. They have not attempted to give parties for him since.

Stories of ostracism of this kind in cases where there was no longer the slightest risk of infection were not infrequent. Whether true or exaggerated, the result had been that some families felt themselves to be outcasts and became determined to keep their past illness a guilty secret. Having themselves experienced such ostracism, too, families often found that they had not the heart to take necessary precautions against the very real risks of infection by a member of their own family. For instance, one woman said that she used to take her small child to see her own ill sister as the latter adored the baby and "it would have been too cruel to keep the baby away from her."

It is perhaps of interest that many of the attitudes and feelings that struck the psychiatric social worker when visiting these families are noted also as the characteristics of children between 6 and 13 years suffering from tuberculosis and in hospital (Dubo, 1950). Dubo noted, among other findings, their intense anxiety and preoccupation with thoughts of death, their attempts at denial, the feeling of being different from other people and stigmatized, and their tendency to take personal responsibility for the illness. She concludes that there is a need for psychotherapy as part of the treatment programme.

Conclusion

Although a tremendous amount has already been achieved in combating it, tuberculosis remains the most important infectious disease at the present time. The close interrelation between adverse socio-economic conditions and incidence and course of the illness has long been recognized, and much has been done in the last decades to improve economic conditions for the tuberculous patient. That a great deal more remains to be done is testified by the enormous case load each welfare officer in a chest clinic still has to carry, these cases being primarily those of families where there is still an urgent need to ameliorate material and economic hardships.

From a psychiatric point of view a number of studies have been made relating tuberculosis to temperament or personality type, either from the point of view of the effects of suffering from tuberculosis on the patient's personality, or of the effects of the patient's personality on the incidence and course of the illness—for example, Wittkower (1949). There appears to be a paucity of studies, however, on the effects of the illness on the patient's social relationships, whether within the family or with the community outside. What struck us so forcibly in this inquiry were the extent of the social and emotional problems resulting from a tuberculous illness in a family, the complexity of the feelings and attitudes aroused, and in particular the tremendous need found in so many of these families to talk about their anxieties. It seemed almost as if this had been their first opportunity for a long time to do so to someone who was prepared to listen at length.

In view of the pressing needs for more preventive work, medical care, sanatorium beds, better housing, and more financial assistance, it may seem premature to ask that help be given to tuberculous families for their emotional and social problems. Yet we believe that these needs will have to be met in future, both for the sake of the families themselves and for that of the community. Not only is there much unhappiness which could be alleviated, but, because of the seriousness of the disease, very strong feelings are aroused which in many cases, instead of leading to wise action, lead the sufferer to behaviour which makes matters worse for himself and others. The more aware health workers of all professions are of such feelings and the greater their skill in handling them, the more effective their work is likely to be as regards both health education and case work with individual families.

The observations reported in this paper were made in the course of a research project sponsored initially by the Sir Halley Stewart Trust and later by the Central Middlesex Group Hospital Management Committee (which manages the Tavistock Clinic) and the International Children's Centre, Paris, for all of whose support we are grateful. We are particularly indebted to Dr. J. C. Roberts and the staff of Harefield Hospital and to the regional hospital boards and county council staffs of the chest clinics which serve the County of Middlesex, for their co-operation in the inquiry, and to Mr. James Robertson, of the Tavistock Clinic, who assisted us in it.

FATAL AGRANULOCYTOSIS DURING TREATMENT WITH CHLORPROMAZINE

BY

J. R. TASKER, M.D., M.R.C.P.

Consultant Physician, Northampton General Hospital

Although only recently introduced, chlorpromazine is already a widely prescribed drug. Serious complications encountered during its use should therefore be made known. The aim of this note is to record the clinical details of a patient who died of agranulocytosis during a course of treatment with chlorpromazine.

Literature

Mild and transient leucopenia during the early weeks of treatment with this drug is well recognized (Andersen, 1954), but fully developed agranulocytosis has seldom been recorded. Lomas (1954) drew attention to a 69-year-old woman who developed agranulocytosis after receiving 6 g. of chlorpromazine in 41 days. The total leucocyte count fell to 680 per c.mm., of which only 11% were polymorphs. The drug was withdrawn and prophylactic penicillin was administered, but after 10 days there was still no improvement in the blood count. The patient was then given five injections of 50 mg. of cortisone. Subsequently the white blood count rapidly became normal. A second case was reported from Denmark by Munch-Petersen (1954). His patient was a 71-year-old woman who was given 10.6 g. of chlorpromazine in 48 days. On the 46th day of treatment she developed diarrhoea and on the 48th her temperature rose. The white-cell count was 800 per c.mm., of which 14% were polymorphs. The patient was treated with repeated blood transfusions, folic acid, and prophylactic penicillin. In spite of a mild bilateral bronchopneumonia she made slow but steady progress, and nine days after the initial blood examination the white-cell count was again normal. A third example has been recorded in Norway by Giacobini and Lassenius (1954) in a 57-year-old woman who was treated with a combination of chlorpromazine and promethazine. The latter antihistaminic drug was used to enhance the sedative effect of chlorpromazine and to guard against any untoward sensitivity reactions. This latter device was notably unsuccessful. On the 40th day of treatment the patient complained of pain in the limbs and lassitude, and on the 45th day a blood count showed 900 leucocytes per c.mm., of which 200 (22%) were polymorphonuclears. The patient was treated with blood transfusion and penicillin, and recovered well. A fortnight after the discovery of agranulocytosis no abnormality could be found in the white-cell count.

All these patients were women, all were of middle or old age, and all recovered. All developed agranulocytosis at about the sixth week of treatment with chlorpromazine, and in none were there any warning signs of sensitivity to the drug. The patient described below differs from them in that she was a young woman, her illness proved fatal, and clear-cut clinical evidence of sensitivity to chlorpromazine preceded the development of agranulocytosis by an interval of 2½ weeks.

Case History

The patient was a married woman aged 38. She had first consulted a psychiatrist in 1943, when she was 27. A diagnosis of hysteria was made, and she subsequently attended the psychiatric out-patient department fairly regularly for a number of years. Her symptoms during this time were very numerous, and no organic cause for them could be found. They did not improve. In 1951 she was admitted to hospital in an hallucinated and maniacal state, which necessitated her early transfer to a mental hospital. There was little or no response to a course of electric

convulsion therapy, and she ultimately returned home. Between 1951 and 1954 she complained frequently of lassitude, syncope, excessive menstrual loss, and pain involving most parts of the body. These symptoms could be temporarily controlled only by frequent changes in treatment. Many remedies were therefore used. They included compound tablets of codeine; sodium salicylate and potassium citrate in simple mixtures; aspirin, phenacetin, and caffeine tablets; "hypon" tablets; and "amenorone" tablets. None of these preparations is known to depress the activity of the bone marrow. Amidopyrine and the sulphonamides were not used.

On August 17, 1954, treatment with chlorpromazine was recommended. The initial dose was 25 mg. three times daily, and this was doubled nine days later, the patient receiving 150 mg. daily on and after August 26. On August 28 she complained of lassitude and fever, and her temperature was 101.2° F. (38.4° C.). Although examination revealed no obvious cause for the fever it was thought best to treat her with procaine penicillin intramuscularly for three days. The fever lasted only two days. On September 1, however, 14 days after the treatment with chlorpromazine had started, she complained that she was passing pale faeces and dark urine. Jaundice was confirmed on clinical examination. Like the fever, this also was short-lived, and on September 4 was barely discernible. On September 6 a third complication arose: an irritating rash developed on the limbs. Two days later the presence of a discrete maculo-papular erythema was confirmed: it involved all four limbs, but particularly the thighs and calves. On September 10 the rash had gone. Up to this point treatment with 150 mg. of chlorpromazine daily had been continued without interruption. It was now continued throughout 2½ weeks of relatively good health. On September 27, however, after receiving 5,475 g. of chlorpromazine in 41 days, the patient developed ulceration of the gums and tongue and her temperature rose to 101.2° F. (38.4° C.). An immediate blood count showed 900 white cells per c.mm. (polymorphonuclear leucocytes 10%, lymphocytes 90%). A diagnosis of agranulocytosis was made. Treatment with chlorpromazine was stopped at once, and the patient was immediately admitted to hospital.

On admission the patient lay still and resented examination. Her temperature was 100° F. (37.8° C.), pulse 100, and respirations 22. Her tongue was dry and furred. There were numerous small ulcers on the mucous membranes of her tongue and pharynx. The gums were also ulcerated. There was no pallor of the mucous membranes, and no jaundice, rash, oedema, or enlargement of the lymphatic glands. The heart and lungs were normal; the liver and spleen could not be felt; and the urine contained neither albumin nor sugar.

In spite of the withdrawal of chlorpromazine and the prophylactic injection of 500,000 units of penicillin intramuscularly twice daily, the patient did not improve. An irregular fever between 99 and 101° F. (37.2 and 38.3° C.) was maintained, and ulcerative stomatitis persisted. Daily blood counts, the results of which are given below, showed a persistent grave granulopenia.

Date	Hb %	R.B.C. per c.mm.	W.B.C. per c.mm.	Polymorphs %	Platelets per c.mm.
27.9.54			900	10	
28.9.54	83		1,600	10	
29.9.54	83	3,800,000	1,500		
1.10.54			1,400		
2.10.54	70		900	15	290,000
4.10.54			800	5	

On October 2 profuse diarrhoea developed, and from this point the patient rapidly deteriorated. Next day she developed right lower lobar pneumonia which failed to respond to 2,000,000 units of penicillin intramuscularly, 500 mg. of oxytetracycline intravenously, and 2 g. of oxytetracycline

intramuscularly, all given within 24 hours. On October 4, one week after admission to hospital and seven weeks after starting treatment with chlorpromazine, the patient died. Permission for necropsy was not granted.

Comment

For two reasons it is difficult to avoid the conclusion that chlorpromazine was responsible for this fatal agranulocytosis. Firstly, the agranulocytosis developed six weeks after the first dose of chlorpromazine; this interval corresponds with that noted in other recorded cases. Secondly, the agranulocytosis followed definite evidence of sensitivity to chlorpromazine. Transient fever, jaundice, and skin rashes are well recognized as complications of treatment with chlorpromazine. The other drugs used before treatment with chlorpromazine began can scarcely be incriminated. They do not carry the reputation of toxicity towards the bone marrow, and they had been taken frequently and harmlessly by this same patient on previous occasions.

This case suggests that evidence of sensitivity to chlorpromazine should be treated with respect. Fever, jaundice, and skin eruptions during the early weeks of treatment should be taken as danger signals and should compel repeated examination of the blood, if not withdrawal of the drug. Ulcerative stomatitis, particularly if it occurs at about the sixth week of treatment, should be an absolute indication for the immediate cessation of chlorpromazine therapy.

CYST FORMATION SEVEN YEARS AFTER A CUTIS GRAFT REPAIR OF HERNIA

BY

A. G. RUTTER, F.R.C.S.Ed.

Consultant Surgeon, Queen Mary's Hospital, Roehampton

The use of skin in the repair of hernia was suggested more than forty years ago in Germany (Loewe, 1913), and was first applied clinically to post-operative incisional herniae (Rehn, 1914). It did not come into any general use for inguinal herniorrhaphy until Mair (1945) published his paper. The possibility of cyst formation due to the persistence of epithelial or glandular elements was not noted in the first two series of cases published (Mair, 1946; Marsden, 1948), but was stressed by Strahan (1950) in a series of 413 cases. Strahan found nine definite cases of cyst or sinus formation, with a number of others in which the presence of a cyst was suspected but not proved by actual operation. Most of the cysts in Strahan's series were small; but two were large, and his Case 3 is very similar to the one reported here.

Case Report

A railway worker aged 48 first developed a left inguinal hernia in 1946. The hernia was operated on in May, 1947, and the transcript of the rather brief operation note reads as follows: "Left inguinal incision. Poor musculature. Direct inguinal hernia. Cutis graft repair performed. Patient to remain in bed three weeks." The patient stated that he had made an uncomplicated recovery after operation, and that he had not returned to his job, which entailed heavy lifting, until August, 1947. He remained quite free from symptoms and from any sign of recurrence until June, 1954—more than seven years after the operation—when he began

to complain of pain in the groin, radiating into the testicle, and later noticed a swelling under his operation scar. He was examined by a surgeon, who diagnosed recurrent left inguinal hernia.

Examination showed a heavily built overweight man with protuberant abdominal wall rather heavily laden with fat. There was a well-healed oblique operation scar in the left inguinal region, and beneath it an elongated smooth solid swelling lying in the long axis of the inguinal canal. It was not reducible, but appeared to have some impulse on coughing. A diagnosis of incarcerated omentum in a recurrent hernial sac was made—the details of the previous operation being overlooked through an over-hasty perusal of a rather illegibly written case record.

At operation the first feature noticeable was the unusually dense fibrotic obliteration of the normal layers of the inguinal musculature. The swelling was obviously solid, and, after it had been separated from the spermatic cord and dissected up, it became apparent that it stopped short

at the internal ring and had no communication with the peritoneal cavity. The swelling, which measured 7 cm. in length and nearly 3 cm. in greatest diameter, was removed intact. Its removal left a potential weakness in the posterior wall of the inguinal canal, which was repaired with silk sutures after a relaxing incision in the anterior rectus sheath.

The patient made an uncomplicated recovery after operation, and left hospital with no evidence of any recurrent herniation.

The swelling, when examined after removal, proved to be a cyst, with walls varying from 2 to 5 mm. in thickness. It contained a waxy inspissated material, and several dark hairs, one of which was an inch (2.5 cm.) in length, were seen lying free in it. Histological examination of the cyst wall showed a well-formed squamous epithelial lining, with a connective-tissue backing resembling normal dermis, though without its papillary structure. The size and shape of the cyst are well shown in the photograph.

Comment

Apart from the cases mentioned by Strahan in his large series, only two cases have been reported in this country of cyst formation after buried skin-graft operations (Clarke, 1952; Powell and Ewing, 1952). Clarke made a thorough review of the relevant literature, and discussed the factors favouring cyst formation. His case, however, like most of the others, was a small cyst discovered coincidentally at operation for recurrent hernia. The possibility of the persistence of buried glandular elements was recognized by Rehn in his original paper. Experimental work by Zimches (1931) showed that a piece of skin inserted free into muscle tissue tends to curl up into a U shape and regularly to form an inclusion cyst; and even if sutured into position

under normal tension the epithelium may grow over the opposing surfaces and so form a cyst. This work was confirmed by Uihlein (1939), and all subsequent writers on the subject have emphasized the necessity of suturing the graft under as great a tension as possible—in contradiction of all the accepted rules for hernia repair. It is obvious, however, that this is a factor which cannot be controlled with complete certainty, and Strahan concluded that, in spite of the most careful technique, any surgeon doing a large number of these operations will inevitably meet some cases of cyst formation. Whilst this does not condemn the method, it must temper enthusiasm for it.

The present case is of interest for the large size of the cyst, requiring operative removal although the hernia itself had not recurred, and for the long interval of seven years between the implanting of the graft and the appearance of the cyst.

Medical Memoranda

Caeco-colic Intussusception Complicating Perforated Appendicitis

The association of caeco-colic intussusception with acute appendicitis seems to be rare, only one case having been found in the literature.

CASE REPORT

A boy aged 22 months was admitted to hospital on January 24, 1954, with a history that 48 hours previously he had had abdominal pain and had vomited once. After a few hours the pain went away, but it recurred 24 hours later, and there had been periods of screaming with evident abdominal pain and pulling up of the legs, and usually a vomit. The attacks lasted for 5–15 minutes and occurred every hour or so. Between the attacks he was quiet, and in the few hours before admission became rather drowsy and disinterested. He had been taking fluids fairly well between the attacks.

Examination showed a flushed and toxic-looking little boy. His pulse was 160 and temperature 101° F. (38.3° C.). The tongue was coated, but there was no evidence of dehydration. The abdomen showed generalized rigidity, maximal on the right side, where there was extreme tenderness. Rectal examination revealed a "bogginess" in the recto-vesical pouch but no blood. The chest and C.V.S. showed nothing abnormal. A diagnosis of peritonitis from appendicitis was made, although the recent history suggested an intussusception.

Operation.—Under anaesthesia a rather bulky, sausage-shaped mass was felt just to the right of and above the umbilicus. On laparotomy through a right paramedian incision a diffusing peritonitis was found and an amount of thin pus with small fibrin flakes was sucked out. The small gut was only slightly distended. The apex of the intussusception had reached the right transverse colon; it was pushed back and easily reduced. The apex was caecal, at the level of the appendicular base, which could not be seen, as the proximal half of the appendix was retroperitoneal. This part of the caecum was thickened and congested and the appearances extended back along 4 in. (10 cm.) of ileum, the mesentery of which was rather bruised. The distal 1½ in. (3.8 cm.) of the appendix, which was visible, was congested correspondingly, and it was obvious that all this gut was

fully viable. Over the area of the appendicular base was a small yellow patch, and on following the appendix back to its base by opening the peritoneum a small abscess surrounding a gangrenous perforated segment was revealed. The base was just clear, and appendicectomy was carried out. A small drain was inserted down to the area and the abdomen was closed.

Post-operatively the patient took fluids orally and was given penicillin and streptomycin by intramuscular injection, and after a slow first 24 hours he made a rapid and completely uneventful recovery. He was discharged twelve days later.

COMMENT

The clinical picture was interesting in that the recent history suggested intussusception, whereas the examination suggested peritonitis from appendicitis. The clear viability of all tissue except the perforated gangrenous segment of the appendix confirms that the appendicitis preceded the intussusception. It obviously must have done, otherwise there would have been no peritonitis. The presence of a localized abscess on the caecal wall initiated the intussusception.

It was remarkable how innocent the visible portion of the appendix looked, and this case may serve to emphasize that the appendix should be closely examined, especially where the apex of an intussusception is caecal. A small caecal abscess as an initiating mechanism was noted by Gavin Cleland (1953), but under different circumstances—following appendicectomy with invagination of the stump. Lipin and Miller (1948) reported a case of acute appendicitis complicated by intussusception in a man aged 21.

I wish to thank Mr. John Talbot for the opportunity of dealing with this case.

BLAIR A. THOMPSON, M.B., F.R.C.S.Ed.,
Senior Surgical Registrar, Harold Wood Hospital, Essex.

Recovery after Penetrating Wound of the Heart

Contrary to the accepted belief of the popular fiction writer, injury to the heart by a penetrating wound of the chest may occur without an inevitably fatal result. The following is a report of a case which came under my care.

CASE REPORT

On April 2, 1953, at about 10.30 p.m., a man of 22 was brought into the General Hospital, Ashton-under-Lyne, following a knife injury sustained during a brawl. He was extremely shocked and suffering from extensive blood loss. His clothing was heavily bloodstained and small cuts were present in his overcoat, jacket, and shirt in the left pre-cordial region. He was semiconscious and irritable, and needed considerable restraint to prevent him falling from the stretcher. Respiration was deep and sighing, there was extreme pallor of the lips, face, and hands; sweating was profuse, and no pulse was discernible at the wrist or in the neck.

After a slow blood transfusion the blood pressure rose to 56 mm. Hg, and it was decided to remove his clothing and examine his chest. There was a vertical incised wound in the fifth left intercostal space, about 1 in. (2.5 cm.) in length and 1 in. lateral to the mid-clavicular line. The wound was not now bleeding. Percussion revealed a stony dullness over the left half of the chest, with considerable mediastinal shift to the right. On auscultation no breath sounds could be heard on the left side of the thorax. A diagnosis of haemothorax was made, probably with injury to the left lung. When the systolic blood pressure had risen to 110 mm. Hg preparations were made for an emergency thoracotomy. However, on arrival at the theatre the blood pressure had fallen to 45 mm. and further resuscitation and transfusion were necessary before the operation could be started.

An incision was made along the line of the fifth rib and costal cartilage, from the mid-sternal to the mid-axillary line. On exposure of the rib, it was seen that the fifth costal cartilage had been severed close to the costo-chondral junction and the parietal pleura was open for about 1½ in. (4.4 cm.) vertically. The rib and cartilage were excised sub-periosteally from sternum to posterior axillary line, and the bed of the rib was incised medially and laterally from the edges of the original wound. After spreading the other ribs to open the wound, it could be seen that the left side of the thorax was occupied by a large quantity of blood clot, obscuring the viscera completely. About 3 pints (1.7 litres) of clot and blood-stained fluid were removed. No evidence of injury to the lung could be found; but a blood clot was protruding through a wound in the pericardium about 1½ in. (3.8 cm.) long on the anterior aspect close to the left border. The opening was enlarged to form an L-shaped flap, which was turned back, and the clots were removed from the pericardial cavity. This rendered the heart visible, and it was seen that ½ in. (1.3 cm.) lateral to the anterior coronary vessels, towards the left border of the heart, there was an incised wound lying in the length of its fibres and about 1½ in. (3 cm.) long. No blood was issuing from this wound and no attempt was made to separate the wound edges, which had adhered to each other. Five interrupted sutures of size 0 chromic catgut were inserted deeply, using each suture as a stay whilst inserting the next stitch, before cutting the ends. As much of the remaining clot as possible was removed from the pericardial space and the pericardium was closed loosely with 00 chromic gut. After further careful inspection the thorax was closed in layers without drainage, the left lung being inflated by the anaesthetist. The patient was then returned to the ward, and at that time his systolic blood pressure was 96 mm.

The following evening the mediastinum had deviated to the right and respiration was becoming laboured. There was dullness at the left base and both lungs were moist to auscultation. Aspiration of the left side of the chest yielded 10 oz. (280 ml.) of heavily blood-stained fluid. A similar aspiration after a further 24 hours yielded 12 oz. (340 ml.) of fluid, not so heavily blood-stained. No further aspirations were necessary, but an attempt was made to regulate the transfusion so that the blood pressure remained at about 100 mm.

The patient made an uneventful recovery and was discharged from hospital four weeks after admission. When seen six weeks later his only complaint was pain at the left base on coughing. There was no dyspnoea on moderate exertion.

I wish to thank Mr. P. W. Bleasdale for permission to publish this case; also the anaesthetist, without whom the operation would have been impossible. Last, but by no means least, I thank the nursing staff and laboratory technicians of the hospital.

R. W. LAWRIE, M.R.C.S.

A Case of Acute Nephritis in Pregnancy

Acute nephritis occurring during pregnancy is said to be rare. O'Dwyer and Montgomery (1954) reported three cases, and state that a search of the literature yielded only a further 23 cases. They suggest that with conservative treatment the course of acute nephritis is not adversely affected by pregnancy.

The following case of acute nephritis occurring in the fourth month of a second pregnancy is reported. The pregnancy resulted in normal delivery at term and apparent recovery of the mother. This was followed two years later by a third successful and normal pregnancy and delivery.

CASE REPORT

A 2-gravida aged 31 was first seen at the antenatal clinic on August 28, 1951, when three months pregnant. Her first pregnancy in 1945 had been normal. Her general condition was satisfactory. The urine contained no albumin,

the blood pressure was 130/70, and the haemoglobin 84% (12.5 g.). She attended again on September 11, when her general health remained satisfactory, the urine contained no albumin, the blood pressure was 120/70, and she had gained 1 lb. (0.45 kg.) in weight. There was no oedema present at either attendance.

On September 15 she developed a sore throat which lasted for three days, but did not seek medical advice until a week later, when she first noticed the dark red colour of her urine. On September 27, after three days of complete rest in bed at home, she was admitted to hospital on account of the rapid appearance of considerable oedema.

On examination on admission she looked ill, her face was pale and distinctly puffy, and there was considerable pitting oedema of the abdominal wall, sacrum, and legs. She was in no pain. The throat appeared normal. Her temperature, heart, and lungs were normal. The pulse rate was 80–84 a minute. The blood pressure was 144/92. There was no tenderness in the abdomen or renal angles and micturition was painless. The uterus corresponded to an 18-weeks pregnancy. The urine was a smoky red, boiled nearly solid, and a catheter specimen showed a heavy deposit of albumin, 6 pus cells per 1/6 field, many red blood cells, and a few epithelial cells. No casts were reported but much amorphous debris. Culture gave a scanty growth of *Bact. coli*. A throat swab showed no β haemolytic streptococci. In the first 24 hours 55 oz. (1.6 litres) of urine was passed and the albumin present measured 2 g. per litre (Esbach).

Treatment at the outset comprised absolute rest in bed and restriction of fluids and salt. Milk, fruit drinks, and glucose were allowed, and added vitamins. During the first 14 days in hospital the urinary output remained satisfactory; the oedema slowly lessened and disappeared. The urine remained, however, smoky red, and on October 10 the albumin measured 6 g. per litre (Esbach). The haemoglobin was 54% (8.5 g.). The retinæ were normal and the patient looked and felt better. The blood pressure varied from 140/88 to 148/92. During the next ten days the urine became normal in colour, the albuminuria diminished to 2.5 g. per litre (Esbach), and the blood pressure fell to 130/80. Oral iron was given and the protein in the diet was rapidly increased. She was discharged home to rest in bed on October 22. She was readmitted twice for a few days in November and again in January for reassessment.

On November 8 albuminuria was 1.5 g. per litre (Esbach) and the blood pressure 112/70, and on January 2, 1952, a catheter specimen of urine showed a faint trace of protein, and the deposit an occasional leucocyte and red cell with some epithelial cells and debris. Cultures showed no significant growth. The pregnancy proceeded normally. The blood pressure was 124/82 and haemoglobin 80%. The patient continued resting, mostly in bed, at home, on a normal diet with added vitamins and iron.

On February 26 she was normally delivered, in hospital, of a healthy 8 lb. 3 oz. (3.7 kg.) infant. The placenta appeared to be normal. At post-natal examination on April 16 she looked well, her blood pressure was 116/90, and an ordinary specimen of urine showed a faint trace of albumin.

Two years later, on March 3, 1954, after a normal pregnancy, she was normally delivered of her third child, a healthy infant weighing 8 lb. 10 oz. (3.9 kg.). Her blood pressure remained normal and was 120/70 at the sixth month, 10 days before delivery, and in the puerperium. The urine remained protein-free throughout. There was no oedema present before delivery. Post-natal examination six weeks later was normal.

I gratefully acknowledge the help given by Mr. William T. Kenny. I also thank Dr. John M. Malins, who kindly saw this case and confirmed the diagnosis of acute nephritis.

Reviews

PERIPHERAL NERVE INJURIES

Peripheral Nerve Injuries. By the Nerve Injuries Committee of the Medical Research Council. Editor: H. J. Seddon. Medical Research Council Special Report Series No. 282. (Pp. 451+xvi; illustrated. 55s.) London: H.M. Stationery Office. 1954.

Early in the second world war, as a direct result of the Medical Research Council's work in the first, a Committee on Nerve Injuries was appointed. This included neurological physicians and surgeons, orthopaedic surgeons, and anatomists. Special peripheral nerve injury centres were established; the work in them was co-ordinated largely through the efforts of the late Dr. George Riddoch, and the clinical workers made their material available to anatomical, physiological, and statistical study. The results of this great work are contained in the present substantial volume. It is mainly clinical, with excellent clinical photographs, diagrams, and photomicrographs. Many of the chapters deal with the surgery and orthopaedic management of the injuries, and there are monographs on rates of regeneration, vasomotor and vascular changes, electromyography, and factors influencing functional recovery, to mention only a few of the contents.

It is in the tradition of the Medical Research Council that it makes its accurate researches available to the hospital worker in a form he can enjoy. This compendium on nerve injuries is an excellent example of that practice. The large number of contributors must be pleased to see the results of so many years of work so clearly available to a wider field. Though the study of peripheral nerve injuries is a very specialized subject, as this book shows, most of us see a few examples each year. The value of this collection of monographs will be as a source of reference to knowledge acquired when, in war, it was possible to raise this subject to the status of a specialty.

DENIS WILLIAMS.

CHEMICAL SPECIFICITY IN BIOLOGICAL INTERACTIONS

Chemical Specificity in Biological Interactions. Edited by Frank R. N. Gurd. (Pp. 234+xv; illustrated. \$6.) New York: Academic Press Inc. London: Academic Books Ltd. 1954.

This is the third memoir of the University Laboratory of Physical Chemistry Related to Medicine and Public Health, Harvard University, and includes a foreword in memory of Dr. Edwin J. Cohn, Professor of Biological Chemistry at Harvard, who died suddenly on October 1, 1953, when the book was nearly ready for the printer.

This volume is largely based on a series of seminars held at Harvard during February and March, 1952. The chapters and authors are as follows: chemical specificity in biological interaction (E. J. Cohn); the effects of x-ray and other radiation on proteins and living tissues (S. Warren); physical and chemical properties of the steroids related to protein binding (R. B. Turner); biochemical problems of the steroid hormones (T. F. Gallagher); some studies on the active principles of the posterior pituitary gland (V. du Vigneaud); the influence of ion-exchange chromatography upon our concept of the structure of ribonucleic acid (W. E. Cohn); special problems in the formation of metal complexes (C. D. Coryell); interactions of metals with small molecules in relation to metal-protein complexes (J. Schubert); the specificity of metal complex formation (G. Schwarzenbach); the interactions of proteins with small molecules and ions (G. Scatchard, W. L. Hughes Jr., F. R. N. Gurd, and P. E. Wilcox). A short memoir of Konrad Dobriner (1902-52) by T. F. Gallagher is also included.

The treatment throughout is largely physico-chemical, and the biological aspects of the subject sometimes take second

place, though Warren's chapter is an exception in this respect. The importance of metals in biological systems is already well realized, and the chapters devoted to the interaction of metals with many different types of substance, and particularly with those of biological significance, is a valuable summary of the situation in an important but diffuse subject and one that is clearly related to the title of the book. References to the original literature follow each chapter, and the volume constitutes a valuable summary of research in selected aspects of an important but limited field of biochemistry.

F. G. YOUNG.

THE THYROID GLAND

Endemic Goiter: The Adaptation of Man to Iodine Deficiency. By John B. Stanbury, M.D., Gordon L. Brownell, Ph.D., Douglas S. Riggs, M.D., Hector Perinetti, M.D., Juan Itoiz, Ph.D., and Enrique B. Del Castillo, M.D. (Pp. 209; 53 figures. 32s.) Cambridge, Massachusetts: Harvard University Press. London: Oxford University Press. 1954.

Lectures on the Thyroid. By J. H. Means, M.D. (Pp. 113; illustrated. 24s.) Cambridge, Massachusetts: Harvard University Press. London: Oxford University Press. 1954.

There is a Means Club in America, but even if there were not the name of Means would be certain of immortality. These two small books display two aspects of his genius: the first is the product of his inspiration, the second its direct secretion.

There are few places to-day where endemic goitre can be studied conveniently in its natural state, unspoiled by the well-intentioned interference of the medical profession. Means conceived the idea of sending an expedition to Mendoza in Argentina, and the first book is the result. It describes in detail our present knowledge of the metabolic pathways of iodine and the manner in which these pathways may be deflected by iodine deficiency; the effects of thyroid administration, and of the exhibition of the blocking agent methimazole and the stimulant thyrotropin. The descriptions have an admirable clarity, and if thereafter the authors stray into somewhat terrifying mathematics they succeed in making even this section clearer than the appearance of the formula-filled pages would at first suggest.

The second book is an easier one for the uninitiated to follow. It consists of a series of lectures given by Dr. Means in various medical schools in the U.S.A. and England, and succeeds in making a lot of confusing subjects readable and clear. The place of the thyroid in the endocrine system, the physiology of the thyroid, the newer treatments of thyroid disorders, the aetiology of Graves's disease, and the place of iodine in physiology are discussed with a charming discursiveness which suggests dinner-table conversation recorded by a tape machine and edited by a scholar.

The first of these books is for the specialist, but the second provides excellent reading for everybody.

RAYMOND GREENE.

PSYCHOSURGERY

Psychosurgery and the Self. By Mary Frances Robinson, Ph.D., and Walter Freeman, M.D., Ph.D., F.A.C.P. (Pp. 118+ix; \$3.) New York and London: Grune and Stratton. 1954.

Prefrontal Leucotomy and Related Operations: Anatomical Aspects of Success and Failure. By Alfred Meyer, M.D.(Bonn), and Elizabeth Beck. (Pp. 60; illustrated. 10s. 6d.) Edinburgh and London: Oliver and Boyd, for the William Ramsay Henderson Trust. 1954.

Psychosurgery and the Self is the production of a non-medical psychologist to which Dr. Walter Freeman contributes a chapter. Taking up the "tremendous challenge to a psychologist"—namely, that batteries of established tests have yielded singularly little in the investigation of the personality changes that occur after operation—the author, Dr. Mary Frances Robinson, as the result of the employment of what she describes as "really three controlled interview techniques," reaches the hypothesis that "psychosurgery changes the structure of the self through reducing

the capacity for the feeling of self-continuity." An attempt is made to elucidate the concept and its implications for psychology and psychiatry. This discussion ranges over a wide field. Few would disagree with the contention that leucotomized patients tend to live to an unusual extent in the present.

Prefrontal Leucotomy and Related Operations, on the other hand, is a monograph of outstanding importance, and has the learning, clarity, and distinction to be expected of any work coming from Professor Alfred Meyer's Department of Neuropathology at the Institute of Psychiatry, Maudsley Hospital. It is based upon the study of 102 cases that came to necropsy, and gives a brilliant survey of what is known at present concerning the problem of the relevant role of quantitative and qualitative—that is, more regional—factors in producing the effects that are observed after operation; which in its turn bears upon the characteristically worded question posed by Freeman: "Do the frontal lobes function by mosaic or by mass action?"

Although Professor Meyer is too polite to say so directly, his work has been handicapped by inadequate case records. Special efforts, too, should be made to preserve the brains of leucotomized patients when they die; material invaluable for research is often wasted.

As the authors point out in the final paragraph of their conclusions: "Medial and orbital cuts are now being given a trial in many neurosurgical centres. The growing experience with these and other selective operations, particularly if in the fullness of time they should be anatomically controlled, will slowly resolve this problem of the relative role of quantitative and qualitative factors." This, from the clinical point of view, means how much to cut and where.

This monograph can be recommended without reserve.

DESMOND CURRAN.

LIVER PATHOLOGY

Pathologie du Foie: Etudes Cliniques et Biologiques. By Etienne Chabrol. (Pp. 214; 26 illustrations. 1,200 fr.) Paris: Masson et Cie. 1954.

This volume on the pathology of the liver is the fourth of a series on various aspects of hepatic disease written since 1941 by this distinguished French clinician. It makes no attempt at a systematic presentation, but comprises a miscellany of 23 chapters, ranging from 4 to 24 pages in length, dealing with topics as diverse as researches on biliary albumin and mucin and the evolution of the spa treatment of hepatic diseases. Despite this apparent diversity, the book retains a distinct sense of unity, partly because it is so obviously based upon the personal experience of a single individual, and partly because of the author's passionate desire to get away from the older concept of organ diseases and to present hepatic disease as only a special manifestation of a general body disturbance.

Anyone unfamiliar with the current French literature on the liver will find here much to surprise and interest him. Great claims are made for the use of antibiotics, especially aureomycin, in the treatment of various hepatic disorders, particularly infective hepatitis and cirrhosis. While appreciating that none of the antibiotics at present available has any effect upon the hepatic viruses, the author is convinced of the great importance of secondary infection and of its susceptibility to antibiotic therapy. Equally stimulating are the views expressed concerning the nature of gall-bladder pain and the role of the female hormones in its genesis, with special reference to their action upon the mucus secreted in the biliary passages.

Because of the obvious ignoring of work done outside France this book can in no sense presume to give an up-to-date presentation of our knowledge of hepatic disease. But as a record of one man's experience of over 50 years' work in both the laboratory and the clinic as the associate of many of the distinguished investigators of liver disease that France may rightly claim it can be warmly recommended.

L. E. GLYNN.

THE HOSPITAL ALMONER

Readings in the Theory and Practice of Medical Social Work. Edited by Dora Goldstone. (Pp. 344+vi; 37s. 6d.) Chicago: University of Chicago Press. London: Cambridge University Press. 1954.

Before 1948 many doctors regarded the main function of the hospital almoner to be assessment of the ability of patients to pay for their treatment. This was not a view which almoners themselves were prepared to accept. For many years they had attempted to establish a role more satisfying to themselves and more useful to patients, and the creation of the National Health Service gave them their opportunity.

For anyone who wishes to learn what almoners now consider to be the nature of their work this book by an American medical social worker (almoner) will be of value. It consists of a series of articles which deal with various aspects of medical social work in the United States, but most of the opinions expressed would probably be endorsed by almoners in this country. It seems clear that almoners now regard their most important task to be the practice of "casework" in a medical setting; but "casework" is variously defined. In one article (p. 109) its object is stated to be "to provide help to ill and disabled people with the personal problems associated with illness, its treatment and prevention"—a statement likely to be generally regarded as unexceptionable. Elsewhere (p. 112) the role of the caseworker is said to be "to help the person in trouble assess his situation, the problems and assets within himself and his environment, in order that he may capitalize on his strength and resources in moving toward maximum responsibility on his own behalf." This is the kind of service about which many doctors and some almoners are doubtful. The task of redefining the role of the hospital social worker is one which requires and merits the attention of doctors as well as of almoners.

THOMAS MCKEOWN.

EMERGENCY TOXICOLOGY

Handbook of Emergency Toxicology. By Sidney Kaye, B.S., M.Sc. (Pp. 303+xviii; 42s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954.

Emergency toxicology—that is to say, the recognition and treatment of acute poisoning at the earliest possible moment with a view to saving life—is the keynote of Mr. Sidney Kaye's handbook, but it also contains much information of great value to those who have to deal with the after-effects of the emergency.

The various poisons are listed alphabetically, with descriptions of their properties, minimum lethal doses, toxic symptoms, and specific identification. A drawback of such a strict classification and compression is an occasional lack of clarity, especially with regard to the symptoms. These are not described in order of appearance, or in terms of their acuteness or chronicity. This applies particularly to the comparatively few industrial poisons listed. Under benzene, for instance, the consequences of long-continued chronic intoxication are not distinguished from the acute effects—rapid irregular pulse, ataxia, dizziness, etc., leading to death.

Undoubtedly the most valuable part of the book is on the analysis of specimens of urine, gastric lavage, vomitus, and blood, and of tablets and capsules. This will be of great value to laboratory investigators who have rapidly to identify and determine the toxic substances concerned. The analytical procedures, described clearly and methodically, include not only isolation by steam distillation and extraction by suitable organic solvents, but also the most modern methods of photoelectric colorimetric estimation and absorption spectrography. This affords great facility for quick reference to any suspected toxic agent.

Suggestions for therapy are backed by the authority of the medical staff of the Department of Legal Medicine, Medical College of Virginia, and make a further admirable contribution to a book which cannot fail to fill a long-felt want in the field of toxicology.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 16 1955

CANADIAN MEDICINE

With the Toronto Meeting casting its agreeable shadows ahead, the sketch of Canadian medical history which appears in the opening pages of this issue gives a useful and in parts a picturesque background to a meeting which itself will be historic. Dr. H. E. MacDermot traces the story of medicine in Canada from the time of the early French settlers to the highly organized medical community which is now serving a nation of 15 million people stretched across the larger part of the North American continent. Canadian medicine has had its written history, notably a two-volume work covering four centuries, published in 1928, but Dr. MacDermot's selective picture, with its reference to outstanding events and personalities, is very welcome and apposite.

The history of medicine in Canada is linked with the history of the country itself. Many of the early doctors shared to the full the hardships, fatigues, and perils of the pioneers in other fields. They took their full part in the advance of settlement and civilization from the banks of the St. Lawrence to the Pacific coast, from the parallel of latitude 49° to the Arctic archipelago. Some of them, like medical men in other parts of the Commonwealth, notably South Africa and Australia, attained political as well as professional eminence and helped their country on its way to responsible government. The first president of the Canadian Medical Association when it was founded in 1867 was Dr. (afterwards Sir) Charles Tupper, who thirty years later became Prime Minister of Canada; and Sir Thomas Roddick, president of the first meeting of the British Medical Association in Canada at Montreal in 1897—indeed the first president of the Association outside the British Isles—was a member of the Federal Legislature.

From rough beginnings there has gradually been established a system of medical education and practice in Canada which is second to none. There are now twelve medical schools, the third to be founded being the University of Toronto, established 110 years ago, and in order of date preceded only by the two universities—French and English—of Montreal. It

was in the University of Toronto that William Osler, himself born in Ontario, began the study of medicine, although his name is more closely associated with McGill. In the department of physiology of the same university Frederick Banting began his researches on the internal secretion of the pancreas. The contributions to medical knowledge of the Canadian medical schools and laboratories make a brilliant list. Canada has also its own medical literature, which is studied all over the world. One of the remarkable features of the earlier period, as Dr. MacDermot points out, was the prolificity of medical journals; and since the first of them in 1826—a French publication—72 journals have been established, most of which have died a natural and generally an early death. There are now 18 journals, and conspicuous among them is the *Canadian Medical Association Journal*, the editorial chair of which Dr. MacDermot, to the general regret, is shortly to relinquish.

At one time Canada had, nominally, some half-dozen Branches of the British Medical Association, but they seem never to have functioned as Branches and to have had only a paper existence. Then in 1924, on the proposal of the Council of the British Medical Association in London, the late Sir Jenner Verrall and the late Dr. Alfred Cox, then secretary, were sent as delegates to Canada, and the result of a most cordial visit was an affiliation of the two Associations. Affiliation was then a new idea, though it has since been adopted in the case of the Medical Association of South Africa and more recently the Indian Medical Association. The bond with Canada which was then formed was more of a sentimental than of a material nature, but it has proved strong and enduring over thirty years, as many such loosely knit bonds do where the British people are concerned. It has been strengthened by much two-way traffic across the Atlantic, and among Canadian visitors none has been more welcome than Dr. T. C. Routley, who will preside over the Toronto Meeting. Dr. Routley became general secretary of the Canadian Medical Association in 1921, at a time when it was in low water after the first world war. The relationship between the professions in the two countries has been further strengthened by the three previous visits of the British Medical Association to Canada—the first, as already stated, in 1897, to Montreal; the second, in 1906, to Toronto, and the third, in 1930, to Winnipeg. With the exception of the Melbourne Meeting in 1935, these are the only occasions on which the British Medical Association has left this country for its Annual Meeting.

The heritage of British institutions has left its stamp on medicine in this the oldest and largest of

the British Dominions, as it has on other aspects of Canadian life. In many respects the progress and pattern of medicine in public affairs, in science, and in education has been the same in the two countries. The ties will be further strengthened by the forthcoming meeting at Toronto, which is looked forward to on both sides of the Atlantic with high expectations.

NEW PATTERNS OF MALARIA CONTROL

The mass of detailed information now gathered on the intensive use of residual insecticides, particularly D.D.T., during the last ten years permits an appraisal of their value and limitations. The eradication of malaria had not previously been considered practicable except in small areas and under special circumstances, but soon after the introduction of the new insecticides the virtual abolition of the disease was envisaged in many places and has been effected in some. In only two areas have the vector anophelines been completely eradicated; in both the mosquito was an introduced species not indigenous to the country. The reason for the failure to eradicate vectors elsewhere is that the indigenous mosquito species probably antedated the advent of man, and, though they have since become more or less domestic in habit, a proportion of them still maintain their original association with wild animals and natural resting places. This sylvan population continues to live independently of man and inaccessible to routine control measures, but it can readily replace the domestic population when this is eliminated by insecticidal campaigns; and, by virtue of its ability to adjust to a new environment, it can become parasitic on man and a vector of malaria.¹

A problem now causing concern is that strains of insects which originally proved susceptible to deposits of these insecticides have sometimes shown an increasing resistance to their effects, at first to D.D.T. but later to other chlorinated hydrocarbon preparations. The resistant strains are no longer susceptible to spraying of insecticides in dilutions and at intervals which are economically practicable. The development of resistance was first observed in houseflies, then in certain other insects, and some recent observations indicate its appearance in at least two anopheline species.²⁻⁴ It probably develops as a result of natural selection and repeated sub-lethal contacts with the insecticides and is transmitted hereditarily. As to

certain other anopheline species which still remain susceptible to deposits of residual insecticides in the dosages normally applied, control by residual spraying has ceased to be effective because the mosquito has changed its habits and stopped frequenting sprayed buildings.⁵

The difficulties that have arisen in residual insecticidal spraying for malaria control have made urgently necessary further intensive study of the reactions of anophelines to these chemicals if they are to go on being as valuable as they have been. The principles on which they are to be applied should also be clearly defined so far as our present knowledge allows, and Pampana⁶ has recently discussed the changing strategy of malaria control. He emphasizes that malaria can be eliminated without elimination of the vector and that it is necessary to control transmission only during the lifetime of the malaria parasites inhabiting their human hosts. When all the plasmodia have died out—after a control period of three to four years for *Plasmodium falciparum* and *P. vivax*, which alone are widespread—further transmission is impossible even though anopheline vectors remain numerous; and provided the disease is not reintroduced the area will remain free of malaria. This is an important revision of an opinion previously widely held—that control by the spraying of residual insecticides had to be continued indefinitely unless the vector was eradicated. Experience has shown that elimination of indigenous malaria vectors is exceedingly difficult, and to spray residual insecticides over a long time is to risk creating an anopheline strain resistant to this method of control. Insecticidal spraying must therefore be restricted to as short a period as allows satisfactory control.

Certain conditions must be fulfilled before the spraying campaign can be safely discontinued. The first essential is the absence of malaria transmission for several years over most of the territory. In order to ensure this, no sources of infection must remain in the control area. In addition to applying the usual criteria for determining endemicity (particularly spleen and parasite rates), cases of malaria must be actively searched for, and they should be shown to be absent for at least a year before discontinuing spraying. The control campaign should be carried on thoroughly and simultaneously over as large an area as possible, which should preferably be surrounded by a zone in which malaria is absent naturally or as a result of control measures. The danger of reimporting the disease from contiguous malarious territories has to be guarded against, and if it can be arranged these areas also should undertake control campaigns simultaneously. Ideally, control should extend over a whole continent, and this objective has been adopted

¹ Logan, J. A., *The Sardinian Project*, 1953, p. 353, Baltimore.

² Livadas, G. A., and Georgopoulos, G., *Bull. Wild Hlth Org.*, 1953, 8, 497.

³ Georgopoulos, G. D., *ibid.*, 1954, 11, 855.

⁴ Garrett-Jones, C., and Gramiccia, G., *ibid.*, 1954, 11, 865.

⁵ Trapido, H., *ibid.*, 1954, 11, 885.

⁷ Vincke, I. H., *ibid.*, 1954, 11, 785.

⁸ Farinaud, M.-E., and Choumara, R., *ibid.*, 1954, 11, 793.

in America. The final safeguard is the introduction of measures to ensure rapid detection of any case of malaria and prompt prevention of transmission. The reintroduction of malaria into a population which as a result of control of the disease has lost its acquired immunity might lead to a grave epidemic, and if the local vector had become resistant to residual insecticidal spraying one of the most efficient and economical control measures would be ineffectual. The new pattern of campaign against malaria outlined here necessitates the organization of exceptionally thorough control programmes over very large areas comprising several territories, and entails greater expenditure than hitherto and better methods of detecting isolated cases of malaria. But it would be more effective and produce more rapid results. Though more costly for a few years, it would lift the burden of indefinitely recurrent expenditure on malaria control.

The problems raised by these new public health measures have stimulated interest in older and proved methods of control. New chemotherapeutic compounds are being tried either alone or in combination with D.D.T., and perhaps in suitable circumstances malaria may be eradicated sooner by a combination of these methods than by D.D.T. alone.⁷ In this way it may be possible to reduce the risk of resistance developing to the insecticide or of behavioural change by the vector while at the same time avoiding the expense of the type of campaign envisaged by Pampana. Although the new insecticides create new and possibly serious problems, malariologists can devise methods of overcoming them.

E.C.T. IN PREGNANCY

Convulsion therapy is now accepted as a reliable means of terminating most attacks of endogenous depression months or years before they would remit of their own accord. The intense suffering of these patients and the constant risk of suicide justify the induction of epileptic fits not only in physically healthy subjects but, with the proper precautions, in patients who would be regarded as increased anaesthetic risks. Depressive states are not infrequent in pregnancy, yet the risk of inducing a miscarriage must have deterred many psychiatrists from giving E.C.T., and one well-known textbook of psychiatric treatment lists pregnancy as a contraindication to it.¹ Information in the literature is scanty, but it hardly supports the view that E.C.T. carries more risk of miscarriage than does a brief anaesthetic. F. B. Charatan and A. J. Oldham,² reporting a case and reviewing the literature (which covers only about a dozen cases), conclude that convulsions can be induced after the fourth

month with little danger of miscarriage. This is consistent with our knowledge of the idiopathic epileptic fit. C. W. F. Burnett³ found that in sixteen pregnant epileptics only one miscarriage occurred, and that was in a patient who had fallen heavily in a fit.

E.C.T. is now usually administered with thiopentone and a relaxant, and there is no reason to suppose that this procedure is more likely to harm the foetus than a brief general anaesthetic given for any other purpose. At the same time, unnecessary anaesthetics are usually avoided during pregnancy, and the number of reported cases in which E.C.T. has been successfully given is small. On inquiry of eight experienced psychiatrists, however, all but one said they had given E.C.T. during pregnancy but had hesitated to put the fact on record. Since the alternative to treatment is an intensely unhappy pregnancy, with the possibility of labour and the puerperium in a psychotic state, and since severe depression in early pregnancy is sometimes considered as justifying termination, there would appear to be slight reason for hesitation. Perhaps the greatest risk lies in anoxia due to a poor airway at the time of treatment, but with an experienced anaesthetist the risk must be small. While an adequate number of records of successful cases is being accumulated, the administration of E.C.T. in pregnancy would seem to be justified when there are strong indications for it—the same precautions being taken as with a general anaesthetic.

MENTALLY HANDICAPPED GIRLS

What happened to 207 mentally handicapped girls after they left school has recently been studied at the department of public health and social medicine in the University of Glasgow.¹ The study covers the social and economic history, but not the medical history, of the girls for a period of six years between leaving one of the special schools for the mentally handicapped in Glasgow and the attainment of age 22.

The social background of these girls was by no means typical of Glasgow as a whole. Almost 90% of the fathers who were still alive when the girls left school could be placed in the lower ranks of the social hierarchy. About 25% of the girls suffered from some degree of speech impairment, while 12% were described as "of poor physique or having some severe physical impairment." When we add to this 31% of the girls "from homes classified as frankly 'bad'" by an experienced social worker, it will be realized that mental dullness was by no means the only handicap with which the girls left school to begin a career. By 1954, when they had reached the age of 22, 55 were already married. If the girls are divided into two groups, according to whether the school measurement of I.Q. was below or above 50, the outstanding fact emerges that all who were married were drawn from the over-50 group. However, the marriage rate of about 28% for this group compares with nearly 40% for all women of the same age in Glasgow enumerated at the 1951 census. The chance

¹ Ferguson, T., and Kerr, Agnes W., *Glasg. med. J.*, 1955, 38, 50.

of marriage for the under-50 group can scarcely be said to exist. So far as could be ascertained the illegitimacy rate among the unmarried was about the same as in Glasgow as a whole.

The employment history of the girls shows the same remarkable dichotomy at the 50 level of recorded I.Q. None of the under-50 group had a record of five or more years in employment, while about 75% of the remainder had. The authors record the number of different jobs held by the girls, but in the absence of comparable data for normal adolescents the figures cannot be interpreted. Of those in employment when the study was made, nearly half were in occupations that would be classed as semi-skilled, but "general labouring work, often dirty, sometimes in foundries" claimed about one in five. The authors point out that in the present industrial conditions there is no lack of work in Glasgow which can be performed by educationally retarded girls. In an era of full employment their problems are social rather than economic.

Should the authors decide to publish a more extended account of their interesting survey they might provide a little more information. In the first place they give no hint of the way in which their 207 subjects were selected, beyond the fact that they had attended a special school for the mentally handicapped. They may have been all who left special schools in a specific year, or all who came within a certain range of recorded I.Q., or all for whom information could be obtained. If the last was forced upon the investigators, then clearly some warning about possible sources of bias will be needed. The tendency to parade our successes and hide our failures is not unknown. Moreover, in making comparisons, the authors do not consider the errors inherent in the sampling process. One or two rough tests suggest that they have satisfied themselves that the points of interest to which they draw attention could scarcely be ascribed to errors of this kind, but attention might well be drawn to the point in view of the small numbers in some of the groups. Finally, some of the comparisons made with Glasgow as a whole may be misleading in view of the social background of the subjects. The marriage rates set out in the study suggest that the chances of marriage for the group with I.Q. over 50 are reduced by about one-third as compared with normal subjects. It is known, however, that the average age at marriage is apt to be low if the social class is low. Had the subjects been compared with a control group drawn from the same social milieu, it seems likely that an even larger difference in the marriage rate might have been brought to light.

BLOOD COAGULATION

The one-stage prothrombin-time test, introduced by A. J. Quick,¹ is a reliable method for controlling dicoumarol therapy, despite the fact that the test is largely empirical and there is much controversy about what it actually measures. The classical theory of blood coagulation held that in the presence of optimum thromboplastin—that is, brain extract—and calcium the rate of thrombin formation depends on the concentration of prothrombin.

If this were true, the one-stage prothrombin-time test would be a specific measure of prothrombin. This thesis was destroyed by the discovery of two coagulation factors, distinct from prothrombin, which play an important part in the activation of prothrombin by brain extract. Quick² noted that the one-stage prothrombin time of oxalated plasma became prolonged during storage, and that this abnormality was corrected by the addition of fresh plasma from which all prothrombin had been removed by a prothrombin adsorbant—for example, barium sulphate, aluminium hydroxide, or Seitz filters—but not by old serum. This factor was termed "labile factor" by Quick. Another factor which affects the one-stage prothrombin time is found in a stable form in plasma and serum, and is therefore called "stable factor." This factor is adsorbed by prothrombin adsorbants. The prolonged one-stage prothrombin time of plasma deficient only in the stable factor is corrected by the addition of prothrombin-free, normal serum. Recent evidence suggests that brain extract undergoes preliminary reactions with calcium, labile factor, and stable factor to form the complete thromboplastin, which activates prothrombin.³⁻⁵ Thus it would appear that plasma is clotted in three stages by brain extract: (1) Brain extract + labile factor + stable factor + calcium form complete thromboplastin. (2) Prothrombin reacts with complete thromboplastin to form thrombin. (3) Fibrinogen reacts with thrombin to form fibrin. The one-stage prothrombin-time test is a measure of the time required for these three reactions. Since the concentrations of calcium and brain extract are standardized, the most important factors which influence the prothrombin time of plasma are labile factor, stable factor, and prothrombin. Quick postulates that plasma prothrombin occurs in an inactive form (prothrombogen) and an active form. He believes that in the presence of optimal calcium, brain extract, labile factor, and stable factor the one-stage test is a measure of active prothrombin, and he and Clara V. Hussey present evidence to support this view in an article at p. 934 of the *Journal* this week. Many other workers in this field would question the hypothesis.

The prolongation of the one-stage prothrombin time produced by administration of dicoumarol is due to reduction of both prothrombin and stable factor. The stable factor rapidly falls to less than 10% of normal, but prothrombin, measured by a two-stage technique, seldom falls below 40% of normal.⁶ This and other evidence suggests that the reduction in stable factor may be more important than that of prothrombin in determining the one-stage prothrombin time in a patient on dicoumarol.⁶

If Russell's viper venom and lecithin are substituted for brain extract, the one-stage prothrombin-time test becomes insensitive to changes in stable factor. With this reagent the test shows prolonged prothrombin time of

plasma deficient in prothrombin and labile factor, but the test is normal with plasma deficient in stable factor.^{7,8} In the presence of optimal labile factor, as in the plasma of a patient on dicoumarol, the one-stage prothrombin-time test with Russell's viper venom and lecithin is a roughly specific measure of prothrombin.⁸ But this thromboplastic reagent has proved to be unreliable in controlling dicoumarol therapy, for serious haemorrhage may occur at a time when the one-stage prothrombin time with Russell's viper venom is only slightly prolonged. Likewise the two-stage test is not a sound method for controlling dicoumarol therapy. Thus there appears to be no correlation between the prothrombin level and the danger of haemorrhage; a reduction in stable factor, or some other coagulation factor, may be more closely related to the risk of haemorrhage during dicoumarol therapy.

Although, as Quick believes, the one-stage test may measure active prothrombin in the presence of optimum labile and stable factors, as in normal plasma, this is not necessarily true for plasma in a patient on dicoumarol, which is deficient in both prothrombin and stable factor. With such plasma the one-stage prothrombin-time test is a non-specific measure of the total coagulation defect produced by a dual deficiency of prothrombin and stable factor. For this reason the test, with brain extract, is a more reliable guide for anticoagulant therapy than methods that are more specific for prothrombin.

PSYCHOSOMATIC APPENDICITIS?

The aetiology of acute appendicitis remains unknown and its varying incidence in different social classes unexplained. At first sight this might seem one of the last conditions in which to invoke a psychosomatic explanation, but if the activities of the colon and the small intestine are influenced by stress and emotion, why not those of the appendix? In an investigation of psychological factors in ulcerative colitis in 1948, J. W. Paulley started using cases of acute appendicitis as controls. He found, however, that they were usually tense individuals with an unduly rigid outlook, and their attack of appendicitis had often been closely related in time to some family disaster or period of emotional strain. They were therefore considered unsuitable as controls after nineteen had been interviewed. He has now examined¹ a further ten consecutive patients with acute appendicitis, and claims to have found the same kind of precipitating situation in eight of the ten. A. L. Ribeiro,² practising in Kenya, has also recently reported fear or anxiety as a cause of appendicitis. He described four cases of negro women in whom appendicitis developed soon after they had been threatened in various ways.

As Paulley says, the records of his 29 cases (or 30 if the well-known case of King Edward VII is added) prove nothing, but they raise interesting questions. The higher incidence of acute appendicitis in the upper social grades seems to be definite. Will this turn out to be due not to differences in diet, but to the in-

creased stress to which the more diligent and responsible members of society are exposed? Perhaps the answer will be found when surgeons take psychosomatic histories from all their patients.

SICKLAEMIA AND FLYING

It has long been known that in those inheriting the sickle-cell trait sickling of the red blood cells is brought about by anoxaemia. This fact is made use of in the commonly used rapid method of detecting sickling, in which a reducing solution consisting of 2% sodium metabisulphite is mixed with the suspected blood.¹ It is to be expected, therefore, that sickling in the blood of those carrying the trait will be accelerated when they are taken to high altitudes in unpressurized aircraft and that this may lead to sickling crises or other complications. Sullivan² first reported such a complication in an 18-year-old coloured American soldier who had sicklaemia and who in May, 1947, while on a flight across the Rocky Mountains complained of nausea and cramp-like pain in the left upper quadrant of the abdomen. The pain persisted for six days, recurred during a return journey six days later, and again persisted for several days. The patient was found to have a firm, tender mass (15 cm. in diameter) in the painful area of the abdomen. The mass regressed but little during the subsequent two months. Cooley and his colleagues³ reported six further cases; these patients were all negroes who had flown for at least one hour in unpressurized aircraft at altitudes between 10,000 and 15,000 ft. (3,000 and 4,600 m.), and in five of them the symptoms—very much the same as those in the case already described—came on while they were crossing the Rocky Mountains en route from Korea. Splenectomy was performed in each case, and massive infarction of the spleen without major arterial thrombosis was invariably found. Conn⁴ has added a further two similar cases to the series. Both the patients were negroes who had flown over the Rocky Mountains: they were treated conservatively, as Sullivan's patient was, with excellent results.

In these nine reported cases there appears to be a clear association between the occurrence of splenic infarction and anoxaemia caused by flying at a high altitude in unpressurized aircraft—the absence of pressurizing is confirmed in six of the cases and may be taken as likely in the remaining three. Findlay, Boulter, and MacGibbon⁵ showed that flight at such altitudes may cause sickling of circulating red blood cells. They carried out experiments on three African volunteers bearing the sickle-cell trait who were taken in an unpressurized aircraft to 15,000 ft. (4,600 m.). No ill effects resulted, though all three had sickled red blood cells in the peripheral blood after 10–15 minutes at that altitude. Findlay and his colleagues rightly concluded that, "though flying for a short time at 15,000 feet does not necessarily induce a sickling crisis through reduction of oxygen tension, it may obviously cause an increased rate

⁶ *J. Amer. med. Ass.*, 1954, 156, 955.

of sickling, and as Africans vary in the reduction of oxygen tension necessary to produce sickling it is possible that sooner or later an African will be found who will sickle when flown at 10,000 or 15,000 feet for a comparatively short time." The splenic infarction reported by the American observers appears to be a direct result of this increased rate of sickling at high altitudes. Among those who have studied such cases, there is, however, one dissenting opinion about the necessity of exposure to high altitudes. Doenges and his co-workers⁶ reported splenic infarction in two negroes after flights at between only 4,000 and 6,000 ft. (1,200 and 1,800 m.). Both patients bore the sickle-cell trait, but were found to have haemoglobin C in their blood as well as haemoglobin S, and this raises the possibility that the presence of haemoglobin C may make the patient more liable to develop this complication under conditions of slight anoxaemia than does haemoglobin S.

The observation of splenic infarction in those carrying the sickle-cell trait need cause no alarm among the air-travelling negro public. Civil airlines do not normally fly unpressurized aircraft at heights greater than 7,000 ft. (2,100 m.), and at this level the condition is unlikely to develop except possibly among the rarer haemoglobin-C carriers. The smallness of the risk is emphasized by the fact that no complications of sicklaemia have yet been reported among the many thousands of negroes carried by the British Overseas Airways Corporation and its associates operating in Africa. The real importance of the observation lies in the fact that those carrying the sickle-cell trait should be excluded when personnel are being selected for piloting aircraft or for other work at considerable altitudes or under conditions of relative anoxaemia.

AMYLOIDOSIS IN RHEUMATOID ARTHRITIS

Amyloid degeneration has been recognized for just over 100 years as a serious but relatively uncommon complication of chronic suppuration and other chronic diseases, especially those associated with much breakdown of tissue such as osteomyelitis and pulmonary tuberculosis. But its incidence in rheumatoid arthritis is generally regarded as low. That this impression is probably based on inadequate necropsy investigation is suggested by the recent reports by D. L. Fingerman and F. C. Andrus¹ and by G. Teilmum and A. Lindahl² of thirteen cases out of sixty-one and of seventeen out of twenty-eight respectively. When the five cases of J. M. Ræce and T. B. Reynolds³ are included, the published reports of generalized amyloidosis associated with rheumatoid arthritis now total ninety-seven. Two-thirds of these cases have been published in the last ten years, a testimony to the growing interest in the rheumatic diseases rather than to any change in their pathological characteristics.

The distribution of the amyloid deposits in these cases is that usually found in so-called secondary amyloidosis. The spleen, kidney, and adrenals are the organs princi-

pally affected, though the liver and lymph nodes are also frequently involved. Albuminuria is the commonest clinical feature calling attention to the onset of amyloidosis; less often splenomegaly, with or without hepatomegaly, may be the presenting sign. In most of the recent cases the Congo red test has been of help in diagnosis.

The association between rheumatoid arthritis and amyloidosis is of the greatest theoretical interest for the light it might throw on the pathogenesis of these two aetiologically obscure maladies. The work of G. Hass⁴ and others has shown that chemically amyloid is closely related to the interfibrillary ground substance of connective tissue. Both are composed of glycoproteins the polysaccharide moieties of which yield on hydrolysis a hexosamine, a hexuronic acid, and acetic and sulphuric acids. As amyloid deposition occurs in the affected organs in close relationship to reticular fibres and just outside capillary endothelium, it is essentially a deposition within the ground substance of substances closely related to it in chemical composition. This suggests that the excessive breakdown of connective tissue might release into the blood stream ground substance components in soluble form capable of precipitation elsewhere as amyloid. Experimental attempts to induce amyloidosis on these lines have consistently failed. The alternative hypothesis, put forward by G. Teilmum,⁵ accounts in a more satisfactory manner for the association of amyloidosis not only with rheumatoid arthritis but with the other conditions with which it is more frequently found. According to Teilmum amyloidosis is the result of a perversion of the protein-synthesizing function of the reticulo-endothelial system, and especially of its pyroninophil derivatives the plasma cells and their immediate precursors. These cells are concerned with the formation of antibodies in response to antigenic stimuli, and according to this author their maintenance of this function is controlled by the antithetic actions of ascorbic acid on the one hand and adrenal corticoids on the other. The breakdown of this control in the face of persistent antigenic stimulation then results in the local deposition of amyloid. Apart from accounting for the pre-eminent distribution of amyloid in the tissues rich in reticulo-endothelial components such as the spleen and liver, it also provides a reasonable explanation for the associated abnormalities in the serum proteins. And, although the evidence for a persistent antigenic stimulus in rheumatoid arthritis is scarcely convincing, the predominant role of the plasma cell in the typical rheumatoid lesions is unquestionable.

Sir Russell Brain was re-elected President of the Royal College of Physicians of London on April 4. He was first elected President of the College in 1950.

At the meeting of the Council of the British Medical Association on April 13, Professor Norman B. Capon, of Liverpool, was presented with the Dawson Williams Memorial Prize for 1955 in recognition of his work in child health, particularly in the field of neonatal paediatrics.

EMERGENCIES IN GENERAL PRACTICE

CORROSIVE POISONING

BY

J. D. P. GRAHAM, M.D., F.R.F.P.S., M.R.C.P.Ed.

Lecturer in Toxicology, Welsh National School of Medicine, Cardiff

A corrosive is a substance which causes destruction of tissue at the site of application; in dilute solution many corrosives merely have an irritant effect, but irritants may corrode at certain sites. According to this definition the effects of a corrosive should be limited to its local action, but some of them produce serious effects from absorption, so the classification is a loose one. Corrosives may be defined more accurately therefore as "substances having an acute and predominantly local action involving destruction of tissue." The speed and the destructive nature of the poisoning constitute an emergency in which early and effective treatment is essential.

Incidence

According to the Registrar-General's Statistical Reviews, corrosives are an infrequent cause of death (see Table).

Deaths from Violent Causes (England and Wales)

Year	Total	All Poisons	Corrosives
1950 ..	18,889	3,274	184
1951 ..	19,756	3,557	157
1952 ..	18,802	3,666	129

A survey of 4,393 reports of post-mortem examinations conducted by the Department of Pathology in the Welsh National School of Medicine during the five years 1948-53 showed that the cause of death was by poisoning in 39 persons. Of these, one was due to carbolic acid and one to ferrous sulphate. A survey of the diagnoses made on 58,540 admissions to the three principal institutions of the United Cardiff Hospitals during 1951, 1952, and 1953 reveals that 251 cases of poisoning were treated. Of these, only nine were due to the classical corrosives taken internally, of which five were due to "lysol" or carbolic. During the same period 201 patients were treated for external burns due to hot objects—fires, electrical apparatus, heating devices, scalds, friction, irradiation, or chemicals. Only four were due to corrosives. Of a total number of 25 cases of burns and chemical injuries to the eye, 15 were due to corrosives. The Annual Report of the Chief Inspector of Factories for 1949 shows that of a total of 8,787 accidents involving the eye, 235 were due to chemicals (167 lime and cement). The precise number due to corrosives is not stated. The same source states that of 569,485 accidents in 1949, 1950, and 1951, 21,595 were due to hot liquids, molten metal, and corrosives. No detailed analysis is available.

It may be deduced from these and other sources that corrosive poisoning is not a common cause of emergency.

Corrosives Likely to be Encountered

The following are the common corrosives: (1) *Acids*: (a) Inorganic—hydrochloric, sulphuric, and nitric; (b) organic—carbolic, cresol and related products, oxalic. (2) *Alkalis*: sodium and potassium hydroxides and carbonates, lime. (3) *Other corrosives*: formaldehyde, salts of certain heavy metals, bichromates.

When taken internally the majority of poisonings are due to lysol and related products, with acid (usually hydrochloric) the next most frequent. From analyses of deaths by poisoning in England and Wales during 1950, 1951, and 1952,* it is seen that of 335 cases of corrosive poisoning 175 were due to lysol, phenol, and related products, and 59 to acid. The common source of the cresols is by purchase of

disinfectant fluids. While most cases are suicidal, a few accidents occur, presumably owing to the keeping of small quantities of disinfectant in old medicine or liquor bottles (19 accidents to 156 suicides in this series). Accidents are evenly distributed between men and women, but the latter preponderate in the use of this method of self-destruction (115 women to 41 men).

Corrosive poisoning from swallowed mineral acid is much more common than that from caustic alkali, and the majority of cases are due to suicidal attempts (12 accidents to 52 suicides). Most of the accidents happen to men, and hydrochloric acid is by far the commonest agent. The same applies in the case of suicide, though the preponderance of males to females is less. The cause for this is obscure, but spirits of salts (hydrochloric acid) may be purchased from the pharmacist and kept in old bottles prior to use as a cleaning agent for glazed surfaces. Hydrochloric and sulphuric acids are widely used in industrial processes, and some may be obtained from the factory for private purposes such as soldering fluid.

Oxalic acid is less common as a corrosive agent than it used to be, but a few cases of poisoning still occur (seven suicides and one accident in the three years). The usual source is the purchase of salts of lemon, or salts of sorrel, from the pharmacist for use as a cleaning agent. The introduction of detergents may have made this poison less readily accessible.

Formalin is not a common agent, three suicides and one accident having occurred during 1950-2. It may be obtained freely for use as a hardening agent in photography, and has been used as a disinfectant for soft furnishings and other unwashable articles. It is used in the plastics and cellulose industries.

Heavy metals when ionized from dilute solutions of a salt act as astringents (blue-stone and silver-stick), but if their concentration is high they may act as corrosives. Of recent years there has been increasing concern about young children having access to ferrous sulphate tablets, which are attractive in appearance, 23 deaths from this cause being reported in the series of 335 mentioned above. Ferrous gluconate and other non-toxic iron compounds are being increasingly prescribed and the incidence of ferrous sulphate poisoning may therefore be expected to decrease. Of 6,598 children admitted as in-patients under the care of the Department of Child Health of the Welsh National School of Medicine during 1951-3, two suffered from ferrous sulphate poisoning, whereas during the seven-year period 1947-53, there were 15 cases.* A part of the syndrome results from absorption of excess iron, but a part of it is undoubtedly due to the local action on the gastro-intestinal mucosa, and perforation or late sequelae of extensive corrosion of the pyloric area of the stomach have occurred. Children who have swallowed these tablets should therefore be treated vigorously and urgently for corrosive poisoning.

When applied externally the circumstances are usually accidental, with the exception of the rare and execrable crime of vitriol throwing. Cases may be divided into two types:

(1) *Chemical Burns of the Skin*.—These are usually due to strong acid or alkali spilled or splashed at work. They are seldom severe, as the substance is easily washed off. Phenol or lysol on the skin can be removed before it does much damage. Emergencies from such causes are therefore rare.

*Watkins, A. G., Bray, P. T., and Gray, O. P., *British Medical Journal*, 1954, 1, 335.

*Pharm. J., 1953, 171, 50; 1954, 173, 284.

(2) *Severe Irritants and Corrosives in the Eye*.—By far the most common cause is lime burn in agricultural and building workers, the solid particles of calcium oxide adhering to and destroying tissue as a result of dehydration, and the hydroxide acting as an alkaline irritant. Accidents usually occur during the process of slaking the lime or while spreading it on fields, etc., or when applying it to walls and floors as a limewash. Cement contains 65% lime.

General Management

Certain principles apply to the management of all cases of poisoning. They apply no less to poisoning by corrosives than by barbiturates or other drugs.

1. The physician should consider each occasion on which the remote possibility of poisoning arises as urgent and make every effort to treat his patient promptly. Most of these occasions will prove to be false alarms, but the day will arrive when speed in giving attention is rewarding. Despite this urgency he must be calm, cool, and unhurried in procedure and obviously in control of the situation to an extent even greater than usual. Corrosive poisoning has a demoralizing effect on the patient's relatives and friends.

2. The first step is to safeguard respiration. Place the patient prone for fear of inhalation of vomitus. If there is any embarrassment to breathing, clear the airway and institute artificial respiration, at the same time requesting the presence of someone who can relieve you of this duty (many people have had training in first-aid methods; the police are expert). Fortunately, this urgent measure is seldom needed at first with corrosive poisoning, but may soon become important if oedema of the glottis develops. For this reason never delay unduly before sending the patient to hospital. Many patients who take fatal doses of corrosive fluids die of suffocation. Tracheotomy* may be necessary.

3. The next step is to remove such amounts of the corrosive as may be still active, or unabsorbed. In a case of external burns this may be the main treatment required; when dealing with a burn of the eye it is difficult but very necessary to be thorough. In the case of internal consumption of strong corrosives it is seldom advisable to use the stomach tube for fear of perforation. Details of gastric lavage will be given in next week's article on "Barbiturate and Aspirin Poisoning," should the physician decide to wash out the stomach.

4. The diagnosis of the probable nature of the corrosive should be established as soon as possible and the medico-legal aspect considered. This involves the questioning of relatives and attendants, the recovery and careful preservation of probable sources of the poison, and inspection of the patient.

5. The collection and preservation of specimens of vomitus and of any remaining portion of the presumed poison or of its container are important. This task may be temporarily delegated to a reliable attendant, but it is the physician's duty to supervise the matter closely. Specimens may be temporarily collected in any clean container—for example, glass jam-jars—but should subsequently be transferred to stoppered and labelled bottles.

6. It may be possible, depending on the probable diagnosis, to institute specific measures to neutralize acid or alkali or to counteract possible results from absorption of other substances. The measures so far taken can then be reviewed, and the degree of urgency in transferring the patient to hospital decided upon.

7. A brief general examination of the patient should be made at this stage and short notes prepared for future reference. If necessary, an analgesic may be administered now—for example, injection of morphine sulphate, $\frac{1}{4}$ gr. (15 mg.) for an adult—if respiration is adequate. Particular attention should be paid to the skin, lips, mouth, breath, vomitus, respiration and circulation, and the mental state.

*For details of the technique of tracheotomy see the article in this series on "Respiratory Obstruction," by Mr. Norman Jory (March 26, p. 781).

8. The nearest suitable hospital should be warned and transport arranged from the emergency ambulance service. The urgent nature of the case should be emphasized if necessary. Oxygen may be needed for the maintenance of respiration during the journey to hospital.

Diagnosis and Emergency Treatment of Individual Syndromes

The principal aid to diagnosis is the history and circumstances of the case. The clinical picture may be helpful, as follows.

Lysol, Phenol, Cresolic Preparations

The patient may have complained of a hot burning taste and severe internal pain, but not for long, as phenol produces a surface analgesia. Vomiting may not occur, or only once. The effects of absorption appear quickly—a few minutes to half an hour—with giddiness, delirium, and perhaps convulsions and coma. The patient is often found in this latter state. The breathing is stertorous, and the pupils are constricted; the mouth is burned dull white with phenol and the lips and chin are stained dark, while with lysol and other cresolic preparations the mouth is burned dark brown. There is usually a characteristic odour. If the physician has reached the case within fifteen minutes of the occurrence he may wish to pass a stomach tube and wash out. The addition of half an ounce (15 g.) of magnesium sulphate or a pint (570 ml.) of milk to the washing water is advantageous. Above all, guard the respiration by placing the patient prone and clearing the throat. Administer 100 mg. of leptazol subcutaneously, or 0.5 g. nikethamide intramuscularly, if breathing is poor; wash the external burns with soap and water, and order hot-water bottles as a simple measure to combat shock while awaiting immediate transference to hospital.

Inorganic Acids and Caustic Alkali

The patient is very collapsed, having experienced severe pain and violent vomiting almost as soon as the corrosive was swallowed. The jaw may be clenched, the mouth full of viscid mucus and shreds of tissue, white, foamy, blood-stained, or, later, coloured yellow or brown (acid). The vomitus contains altered blood and shreds of mucosa, apart from food. Hydrochloric and nitric acids produce an irritant fume and suffocation is often marked. Little can be done for it, as the air passages are affected. The skin around the mouth may be burned brown (acid) or white and soapy (alkali). The mind remains clear. Place the patient prone; clear the throat; do not use a stomach tube. For acid burns, endeavour to give sips of "milk of magnesia," if available, diluted 50% with water; chalk, or any gastric antacid, or dilute toilet soap in water; or the whites of two eggs in a pint (570 ml.) of water; or, if none of these is available, weak sodium bicarbonate (one teaspoonful to one pint (570 ml.) of water). The danger of the latter is the violent evolution of gas. For alkali give one part of domestic vinegar to three parts of water. Administer $\frac{1}{4}$ gr. (10 mg.) of morphine and 1/100 gr. (0.6 mg.) of atropine intramuscularly. If oxygen is available, administer it. Keep the patient warm, and give 0.5 g. of nikethamide intramuscularly if the circulation is failing. Send the patient to hospital as soon as possible.

External burns should be well washed with soap and water (acid) or diluted vinegar (alkali), and dressed with weak solution of bicarbonate (acid) or saline (alkali), and the patient transferred to hospital for further treatment. To prevent subsequent infection an injection of 300,000 units of procaine benzylpenicillin with 100,000 units of benzylpenicillin B.P. may be given with advantage.

Oxalic Acid and Oxalate

These have a rapid double action—immediate corrosion and subsequent depression of the heart and nervous system. A concentrated solution has similar effects to the inorganic acids, giving rise to pain, vomiting of altered blood,

suffocation, shock, and collapse. If the solution is less concentrated or salts of sorrel have been used, vomiting may be delayed, in which case the stomach should be washed out as soon as possible. Send to the nearest pharmacy for a pint (570 ml.) of lime-water, dilute it with an equal quantity of water and use it as the washing fluid, leaving the last half-pint (280 ml.) in the stomach. If a washout is not undertaken administer 4 fluid ounces (110 ml.) by mouth. If chalk is more readily available, give a teaspoonful stirred up in milk and repeat the dose three or four times. Respiratory or circulatory failure may require the injection of leptazol, 100 mg., with or without the administration of oxygen. Send the patient to hospital as soon as possible.

Formalin

Formalin causes acute pain and vomiting, and suffocation from the fumes. The stomach should be washed out with a solution of a teaspoonful of baking soda to a pint (570 ml.) of water, otherwise sodium bicarbonate should be given by mouth in warm water. Respiratory distress may require oxygen. Admit all cases to hospital, as sequelae may develop.

Ferrous Sulphate

This substance displays two actions—immediate irritation with possible corrosion, and late effects from absorption. The patient is usually a child, and the case presents with retching and vomiting, often of altered blood or mucosal shreds, pallor, tachycardia, and great drowsiness with restlessness; collapse occurs later. Hold the child upside down and tickle the fauces to promote vomiting. If gastric lavage is undertaken use a teaspoonful of sodium bicarbonate to a pint (570 ml.) of water and leave 100–250 ml. in the stomach. Guard against inhalation of vomitus, apply warmth, and send the patient to hospital.

Lime Burn of the Eye

Immediate treatment consists in vigorous washing with water poured from a jug, kettle, or tap. As blepharospasm is severe try to introduce cocaine eye-drops to facilitate this. Continue the washing for half an hour, and when the conjunctiva is cocaineized inspect it carefully, evert the upper lid, and remove any adherent particles. Forceps or even fine scissors may be needed. Particularly effective in removing lime from the cornea is a solution of 2 oz. (57 g.) of ammonium tartrate in one pint (570 ml.) of distilled water, which should be kept in all first-aid rooms in workplaces where lime or cement is used. Unfortunately this solution must be used fresh. It is therefore necessary to keep the ingredients in separate bottles and to mix them immediately before use as an eyewash. When the eye has been cleaned, instil homatropine eye-drops, followed in a few minutes with liquid paraffin, cover the eye with a pad, and send the patient to an ophthalmic centre. Time spent by the practitioner on this treatment is more important than hasty evacuation of a patient who may still have lime particles in the eye.

Medico-Legal Aspects of Poisoning

If the patient dies before the arrival of the doctor or before removal to hospital, report the matter to the coroner or fiscal, who will in due course decide on the cause of death. If the patient is alive on arrival a decision must be reached whether the cause of the poisoning was accident, attempted suicide, or attempted homicide.

(a) If the poisoning is due to accident there is no obligation to report the matter unless the poisonous agent is one referred to in the Factories Act, 1937, administered while the patient was at work. The common corrosives are not included in the list of notifiable conditions.

(b) If the case is one of attempted suicide the practitioner should, in law, notify the police. However, this is an obligation which is more honoured in the breach than in the observance, and I have no knowledge of any practitioner having ever been prosecuted for failure so to do.

(c) If there are reasons to suspect foul play it is essential to supervise the removal of the patient to hospital. If suspicion is strong, notify the police as quickly as possible; if weak, consult the hospital authorities and let them confirm or refute. If the patient is *in extremis* and there is any reason to suspect a homicidal attempt, a dying deposition should be taken before removal. Disturb the scene as little as possible, and endeavour to ensure that no one else does so, if possible by locking up the place of death.

When the patient is transferred alive to hospital, all relevant details should be communicated by sealed letter to the medical man in attendance, especially the diagnosis of corrosive used and the treatment already given. Secure the poison container and any residues, and remove and label them. The specimens of vomitus, stomach washout, urine, etc., should be taken away in clean jars and transferred to bottles with screw tops, fixed with adhesive, and labelled with the patient's name and address, date, and nature of specimen. Lock them up in the surgery with an inventory so that they can be produced and identified if needed. Take notes at the time of the occurrence or immediately after, paying attention to the chief symptoms, the stated history, the time at which one was summoned, and the time of arrival, the alleged time at which the poison was taken, the time of death if that has occurred and is known, and any relevant statement made by the patient (in his own words). Consult the patient's medical record and make a note of any previous illness which might have some bearing on the present problem.

In the case of an external burn fairly full notes should also be taken in case of subsequent proceedings for compensation. If an accident has occurred at work, advise the patient to have the matter recorded in the "accidents book" if that has not already been done. Should death occur subsequently these notes will be needed in connexion with the inevitable coroner's or fiscal's inquiry; should the patient recover and no public inquiry ensue, the specimens may be destroyed and the notes filed with the case sheet for reference should late sequelae develop.

Next article on Emergencies in General Practice.—"Barbiturate and Aspirin Poisoning," by Dr. T. J. Thomson and Professor S. Alstead.

MODERN ASPECTS OF LIVER AND BILIARY DISEASE

[FROM A SPECIAL CORRESPONDENT]

A highly successful symposium on "Modern Aspects of Liver and Biliary Disease" was held for consultants at the Postgraduate Medical School, Hammersmith Hospital, London, from March 28 to April 1. The programme consisted of lectures, discussions, case demonstrations, films, and the demonstration of techniques used in the investigation of liver disease. It is possible to pick out only a few of the topics discussed.

Management of Jaundice

Professor N. F. MACLAGAN (Westminster Hospital) outlined the biochemical methods used in the diagnosis of liver disease. As a routine, the urine—preferably passed in the afternoon—should be examined for bilirubin, urobilinogen, and bile salts. In addition, serum bilirubin, alkaline phosphatase, and one or two of the flocculation tests should be done: he favoured the thymol turbidity and colloidal gold tests. Estimation of serum proteins and bromsulphalein excretion might give useful evidence of liver cell function. In the majority of cases these biochemical tests would confirm the clinical diagnosis.

Dr. SHEILA SHERLOCK (Postgraduate Medical School) stressed the importance of pain and pruritus, together with deep jaundice, as features of obstructive jaundice. Pruritus

was only a transient symptom in infective hepatitis, and the appearance of spider naevi suggested this diagnosis. Daily inspection of the stools was of great value in assessing the degree of obstruction, and the presence of occult blood suggested the presence of a carcinoma. In a few patients, where jaundice was prolonged or deep, a liver biopsy or even laparotomy might be necessary to establish the cause, but it was wise to wait three weeks. Treatment of infective hepatitis consisted of rest in bed until jaundice had disappeared, together with a nutritious diet. It was probably unnecessary to give excess protein or to restrict fat. Severe exertion and alcohol should be forbidden for at least six months after the attack. Obstructive jaundice which could not be relieved surgically was associated with three factors which required treating: pruritus, steatorrhoea, and a tendency to haemorrhage. Testosterone propionate given sublingually sometimes relieved itching. The patient should take a high protein, low fat diet, with large doses of calcium by mouth, and the fat-soluble vitamins, A, D, and K, should be given by injection once or twice a month.

Portal Hypertension

Dr. P. C. REYNELL (Oxford) said that the majority of cases of portal hypertension were due to obstruction within the liver—cirrhosis—or to extrahepatic obstruction of the portal venous system. A collateral circulation between the portal and systemic veins developed in the region of the oesophagus, rectum, umbilicus, diaphragm, and retroperitoneal tissues. Of these only the oesophageal vessels were important because of their liability to rupture, the other channels serving as useful means of decompressing the portal venous pressure. Splenomegaly was also a feature of portal hypertension, but occasionally the spleen could not be palpated. Haematological changes also occurred: anaemia was often due to bleeding, while leucopenia and thrombocytopenia were part of a non-specific "hyper-splenism" and seldom required treatment. Haemorrhage from oesophageal varices was the most important effect of portal hypertension, and occurred in about 25% of patients with cirrhosis. It was often fatal.

Professor R. MILNES WALKER (Bristol) stressed that the only indication for surgery was the danger of serious haemorrhage. Patients with jaundice, ascites, and serum albumin levels below 3 g. per 100 ml. were bad operative risks. The new technique of splenic venography—the injection of radio-opaque dye into the spleen so as to outline the portal venous system—was of great value to the surgeon in demonstrating a patent vein for anastomosis. End-to-side porta-caval anastomosis was the operation of choice, but in patients with abnormalities of the portal vein end-to-side spleno-renal anastomosis might be possible if the splenic vein was patent. Direct operations on the varices, often combined with splenectomy, were less satisfactory, but could be undertaken to control bleeding. It should be remembered that gastro-intestinal bleeding in patients with cirrhosis might be due to peptic ulceration. Thirty-five out of 42 patients who had undergone porta-caval anastomosis were well up to four and a half years after operation, and the recurrence rate of bleeding after this operation was only 5%, a much better figure than with any other form of therapy.

Ascites

Dr. R. I. S. BAYLISS (Westminster Hospital) said that two primary factors were needed for the production of ascites—namely, a lowered plasma albumin level and an increased portal venous pressure. There was abundant evidence, both clinical and experimental, that neither alone resulted in ascites. A number of secondary factors had been invoked, the most popular at present being increased adreno-cortical activity. It was well known that patients with cirrhosis and ascites retained sodium extremely avidly, the sodium content of body secretions being negligible, even on a normal salt intake. This suggested a humoral factor, and similar changes could be produced by the administration of aldosterone. Nevertheless it was possible that aldosterone is secreted in

response to sodium retention. The damaged liver could not conjugate corticoids efficiently, and this might be a factor in perpetuating ascites. The part played by the anti-diuretic hormone of the posterior pituitary was difficult to evaluate because of unsatisfactory methods of assay, but the patient with cirrhosis could metabolize exogenous pitressin normally. Finally, reduction in renal blood flow has been reported, and this may lead to increased reabsorption of sodium.

Dr. A. PATON (St. Thomas's Hospital) pointed out that the patient with ascites due to cirrhosis always had a poor liver, and that therefore any form of operative treatment was extremely hazardous. Surgical methods of lowering portal venous pressure had been advocated, but all had disadvantages. Talma-Morrison omentopexy and hepatopexy (the application of magnesium trisilicate to the abraded liver and diaphragm advocated by Madden) were simple operations which would increase intervals between tapings, but were probably no more effective than strict medical regimes. Porta-caval anastomosis was almost always contraindicated, and the latest operation of hepatic artery ligation unphysiological. Measures aimed at raising serum albumin were also unsatisfactory, though good results had been claimed with the use of salt-poor human albumin. However, this substance was expensive, large quantities must be given intravenously, and severe reactions had been reported. Paracentesis abdominis had many disadvantages, and should never be used as the sole means of treatment: infection, shock, a low-salt syndrome, and hepatic coma were all potential dangers, but even more important was the removal of large quantities of albumin in the ascitic fluid.

The majority of patients with ascites would respond to a strict low-salt diet, containing less than half a gramme of sodium a day, together with mercurial diuretics and 1–3 g. ammonium chloride by mouth daily. It was wise to give 1 g. potassium chloride also to make up for the loss of potassium which accompanies the diuresis. This regime might take a month or two to control ascites formation, and an initial paracentesis was often necessary. There was then a striking increase in sodium excretion in the urine and the serum albumin level rose; it might be possible eventually to relax sodium restriction. A few cirrhotics developed ascites as the result of some recognizable precipitating factor, such as alcohol, bleeding, or infections. Here treatment should be directed against the responsible factor. Another small group had intractable ascites which would not respond to the low-salt regime. These were often young patients with an "active" cirrhosis, and their prognosis was extremely bad.

Hepatic Coma

Dr. SHERLOCK discussed the neurological manifestations of liver disease, which she has termed "portal-systemic encephalopathy." The syndrome might occur in both portal cirrhosis and infective hepatitis, and recognition was important because it was often reversible and preventable. Mental changes resembled those of other organic dementias. The onset was often insidious and consisted of a change in behaviour, together with confusion and disorientation, which might be followed by stupor and coma. Patients with the syndrome had sometimes been admitted to psychiatric hospitals before the underlying liver disease was recognized. Motor disturbances consisted of a characteristic "flapping" tremor of the outstretched hands, rigidity, exaggeration of the tendon reflexes, and ankle clonus. The plantar responses were usually flexor. The tremor might spread to involve the whole body, and dysarthria and ataxia result. There was a characteristic fluctuation in the neurological features, and it was extremely rash to give a prognosis in the individual case. If the syndrome occurred in infective hepatitis it was usually rapidly progressive and the prognosis extremely bad. In portal cirrhosis, however, it might appear in a chronic form, or be precipitated by such factors as haemorrhage, operations, paracentesis abdominis, infections, alcohol, and the intake of nitrogenous substances. Hepatic coma was believed to be due to the inability of the liver to metabolize

nitrogenous compounds absorbed from the intestine, either because of poor liver-cell function or because these substances pass the liver through the extensive collateral circulation generally found in portal hypertension. Treatment in these cases should be directed at the precipitating factors, and in the chronic cases restriction of protein intake had proved effective.

Mr. A. G. RIDDELL (Manchester) said that normally ammonia absorbed from the gut was removed by the liver. In patients with liver disease it might get into the general circulation in the manner suggested by Dr. Sherlock. Ammonia, which was known to produce similar effects in animals, had been incriminated as the cause of hepatic coma, and certainly high blood-ammonium levels could be demonstrated in some, but by no means all, patients with hepatic coma. The syndrome could be produced by giving a high-protein diet, urea, ammonium chloride, or ammonium-containing ion exchange resins to patients with cirrhosis. It was seen also in patients who had undergone porta-caval anastomosis, about 10% developing episodes of stupor following the operation. Haemorrhage from varices was a well-known cause of hepatic coma, and it was interesting that blood introduced into the stomach of a cirrhotic would reproduce the syndrome. Treatment consisted in withholding any substance containing ammonia. Haemorrhage must be arrested as soon as possible by the use of an oesophageal balloon, and enemata should be given to remove blood from the intestines. The diet should consist largely of glucose, and chlortetracycline might help by depressing bacterial activity in the gut. Glutamic acid, either intravenously or by mouth, might be useful supportive therapy in coma following bleeding, but was of no value in the chronic syndrome or in the fulminant type associated with infective hepatitis.

Nova et Vetera

A DOCTOR IN CANADA IN 1862

In 1935 the Association held its Annual Meeting at Melbourne. Half of the party from Britain travelled via Canada and Vancouver, the other half via U.S.A. In March, 1935, the *British Medical Journal* published an account of the influence of the late Dr. W. B. Cheadle in promoting the development of Western Canada and the construction of the Canadian Pacific Railway. A correspondence which followed produced some further facts: from these sources what here follows is compiled.

Dr. W. B. Cheadle, M.D., F.R.C.P., who died full of years in 1910, was then consulting physician to St. Mary's Hospital and to the Hospital for Sick Children, Great Ormond Street, a much-esteemed London teacher and consultant. In 1862-3 he accompanied the late Viscount Milton on a buffalo-hunting expedition to the middle west of Canada. After travelling 500 miles by canoe, and more on foot, from the most westerly settlements, they wintered in a log hut, subsisting on frozen salmon and dried buffalo beef. When spring came they went further westwards, crossed the Rocky Mountains by the Tête Jaune Pass, and narrowly escaped death by starvation on the far side. Cheadle was a man of exceptional physique; it was his strength and endurance that saved the party from disaster (he lost 41 lb. in weight during the journey). Returning to England, they published a book, which they called *The North-West Passage by Land*, describing their adventures. The title-page says it is by Viscount Milton and Dr. Cheadle, but Cheadle was actually the sole author. The book is very well written, and became a best seller: many editions were published in the next 15 years.

Cheadle was very insistent upon the potential agricultural wealth of Western Canada. He wrote: "From the Red River to the Rocky Mountains, along the banks of the Assiniboine and the fertile belt of the Saskatchewan, at least 60 million acres of the richest soil lie ready for the farmer

when he shall be allowed to enter in and possess it. This glorious country, capable of sustaining an enormous population, lies utterly useless except for the support of a few Indians, and the enrichment of the shareholders" (of the Hudson's Bay Company). He pleaded strongly for the construction of a transcontinental railway, without which, he pointed out, no settler could embark on farming. Parliamentary questions were asked, both in England and in Canada; as a result the Canadian Government sent out a commission of railway engineers, whose report disclosed no difficulties that could not be overcome. A Canadian Pacific Railway had already been advocated for some years: Cheadle's support hastened the realization of a project which would, of course, have anyhow materialized sooner or later. He is commemorated by a town named after him in Alberta. His companion, Viscount Milton, did not outlive his father, the sixth Earl FitzWilliam, and thus did not succeed to the earldom. His son was the seventh earl and his grandson was the eighth: Lady Juliet FitzWilliam is his great-granddaughter. The present (tenth) earl is a collateral relative, but not a direct descendant. A copy of the book, it may be added, is in the Association's library.

HENRY ROBINSON.

THE APPRENTICE IN MEDICINE*

A few years ago Dr. Harold Brodribb, of St. Leonards-on-Sea, showed me the indenture of his great-grandfather putting himself apprentice to William Randall, of Southampton, Apothecary and Citizen of London.† This form of indenture was used with only minor changes for at least the three hundred years after the Statute of Labourers and Artificers of 1563, and for every kind of apprentice. From the earliest recorded times young men were not considered responsible until the age of 23 years, and all technical education rested on an apprentice basis in the interval between 16 years, when the general grounding in the humanities ended, and this technical coming-of-age. Beyond the teacher-pupil relationship in the art, master and apprentice undertook towards each other mutual responsibilities in the conduct of life. The terms sound as archaic a note to-day as does the underlying philosophy of a strict contract with human behaviour as the subject. Such attempts to control the freedom of choice in others would not be tolerated in the free society of to-day: "What I do out of hours is none of your business."

This control took odd forms at times, when, for example, in 1556 no surgeon's apprentice was "to wear a beard past fifteen dayes growing upon a pain of his master's losing 6s. 8d." This was rescinded in 1557—how fascinating to know as the result of what petition, manifesto, or strike action. The master at his best taught his pupil not only technique but how he must live.

In the forties of last century references to behaviour drop out in some or are attenuated in others to teaching by the master and a promise to "obey and protect and serve" by the apprentice, although the original wording was in use at least until 1846. In some of the latest forms permission is given during the last two years to attend "such lectures and anatomical schools and hospitals as are usually commonly attended" (1851). Brodribb spent the sixth and seventh years of his apprenticeship at St. Bartholomew's, at the feet of Abernethy, Lawrence, and Stanley, although no permissive clause appears in his indenture.

In 1815, the year before Brodribb's indenture, an Act extended the sphere of influence of the Apothecaries' Society from London and seven miles beyond to the whole country, ordaining a five-year apprenticeship. This gave the Society, founded as a craft guild in 1617 as a splinter from the Grocers' Company, a chance to control and represent the general practitioner. But the leaders of the profession were college men, and college influence and the growth of universities, including London University, in the nineteenth

*Abridged version of a paper read to the Osler Club of London. †Owing to the impossibility of reproducing the indenture clearly, only the capital initial is in facsimile.

century won the day. Real power rests, as it ever did, with those who control the register, the curriculum, and the examination. Meanwhile the apprentice system had failed to keep pace with the expansion of trades and crafts caused by the discoveries of drawing-room scientists—the eighteenth century's version of to-day's back-room boys. In 1814 an Act of Liberation allowed any man to exercise any craft or trade he pleased whether apprenticed or not, and trade apprentices began to live at home and to earn wages while training. The growth of trade unions led from time to time to restrictions of numbers and proportions of apprentices and of conditions of employment, restrictions curiously like those imposed by the guilds six or seven hundred years before.

Medicine follows these trends after the long and dignified delay that befits a learned profession. Only in recent years have the hospital resident medical staff earned a salary while serving an apprenticeship of learning at the end of training. Many of those who apply for admission to a medical school, like those who embark on the career of general practice to-day, must feel that there is now a very definite restriction of entry into the profession.

Views on the Apprentice System

Modern thought about medical education calls for a re-examination of the apprentice system. Has anything been lost that should be rescued? Walter Rivington, surgeon to the London Hospital, in his publication *The Medical Profession of the United Kingdom* (Dublin, 1888), has something to say on this point. He was a man of foresight, and advocated in those early days whole-time clinical professors and the linking of all dispensaries and hospitals with medical schools.

"Another subject is how to secure the advantages which sometimes resulted from the old system of apprenticeship? How, in other words, can certain deficiencies in hospital education be supplied? A completely qualified student brought up only at a hospital school, may be deficient in the very points which are needed for his success in practice. His 'diplomatic functions'

may have been uncultivated—he may have no tact—he may be unable to prescribe well, have never seen cases of measles, scarlet fever, smallpox, and many children's ailments; may not know how to deal with patients, or to keep books, or to arrange a surgery. All these wants can be fully supplied by residence with a busy general practitioner, and the best period of residence is either after the end of the third year, or after obtaining a qualification to practise. We should be inclined to require every assistant to a general practitioner to have passed the proposed examination at the end of the third year. The passage of this examination should entitle a student to a certificate that he was fit to attend midwifery cases not requiring instrumental interference, and to perform those minor acts for which assistants—unqualified assistants—are required. He should not be allowed to sign death certificates: students living with practitioners before this period should be called, not assistants, but pupils. There should be no more unqualified assistants, but there should be 'certificated assistants,' and any infringement of the rules laid down as to the extent of assistance for which the certificate should be granted, should be visited with serious penalties on the general practitioner. Certificated assistants should not be permitted to manage bogus dispensaries or to carry on branch practices. . . .

In this statement of 66 years ago there seems to be a foreshadowing of the pre-registration house appointment and the trainee assistant. Is it possible that these can achieve the balance, so much desired, between technical education in the science and craft of medicine and training for the life of the doctor?

Pieté demands a footnote on the life of that William Perrin Brodribb (1800-69) whose apprenticeship indenture is here illustrated. He was the son of Uriah Brodribb, of Warminster, and the family had farmed their own land at Clifton, in Somerset. Henry Irving (Brodribb) was of the same family.

William Perrin, after apprenticeship to a doctor in Southampton at the age of 16, finished his training at St. Bartholomew's Hospital. He qualified M.R.C.S. (1822) and L.S.A. (1823), and these certificates are still in existence. In 1838 he moved from Southampton to 12, Bloomsbury Square, London. His second wife was Miss Aitken, daughter of a neighbouring doctor, Charles Rachemont Aitken, into whose

His Indenture witnesseth, That *Wm Perrin Brodribb* Son of *Uriah Brodribb of Warminster, Grocer*

doth put himself Apprentice to *William Randall of Southampton, Apothecary & Citizen of London*

to learn his Art; and with him (after the Manner of an Apprentice) to serve from the Date hereof until the full End and Term of Seven Years, from thence next following, to be fully complete and ended. During which Term, the said Apprentice his said Master faithfully shall serve, his Secrets keep, his lawful Commands every where gladly do. He shall do no Damage to his said Master, nor see it to be done of Others, but that he to his Power shall let or forthwith give Warning to his said Master of the same. He shall not waste the Goods of his said Master, nor lend them unlawfully to any. He shall not commit Fornication, nor contract Matrimony, within the said Term. He shall not play at Cards, Dice,

Tables, or any other unlawful Games, whereby his said Master may have any Loss. With his own Goods or Others, during the said Term, without License of his said Master, he shall neither buy or sell. He shall not haunt Taverns or Play-houses, nor absent himself from his said Master's Service Day or Night unlawfully. But in all Things, as a faithful Apprentice he shall behave himself towards his said Master, and all his, during the said Term. And

(the Sum of *Three hundred & fifteen pounds* of lawful Money of Great Britain, being

paid or secured to the said Master, as the Consideration for taking his said Apprentice) the said Master his said Apprentice, in the same Arts which he useth, by the best Means that he can, shall teach and instruct or cause to be taught and instructed; finding to his said Apprentice, Meat, Drink, Apparel, Lodging, and all other Necessaries, according to the Custom of the City of London, during the said Term. And, for the true Performance of all and every of the said Covenants and Agreements, either of the said parties bindeth himself unto the other by these Presents.

In Witness whereof, the Parties above-named to this Indenture have put their Hands and Seals, the *third* Day of *September* in the *fifty sixth* Year of the Reign of our Sovereign Lord *George the third* by the Grace of God, of the United Kingdom of Great Britain and Ireland, King, Defender of the Faith, and in the Year of our Lord, One thousand Eight hundred and *sixteen*

Sealed and delivered (being first duly stamped) in the Presence of

S. Buckler

William Randall

William Perrin Brodribb

house he later moved (No. 7, Bloomsbury Square). He had a successful private practice in this middle-class neighbourhood and he was surgeon to the Magdalen Hospital, then in Blackfriars Road. For the last seven or eight years of his life he was Secretary to the Court of Examiners of the Apothecaries Hall.

He had three sons—the first, a Fellow of St. John's College, Cambridge, later achieved fame by a translation, with Church, of Tacitus. By his second wife he had A. A. Brodribb, for many years Parliamentary Correspondent of *The Times*, and C. A. Brodribb, whose descendants carry on, without a break, the medical tradition founded by W. P. Brodribb.

I am indebted to Dr. Harold Brodribb for a photograph of the indenture and to Mr. Poynter, of the Wellcome Historical Medical Library, for gathering the indentures in that library for my inspection.

A. WHITE FRANKLIN.

Reports of Societies

PRESENT STATUS OF HYPOTHERMIA IN ANAESTHESIA

On April 1, under the chairmanship of Dr. BERNARD JOHNSON, dean of the Faculty of Anaesthetists of the Royal College of Surgeons, the Section of Anaesthetics of the Royal Society of Medicine debated the present status of induced hypothermia. The opening papers were both by anaesthetists with wide experience of this technique.

Dr. C. F. Scurr (Westminster Hospital) opened with a review of the physiological changes that accompany a general lowering of the body temperature. He pointed out that at normal body temperature tissue anoxia from circulatory arrest leads to cellular death unless rapidly relieved. In cases of cardiac arrest, for example, the heart might be restarted by massage, but often as a result of the delay the brain suffered irreversible damage. Hypothermia reduced the cell metabolism in a linear fashion so that cells could survive anoxia for longer periods. Animal experiments had shown that at a body temperature of 25° C. the circulation to the brain could be completely occluded for 20 minutes without either physiological or histological evidence of cerebral damage. Recently, Bailey had reported a case of complete circulatory interruption in a child for 22 minutes at a temperature of 21.6° C. in whom there was no evidence of cerebral damage 30 hours after operation.

Benefits and Dangers

The indications for hypothermia were fourfold, said Dr. Scurr. First, intracardiac procedures requiring an open heart, temporary occlusion of the venae cavae, and cessation of the circulation. Second, certain congenital cardiac anomalies in which there was cyanosis or the great vessels required transplantation. Third, intracranial procedures involving temporary arrest of the circulation to part of the brain: it had been suggested here that hypothermia might also increase the margin of safety of induced hypotension for neurosurgical procedures. Finally, operations or grafts to the great vessels supplying vital organs. Under normal conditions the kidney and spinal cord could barely withstand 30 minutes of circulatory arrest, but under hypothermia (27–28° C.) ischaemia of two hours' duration had been reported with only minimal—although definite—signs of transient paraplegia.

Amongst the disadvantages of the hypothermic state was the increased irritability of the myocardium which might lead to spontaneous ventricular fibrillation. The exact cause of this irritability was imperfectly understood. The evidence that ionic changes or anoxia of the myocardium were the sole cause was contradictory. A possible cause was that during hypothermia acetylcholine production was depressed, so that the pacemaker lost its dominance and ectopic foci appeared. The fact that neostigmine has a powerful protective action against ventricular fibrillation was in keeping with this theory. Most workers of experience agreed that

hyperventilation, with carbon dioxide absorption, helped to reduce the incidence of cardiac irregularities during hypothermia. Nevertheless continuous electrocardiographic control was essential throughout the operation, as the appearance of arrhythmias or ectopic foci was regarded as a danger signal.

Other disadvantages of hypothermia were the production of the stress response to cold and the increase in viscosity of the blood as the temperature fell.

Technique

Of the two main methods of reducing the body temperature—namely, surface cooling and the extracorporeal circulation—the surface method, using a cooling blanket, had been the most favoured at the Westminster Hospital, continued Dr. Scurr. The patient was anaesthetized with ether, cyclopropane, or thiopentone/nitrous oxide/oxygen and a muscle-relaxant to prevent shivering. The body was then wrapped in a cooling blanket, through which water circulates at 2–4° C. Before the desired temperature was reached the pump was stopped and warm water passed through the blanket. This reduced the tendency of the body temperature to continue to fall after the cooling process had ceased.

Dr. T. CECIL GRAY then described the experience of members and associates of the Liverpool Department of Anaesthesia with 110 operations under hypothermia. In the first 40 cases the technique originally described by the French authors had been used, intermittent doses of chlorpromazine, pethidine, and promethazine hydrochloride being administered. This method had now been abandoned because of the difficulty in controlling the shivering and the length of time to lower the temperature. The present method was to induce light anaesthesia with thiopentone/nitrous oxide/oxygen, prevent shivering with a muscle-relaxant (D-tubocurarine), and then give moderate doses of chlorpromazine to aid the cooling process. Surface cooling with either ice-bags or a cooling blanket was preferred. The patient's position should be changed every 15 minutes to prevent pooling of the blood, which would otherwise result in a sudden fall in the body temperature when the patient was finally moved. A colour film demonstrating the method used for cooling a patient prior to an operation for porto-caval anastomosis was then shown.

Mortality and the Reaction to Cold

Dr. Gray went on to say that he agreed in principle with Dr. Scurr's indications for hypothermia in clinical surgery, with two modifications. First, he did not think that cooling was necessary in cases of congenital heart disease undergoing a Blalock operation. Second, in general surgery it appeared to provide some protection against surgical trauma as well as permitting the use of hypotension in subjects who might otherwise be considered unsuitable for this. To date, investigation of patients undergoing hypothermia had failed to confirm the view that pituitary-adrenal responses were modified by cold. On the other hand, an investigation in animals suggested that inhibition of the stress response might account for some of the benefits of hypothermia.

In the Liverpool series there had been 13 deaths in the 110 cases. The high mortality was largely due to the nature and magnitude of the surgical procedures. There were, however, three cases of fatal pulmonary embolus in this group, which might be significant. Dr. Gray concluded by stating that hypothermia was a specialized technique which carried very definite risks, and at present it should be used only in the larger centres. Provided the temperature was not reduced below 28–30° C., the lowered metabolism and possible diminution of the stress response had proved of value in selected cases for general surgery.

Discussion

In the discussion that followed, Dr. J. W. DUNDEE (Liverpool) described a neurosurgical case in which the middle cerebral artery had been occluded for eight minutes at a body temperature of 30° C. without any signs of post-operative cerebral damage. In another case at a similar

temperature hypotension in the head-up position had been maintained for four hours without ill effect.

Dr. B. G. B. LUCAS (University College Hospital, London) stressed the difference, under hypothermia, of the heart and the brain in their tolerance of ischaemia. At normal temperature the brain was the more sensitive to ischaemia, while at temperatures of 25° C. the brain would withstand circulatory arrest for 30 minutes, whereas the heart would tolerate arrest for no longer than 15 minutes. Therefore for endocardial surgery taking some time, either some form of coronary perfusion was necessary or much lower temperatures would have to be used.

Mr. C. E. DREW (Westminster Hospital) thought that operations on children with congenital cyanotic heart disease were better done under hypothermia, as this allowed the surgeon greater freedom in choice of operative technique if some unusual malformation were encountered. It also lessened the risk of cerebral thrombosis in these patients.

Dr. G. JACKSON REES (Liverpool) thought that hypothermia should not be used for children with congenital cyanotic disease undergoing a Blalock operation, as this only increased the risk without providing any benefits. Adequate ventilation with a high percentage of oxygen was far more important.

Preparations and Appliances

BED FOOT-REST

Mr. G. T. F. BRADDOCK, orthopaedic registrar, Whittington Hospital, London, N.19, writes: The foot-rest here shown has been simply made by the hospital carpenter and the theatre technician from old orthopaedic traction fittings. This attachment fulfils the following functions: (1) It allows the patients to push themselves up in bed, and to keep themselves from sliding down the bed when traction is

applied to the other limb. (2) It encourages constant use of the good limb, and therefore reduces the tendency to thrombotic complications as well as maintaining muscle tone. (3) It prevents foot-drop. (4) It acts as a bed cradle and prevents the clothes from touching the unaffected foot. It is unnecessary to remove the foot-rest during sleep. (5) It prevents the development of a sore heel, which is very common when the patients have to push themselves up in bed with their heels. (6) It reduces the energy necessary, by the nursing staff, in lifting patients up the bed.

Patients who have had the benefit of this attachment complain bitterly if it is removed. Its use need, of course, not be confined to patients in traction. All of us who read in bed are conscious of the difficulty in keeping up.

Correspondence

Primary Aldosteronism

SIR,—Dr. J. G. LLAURADO's interesting letter (*Journal*, April 2, p. 851) raises several matters requiring further explanation. Professor Conn¹ has now published a preliminary account of the first recognized case of primary aldosteronism, and ends by stating that a right adrenal cortical tumour, 4 cm. in diameter, has been excised. Information regarding the effects of the operation on the disease is awaited with great interest. This pioneer work makes it very probable that the case reported by Evans and Milne² as "potassium-losing nephritis" was in fact another example of primary aldosteronism. The patient has improved dramatically with medical measures alone, and is not fully convinced of the necessity of further investigation. It is hoped, however, that further investigations may become possible.

We agree with Dr. Llauro that the two cases he quotes are probably examples of this disease, as is also the case described by Earle *et al.*³ The reason for the emphasis on impaired renal function in all these cases is that potassium deficiency produced by primary aldosteronism or by other causes will result in a nephropathy which may closely simulate primary renal disease. Many cases have now been published^{4–8} in which severe potassium deficiency has produced this nephropathy associated with vacuolization of the cytoplasm and pyknosis of the nuclei of renal tubular cells, the so-called "clear cell nephrosis." The resulting renal functional impairment has been studied by Schwartz and Reiman,⁹ who found a reduction of the glomerular filtration rate and renal plasma flow with complete isothermia. These functional defects were abolished by treatment with potassium supplements. One of us¹⁰ has shown that a corresponding defect in the urinary acidification mechanism can be produced by comparatively mild experimental potassium depletion.

So-called "potassium-losing nephritis" is certainly not invariably due to primary aldosteronism. We consider that the following points would favour a diagnosis of primary aldosteronism: (a) absence of definite evidence of a primary nephritis; (b) the need for very large potassium supplements to maintain a normal serum potassium level—in the patient of Earle *et al.*,³ 625 mEq daily (equal to 46 g. potassium chloride) was needed to do this; (c) evidence of an adrenal tumour; (d) excretion of excess aldosterone; (e) renal biopsy showing the characteristic tubular lesions of potassium deficiency without evidence of primary nephritis.

At the time our joint studies were made we were unable to tell whether or not the aldosterone output was primary or secondary to the electrolyte abnormalities. As it was already accepted then that aldosterone output is increased in the nephrotic syndrome and in other oedematous states, a secondary cause for this high output seemed to ourselves and to Dr. Llauro to be more probable. We were relieved, therefore, to observe that Dr. Llauro does not claim any priority in the description of the syndrome of primary aldosteronism. In our opinion Professor Conn deserves full credit for his brilliant exposition of this interesting but rare new disease.—We are, etc.,

Sickling and Malaria

SIR,—With reference to the recent correspondence published in the *Journal* on the subject of the possible relationship between sickling and malaria (*Journal*, November 13, 1954, p. 1162, and January 29, p. 285) may we add a brief note quoting the preliminary findings of some malarionetrical indices investigated in an African child population aged between 5 and 12 years?

Of the total of 529 children recently seen in the course of two surveys in Southern and Northern Nigeria 107, or 20.2%, were showing the sickle-cell trait. The comparative results of two malarionetrical indices, crude parasite rate and positive parasite density index in sicklers and non-sicklers respectively, are shown in the following tables.

TABLE I.—*Sicklers*

Age Group (Years)	No.	Crude Parasite Rate	Positive Parasite Density Index
5-7	36	64.0	2.61
8-10	38	55.2	2.29
11-15	19	68.5	1.93
Total	93	61.2	2.32

TABLE II.—*Non-sicklers*

Age Group (Years)	No.	Crude Parasite Rate	Positive Parasite Density Index
5-7	148	47.3	2.89
8-10	178	65.8	2.19
11-15	110	49.0	1.63
Total	436	55.3	2.20

The figures quoted above do not indicate any constant relationship between the two malarionetrical indices and the presence of the sickling trait. In particular there is no evidence of any contrast between the positive parasite density of sicklers and non-sicklers. In the 5-7 age group the difference between the index figures of 2.89 and 2.61 corresponds to a difference of geometric means of approximately 470 and 380 parasites per cubic mm. This difference between two mean parasite densities is too small to warrant our concluding that the malaria affecting these Nigerian children differed in severity in sicklers from that seen in non-sicklers. This investigation continues now on a larger scale.—We are, etc.,

H. M. ARCHIBALD.

Clinical Staging of Carcinoma of the Breast

SIR,—The letter by Mr. Michael Harmer (*Journal*, March 26, p. 790) must meet with the approval of all clinicians interested in the study of carcinoma of the breast. Any progress in the assessment of the results of treatment is materially hampered by inadequate clinical staging, and Mr. Harmer enumerates reasons why the breast is peculiarly suitable for a universal agreed staging.

The survey of cancer published in 1952 by the British Empire Cancer Campaign collected over 2,000 cases—nearly 30% of all the cases of cancer in the female. And the average age was in the fifties, so it is not primarily a disease of old age. In addition, various advances in treatment—especially endocrine control—have increased the relatively good survival rate even further.

But there are so many centres and so many surgeons that a simple staging seems essential. A complex staging will never succeed except in those few well-equipped and staffed centres: simplicity is the keynote, even if it can allow considerable clinical variations. If surgeons could be persuaded to indicate in the notes their estimated clinical staging at the first attendance of the patient it would save much tedious perusal of records with its consequent difficult reassessment. Prior to the war I was associated with the Clinical Research Committee of the British Empire Cancer Campaign, and more recently have followed up our cases

here in Leicester. In both instances the clinical staging was the stumbling-block in the investigation, and much time was expended in sifting out the relevant clinical details. If a simple staging was adopted then it can be widely disseminated and we can start to assess results, knowing exactly that we are discussing the same problem.

I welcome Mr. Michael Harmer's initiative and wish him every success in his quest for a universal staging: for a sound basis of staging is the firmest foundation in the study of the results of treatment.—I am, etc.,

Leicester.

G. C. SAWYER.

SIR,—I should like to be allowed to add a footnote to Mr. Michael Harmer's letter (*Journal*, March 26, p. 790).

There is associated with this department, which is responsible for statistical analysis of data relating to cases of cancer registered in England and Wales, a committee under the chairmanship of Dr. A. H. T. Robb-Smith which advises on cancer statistics generally and on the national registration scheme in particular. At recent meetings this committee, which is a subcommittee of the Registrar-General's Medical Advisory Committee (chairman, Sir Ernest Rock Carling), has been much concerned with the problem of establishing uniform systems of staging. Largely for the reasons enumerated by Mr. Harmer, it has selected the breast as the most suitable site for immediate study. In doing this, the committee is, of course, taking account of various existing methods of staging, including those considered at the sixth congress of the International Union against Cancer.—I am, etc.,

General Register Office,
London, W.C.2.

R. M. BLAILEY.

Manipulation and Low Back Pain

SIR,—In your recent spate of articles and correspondence on low back pain, we see a reawakening of interest in manipulation. Twenty years ago there was a flurry in the medical profession created by the success of certain bone-setters. Orthopaedic surgeons enthusiastically tried out some rather rough and ready manipulative techniques, but because the results with powerful manipulation under anaesthesia were unsatisfactory their interest waned, and in fact waxed in the opposite direction, condemning manipulation as a dangerous practice. Now, since intervertebral disk lesions are better understood, a new wave of interest has sprung up and we have an impressive array of medical men strongly advocating manipulation in the treatment of low back pains: R. Barbor, J. F. Bourdillon, L. S. Calvert, A. B. Coyer and I. H. M. Curwen, E. J. Crisp, J. Cyriax, A. C. Elkin, W. Grant Waugh, D. B. Ramsay, G. O. Tippet, W. E. Tucker, and R. W. R. Watson.

Bourdillon (*Journal*, March 19, p. 720) and Watson (*Journal*, February 12, p. 413) strongly advocate the osteopathic method of manipulation. Cyriax has claimed a method of manipulation, now so often referred to as the Cyriax technique, which is essentially derived from the osteopathic methods. Many others are striving to develop techniques of manipulation themselves. What a pity that the experience of 80 years in the art of manipulation as exhibited by the best osteopaths is not being utilized by the medical profession as a whole. It is not the fault of the osteopaths. They are there and ready to help in the training of medical men. The London College of Osteopathy has been training doctors for the past ten years, and, as we see from Cyriax's article (*Journal*, January 15, p. 140), osteopathy has become recognized in France and Switzerland, and for a long time now has been recognized in the U.S.A. Why is Britain so far behind in this matter? It is high time that we here in England appointed a committee of medical men interested in this field to get together and study the matter so that the public at large can benefit from the undoubted advantages, which can accrue from the osteopathic methods of manipulation.—I am, etc.,

London, W.1.

ALAN STODDARD.

Chicken-pox Quarantine

SIR,—I do not entirely agree with Dr. M. Curwen (*Journal*, March 19, p. 727) that chicken-pox is a trivial disease at all times.

Some 15 years ago I was called to attend a boy 6 years old who was suffering from chicken-pox and who was allowed to go about the house for about a week without medical attention. The parents thought it "was only chicken-pox, and the whole school had it." I was called in because the boy was walking in circles and to one side all the time, and was unduly sleepy. This case turned out to be one of encephalitis lethargica, and a consultant called in confirmed the diagnosis of encephalitis lethargica caused by the chicken-pox virus. The patient recovered, leaving sequelae of enuresis and stammering. The enuresis got better after a few years but the stammering persists to this day.

It would be interesting to know the views of fever consultants on the opinion expressed by Dr. Curwen.—I am, etc.,

London, N.9.

M. P. K. MENON.

Ovariectomy and Coronary Disease

SIR,—The work of Rivin and Dimitroff,¹ Paul White,² and Leitner³ (see Dr. Z. A. Leitner's letter, *Journal*, April 2, p. 852) is of considerable moment to the gynaecologist. This research proves that excess cholesterolaemia has an intimate connexion with coronary heart disease. If this be so, then the school of thought that maintains that every hysterectomy should include total ablation of both ovaries is annihilated, for it would appear that, quite apart from the disastrous menopausal symptoms so produced, such a patient is in imminent danger of becoming what Paul White calls a "coronary individual"—a condition which may exist until she is 60 or over. Moreover, it emphasizes the great danger of using radium or x-rays for fibroids, metropathia, or functional conditions. It would seem, therefore, that in addition to conserving the ovaries in all non-malignant conditions we should give very careful instruction as to the avoidance of a dietary rich in fat in such patients, for the incidence of severe coronary atherosclerosis in castrated females approximates that in males, a ratio that normally is in the region of one in ten. Indeed, this remarkable sex difference in the incidence of atherosclerosis suggests that oestrogenic hormones exert an inhibitory effect upon the pathogenesis of coronary disease.—I am, etc.,

Natural Childbirth

SIR,—If a woman is fortunate in being helped to have a happy, healthy pregnancy it is a pity if she expects, in this far from perfect world, to go through childbirth too without any disappointment or physical distress, and I hope no class in training for natural childbirth is led to expect absolute perfection every time. I, too, have been enthusiastic in recommending intelligent mothers to learn to help themselves by relaxation and exercises, and found this of great value in my own case. I did not have the benefit of training in a class: I had to read and practise on my own. One of my reasons for wanting to try natural childbirth was the way in which a patient, having a normal confinement in hospital, seemed to be deprived of full consciousness at a time when she could be of most use in delivering herself. Even in first-stage labour, under practically any medication, she seemed to require more rather than less nursing attention; I asked myself if I should not prefer full consciousness and the ability to lie quietly (though I did not know

anything about relaxation then), rather than be under the influence of one of the analgesics then in use and not be sure of my even remaining on one of the narrow hospital beds. In my three confinements the end of the first stage was the most trying, and control was most likely to be lost then; but one knew that the second stage was not far away, with something to see for one's hard work. Incidentally, I would like to hear more nurses and doctors referring to "contractions" instead of "pains." In all fairness, it should be noted that natural childbirth is not claimed to be painless childbirth.

Some benefits, which are obviously not in doubt, are (1) increased co-operation of the patient—childbirth is not a passive event; (2) reduction of ignorance and of fear of the unknown; (3) giving of hope and a feeling of security, even when there seemed very little to feel secure about, as during the war years.—I am, etc.,

Old Cumnock, Ayrshire.

MARY MACK.

SIR,—May I add a letter to the recent correspondence in the *Journal* concerning natural childbirth? I am a doctor's wife, but not medically qualified, and had my first baby seven months ago. I too was an ardent believer in Dr. Read's ideas and attended antenatal classes. The birth of my baby was a wonderful experience which I have no wish to forget. Everything went as I had been led to believe. Lest it should be thought that I was one of those women who would have had an easy time in any case, may I state that my pelvic measurements were anterior-posterior diameter 105 mm., transverse diameter 105 mm., and the head did not engage until a few hours before the actual birth, labour lasting 24 hours in all? Relaxation enabled me to wait patiently through a long first stage—the second stage lasted only 20 minutes.

I do not understand Mrs. Constance Lynn's reference (*Journal*, April 2, p. 851) to the exercises she had to do during labour, as there are none. The exercises one does throughout pregnancy are to prepare one's muscles for the hard work they will have to do during the second stage, which in my case they certainly did, as I was able to make the fullest use of my contractions. Mrs. Lynn was misled if she believed that nothing was required of her but to "contentedly await events." I was warned that labour meant what it said—hard work—and that I would experience some degree of discomfort, perhaps acute at some stage. However, my son's indignant wail as he entered the world amply rewarded my hard work. I felt no exhaustion either immediately after the birth or later.

I do feel, however, that a labouring woman needs an attendant to encourage her towards the end of the first stage, when even the best-trained mother can forget what she has been taught and lose control over her emotions. I had my husband to help me here, but I realize not all mothers are so fortunate. Perhaps a rearrangement of hospital routine which cut out the inessential jobs (is it really necessary to do five or six swabbings a day?) would leave the midwife free to do her real job of attending to the mother instead of the mother being left on her own "to get on with it."

Incidentally, I too have compared notes with other relaxation patients, the great majority of whom agree that relaxation was a wonderful help. The midwives at the hospital I attended also said that relaxation patients had easier births than other patients.—I am, etc.,

Yeovil.

P. M. LEADLEY.

SIR,—It seems fair enough that doctors' wives should have their say in this correspondence. Therefore, as the mother of three children, and also as a speech therapist with some experience of teaching relaxation, I should like to reply to Mrs. Constance Lynn's letter (*Journal*, April 2, p. 851).

First, good and effective relaxation is, as much as anything, an attitude of mind, and is achieved not by "trying to relax," or by diligent practising of a set of exercises, but by learning to "let go" mentally and physically. For this reason I

should be most careful to avoid the word "exercise," with its associations of gymnastics and effort, in connexion with relaxation. Secondly, those who teach relaxation to expectant mothers should be very careful to make it quite clear that the aim is to minimize pain in childbirth, and not to give a completely effortless and carefree labour. Anyone who has tried it will probably agree that giving birth to a child is the hardest work that a woman is ever likely to do, and it is most important that she should realize this. Mrs. Lynn states that she herself was "totally unprepared for the really serious and hard business involved."

My own confinements were all normal and straightforward, and during each I was able to practise relaxation with excellent results. For the first I was Dr. Dick Read's patient, and had no anaesthetic or analgesic. The only really unpleasant part was at the end of the first stage, and during the birth of my second child the pain at this point was effectively relieved by pethidine.

During my third labour I was led by sheer curiosity to try the gas and air machine brought along by the midwife, but I most certainly would not use it again. In my opinion it leads to lack of co-ordination, with subsequent loss of control and ability to co-operate in the second stage. Most people with no personal experience of childbirth seem to think that some form of anaesthetic is necessary at the moment of crowning, but I have not found this to be painful, although naturally it is extremely uncomfortable. For a woman who is still alert and unfuddled this can be an exciting moment of approaching achievement, and it is so soon followed by the joy of hearing the child's first cry that it is well worth the discomfort.

It seems to me that in normal conditions, knowing how to relax and how to use that knowledge, with possibly some relief from pain when full dilatation is near, the average woman should be able to achieve and enjoy natural childbirth. That she does not do so in many cases leads one to suspect either that she has been taught wrongly or that she herself is, for one reason or another, incapable of relaxing properly. I feel that Mrs. Lynn is a little hard on a system which many people have found helpful, her only evidence being that it does not work for her personally.—I am, etc.,

London, N.10.

ALISON DUDDINGTON.

SIR,—As one who has obviously followed the correspondence "Whither Natural Childbirth?" I feel justified in replying to Mrs. Constance Lynn's letter (*Journal*, April 2, p. 851) not only as a mother of two children—the first born after I was aged 30 by caesarean section and the second, a 9 lb. (4 kg.) boy, three and a half years later, absolutely naturally after a labour lasting less than four hours—but also as one who has taught some hundreds of women this approach to childbirth and been present at the labours of most of them. Therefore I write as a teacher with considerable labour ward experience, and as a mother.

With all due respect to this lady's ability, I cannot help feeling that in fairness to her instructress, and perhaps those who attended her confinement—before she states "categorically . . ."—a full description of her conduct during labour should be made clear to her readers. It seems strange to me that, if she had been taught this method in its entirety, she could have been "totally unprepared for the really serious and hard business involved." I find this difficult to understand if her antenatal teaching had been correctly carried out, for the woman, adequately instructed, is always told to expect "serious and hard work." After all, is this not the meaning of the word "labour"? I also find it difficult to understand her remark, "A great deal of what I was taught to do was physically impossible in labour, and much of what was possible, one hadn't the inclination to do at that time." It appears that Mrs. Lynn, once my husband's "most ardent and loudest fan," allowed her enthusiasm to override a practical and commonsense approach to a perfectly natural function—woman's most cherished heritage.—I am, etc.,

Petersfield.

JESSICA DICK READ.

Purpuric Drug Eruption Caused by Carbromal

SIR.—Dr. Peter Borrie (*Journal*, March 12, p. 645) cites six cases of a purpuric eruption which he attributes to carbromal. During the course of my practice over a number of years I have prescribed carbromal in one of the forms mentioned—that is, "persomnia"—regularly to many patients, including many children, and never have I encountered, as a result, any skin eruption or, indeed, any other untoward side-effects.

In the article Dr. Borrie emphasizes that the dose of carbromal (which varied between 3 gr. (0.2 g.) and 20 gr. (1.3 g.) nightly) "bore no relationship to the severity of the eruption." This seems to be an indication that individual idiosyncrasy (allergy) was the possible causal factor involved, although my own experience tends to indicate that the incidence of such an idiosyncrasy, if present, is less than that which one commonly associates with penicillin or aspirin. In view, therefore, of the efficacy and enormous margin of safety of carbromal and other of the open-chain ureide series, compared with the barbiturates, the incidence of any such side-effects would appear to be almost clinically negligible. It is also worth noting that all the cases described apparently cleared up completely without treatment.—I am, etc.,

London, E.18.

G. F. NEWBOLD.

Chronic Discoid Lupus Erythematosus

SIR.—I was very interested to read the article (*Journal*, February 5, p. 329) by Dr. H. J. Lewis on the treatment of chronic discoid lupus erythematosus with chloroquine sulphate. Since reporting a case so treated in 1953¹ I have had the opportunity of treating five more cases without a failure, and I can completely endorse Dr. Lewis's conclusion that chloroquine sulphate is as efficient a form of palliative therapy as any previously used. The average maintenance dose has been one tablet of chloroquine sulphate daily—equivalent to 150 mg. of base.

My original patient, who has been on therapy for almost two years, has continued to improve, although on one occasion when she stopped her treatment there was an almost immediate relapse.—I am, etc.,

Bulawayo, S. Rhodesia.

J. CHARLES SHEE.

Swallowed Hair-grips

SIR.—In view of the recent correspondence on the above subject, may I submit details of an interesting and unusual case which came under my care whilst resident surgical officer at the Barnsley Beckett Hospital some years ago?

A single girl of 19 said she had swallowed a hair-grip several days previously. X-ray showed the presence of a hair-grip placed centrally in the lower hypogastric region, considered therefore to be in the lower coils of the ileum. She was asked to attend again in two days' time. Further x-ray then showed no appreciable change in the position of the hair-grip; she had no symptoms. A third x-ray two days later showed no change. She complained of suprapubic ache and discomfort, but there were no abnormal physical signs. She was admitted for observation. Next day she passed a small amount of blood in her urine. She was cystoscoped, and the hair-grip was seen in the bladder, covered with greyish-white phosphatic concretion, with a globular enlargement over the crook of the hair-grip, looking very much like a small doll. There was an associated cystitis. She readily gave written consent to operation and removal. I removed the foreign body by suprapubic cystotomy and noted that her uterus was enlarged to the size of approximately a 10- to 12-weeks gestation. She was discharged on the tenth day without complications.

It was difficult to determine when this hair-grip was inserted, although it was obvious that she had used it in

an attempt to induce abortion. She persistently maintained that she had swallowed the hair-grip, and denied vigorously that she was pregnant. I understand that subsequently she was delivered of a full-term infant.—I am, etc.,

Leeds.

ISAAC ROSE.

Malignant Melanoma and Pregnancy

SIR.—We were interested in Dr. H. Stewart's report (*Journal*, March 12, p. 647) of a case of malignant melanoma in which neoplasia was stimulated during pregnancy, and his comment that this association has rarely been reported.

We have recently seen a case of malignant melanoma in a woman of 29. A pigmented naevus was removed from the patient's left leg in June, 1953, during her second pregnancy. The area was widely excised, when the section showed a malignant melanoma. Her child was safely delivered and she was well and showed no signs of recurrence until January, 1955, when a lump was first noted in the left groin. She was then in the 24th week of a further pregnancy. Excision proved this to be a secondary deposit from a malignant melanoma and she has now been evacuated to England for further treatment.—We are, etc.,

M. A. W. ROBERTS.

E. I. KOHORN.

Benghazi.

Hypoglycaemia in Chronic Alcoholism

SIR.—Dr. J. S. Taylor (*Journal*, March 12, p. 648) described the interesting case in a chronic alcoholic of fatty liver changes producing hypoglycaemic attacks. Fatty liver is very common in chronic alcoholics, in whom its incidence has been estimated at 75%.¹ Of 150 alcoholics at Warrlingham Park Hospital—the great majority of whom showed no liver enlargement—approximately 75% had abnormal results in at least one out of a number of liver function tests (carried out by Dr. W. W. Kay). Most frequently positive was the bromsulphalein test—that is, in approximately one-third of the 80 patients in whom it was performed.

As far as hypoglycaemia in alcoholism is concerned it has been pointed out that the symptoms of impending hypoglycaemic shock resemble alcoholic "jitters,"² and it has been suggested that hypoglycaemia may be responsible for neurotic symptoms occurring in chronic alcoholics.^{3,4} Tintera and Lovell⁵ suggest that, following primary and secondary hypofunction of the adrenal cortex in alcoholics, craving for alcohol results when blood sugar falls to a certain low level. Lovell⁶ explains the alcoholic's apathy, physical weakness, etc., as being caused "to a large measure" by his low blood sugar (according to others⁷ the chronic alcoholic's fatigability is "in great part . . . a consequence of protein, and particular vitamin, shortage"), and ascribes the "often astonishingly rapid" response of alcoholics to adrenal cortex extract to the restoration of the blood sugar balance and of liver functioning. The importance of the restoration of blood sugar balance in alcoholics has been stressed repeatedly,^{8,9} and according to Lolli¹⁰ "some cases of alcohol addiction are precipitated (but not caused) by an underlying spontaneous hypoglycaemia, correction of which is an adjuvant to treatment of the addiction."

An investigation in 21,000 non-alcoholics showed hypoglycaemia below 80 mg. in 11% of cases.⁸ In alcoholics relatively low fasting blood sugars were frequently found by Strecker and Chambers²; Voegelin *et al.*⁹ found hypoglycaemia in 17.1% and hyperglycaemia in 6.6% of 303 chronic alcoholics. Feldman¹¹ saw among 150 alcoholics a level below 0.80 g./l. in 1.34%, between 0.80 and 1.10 g./l. in 95.33%, and between 1.11 and 1.20 g./l. in 3.33% (Hagedorn's method), and Valera *et al.*¹² found no difference between alcoholics and non-alcoholic controls. In our own material of 135 alcoholics the average blood sugar level for 102 males was 86 mg./100 ml., for 33 females 97 mg./100 ml., for the total of 135 89 mg./100 ml. (method modified after King). The level was—in mg./100 ml.—below

80 in 35%, between 80 and 120 in 61%, above 120 in 4%. According to King,¹² 80% of normal adults have a fasting blood sugar value between 68 and 96 mg./100 ml., 10% have a lower and 10% a higher level; the corresponding percentages among our alcoholics were 58, 14 (below 68 mg./100 ml.) and 28% (above 96 mg./100 ml.) respectively.

Results of glucose tolerance tests too show great differences. "Lower than average" curves "as a whole" were noted by Strecker and Chambers,² no difference in glucose tolerance between a group of male alcoholic addicts and a control group of male abstainers and social drinkers was observed by Valera *et al.*¹² a decrease in glucose tolerance in 41% of 303 alcohol addicts was found by Voegelin *et al.*⁹ an increase in tolerance in 44% of 50 alcohol addicts by Karlan and Cohn.¹³

The considerable variation in the findings of different observers seems to support the view of Valera *et al.*¹² that whilst "a sizable proportion of alcohol addicts exhibit a normal glucose tolerance," "the population of alcohol addicts is sufficiently irregular, in respect to glucose tolerance, to yield different results in different samples," thus reflecting also in this aspect the fact that alcoholics are not a homogeneous group of people.—I am, etc.,

Tetracycline

SIR.—In your annotation on tetracycline (*Journal*, April 2, p. 838) you mention a paper by Frei and his co-workers¹ in which they compared the use of penicillin and tetracycline in the treatment of pneumonia. Twenty-six patients were given tetracycline in what they state "a relatively high dosage of 4 grammes a day," and 31 patients were given a relatively small dosage of 600,000 units of aqueous potassium penicillin. What were they trying to find out? They had read that Finland² had demonstrated that with the use of chlortetracycline, oxytetracycline, and tetracycline the frequency of diarrhoea differed directly with the dosage. When tetracycline was used in a dosage of 1 to 1.5 g. daily, 2% of patients had diarrhoea. When the dosage was increased to 2 g. a day this percentage rose to 5, and they have now demonstrated that on 4 g. a day this side-effect occurred in 15% of patients. All the 31 patients in the penicillin group suffered no ill-effects. A similar study in the treatment of pneumonia was carried out by the Medical Research Council in 1951.³ Patients in this study were given an initial dosage of 2 g. of aureomycin, and then 1 g. every six hours. As was to be expected with this dosage, side-reactions with aureomycin were much greater than with penicillin.

These two studies did not take into account the recommended dosage of aureomycin. This dosage was arrived at after consideration of extensive pharmacological investigations and the results of clinical studies undertaken throughout the world. In the large majority of cases the dosage of aureomycin and tetracycline should not exceed 1 g. a day for an adult. Each 250 mg. capsule should be given with a glass of cold milk or bland fluid. By this means side reactions may often be avoided.⁴ Further comparative studies on how much more of the tetracyclines the patient can stand are, in my opinion, of little value. In the light of recent work on the effectiveness of small amounts of

antibiotics* surely it should be the aim of clinical investigators to determine the smallest amount of antibiotic that is effective therapeutically. It has been stated* that if the lowest effective dose of an antibiotic is used the infecting organism is unlikely to become resistant. Since the development of resistance to all the antibiotics is a subject of major clinical importance, and the excessive use of antibiotics appears to predispose to this development, it cannot be too strongly emphasized that practitioners should not use at the present time a dosage in excess of that recommended in the *British Pharmacopoeia* (1953). The publication of papers on ill effects produced by excessive dosage of antibiotics will have one good result if it focuses attention on the importance of correct dosage.

Your annotator also comments that if tetracycline produced fewer side-effects than either aureomycin or terramycin, the importance of this advantage should not be minimized. That terramycin produces fewer side-effects has been shown in at least six published papers in the last few months. In this country Abbott and Parry,⁷ using a dosage of 1-2 g. daily of tetracycline, found no side-effects from its use. In a study of tetracycline Wilson⁸ stated that "side-effects were uncommon and unimportant." In a comparison of 180 patients treated with the tetracyclines Weaver and McCorry⁹ have noted that the incidence of side-effects with tetracycline was half that encountered with the use of oxytetracycline. The paper of Finland has already been referred to in which he noted that side-effects from tetracycline were minimal. The evidence available shows that tetracycline has certain unmistakable advantages over oxytetracycline and chlortetracycline which cannot be arbitrarily dismissed with the statement that the tetracyclines have the same toxicity.—I am, etc.,

Temporal Lobe Epilepsy and the Psychoses

SIR,—I was interested in the valuable paper on "Psychical Phenomena in Temporal Lobe Epilepsy and the Psychoses" by Drs. Shafica Karagulla and E. Elizabeth Robertson (*Journal*, March 26, p. 748), but I wonder how justified are their comparisons between the two diseases. Surely the analogous symptoms are produced by the fact that they are both the result of a disorganization of the same machine, but this does not imply that the nature of the disorganization is similar. To take a simplified example, a "knock" in an internal combustion engine can be produced by poor fuel, a wrongly timed ignition, or a worn big end. Yet no one suggests that the causation is similar.

Again, what of those psychoses which are produced rapidly in a few hours by great strain? Or in a case which I saw many years ago in which the psychosis disappeared almost instantly? This was that of a woman about 40 years of age who was suffering from a paranoid psychosis and a coincidental mitral stenosis. She was grossly hallucinated and deluded, and spent most of her time parading the ward shouting at those who seemed to be persecuting her. Suddenly in the midst of her shouting she developed an embolus in her left middle cerebral artery. She did not lose consciousness, but at once had a right-sided hemiparesis and complete aphasia. After many weeks her paralysis recovered and her speech came back. She was then able to tell me that the "voices" had ceased at once, at the very moment her limbs became paralysed and she lost her power to talk. Obviously,

with the abolition of her power to express herself in words the internal ideational constructive power was abolished. This was the source of the hallucinations, and the "voices" ceased magically. Such an experience does much to uphold J. B. Watson's¹ view that thought is only suppressed speech. It suggests also that schizophrenia is a purely functional illness and that it is not caused by foci of deterioration such as one finds in epilepsy.—I am, etc.,

Speaking Up

SIR,—The correspondence on poor standards of speech at medical meetings (*Journal*, April 2, p. 853) gives me the opportunity to comment without, I hope, appearing impertinent to my seniors. I submit that the pathetic and irritating mumbling usually inflicted on the audience at learned medical societies is due to the following factors: (1) nervousness, and the traditional Englishman's reluctance to make himself conspicuous; (2) the fear that emphatic oratory will be ridiculed as conceit or charlatanism; and (3) laziness; many eminent doctors do not seem to realize the importance of clear and emphatic public speaking, and would consider it beneath them to learn how to prepare and deliver an address.

Frequently the speaker resorts to reading (or mumbling) verbatim from a script. But why "read papers"? Matter designed to be assimilated by the eye is seldom ideally composed for absorption by the ear, even if clearly read. Medical papers should be printed in the appropriate journal or "proceedings" shortly before the meeting. The writer could then deliver (not read) a short summary, and the matter could then be discussed (surely the real value of such gatherings) before most of the audience had left to catch trains or sunk into coma.—I am, etc.,

London, W.1.

NORMAN A. PUNT.

Night Cramps

SIR,—May I point out that your annotation on night cramps (*Journal*, March 12, p. 653) omitted to mention the value of nicotinic acid or nicotinamide in preventing such cramps? Nicotinic acid was recommended some years ago in answers to "Any Questions?" and I have found it to be efficacious.—I am, etc.,

Chalfont St. Giles.

Hysterical Hyperventilation with Carpopedal Spasm

SIR,—A girl of 8 years was seen recently who had developed a morbid fear of appendicitis. One of her school-friends had recently had her appendix removed, and, from personal knowledge of this latter child, I am sure that no morbid details were spared in conversation. The former child was the third in a family of four girls, and, unlike the others, seemed to be withdrawn and perhaps a little emotionally unstable.

The first episode occurred one evening when she cried out with sudden severe abdominal pain. The pain continued for half an hour and was alleged to be in the umbilical region. A full clinical examination failed to provide a diagnosis, and, as the pulse rate and temperature were normal and the pain had mysteriously passed away, the child was reassured and was soon playing quietly. A visit several hours later revealed no further developments. The second episode occurred 24 hours later. This time there were pains in the abdomen, a choking sensation, and painful, paralysed arms and legs, with tingling. The child was sobbing uncontrollably and was hyperventilating for about 20 minutes. The hands were typical "*les mains d'accoucheur*." The child was reassured and a minute or so of breath-

holding stopped the painful spasm, and within five minutes the adducted thumbs relaxed. Shortly afterwards the choking sensation (due to a lump, presumably "globus hystericus") disappeared and a full clinical examination revealed nothing to suggest appendicitis.

The mother admitted that the child had a dread of developing appendicitis. This started about the time the school-friend returned from hospital with an account of her experiences.—I am, etc.,

J. CLARKE.

Acute Respiratory Obstruction

SIR,—I have read with great interest Mr. Norman Jory's article on acute respiratory obstruction (*Journal*, March 26, p. 781). In the paragraph on laryngoscopy he states that if the mouth cannot be opened because of spasm this may be overcome by the intravenous injection of 50 mg. of suxamethonium chloride. This is undoubtedly most effective. However, I feel that it should be emphasized that not only will this relax the jaw muscles but that it will also relax the glottis and paralyse some, if not all, of the muscles of respiration, depending on the size of the patient, for a period of from three to five minutes. One will probably then be dealing with an apnoeic patient; certainly there will be no deep breath.

I suggest, therefore, that if this line of treatment be carried out it should be stressed that one must be prepared to apply adequate artificial respiration, preferably with oxygen, until such time as the effect of the relaxant has ceased.—I am, etc.,

Blackrock, Co. Dublin.

K. P. O'SULLIVAN.

Selection of Patients for Psychotherapy

SIR,—Dr. E. A. Bennet's lecture at the St. Marylebone Hospital for Psychiatry and Child Guidance, as summarized in the *Journal* (April 2, p. 844), comprises the broad wisdom which is linked with his name. The address, as such, would most certainly have met the wishes of his audience; he could, however, have delivered it with equal facility 30 years ago.

It is a sombre reflection, if valid, that advice on psychotherapeutic procedure remains a personal rather than a clinical issue. It is a distressing thought, if true, that the word depressive is used to denote the indication for either electric convulsion therapy or psychological interference. It is a disconcerting cogitation that the diagnosis of obsessional neurosis, as described by Freud during his formative years in Vienna, bears little resemblance to the nowadays use of the term obsessional. The latter depicts a psychiatric state which, dependent on the predilection of the physician consulted, may be treated either by prefrontal leucotomy or one or other of the disparate psychotherapeutic techniques.

The inference seems to be that competent selection of patients for psychotherapy demands a strict application of intelligence of the head rather than what Dr. Bennet calls an "intelligence of the heart."—I am, etc.,

Obituary

A. F. MacCALLAN, C.B.E., M.D., F.R.C.S.

Mr. A. F. MacCallan, consulting ophthalmic surgeon to the Westminster Hospital and the Royal Eye Hospital, and pioneer in the study and eradication of trachoma, died in Westminster Hospital on March 31 after a short illness. He was 83 years of age, and had continued in active practice until a few weeks before his death.

Arthur Ferguson MacCallan was born on October 23, 1872, the only son of the Rev. J. Ferguson MacCallan, vicar of New Basford, Notts. He was educated at Charterhouse, Christ's College, Cambridge, and St. Mary's Hospital Medical School, where he was a university exhibitioner. After qualifying in 1898 he graduated M.B., B.Ch. in the following year and also took the F.R.C.S. He completed his ophthalmic training by three years as house-surgeon at Moorfields Eye Hospital, and almost immediately afterwards (1903) was appointed as ophthalmologist in the department of public health, Cairo. Here he remained for 20 years, interrupted only by his service in the R.A.M.C. during the first world war, when he was mentioned in dispatches.

It was while MacCallan was in Egypt that Sir Ernest Cassel, having successfully financed the building of the Great Aswan dam, had decided to confront the vast problem of trachoma, which had been a scourge of Middle East countries since prehistory, by the training of a corps of Egyptian oculists. To this end a travelling eye hospital was formed which offered scope for all the energy, enterprise, and administrative ability that MacCallan so happily embodied. His success was immediate, and eye hospitals were built in all the major provinces staffed by his enthusiastic pupils. By the time he returned to England mass treatment had been instituted, and the disease seemed to be at least under some sort of control. He retired with the honours that he deserved, receiving for his ophthalmic services to the Egyptian Government the Order of the Nile (second class) and the Order of Medjidieh (third class), and being appointed C.B.E. in 1920 and an officer of the Order of St. John of Jerusalem. His work was commemorated in 1931 when a bronze bust, commissioned by the ophthalmic surgeons of Egypt, was unveiled by the British High Commissioner. His major textbook on trachoma, published in 1936 and translated into many languages, remained for many years an authoritative guide.

MacCallan returned to England in 1924 and started a practice in London. In the same year he saw an advertisement in *The Times* for the post of assistant ophthalmic surgeon to Westminster Hospital, and he successfully applied for this. He was later appointed also as surgeon to the Royal Eye Hospital. On reaching the age of 65 in 1937 he retired from the active staff of the Westminster, but he returned to the hospital during the second world war, when the ophthalmic department had been depleted of consultant staff on the death of Mr. A. D. Griffiths. Thereafter he still continued his researches in trachoma in a laboratory at the Westminster Medical School. In 1935 he was appointed as second president of the International Organization against Trachoma, a high office that he held for 20 years until, at the International Congress of Ophthalmology in Montreal last autumn, he handed over the

active leadership to Dr. G. B. Bietti, but was himself appointed honorary life president in recognition of his great and long services: by the same token he was also appointed a life member of the Ophthalmological Society of the United Kingdom, of which he had been vice-president. He had also served as secretary and vice-president of the Ophthalmological Section of the Royal Society of Medicine, and was a distinguished member of many foreign ophthalmological societies. In 1918 he married Hester, daughter of the late Bishop Boyd Carpenter, and she survives him, together with two sons and a daughter.

P. D. T.-R. writes: A. F. MacCallan was an unforgettable personality. From his early days in the mid-Victorian vicarage, through a long and inspiring term of office in Egypt, at his English hospitals, and finally as chairman of his own parish council in Hertfordshire, his life was coloured by a sense of duty and dedication that fully merited the renown he won. Forthright and vigorous, intolerant of obstruction, he was ideally suited to driving through the inertia that has blocked progress in the Egyptian health services for so many years. Yet his dynamic mien was at all times leavened by especial charm of manner and a readiness of humour that stole the affection even of his critics. He belonged to a vanished generation of empire builders, and his war against the trachoma virus was on a heroic scale; while the gratitude of countless near-blind is his just reward.

G. F. PETRIE, M.D.

Dr. George Petrie, who was for many years on the staff of the Lister Institute of Preventive Medicine and finally retired in 1944, died on March 17, aged 81.

After a short period as a student at Edinburgh University George Ford Petrie continued his medical education at Aberdeen, where he graduated M.B., Ch.B. in 1898; five years later he proceeded to the M.D. with highest honours. It was while he was a student that he developed a keen interest in pathology and bacteriology, and after a short period as an assistant in general practice in Yorkshire and as a research student in the Lister Institute he was appointed assistant bacteriologist to the Institute in 1902, working in the serum department at Elstree under the late Dr. George Dean. From then on he took an increasingly important part in many of the investigations designed to throw light on the aetiology and control of epidemic diseases. In 1905 he was a member of the Indian Plague Commission under the late Sir Charles Martin, and from 1911 to 1913 was bacteriologist under Dr. Charles Todd to the Plague Investigation Commission set up by the Egyptian Public Health Department. He also went with the British Delegation to the International Plague Conference in China in 1911, contributing a review of an outbreak of plague in North China to the published proceedings of the conference. About this time he was the author of several other articles on the subject of plague, including a report on the examination of rats collected in Suffolk and Essex. After serving in the R.A.M.C. as a bacteriologist in France during the first world war, he returned in 1919 to the serum department of the Lister Institute, succeeding Dr. MacConkey as bacteriologist in charge in 1926. He became a leading authority on antisera, particularly in connexion with their production in quantity, and it was largely due to his work that it was possible to produce quickly the large amounts of tetanus antitoxin required for the civil population in the last war. He should have retired in 1939, but after a very brief period of rest he returned to work in October, 1940, first to take charge of the library of the Lister Institute, then temporarily housed in Aldenham School,

and in 1941 he again took over the supervision of the serum department during the absence of Dr. C. R. Amies in the R.A.M.C.

Dr. Petrie was the author of many papers on subjects connected with his specialty, and in 1934 he collaborated with the late Sir Alexander Fleming in writing *Recent Advances in Vaccine and Serum Therapy*. After he had retired he compiled an anthology of *British Medical Science and Practice*, and he was engaged on other literary work at the time of his last illness.

O. D. BROWNFIELD, C.B., O.B.E., M.B.

Surgeon Rear-Admiral O. D. Brownfield, who served in the Royal Navy for nearly 36 years, died on March 29 aged 64.

Owen Deane Brownfield was born on February 22, 1891, the son of Dr. H. M. Brownfield, of Petersfield. From Epsom College he went on to St. Thomas's Hospital, qualifying in 1914. He entered the Royal Navy as a temporary surgeon-lieutenant in October of that year, and during the first world war he served at the R.N. Hospital, Haslar, and in H.M.S. *Excellent*, H.M.S. *Chester*, and at the R.N. Barracks at Portsmouth. In 1919 he was awarded the O.B.E. for valuable services given while serving in these appointments. Having graduated M.B., B.S., London, after the war he was transferred to the permanent list of the Royal Navy towards the end of 1919, and promoted surgeon lieutenant-commander. From 1931 to 1935 he was medical specialist at the R.N. Hospital, Malta, holding the rank of surgeon-commander, and then after a period at sea he was placed in charge of the cadets' sick quarters at the R.N. College, Dartmouth, in 1937. In 1940 he was appointed to H.M. Hospital Ship *Vita* as medical officer in charge and holding acting rank as surgeon-captain. He was confirmed in this rank in 1941. After a period of service at the R.N. Auxiliary Hospital, Barrow, Burney, he became medical officer in charge at the R.N. Auxiliary Hospital, Trincomalee, Ceylon. On his return to the United Kingdom in 1945 he was principal medical officer at H.M.S. *Collingwood* until 1947, when he was promoted surgeon rear-admiral. Until his retirement in 1950 he was medical officer in charge at the R.N. Hospital, Malta. Surgeon Rear-Admiral Brownfield was appointed C.B. in 1948, and for three years before he retired he was King's Honorary Physician.

After his retirement he returned to live in Petersfield and became a member of the Council of the B.M.A. in 1951. He was also a member until the time of his death of the Armed Forces Committee and the Waverley Evidence Committee, playing a full part in the deliberations of these committees. His many old friends in the Navy and the new friends he made as a result of his interest in the work of the B.M.A. will regret the passing at a comparatively early age of one who served his country and his profession so faithfully and so well.

E. C. SPRAWSON, M.C., D.Sc., F.D.S. R.C.S. M.R.C.S.

The sudden death of Professor Evelyn Sprawson, which took place at a committee meeting in London on April 6, removes a considerable figure from the field of dental surgery and research. He had held the chair of dental surgery and pathology of the University of London, and was consulting dental surgeon to the London Hospital, where he had formerly been director of dental studies.

Evelyn Charles Sprawson was born on February 18, 1881. From King's College School, London, he went on to study dentistry at the Royal Dental Hospital, where he won the Walker and Saunders scholarships. After a further period of study at Charing Cross Hospital he qualified in medicine in 1905, winning medals for ophthalmology and midwifery, and shortly afterwards he joined the staff of the dental school at the London Hospital, where in the course of his career he achieved great distinction not only as a practising dental surgeon and as a teacher but also as a wise adviser in the affairs of his profession. He served on numerous Government committees and as one of this country's representatives at international congresses all over the world. An obituary column could readily be filled with the titles of the various offices he held during his career. He had been deputy chairman of the Dental Advisory Council; chairman of the Board of Studies in Dentistry and member of the Faculty of Medicine of the University of London; and examiner in dental surgery to the Royal College of Surgeons, to several universities (including two overseas), and the Dental Board of the United Kingdom. He served on the Medical Research Council committee for the investigation of the causes of dental diseases, and was a member of the Home Office Tribunal for the Dangerous Drugs Acts. The reputation he had gained as an investigator was shown by his election to the presidency of the International Association for Dental Research and to the honorary presidency of the Section of Histology when the International Dental Congress met in Paris in 1931. The year 1940 saw his election to the presidency of the Odontological Section of the Royal Society of Medicine, in which he was for many years a frequent contributor to the discussions. He had also been president of the Dental Officers Group of the Society of Medical Officers of Health. Sprawson, who held the degree D.Sc. of London University, was elected F.D.S. R.C.S. in 1947. Ten years earlier he had been Hunterian Professor at the College, and he was the Sir John Tomes prizeman in 1930.

In all that concerned the welfare of his profession Sprawson took an eager interest. His work on the council and committees—often very detailed and anxious work—of the Medical Protection Society occupied much of his time. He had been a member of the British Medical Association for 45 years.

Many papers by Sprawson appeared in the proceedings of scientific bodies concerned with dentistry and allied subjects, and he collaborated in the editorship of the last four editions of *Dental Surgery and Pathology*, the work so closely associated with his old colleague and chief, Sir Frank Colyer. He was also editor of the *British Dental Annual*. In the first world war Sprawson served with the R.A.M.C. in the British Expeditionary Force and was mentioned in dispatches and awarded the Military Cross. For many years he was a member of the 28th Battalion of the County of London Artists Rifles and received the Territorial Forces efficiency medal. In the last war he was consulting dental surgeon in certain of the sectors of the Emergency Medical Service. His chief interest outside his profession was aviculture, which he followed at his Surrey home and on which he wrote occasional papers.

We are indebted to Mr. A. M. A. MOORE for the following appreciation: By the sudden and unexpected passing of Professor Evelyn Sprawson, England has lost one of her most distinguished dental surgeons. He was an eminent

contributor to our knowledge of many of the problems of dental surgery, and very many members of the dental profession in practice to-day owe much to his teaching and inspiration.

Sprawson was a shy, quiet, and retiring man, who took the greatest personal interest in the students working in his department, and he will always be remembered for his many kindnesses and acts of generosity to those in need. For many years he held the post of honorary consultant dental surgeon to Dr. Barnardo's Homes, and continued to attend the children at the homes long after his retirement from the staff of the London Hospital. It gave him great joy to feel that he was helping in some way to carry on the work of the founder, and it was a constant pleasure for the members of the staff to meet and work with this remarkable man.

Sprawson had much to do with the original establishment of the dental department at the London Hospital, which has now grown into one of the larger teaching units of dental surgery in the University of London. He played an active part in the life of the university and was one of the few dental professors to be granted the degree of doctor of science. Before his retirement from the staff of the London Hospital some years ago he was presented with his portrait by past and present members of the dental school—the only dental surgeon of the London Hospital to be honoured in this way so far. This portrait now hangs in the students' dining room of the London Hospital Medical College, and will be a constant reminder to future generations of a very great man.

Medico-Legal

MISTAKE NOT NEGLIGENT

A young, newly qualified hospital doctor, in discharging a man who went out into the street and collapsed and died of coronary thrombosis, made a mistake but was not negligent, said Mr. Justice Ashworth at Liverpool Assizes on April 1. He was giving judgment for the West Cumberland Hospital Management Committee and Dr. J. P. Graham in an action for damages brought against them by Mrs. Elsie A. Parkinson, of New Brighton, Cheshire. Her husband, Mr. S. A. E. Parkinson, aged 39, a crane driver, was found dead near Workington Infirmary on July 11, 1953.

In his judgment Mr. Justice Ashworth said that Parkinson went to the infirmary soon after 4 a.m. on the day he died and complained of chest pains. Dr. Graham, then house-physician there, gave him two tablets of codeine and told him to return later for x-ray examination. A quarter of an hour afterwards Parkinson was found dead near the hospital, and the judge said he was satisfied he died from a massive coronary thrombosis. The fact that Dr. Graham took an hour over the examination showed he was anxious on this, his fourth day at Workington, to acquit himself well, and the judge accepted his account of what he saw and did. It was conceded that the diagnosis was mistaken.

After hearing medical witnesses the judge said he had come to the conclusion that Dr. Graham was not negligent in failing to diagnose coronary thrombosis, and was not negligent in rejecting coronary thrombosis. If that was so, he was not negligent in sending Parkinson home, and there was not a sufficient element of uncertainty in his mind to require him to send for his superior. He made a mistake, but was not negligent. The judge said that even if the plaintiff had succeeded the damages would have been very small. Even if rest or treatment might have prolonged Parkinson's life, his future contribution as a breadwinner would have been negligible.

Dismissing the claim, the judge said: "I would like to add that if one merely knows that a man has died in the street in the early hours of the morning, after being discharged from a hospital to which he went in pain, one is

inevitably tempted to draw the conclusion that it ought not to have happened. That illustrates the danger of only knowing part of the story. Once one adds that in the hospital he was examined carefully for nearly an hour, and that the signs and symptoms on balance negated any serious condition, then that first conclusion must in fairness be disregarded."

The defendants did not ask for costs.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Graham.

ULNAR NERVE PARALYSED

An agreed settlement has been reached in an action for negligence brought at Leeds Assizes against two doctors and members of the nursing staff of Castleford, Normanton and District Hospital. The allegations against one doctor and against the nursing staff were withdrawn. The action was brought by Robert Bucktrout, aged 50, of Castleford, who claimed damages for personal injuries from the Leeds Regional Hospital Board and also from Dr. Elva M. Chivers, an anaesthetist, of Pontefract, and Dr. N. I. A. Shohet, then resident surgical officer at the hospital.

Bucktrout's case was that he was admitted to hospital on November 28, 1951, for operative treatment of perforated peptic ulcer. A male nurse, Mr. F. Calvert, first gave him an injection, and then in the operating theatre he was given an injection by Dr. Chivers in his left arm. The latter injection, he said, caused him pain before he became unconscious. Dr. Shohet performed the operation. When Bucktrout recovered consciousness he saw that his left arm had been tightly bandaged between the shoulder and elbow, and when the bandage was removed he saw the arm was black and swollen. The sequel to the operation was that the ulnar nerve was paralysed and Bucktrout was under hospital treatment until January, 1953.

When the hearing had been proceeding for five days a consultation between the parties resulted in their coming to terms on the basis that judgment should be given to the plaintiff with costs for £350 against the hospital board and against Dr. Chivers. As to Dr. Shohet, he was exonerated from any charge of negligence, and judgment was given for him against the plaintiff. Dr. Shohet did not press for costs. The hospital board and the doctors agreed to the settlement on the understanding that the plaintiff withdrew all allegations not only against the hospital board and the two doctors but also against the nursing staff of the hospital, and particularly against Mr. Calvert. The £350 damages were apportioned between the hospital board and Dr. Chivers.

Mr. Justice Slade said he thought the parties had been well advised, and he regarded it as a satisfactory settlement.

The Medical Protection Society instructed Messrs. Le Brasseur and Oakley, solicitors, to act for Drs. Chivers and Shohet.

Medical Notes in Parliament

Group Practice Loans

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, told Mr. J. K. VAUGHAN-MORGAN (Reigate, Con.) on April 4 that at the end of March, 1955, some £36,000 had been paid to 11 partnerships in England and Wales, including 38 doctors, as loans for the establishment or improvement of group practice.

Inspection of Doctors' Surgeries

Mr. VAUGHAN-MORGAN asked when the current inspection of doctors' surgeries was expected to be completed. Miss HORNSBY-SMITH stated that inspections were being carried out under arrangements made by the British Medical Association and were, she understood, progressing well; but the Association could not yet say when they would be completed.

Poliomyelitis Research

Mr. GEORGE DARLING (Sheffield, Hillsborough, Lab.) asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, whether he was satisfied with the scope of the research being undertaken to discover an anti-poliomyelitis vaccine, in view of the recent report of the World Health Organization, which showed that the incidence of poliomyelitis increased with improvements in living standards, that current methods of treatment had proved to be inconclusive, and that all hopes of dealing successfully with the disease depended on the discovery of a suitable vaccine. Mr. J. R. BEVINS, replying on April 4, said that an extensive programme of research on poliomyelitis vaccines was being supported by the Medical Research Council, by the National Fund for Poliomyelitis Research, and by certain pharmaceutical firms. The effort in this country was being co-ordinated by the Medical Research Council, and he was advised that all promising lines were being developed.

Colouring Matter in Food

Dr. A. D. D. BROUGHTON (Batley and Morley, Lab.) asked the Minister of Food what comments he had now received from the catering industry, from manufacturers of colouring materials used in food, or from other interested bodies on the report of the preservatives subcommittee of the Food Standards Committee concerning the preparation of an approved list of substances which might be added to food. Mr. HEATHCOAT AMORY stated on April 4 that the comments received to date related for the most part to points of detail concerning the recommended colours. Some objections had also been lodged against the principle of a restricted list of colours for use in food. Replying further to Mr. N. DODDS (Dartford, Lab.), he said that a period had been allowed for anyone who desired to do so to make representations. That period—to March 31—was now over, and he was actively considering what action was required. Dr. BROUGHTON asked the Minister to regard the matter as one of urgency in view of statements made in the report, and to make sure that coal-tar derivatives used in colouring food should be prohibited in the near future. Mr. AMORY assured him that there would be no avoidable delay in taking action.

Mr. DODDS asked the Minister of Food if he would ban the colouring of kippers with coal-tar dyes, and encourage a return to the practice of producing the appetizing appearance and health-giving properties by smoking instead of painting. Mr. AMORY replied that the addition to food of colouring matters including coal-tar dyes had been the subject of a recently published report by the Food Standards Committee. Consideration was being given to representations from interested parties with a view to a decision on the committee's recommendations. Mr. DODDS asked if the Minister could give a categorical denial that the dyeing of kippers was harmful to health. Mr. AMORY explained that his intervention must be limited to harmful effects. He was anxious to consider the recommendations and the representations made in connexion with these before he reached a decision.

Edinburgh Doctors' Survey

Mr. E. G. WILLIS (Edinburgh, East, Lab.) asked the Minister of Pensions and National Insurance if he was aware that in a recent survey made by 159 doctors of 5,086 elderly persons in Edinburgh it was found that over 200 were in need of financial assistance; and whether he would take steps to meet this hardship. Mr. MARPLES, the Parliamentary Secretary, replied on April 4 that he had seen an account of this summary in the Press, but he did not know on what basis the statements about financial need had been made. It was open to anyone in need to apply to the National Assistance Board.

Mr. WILLIS asked the Secretary of State for Scotland the following day if he was aware that in this survey it was discovered that there was a large need for physiotherapy;

and that of these elderly patients some 1,274 had need of domestic medical assistance and 1,270 were in need of nursing, hospital treatment, or rehabilitation; and whether he would take steps to deal with this. Commander GALBRAITH, the Under Secretary, replied that this survey was conducted as part of a joint study, in which Edinburgh Corporation and the South-eastern Regional Hospital Board were participating, of the needs of elderly patients in Edinburgh. The assessment of its findings, in particular as to the relative importance of the various needs reported by the general practitioners, was a matter primarily for these authorities, who would take careful note of them in considering the development of the various services for which they were responsible under Statute. Mr. WILLIS commented that the results of the survey should completely destroy the complacency of the Government about the conditions of old folk. Commander GALBRAITH retorted that there was no complacency. These particulars were collected so that a study could be made, and that was going on.

Army Medical Practice

Mr. S. HASTINGS (Barking, Lab.) on April 5 asked the Secretary of State for War what administrative arrangements were made to ensure that in peacetime a soldier who felt unwell could, as a right, claim to be seen by a doctor. Mr. ANTHONY HEAD told him that there was normally a daily sick parade at a fixed time attended by a doctor. A soldier who needed urgent medical attention would be seen either by the regimental medical officer or else, if special circumstances demanded, by a civilian doctor. He assured Mr. Hastings that the War Office aim was that in all cases decision whether a soldier should be seen by a doctor or not should not be taken by a person without medical training.

Mr. F. GOUGH (Horsham, Con.) asked when, and why, Royal Army Medical Corps surgical teams were removed from the establishment of a parachute battalion. Mr. HEAD stated that field surgical teams manned by the Royal Army Medical Corps had never been included in the establishment of a parachute battalion. They were held as an Army pool, and six were allotted to the Airborne Division. In airborne operations they dropped with the field ambulances providing medical aid. Mr. GOUGH said that during the war there were surgical teams with the battalions, who dropped with the battalions, and who saved thousands of lives. Mr. HEAD agreed, but said they were still held in a pool and attached to the battalions for operations, possibly for a prolonged period.

Hydrocortisone Ointment

Mr. A. R. W. LOW, Minister of State, Board of Trade, told Mrs. L. JEGER (Holborn and St. Pancras, South, Lab.) on April 5 that there were 91 licences issued in respect of hydrocortisone acetate ointment, to a value of £321, since January 1. Mrs. JEGER said the ointment was manufactured near Folkestone. It was only because of the unhelpful attitude of the Minister of Health that doctors outside the hospital service could only get the ointment by reimporting it. This was a waste of everybody's time. Would Mr. Low have a word with the Minister of Health and see if things could be improved? Mr. Low replied that Mrs. Jeger would not like to deprive the people who were allowed to import the ointment of the right to do so.

Hospital Pharmacists

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Health whether he was aware of the shortage of pharmacists in the hospital service; and for how many assistants and senior assistants there were vacancies at the nearest available date. Mr. MACLEOD stated on April 4 that in August last there were deficiencies on complements of 281 in the basic grade and 64 in the senior grade. Dr. STROSS asked what the Minister had in mind to remedy the deficiency. Mr. MACLEOD answered, "Nothing very much at the moment." The main and obvious question was about salaries, and that was a matter for the Whitley Council.

Recruits to Dentistry

The MINISTER OF HEALTH announced on April 1 the following members of the Interdepartmental Committee which the Secretary of State for Scotland and he are setting up to inquire into the shortage of recruits to the dental profession: Sir Arnold McNair, Q.C. (chairman), Mr. J. E. H. Duckworth, L.D.S., Dr. J. L. Trainer, L.D.S., Dr. R. O. Walker, L.D.S., Sir Wilfred Fish, F.D.S., Professor F. C. Wilkinson, F.D.S., Mr. G. E. Gittins, M.A., Mr. I. D. McIntosh, M.A., Mr. G. R. Moxon, Mrs. Mary Stocks, B.Sc., and Professor A. P. Thomson, F.R.C.P.

Atmospheric Radioactivity

Mr. J. R. BEVINS, Parliamentary Secretary to the Ministry of Works, informed Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) on April 6 that no measurements of atmospheric radioactivity in London earlier than 1947 were known. Since that date measurements of radiation backgrounds had been made in the physics department of the Royal Marsden Hospital; these were the measurements made under the auspices of the Medical Research Council. Other measurements made there since 1930 were designed to ascertain the degree of exposure of workers using x-ray apparatus and radium.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked if the Government would initiate an inquiry into the genetic effects of radioactivity on human beings by means of an investigation of the biological history of those who were engaged in x-ray work some 40 or more years ago. Mr. BEVINS said that it was thought wise to await the report which the Government had invited the Medical Research Council to make. The Council's attention had, however, been drawn to Mr. Hastings's suggestion.

He added in a reply to Mr. ROY MASON (Barnsley, Lab.) that measurements of the radioactivity in the atmosphere at various heights showed that no danger had existed over these islands from thermonuclear explosions.

Fluoride Content in Water

Mr. J. GRIMOND (Orkney and Shetland, Lib.) on April 6 asked the Minister of Housing and Local Government what steps his department had taken under Section 111 of the Public Health Act, 1936, to check that water did not contain a degree of fluorine which rendered it unwholesome. Mr. D. SANDYS told him that the section mentioned required local authorities to satisfy themselves that the water supplies in their districts were wholesome. The advice of his medical and technical officers was available to them. Before he approved the use of a new public source he had to be satisfied that the proposed supply was wholesome, and in recent years particular attention had been paid to fluoride. His officers were collecting information about the fluoride content of the water supplied by statutory water undertakers in England and Wales, beginning with those serving a population of more than 100,000.

Claims for War Disability

Brigadier J. G. SMYTH told Mr. F. H. HAYMAN (Falmouth and Camborne, Lab.) on April 5 that the numbers of applications for war disability pensions referred to independent medical experts in each of the past three years, and the numbers in which advice favourable to the applicants was given, were: 1952, 49 and 10; 1953, 21 and 8; 1954, 18 and 3.

He gave Mr. Hayman the following totals of war disability claims and their result:

Year	Received	Accepted	Rejected
1952	27,850 (1,040)	11,940 (85)	13,060 (810)
1953	27,100 (1,260)	11,710 (105)	13,900 (740)
1954	23,200 (910)	9,600 (120)	12,550 (640)

The figures in parentheses relate to the 1914 war and are included in the main figures. As a number of the claims accepted or rejected in each of the years 1952-4 were made in previous years, the sets of figures are not strictly comparable.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 26 (No. 12) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Tuberculosis and Cancer in 1954

The total number of deaths in England and Wales from respiratory tuberculosis in 1954 was 7,069 (against 7,913 in the previous year), giving a provisional death rate of 160 per million persons. This is a decrease of 11% compared with the previous year, and means that since 1947 the death rate has fallen by more than 65%. The death rate from other forms of tuberculosis was 19 per million persons, compared with 22 for 1953.

The provisional death rate for all forms of cancer for men was 2,222 per million population, and for women 1,862: the 1953 figures were 2,165 and 1,835, respectively.

The rise in the rate for men includes an increase from 607 to 657 per million population for deaths assigned to cancer of the lung and bronchus, making a total increase since 1947 of 70%. The rate for cancer of the lung and bronchus for women increased from 98 per million in 1953 to 102 in 1954. Of the male deaths from cancer (47,319), 30% were certified as due to cancer of the lung and bronchus. Of the deaths of women (42,780), only 5% were so certified.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ----, the figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

A small decline occurred in the number of notifications of infectious diseases in England and Wales during the week ending March 26. The largest falls were 336 for measles, from 29,018 to 28,682, 57 for whooping-cough, from 1,924 to 1,867, and 24 for scarlet fever, from 839 to 815.

The largest declines in the incidence of measles were 422 in Lancashire, from 2,264 to 1,842, 348 in London, from 3,685 to 3,337, 239 in Derbyshire, from 1,053 to 814, 184 in Lincolnshire, from 1,361 to 1,177, 145 in Durham, from 986 to 841, 137 in Northumberland, from 972 to 835, and 125 in Kent, from 1,206 to 1,081, and the largest rises were 540 in Warwickshire, from 2,370 to 2,910, 163 in Middlesex, from 1,411 to 1,574, and 119 in Leicestershire, from 87 to 206. The only large fall in the returns of scarlet fever was 37 in Yorkshire West Riding, from 104 to 67. The chief fluctuations in the trends of whooping-cough were a rise of 41 in Cheshire, from 32 to 73, and a fall of 39 in Kent, from 134 to 95. 11 cases of diphtheria were notified, being 1 more than in the previous week.

10 cases of acute poliomyelitis were notified, and these were 4 fewer for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 3 and London 2.

1,815 cases of dysentery were notified, being 1 less than the very high level recorded in the preceding week. The largest returns were Lancashire 629 (Oldham C.B. 157, Blackpool C.B. 155, Blackburn C.B. 58, Manchester C.B. 48, Liverpool C.B. 34, Chadderton U.D. 32, Whiston R.D. 18, Milnrow U.D. 16, Middleton M.B. 15, Preston R.D. 15, Southport C.B. 14, Crompton U.D. 10), London 204 (Hackney 91, Shoreditch 36, Islington 22, Southwark 10), Durham 177 (Sedgefield R.D. 35, South Shields C.B. 21, Seaham U.D. 20, Felling U.D. 19, Hebburn U.D. 18, Stanley U.D.

16, Easington R.D. 14), Northumberland 111 (Newcastle-upon-Tyne C.B. 27, Blyth M.B. 25, Bedlington U.D. 19, Hexham U.D. 10), Yorkshire West Riding 81 (Leeds C.B. 29, Dewsbury C.B. 18), Leicestershire 79 (Leicester C.B. 64), Norfolk 73 (Norwich C.B. 55), Lincolnshire 44 (Scunthorpe M.B. 29, Stamford M.B. 10), Warwickshire 43 (Birmingham C.B. 22, Nuneaton M.B. 16), Cheshire 38 (Stockport C.B. 26), Glamorganshire 35 (Cardiff C.B. 21), Northamptonshire 35 (Northampton C.B. 17), Surrey 33 (Carshalton U.D. 11), Yorkshire North Riding 25 (Middlesbrough C.B. 22), Rutland 22 (Oakham U.D. 22), Sussex 21 (Chichester R.D. 19), and Cumberland 20 (Whitehaven M.B. 12).

Scotland in 1954

The preliminary return for 1954 shows that the birth rate, 18.0 per 1,000 population, was slightly above the rates for the four preceding years. Infant mortality was 31 per 1,000 registered births and was the same as in 1953, which was the lowest recorded. The stillbirth rate, 25 per 1,000 total births, was also the same as in 1953. The death rate was 12.0 per 1,000 population, and was 0.5 above the rate for 1953 but 0.3 below the average of the five preceding years. The death rate from all forms of tuberculosis was 22 per 100,000 population and 20 from respiratory tuberculosis; these rates were 23 and 19, respectively, below the average of the five preceding years. The number of deaths from the principal epidemic diseases was 254, 133 fewer than in 1953. These deaths included 176 from influenza, 41 from meningococcal infections, 25 from whooping-cough, 8 from measles, 2 from diphtheria, 1 from typhoid, and 1 from scarlet fever. In addition there were 20 deaths from acute poliomyelitis.

Quarterly Returns for Scotland

The birth rate for the December quarter of 1954 was 17.0 per 1,000 population, being 0.1 below the rate for the December quarter of 1953 and 0.1 above the average of the five preceding fourth quarters. The infant mortality rate was 31 per 1,000 registered births; this was 1 below the rate for the corresponding quarter of 1953 and 8 below the five-years average. The general death rate was 11.9 per 1,000 population, being 0.6 more than in the December quarter of 1953 but 0.2 below the five-years average. The death rate from tuberculosis was 20 per 100,000 population and that for respiratory tuberculosis was 18; these rates were 22 and 19 respectively below the average of the five preceding fourth quarters. Deaths from the principal epidemic diseases numbered 78, including 62 from influenza, 10 from meningococcal infections, 5 from measles, and 1 from whooping-cough. No deaths were reported from diphtheria, scarlet fever, or typhoid.

Medical News

Ophthalmic Hospital of St. John.—Sir STEWART DUKE-ELDER has just returned from the tour of the Middle East which he undertook with the object of finding a site for the rebuilding of the Ophthalmic Hospital of St. John in Jerusalem (see *Journal*, March 12, p. 677). A new site for the hospital and the proposed research institute has been purchased outside the Old City, and it is hoped that the building will be finished by the end of 1956. The present hospital has 45 beds, but the new one will have 70 beds and, in addition, a special wing to house the research institute. The latter will have a separate staff, but will be under the overall control of the Order of St. John. The staff of the institute, when complete, will consist of a medical director, three British scientists, three Arab scientists, and a number of technicians. Research on trachoma will be an important part of the work of the institute. The initial cost of the hospital and institute is expected to be about £250,000.

Dr. Charles Hill.—It was announced from Downing Street on April 7 that Dr. CHARLES HILL, formerly Secretary of the British Medical Association, had succeeded Lord DE LA WARR as Postmaster-General. He had been Parliamentary Secretary at the Ministry of Food since 1951.

Poliomyelitis Vaccine.—Successful vaccination against poliomyelitis was claimed in the U.S.A. on April 12 for the vaccine developed by Dr. JONAS E. SALK. According to Press reports, Dr. T. FRANCIS stated that the vaccine was safe, effective, and potent. Preparations are now proceeding in the United States to make the vaccine widely available. In Britain, commenting on the news, a Medical Research Council spokesman said that two British pharmaceutical houses are already developing a similar vaccine. The firms concerned are understood to be Glaxo Laboratories and Burroughs Wellcome and Co.

Individual Efficiency in Industry.—A conference on "Individual Efficiency in Industry," arranged by a joint committee of the Medical Research Council and the Department for Scientific and Industrial Research, was held in Cambridge from March 31 to April 3, under the chairmanship of Sir GEOFFREY VICKERS, V.C. The conference was attended by both representatives of industry and research workers. The subjects discussed included the effects of environment and continuous work on performance, training problems, and the physiological and psychological aspects of machine design. The last session was on "The Industrial Application of Research Results." During the conference there were demonstrations at the Medical Research Council's unit for research on applied psychology and at the university engineering laboratories.

Hammersmith Premature Baby Unit.—A small party was held at the Hammersmith Hospital, London, on April 5 to welcome the 1,000th baby to be admitted to the premature baby unit. The unit was opened on December 1, 1947. Most of the babies cared for in the unit have been born in the obstetric department of the Hammersmith Hospital, but over one-third of admissions have been of babies born at home or in other hospitals and nursing-homes. About 800 nurses from Great Britain and 19 other countries have received periods of training from a few weeks to six months in the unit in the past seven years. In addition there have been over 7,000 visitors to the unit.

Birmingham University.—Mr. A. L. D'ABREU, part-time lecturer in surgery, has been given the title of reader in thoracic surgery. Dr. W. TREVOR COOKE has been appointed to a part-time readership in medicine.

Sir Harry Platt, P.R.C.S., is to receive the honorary LL.D. of Manchester University on May 11.

COMING EVENTS

Medical Art Society.—Annual exhibition at Walker's Galleries, 118, New Bond Street, London, W.1, from April 15 to 30, 10 a.m. to 5 p.m. (except Saturdays, 10 a.m. to 1 p.m.).

Institute of Diseases of the Chest.—Clinical demonstrations, open to medical practitioners without fee, will be given by Dr. J. G. SCADDING in the lecture-room of the Institute (in the grounds of the Brompton Hospital, Fulham Road, London, S.W.3) on Fridays at 5 p.m., from April 22 to July 8.

North-Western Tuberculosis Society.—A joint meeting with the British Tuberculosis Association is being held in the Clinical Sciences Building of Manchester University on April 22. The programme includes a symposium on chronic bronchitis. Details from Dr. M. J. GREENBERG, Manchester Chest Clinic, 352, Oxford Road, Manchester 13.

Medical Society for the Care of the Elderly.—Annual general meeting at the Whittington Hospital, London, N.19, on May 6 and 7. Details from the hon. secretary, Dr. A. N. EXTON-SMITH, at the Whittington Hospital.

NEW ISSUES

British Journal of Venereal Diseases.—The new issue (Vol. 31, No. 1) is now available. The contents include:

NORWAY CONQUERS VENEREAL DISEASES. Thomas D. Elliot.
TOPICAL CORTISONE IN SYPHILITIC INTERSTITIAL KERATITIS. Gordon O. Horne.
TREATMENT-RESISTANT SYPHILIS. R. V. Rajam and P. N. Rangiah.
YAWS IN MANCHESTER. Sydney M. Laird.
EFFECT OF ROOM TEMPERATURE ON SEROLOGIC TESTS FOR SYPHILIS. Hilfred N. Borsick, Ad Hattis, and Sidney Olansky.
VDRL SLIDE FLOCCULATION REACTION FOR SYPHILIS PERFORMED ON ACTIVE SERA. Ekkehard E. Schmid and T. Vclaudapillai.
COMPARISON OF THE IDE AND HARRIS (VDRL) SLIDE FLOCCULATION TESTS IN NIGERIA. L. R. Boulger and D. A. Cannon.

Thorax.—The new issue (Vol. 10, No. 1) is available. The contents include:

OSTEOPLASTIC THORACOPLASTY. Sir Russell Brock.
PATHOLOGICAL STUDIES OF MODIFIED PNEUMOCOCCUS IN COAL-MINERS WITH RHEUMATOID ARTHRITIS (CAPLAN'S SYNDROME). J. Gough, D. Rivers, and R. M. E. Seal.
THE TECHNIQUE AND COMPLICATIONS OF PULMONARY VALVOTOMY WITH SPECIAL REFERENCE TO THE TRANSARTERIAL APPROACH. Frederik Therkelsen.
INDICATIONS FOR THORACIC AORTOGRAPHY. Walther Falholt, Gregers Thomsen, and H. Gosta Davidsen.
CLOSURE MECHANISMS AT THE CARDIA WITH SPECIAL REFERENCE TO THE DIAPHRAGMATIC-OESOPHAGEAL ELASTIC LIGAMENT. P. M. Peters.
DOUBLE AORTIC ARCH. R. E. Steen and S. J. Douglas.
RARE CARDIAC ANEURYSM IN A YOUNG ADULT. Kevin P. Clearkin and Henry Budic.
THE MANAGEMENT OF CONGENITAL OESOPHAGEAL ATRESIA AND TRACHEO-OESOPHAGEAL FISTULA. Keith D. Roberts, Ivo J. Carré, and James McN. Inglis.
SARCOMA OF THE OESOPHAGUS. D. Millar Bell.
NON-SPECIFIC OESOPHAGITIS. K. V. Lodge.
THE MECHANISMS OF BREATHING IN NEWLY BORN BABIES. M. B. McIlroy and E. S. Tomlinson.
FRACTURE OF THE TRACHEA AND BRONCHUS. John Dark and P. Jewsbury.
AN ANALYTICAL REVIEW OF SPONTANEOUS HAEMOPNEUMOTHORAX. R. J. Calvert and Eric Smith.
TWO CASES OF INTRALOBAR SEQUESTRATION OF THE LUNG. C. McDowell, Douglas Robb, and J. S. Indyk.
MEDIASTINAL EMPHYSEMA AND ITS OCCURRENCE IN ARTIFICIAL PNEUMOPERITONEUM. C. S. Breathnach.

Published quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, April 16

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Bow Arrow Hospital, Dartford, 10.30 for 10.45 a.m., Dr. M. O. J. Gibson: Tuberculosis in Childhood.

Monday, April 18

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture demonstration by Dr. E. Siegel.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., First Lettsomian Lecture by Dr. J. G. Scadding: Treatment of Pulmonary Tuberculosis.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Professor C. A. Wells: Cancer of the Bladder; 6.30 p.m., Mr. F. W. Holdsworth: Traumatic Paraplegia.

Tuesday, April 19

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Dr. Robert Forbes: Recent Developments in Medical Litigation.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumleian Lecture by Dr. A. M. Cooke: Some Aspects of Skeletal Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor John Foster: Evaluation of Current Methods of Treatment of Idiopathic Stricture of the Valve of Krause.

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., Mr. F. T. Hillier: Handwriting in Relation to Drug Addiction and Alcoholism (illustrated).

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Mr. K. M. Walker: Sexual Problems in General Practice.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., neurological demonstration by Dr. N. G. Hulbert.

Wednesday, April 20

CHADWICK TRUST.—At Reardon Smith Lecture Theatre, National Museum of Wales, Park Place, Cardiff, 3.30 p.m., Dr. N. R. Beattie: Role of the Public Health Inspector.

●HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Dr. Denis E. R. Kelsey: Rationale of Hypno-Analysis.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At London Airport, 2.30 p.m., tour; 5 p.m., Dr. A. S. R. Fellers: Transport of Sick Persons by Air.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. A. W. Marsden, M.Sc.: Supply of Milk and Dairy Products to the Public (illustrated).

Thursday, April 21

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., debate with Dialectic Society.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumleian Lecture by Dr. A. M. Cooke: Some Aspects of Skeletal Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor N. R. Barrett: Primary Tumours of Rib.

●WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—7 p.m., dinner at Falsstaff Hotel, 7.30 p.m., visit to Fleet Street; 9 p.m., lecture by Mr. W. Redpath: The Bones at St. Bride's; 10 p.m., to see the Daily Express "put to bed."

Friday, April 22

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Serous Otitis

Q.—A woman of 60 complains of intermittent deafness and gurgling noises in her ears for the last three years, worse in the morning. On auriscopic examination, bubbles are seen passing through clear fluid in the middle ear. This becomes more marked when the cheeks are blown out with the mouth and nose closed. What is the cause of this, and the treatment?

A.—The appearance described by your correspondent suggests the presence of a clear fluid in the middle ear cavity, a condition known as serous otitis. Attention was drawn to the comparative frequency of this condition by Hoople and Blaisdell.¹ Since then it has been diagnosed more often, and it now appears to be one of the regular causes of conductive deafness. An allergic basis has been suggested for this condition, but the absence of eosinophils in the exudate or of other allergic manifestations makes this unlikely. It may be the result of blockage of the eustachian tube, and in fact some authorities feel that prolonged blockage of the eustachian tube is the most probable cause.

The treatment is removal of the fluid either by needle aspiration through the tympanic membrane or by making a small hole through the tympanic membrane with a paracentesis knife and blowing any fluid out by inflation through the eustachian tube. In some cases one such treatment is sufficient, but not infrequently repeated aspiration will be necessary. Efforts to clear the eustachian tube should not be overlooked. The possibility of mastoid drainage in persistent cases where there is a copious exudate may very occasionally have to be considered.

"Once a Caesarean"

Q.—It not infrequently happens that a young healthy primipara with ample pelvic measurements has a caesarean section for a central placenta praevia. At a recent clinical meeting the statement was made that only one vaginal delivery should be allowed after this. What is your expert's opinion?

A.—A similar statement is made by Professor Bruce T. Mayes, who, on page 424 of his *Practical Obstetrics* (Angus and Robertson; Sydney, 1954), writes: "If the patient has already had a vaginal delivery following caesarean I should do another caesarean," his argument being that the second pregnancy and labour may stretch and weaken the scar. Although this teaching may well be applied with profit to individual cases with special circumstances, it is not one which is widely accepted as a general principle. Indeed, if the uterine scar can be depended on to withstand only one labour, it could be argued with some force that it is illogical to allow the patient to risk vaginal delivery even of the second child, and that it is better to adopt the old rule of "Once a caesarean, always a caesarean," and to carry out three successive operations, sterilizing the patient at the third. The whole idea behind allowing the patient to attempt to deliver herself in the second pregnancy is that it will show whether her reproductive function is so unimpaired that she may continue to have a reasonably unrestricted number of further vaginal deliveries in the future if she wishes.

The management of a young woman who has previously had a caesarean section for a non-recurrent indication depends mainly on the details of the operation. If it is carried out through a transverse incision placed so low that it is wholly in the lower segment, and is done by an expert obstetrician working in good surroundings, the risk of the scar rupturing in any subsequent labour is very small. The exact extent of the risk is unknown, most of the published figures applying either to classical caesarean section or to a vertical incision in the lower segment, both of which are considerably more dangerous in this respect. Nevertheless, the transverse scar can rupture, and it may do so in one area only, and so silently that the accident is unrecognized. If this happens in the first labour after caesarean section, then in any subsequent labour, or indeed pregnancy, the defect may extend to involve the whole scar with serious results. Such an occurrence can be avoided by the following procedure.

Assuming the type and circumstances of the original section are favourable, the woman having her second baby should be allowed to deliver it vaginally provided the labour proceeds smoothly. As soon as the placenta is delivered, and before if the third stage is prolonged, the patient should be anaesthetized and a hand inserted into the uterus to examine the scar over its whole length. This is not only the best means of excluding a silent rupture in any part of it, but it allows an assessment of the thinness, width, and irregularity of the scar, which are fairly good guides to its strength from the standpoint of further childbearing. If the scar is found to be defective in any way the next baby should be delivered by caesarean section. If it is sound, and it usually is, there is no reason why future babies should not be delivered vaginally. One precaution which should always be taken, however, is that a woman who has a caesarean scar in the uterus should have every subsequent delivery in a fully equipped maternity hospital unit.

Estimation of Protein-bound Iodine

Q.—Will you kindly give me references to the procedure for estimating protein-bound iodine, and describe the significance of the findings obtained?

A.—Recent descriptions of the procedure will be found in the papers by de Mowbray and Tickner¹ and O'Neal and Simms.² The normal values run from 4 to 8 µg. per 100 ml. of plasma, and the test gives a good general correlation with alterations in thyroid function in both directions. However, high values may be seen without thyrotoxicosis in pregnancy and after previous iodine therapy. Values below normal without myxoedema have been reported in nephrosis. The technique is somewhat laborious and is not easily carried out in a busy routine laboratory.

Side-effects of "Diamox"

Q.—Two of my patients on the oral diuretic "diamox" developed peripheral neuritis within seven days. Each was having 250 mg. daily. The neuritis disappeared on discontinuing the drug. What are the side-effects of diamox, and is peripheral neuritis one? Is it safe to give diamox to these patients again, perhaps in a lower dosage?

A.—Diamox (acetazolamide) acts therapeutically by inhibiting the reabsorption of bicarbonate in the renal tubules, and so increasing the excretion of bicarbonate which carries with it base (sodium or potassium) into the urine. The most direct "side-effect" of diamox is thus to produce a lowering of the bicarbonate content of plasma—i.e., a metabolic acidosis. In patients on a low salt diet most of the base excreted may be potassium rather than sodium: the drug then fails in its object of reducing oedema, and

some potassium depletion may be induced. In high doses diamox can cause paraesthesiae, and also drowsiness and even psychosis; the mechanism of these neurological disturbances is not established. If the effect in the two patients mentioned is limited to tolerable subjective sensations, and the drug is otherwise effective, it should be continued; but more severe neurological involvement would be an indication for stopping the drug completely and trying other methods of therapeutic sodium depletion.

Acetylcholine in Psychiatry

Q.—*Acetylcholine has been used to treat cases of anxiety or obsessional behaviour. Could you give me further details about the type of case suitable for the treatment and the results obtained?*

A.—Acetylcholine treatment, as the inquirer states, has had its most successful effects in certain obsessional and anxiety states. The obsessional patients who have done best with it are those in whom the symptoms took predominantly the form of compulsive ruminations; patients in whom the ruminative tendency did not bulk large, but who suffered from repetitive routines of behaviour, etc., have not been found to respond nearly so well. Compulsive behaviour is usually little influenced by the treatment. The treatment is certainly worth trying in patients aged from 25 to 50—that is, neither the very young nor the old—and when the illness is not of very long duration. The tendency to rumination is reduced and the associated tension as a rule diminishes to a very satisfactory degree.

In patients suffering from anxiety states it is again the symptom of tension which is most favourably affected by the treatment. Fluctuating tension responds better than persistent tension. Anxiety states in which somatic symptoms, tachycardia, sweating, tremor, etc., are prominent do not do so well.

Persons of athletic build respond better than those of asthenic build. The treatment should not be given where there is any evidence of cardiac disease. Phillips and Hutchinson¹ in a selected series reported 70% improvements.

Trace Elements

Q.—*The agricultural community in which I work in Southern Rhodesia is very trace-element conscious, though most farmers lack the facilities and cash for accurate soil analysis. Undoubtedly our soils are poor, and one of the remedies suggested is the application of powdered seaweed. The argument is that dairy and poultry products from stock fed on crops grown with this as fertilizer will contain all the trace elements and be better human food. Is this correct?*

A.—The mineral nutrients essential for man are of two main groups; the first includes iron, calcium, sodium, potassium, phosphorus, and chloride, which are needed in considerably larger amounts than those in the second group, the trace elements proper, which are needed in exceedingly small quantities. The desirable dietary levels of some of these elements—e.g., copper, iodine, and fluorine—are known, but relatively little is known about those for such elements as cobalt, molybdenum, zinc, manganese, and magnesium, all of which are, however, known to be essential components of various biological systems.

It is generally believed that sufficient of each of the trace elements is present in ordinary diets; on the other hand, evidence of deficiency of such elements as cobalt and molybdenum has been recognized clinically in domestic animals. It would seem that the proper treatment of mineral deficiencies in livestock is to apply fertilizers containing the trace elements which are deficient in the soil so that the amounts of those elements in the crops are increased. Not only are adequately fertilized soils important for obtaining

a satisfactory mineral content of the crops raised thereon, but the health and yields of crops and of livestock and the nutritional value of animal food products will be improved, and to the extent to which man obtains his food from such sources his dietary supply of the necessary trace elements will be secured.

The risk inherent in relying on a single source for a group of nutrients is that, in taking the amount necessary to supply some of them, certain other constituents may be taken in the wrong proportion. One example well known to South African farmers is the problem of administering to cattle minerals from certain sources: they are sometimes faced, when providing calcium and phosphorus, with the risk of producing fluorosis. Generally the procedure of choice is to inject the minerals which are in short supply into the biological cycle as a soil fertilizer, but, as in nutritional evaluations of food for man and animals, it is not enough merely to rely on chemical analyses. If indeed facilities for research are limited, it would be preferable to make suitable fertilizer trials rather than chemical analyses when trace-element deficiencies are suspected. As in animal nutrition, the new knowledge of "clinical" signs of malnutrition in plants, as well as yield data, may be used as criteria of the nutritional value of the soil and fertilizer. An outstanding exception to this general procedure is the correction of iodine deficiency by iodization of domestic salt.

Facial Hair in a Girl

Q.—*Have you any information, please, regarding the removal of facial hair in a girl of 18? Her mother asked me about electrolysis, but I think there is bound to be minute scarring after it, and I also understand that there is a general distribution of excess hairiness over the body. Menstruation is normal. I wondered whether there is any hormone treatment available.*

A.—In the great majority of cases no medical treatment is any good. In particular hormone treatment is valueless. However, a small minority of cases of hypertrichosis are due to adrenal hypertrophy, and this diagnosis should be excluded by urinary hormonal estimations.

Electrolysis, skilfully applied, leaves negligible scarring, but of course every hair has to be separately treated, and it is therefore not a very suitable method when the hypertrichosis is very severe or very widely distributed. It is worth noting that the popular view that shaving stimulates the growth of hair is untrue, and in many instances this is the best line of treatment if the patient can be persuaded to adopt it. It has to be admitted that our knowledge of this subject is at the present moment extremely small.

Corrections

In his article entitled "A Purpuric Drug Eruption Caused by Carbromal" (March 12, p. 645), Dr. Peter Borrie mentioned that preparations containing carbromal are being fairly widely advertised to the public. In this connexion CLINICAL PRODUCTS LTD. write: "We wish to avoid any misunderstanding by pointing out that 'persomnia' public advertising was discontinued in June, 1950, and 'dormiprin' has never been advertised to the public."

In the last sentence of the first paragraph of Dr. H. S. Russell's letter (*Journal*, April 9, p. 909) on "Post-maturity and Asphyxia," "intact peritoneum" should have read "intact perineum."

CROSS-INFECTION OF WOUNDS WITH ANTIBIOTIC-RESISTANT ORGANISMS*

BY

E. J. L. LOWBURY, B.M., B.Ch.

(From M.R.C. Industrial Injuries and Burns Unit, Birmingham Accident Hospital)

The dilemma of hospital infection has been complicated rather than solved by chemotherapy. An appraisal of the problem in terms not only of the disease but of the micro-organism (cf. Okell and Elliott, 1936; Wright, 1940) gave promise of a better insight into and control over the transfer of infection. But the bacteriological index is in some respects much more sensitive than the clinical, and its application has revealed surprising weaknesses in the customary routine for control of cross-infection. A special problem to-day is the frustration of chemotherapy by the spread of resistant organisms among the staff and the patients—a possibility forecast by Miles (1944), when he pointed out the errors of excusing perfunctory asepsis on the grounds that the sulphonamides and penicillin were available. This lesson has, however, been fully demonstrated only during the past few years with the arrival of more antibiotics.

It is in surgery that the new dilemma is particularly evident, because the organisms which cause infection of wounds include some that are outstanding in their ability to acquire resistance to chemotherapeutic agents, and some that are insensitive, or relatively insensitive, to all the agents made available so far. I shall consider separately the two basic problems, prevention of the emergence of resistant bacteria and prevention of the transfer of bacteria—especially of resistant strains—from the environment to the patient. In both of these departments, moreover, it is necessary to consider each chemotherapeutic agent and each bacterial species as a separate problem; indeed, within each species fundamental differences of behaviour may be found, and generalizations about cross-infection or acquired resistance referring to all species are almost sure to be wrong.

Prevention of the Emergence of Resistant Bacteria

Briefly, two mechanisms, selection and adaptation, are generally postulated to account for the phenomena of acquired resistance. Selection of resistant organisms may occur in the presence of an antibiotic, either when these are normally present together with sensitive ones—for example, as a very small proportion of the total—or when they emerge independently as mutants from sensitive parent cells. In either case the resistant organism arises independently of the antibiotic, which merely selects it from a mixed flora (Demerec, 1945, 1948). The other mechanism presupposes modification of the bacterial metabolism caused by contact with the chemo-

*Based on a paper read to the Medical Society of the Birmingham Accident Hospital on December 20, 1954.

therapeutic agent, an adaptive change for which evidence has been presented by Hinshelwood (1952), Barber (1953), and others. An additional mechanism may be the transfer of resistance from resistant to sensitive organisms in a mixed culture (see Hotchkiss, 1951). It is probable that resistance may be acquired both by selection and by adaptation, and any controversy on this question is pointless except when it refers to the action of a particular agent on a particular organism.

Special Features of the Commoner Chemotherapeutic Agents

Streptomycin is exceptional among antibiotics in that any (or almost any) bacteria can be rendered resistant to it after relatively short contact *in vitro* or *in vivo* (Florey *et al.*, 1949). Penicillin is also exceptional in that resistance is often due to production of a penicillin inactivator (penicillinase), a property of the organism which may be enhanced by culture in the presence of the antibiotic (e.g., Segalove, 1947). The other antibiotics are not destroyed by organisms resistant to them.

It is of interest that the ease with which an organism may be rendered resistant by subculturing it through media containing an antibiotic is no index of the likelihood that resistant bacteria will emerge during treatment with the antibiotic. For example, it is easy to render staphylococci highly resistant to penicillin *in vitro*, but such resistant strains do not produce penicillinase (cf. Abraham *et al.*, 1941; Bondi and Dietz, 1944). These would seem, therefore, to be different in origin from the penicillin-resistant staphylococci isolated from wounds and from the nares of patients in hospital, which are almost uniformly penicillinase producers (Barber, 1953). We have found it easy, by *in vitro* methods, to produce strains of *Staphylococcus aureus* resistant to neomycin, but such strains have not appeared on burns during a controlled trial of neomycin.

Special Features of the Commoner Wound Bacteria

Streptococcus pyogenes, the most feared of the commoner aerobic organisms, has shown less tendency to acquire resistance to the antibiotics than some of the other pathogens. The successful control of streptococcal infections in recent years must in great measure be attributed to this property. Strains of *Str. pyogenes* resistant to penicillin have not yet been recognized. Resistance to sulphonamides, however, does occur, and strains resistant to the tetracyclines ("aureomycin" and "terramycin") have occasionally been found—for example, on burns (Lowbury and Cason, 1954). Other

streptococci and pneumococci do not share this exceptional vulnerability, and the ubiquitous *Staph. aureus* has, in complete contrast, an exceptional capacity for acquiring resistance to antibiotics and other agents. Phage-typing shows that this property is associated principally with certain phage types and patterns of the species, classified as group III (Williams *et al.*, 1953), which appear to be less stable in their genetic structure than the others (Barber and Whitehead, 1949; Barbour and Edwards, 1953; Lowbury and Hood, 1953), and which have largely replaced the less adaptable members of the species in hospitals, where the use of antibiotics has favoured their survival at the expense of the others.

Among the Gram-negative bacilli, *Ps. pyocyanea* has shown an almost uniform sensitivity to polymyxin, and, surprisingly, no tendency to acquire resistance to this antibiotic either *in vitro* or *in vivo* (Jackson *et al.*, 1951a). This contrasts with its frequent resistance to streptomycin (Seligmann and Wassermann, 1947), and, in smaller measure, to neomycin (Goldin, 1953). Members of the genus *Proteus*, by contrast, are resistant to polymyxin, and not sufficiently or uniformly sensitive to any of the agents at present available (e.g., Poole, 1954). The problem of acquired resistance is therefore relevant only in therapy of individual infections with this organism, not in prophylaxis.

Origin of Reservoirs of Resistant Strains in Hospital

There can be little doubt that cross-infection is the important factor which determines the accumulation of resistant staphylococci in hospitals. This is particularly evident in the case of antibiotics against which the organisms do not readily acquire resistance—for example, chlortetracycline. We used chlortetracycline for several weeks in the treatment of burned patients before resistant staphylococci began to appear in the burns of some of them; not long after this, however, the majority of staphylococci isolated from burns were found to be resistant to chlortetracycline, and most of these were isolated from patients who were not receiving the antibiotic. In treatment with streptomycin, resistance is so likely to be induced in wound bacteria that control of cross-infection is not the crucial factor in determining its continued value as an antibiotic—though cross-infection with such organisms is undoubtedly very common.

The importance of cross-infection in producing reservoirs of resistant bacteria receives further support from our experience with *Str. pyogenes*. In contrast with *Staph. aureus*, cross-infection with this organism can for various reasons be substantially limited, and, although chlortetracycline-resistant streptococci have emerged on several occasions in the burns of patients treated with the antibiotic, no reservoir of such organisms has been built up in the Burns Unit.

Methods of Preventing Emergence of Resistant Bacteria

Three procedures may help to prevent, or at least delay, the emergence of resistant bacteria: (1) economy in the use of chemotherapeutic agents; this implies not only restricting their use for cases in which they are specially indicated, but also giving them in sufficient amount to achieve a complete effect in the shortest possible time—an approach to the *therapia sterilisans magna* of Ehrlich; (2) avoidance of agents which readily induce resistance—especially streptomycin—when other agents will do as well; and (3) the use of two or more agents together. This third method has been vindicated in the treatment of tuberculosis by combinations of streptomycin, para-aminosalicylic acid, and isoniazid (M.R.C., 1949, 1953). If the resistant organisms emerge by selection of mutants, the use of two unrelated antibiotics will provide a barrier against the emergence of

any mutants except those in which resistance to both antibiotics has been acquired at the same time, and the proportion of all divisions which give rise to such double mutation is likely to be exceedingly small. Moreover, two unrelated antibiotics used together will interfere with different metabolic processes and so reduce the chances that the organism will establish an alternative metabolism to the one which has been blocked (Garrod, 1953). If two agents fail to prevent the emergence of resistant strains, three or even four agents may still have this effect (cf. Carpenter *et al.*, 1945).

In addition to its effect in preventing the emergence of resistant bacteria, combined therapy may be associated with synergistic action—enhancement of the bactericidal effects of one agent by combination with other agents (Ungar, 1943; Garrod, 1953). The converse effect—antagonism—may also be found with some combinations (see Jawetz, 1952).

Efforts to Prevent Emergence of Resistant Staphylococci in a Burns Unit

This is essentially a study of *Staph. aureus*, since the other species which have been studied are either resistant to chemotherapy or not liable to become resistant to the chosen antibiotics. Recently in trials of chemoprophylaxis against *Staph. aureus* in burns we have obtained results which give some grounds for hope; but before describing them I must recall some of the earlier hopes which were not fulfilled during studies on burns in the past 12 years.

From the Glasgow burns unit, Colebrook and his colleagues (Clark *et al.*, 1943) reported successful chemotherapy for *Staph. aureus* in burns by local application of a penicillin cream. Five years later this effect was not maintained (Colebrook, Duncan, and Ross, 1948), and when shortly after this we made a controlled prophylactic trial of penicillin cream on burns it showed no prophylaxis whatever against staphylococci, though there was a highly significant effect against *Strep. pyogenes* (Jackson *et al.*, 1951b). During this trial about 70% of the staphylococci isolated from burns were resistant to penicillin. A short trial of dibromopropamide—brought to an end because of local toxic action (Cruickshank *et al.*, 1955)—was accompanied by an increased resistance of staphylococci in the burns to this compound.

Next we made a trial of chlortetracycline, which had recently been introduced and which was apparently active against all the staphylococci from burns in our unit. An assessment of this trial after a few weeks showed a significant prophylactic effect against *Staph. aureus*; but from about the sixth week we began to detect chlortetracycline-resistant staphylococci, which became predominant in the ward soon afterwards. With this emergence of resistance we found that chlortetracycline was no longer protecting burns against *Staph. aureus* (Lowbury, Topley, and Hood, 1952). Staphylococcal phage was then tried, and after showing promise of prophylactic value it selected a breed of phage-resistant staphylococci in the burns (Lowbury and Hood, 1953). Finally, erythromycin, which we were investigating as an antibiotic for streptococcal infections, left us a legacy of resistant staphylococci—after eight months in which no resistant strains appeared (Lowbury and Cason, 1954).

Before embarking on trials of combined prophylaxis we thought it worth while testing the prophylactic value of certain compounds suitable for topical rather than for systemic administration, including neomycin and a synthetic compound, 1:6-di-4'-chlorophenyl-diguandiohexane (I.C.I. 10,040, or "hibitane") (Davies *et al.*, 1954). Our purpose was to use each of these agents for a short time, and switch from one to another after three months, or as soon as resistant strains began to appear; these, it was argued from previous experience, should soon be diluted out of the resident flora when there is nothing to favour them rather than other staphylococci. Moreover, we were anxious to know whether these agents had any value when used alone.

And then, since sensitive strains—for example, of *Str. pyogenes*—not infrequently appear on burns in spite of the presence of penicillin, it seemed to us that combined therapy may perhaps be relatively ineffective in preventing acquired resistance during prophylaxis of burn infection. Finally, we had reasons, from initial laboratory tests, to believe that staphylococci might be rendered resistant to neomycin and to hibitane less readily than to the other chemotherapeutic agents which we had studied.

Preliminary trials—first of neomycin for three months, and then of hibitane for four months—were carried out as follows.

Eligible patients were those who (a) had burns of less than 20% body area, (b) were not given skin grafts on admission, and (c) were regarded as suitable for treatment by the closed method. These patients were allocated by random selection to groups which received local applications either of penicillin cream (controls) or of penicillin cream plus (in the first trial) neomycin (2 mg./g.) or (in the second trial) hibitane (1 mg./g. of the dihydrochloride) on admission and at all dressings till healing, discharge, or operation. Burns were sampled with moistened swabs on admission and at every dressing or operation. The swabs were inoculated on a variety of media and investigated by methods described elsewhere (see Jackson *et al.*, 1951a, 1951b). The results of the trial of neomycin are shown in Table I.

TABLE I.—Neomycin Prophylaxis for *Staphylococcus Aureus* on Burns (During First 14 Days)

Cream Applied at Dressings Containing	Staphylococcus		Total	% Acquired
	Acquired	Not Acquired		
Neomycin	5	28	33	15
No neomycin	18	12	30	60
Total	23	40	63	

$$\chi^2 = 11.59. \quad P < 0.001.$$

TABLE II.—Hibitane Prophylaxis for *Staphylococcus Aureus* on Burns (During First 14 Days)

Cream Applied at Dressings Containing	Staphylococcus		Total	% Acquired
	Acquired	Not Acquired		
Hibitane	6	23	29	21
No hibitane	28	5	33	85
Total	34	28	62	

$$\chi^2 = 23.11. \quad P < 0.001.$$

Whereas 18 out of 30 (60%) burns treated with the control penicillin cream picked up *Staph. aureus* during the first 14 days after admission, only 5 out of 33 (15%) of the burns treated locally with neomycin and penicillin picked up the organism in that period. Table II summarizes the results of the trial of hibitane. Of 33 burns treated with penicillin cream, 28 (85%) picked up *Staph. aureus* during the first 14 days after admission; by contrast, only 6 (21%) of the 29 burns treated with hibitane cream picked up the organism.

None of the staphylococci isolated from burns during this time has been resistant to either agent. This fact is consistent with our failure to induce resistance of staphylococci to hibitane *in vitro*. Neomycin-resistant organisms, which can be obtained by *in vitro* methods, are small colony forms, and we have found that they show a diminished virulence for mice by the intramuscular test (Selbie and Simon, 1952). In this respect they are different from staphylococci in burns resistant to penicillin, chlortetracycline, chloramphenicol, and erythromycin. It is possible that the neomycin-resistant strains are also less well adapted for survival in the mixed flora of wounds and burns, as the non-penicillinase-producing penicillin-resistant staphylococci appear to be (Barber, 1953).

This study of prophylaxis must not, of course, be held to apply also to therapy of established infection. Separate

trials are needed to determine the possible therapeutic value of local applications of neomycin and hibitane. Moreover, three or four months of prophylactic trial is too short a time to justify any confidence that resistant strains may not turn up later.

PREVENTION OF THE TRANSFER OF RESISTANT ORGANISMS

Staph. aureus is the conspicuous organism in this study not only because of its exceptional powers of emerging resistant but also because it occurs normally and abundantly in the nose and on the skin of so many healthy people. The second front of our attack—on the prevention of spread—is therefore again, to a great extent, a problem of *Staph. aureus*.

Barber (1947) and Barber and Rozwadowska-Dowzenko (1948) drew attention to the large and increasing proportion of staphylococci isolated from hospital patients and staff which were resistant to penicillin. These strains were apparently being selected as the result of treating patients with the antibiotic, but their prompt appearance in the nares of nurses and in many patients who had not received the antibiotic showed that cross-infection with resistant strains must be occurring on a large scale. Similar observations in respect of penicillin and of other antibiotics were made by many workers (for example, Rountree and Thomson, 1949; Forbes, 1949; Clarke *et al.*, 1952; Lowbury, Topley, and Hood, 1952), and it is now common knowledge that the classical methods for controlling cross-infection—barrier nursing, cubicle isolation, aseptic techniques—are quite inadequate for the exclusion of resistant staphylococci from susceptible sites of hospital patients.

For the limited objective of preventing cross-infection with resistant, as distinct from sensitive, organisms there is one recommendation—to stop using the antibiotic in question. Resistant strains will then no longer be favoured, and sensitive strains should have an equal opportunity of growing. During a prophylactic trial of chlortetracycline we found that the proportion of resistant staphylococci in the ward tended to fall after use of the antibiotic was discontinued at about the same rate as it increased while the antibiotic was in use, though a residue of resistant organisms persisted in the burns of patients who remained in hospital for many weeks. The dilemma is acute, as we are scarcely justified in withholding an effective antibiotic from a case of severe infection merely in order to preserve its effectiveness, unless equally good alternatives are available. The discovery of new antibiotics is therefore of the highest importance, and there is no pointless redundancy in having half-a-dozen alternative agents for the chemotherapy of *Staph. aureus*, provided that they differ from each other in their mechanism of action and therefore in the pattern of resistance which develops against them.

Prevention of Cross-infection as a General Problem in Surgery

Lister's achievements were apparently so complete that the unsolved problems of cross-infection in surgery were overlooked for some time afterwards, both by surgeons and by bacteriologists. The natural defences of healthy tissues are capable of accounting for many contaminants, and this undoubtedly exaggerated the apparent victory of asepsis. The surgical experience of two world wars and the development of the newer fields of operative surgery, however, revealed that a considerable amount of contamination passed through the aseptic barriers, and gave rise to clinical infection of varying severity (Stokes and Tytler, 1918; Fleming and Porteous, 1919; Miles *et al.*, 1940). But the failure of asepsis was still wider than the clinical data could show, for many wounds in which clinical signs of infection were absent could be found to heal more slowly when certain organisms were present than when they were kept free from those contaminants (Gissane *et al.*, 1944; Clayton-Cooper and Williams, 1945; Jackson *et al.*, 1951b). Such

"silent" infection was demonstrated by controlled study of methods which protected a random selection of the wounds at risk against contamination.

It is well known that transmission of bacteria from the environment to the patient may be through the air (by droplets, droplet-nuclei, or dust) or by contact (immediate or intermediate), but the factors which determine the relative importance of each route are complex and still imperfectly understood. Important factors are the viability of the organism outside the body—for example, Gram-positive cocci in general survive the evaporation of their suspending menstrua better than Gram-negative bacilli (Heller, 1941; Lowbury and Fox, 1953); the presence or absence of organisms in carriers among staff and patients—staphylococci, for instance, are commoner on the hands than streptococci, and therefore more apt to be transmitted by contact; the exposure or protection of the site of entry of organisms—for example, a wound of the hands or feet can be protected against contamination by dressings more easily than one of the trunk or face (Lowbury and Fox, 1954; Lowbury, Crockett, and Jackson, 1954).

Specific recommendations for the elimination of reservoirs of infection, for blocking the routes of transfer, and for increasing the resistance of the patient have been built up piecemeal with our increased knowledge of these mechanisms. After the early development of antiseptics and asepsis in operating theatres, of cubicle isolation, and of barrier nursing, there followed attempts to reduce air contamination by dust-laying with oils (Van den Ende *et al.*, 1940, 1941a, 1941b), by dispersion of chemical disinfectants such as hypochlorites, triethylene glycol, and lactic acid (Douglas *et al.*, 1928; Masterman, 1938; Robertson, 1946; M.R.C., 1948), by ultra-violet irradiation of air or surfaces (Hart, 1936; Hollaender *et al.*, 1944; M.R.C., 1948), and by air-conditioning with filtered air (Bourdillon and Colebrook, 1946).

Some of these methods contributed less than laboratory experiments had led one to expect, particularly ultra-violet irradiation—for example, M.R.C., 1954—and chemical disinfection (for example, Lidwell and Williams, 1954). In these examples the relative failure may have been caused, in part, by the impossibility of sterilizing dust by either of these methods at levels which are safe for the persons exposed (cf. Lidwell and Lowbury, 1950). Even dust-laying and air-conditioning, however—methods which do not depend on the killing of bacteria—achieve only a partial effect, not only because they too are imperfect but because they attack only one of the vectors of cross-infection. The relative importance of this vector probably varies greatly in different kinds of ward and with different organisms; this may explain the conflicting reports on protection against cross-infection by oiling of floors and bedclothes (Wright *et al.*, 1944; Clarke *et al.*, 1954).

The newer methods of combating contact infection involve the extension of aseptic methods beyond the operating theatre to the dressing of wounds in casualty dressing-rooms and wards. The value of no-touch technique was demonstrated in the dressing of neurosurgical wounds (McKissock *et al.*, 1941), and has been further validated in studies on added infection rates of a wider range of wounds in hospital (Williams *et al.*, 1945) and in factory surgeries (Clayton-Cooper and Williams, 1945). Involving no antibiotic barrier, such prophylaxis is equally effective against sensitive and resistant contaminants.

Colebrook's machinery for excluding bacteria from burns also involved the extension of aseptic principles—in this case to a field which Lister had ignored and in which asepsis had been thought unattainable. So, indeed, it remained in all but the smallest burns, if by asepsis was meant the total exclusion of bacteria. But the exclusion of some pathogens from some of the lesions—a lessening of the risks of sepsis—is an end worth attaining. It is the end that was achieved in trials of the no-touch dressing technique. For burns, Colebrook introduced more complex machinery of physical and chemical barriers against contamination by contact and

from the air—the use of no-touch technique in an air-conditioned dressing-station with filters, together with local application of penicillin cream under ample dressings (Colebrook, Duncan, and Ross, 1948; Colebrook, 1950). The one organism which responded to this combined prophylaxis—*Str. pyogenes*—happened to be the most formidable pathogen commonly found on burns. It was also the one which was uniformly sensitive to penicillin. A trial of local penicillin (Jackson *et al.*, 1951a) confirmed the prophylactic effect of penicillin against *Str. pyogenes* and the absence of any effect on the other common flora—for example, *Staph. aureus*, which was predominantly resistant to penicillin at this time, and the coliform bacilli, *Ps. pyocyanea* and *Proteus*, which were uniformly resistant. This aroused a suspicion that the benefits which Colebrook reported after the combined attack on cross-infection with penicillin and dressings under filtered air might be attributable entirely to penicillin.

We found an answer to this question in a controlled trial of the air-conditioned dressing-station in the Burns Unit here (Lowbury, 1954). A significantly smaller proportion of burns dressed in the ventilated room acquired *Ps. pyocyanea*, *Proteus*, and antibiotic-resistant staphylococci than were acquired by the burns treated in the room with the ventilators switched off. *Str. pyogenes* was uncommon in burns during the trial, and the chances for its transfer were small, because burns carrying the organism were dressed at the end of each dressing list. Coliform bacilli appeared on approximately the same number of burns in the two groups—an indication that these organisms were probably acquired by self-contamination. A further point of interest in this trial was the significantly higher proportion of *Staph. aureus* resistant to chlortetracycline and penicillin and showing the "hospital strain" phage patterns (group III) which we found in the nares of patients dressed in the room with the air-conditioning plant switched off. This index of added infection is of special interest, as the patients spent only a small fraction of their total hospital time in the dressing-station.

The benefits of air-conditioning with filters, like those of the no-touch technique and other physical methods, cannot be lost through the emergence of resistant mutants.

Relative Importance of Wards, Dressing-stations, and Operating Theatres as Sites of Cross-infection

The trial which I have just described showed that the frequency of cross-infection could be reduced by changing the dressings, not in the ward but in a special room ventilated by filtered air under positive pressure. In spite of the elimination of this ward risk, however, the opportunities for transfer of infection to patients while they are in the ward must be great. Blankets, sheets, clothing, handkerchiefs, and other fabrics are known to be potential sources of cross-infection (Hare, 1941; Duguid and Wallace, 1948; Dumbell *et al.*, 1948), but soiled dressings must be regarded as a more important reservoir, from which both airborne and contact spread are liable to occur—the latter particularly if the dressings become soaked through with infected exudate. At the receiving end, burns or wounds which are imperfectly covered, and those with dressings that have become soaked with sterile exudate (Colebrook and Hood, 1948), present a good target for contaminants. Exposed burns, before their exudate has dried, are liable to pick up the airborne bacteria, and do in fact show *Str. pyogenes*, *Ps. pyocyanea*, *Staph. aureus*, and other bacteria more often than perfectly covered burns of feet and hands (Lowbury, Crockett, and Jackson, 1954).

Evidence that much of the cross-infection occurs in the ward if dressings are done in a separate room has come to light in recent studies on one organism, *Ps. pyocyanea* (Lowbury and Fox, 1954). For a period of seven months all the *Ps. pyocyanea* from burns in this unit were typed by an agglutination method (Christie, 1948; Fox and Lowbury, 1953). It was possible to divide the strains into three major groups, each consisting of a large number of apparently variable subgroups or patterns. The patients

from whom the strains were isolated were in two wards, E and F, but had their dressings and operations in the same dressing-station and operating theatre. Nevertheless, each ward had for a time its own predominant strain, which was serologically different from the predominant strain of the other ward.

How much added infection occurs in operating theatres? For many years the efficiency of our aseptic drill has been taken for granted, though individual flaws have from time to time been exposed. For example, Devenish and Miles (1939) found that a proportion of rubber gloves used in the operating theatre had minute holes through which skin staphylococci and other organisms could pass into the wounds. Cleansing fluids—for example, 1% cetrimide, 10% "dettol," soap solution—were commonly found to be contaminated with *Ps. pyocyanea* when dispensed in bottles with corks—the organism apparently being protected by the cork (Lowbury, 1951). Reports of tetanus (Sevitt, 1949) and of gas gangrene (Sevitt, 1953) apparently acquired in an operating theatre focused attention on the unsatisfactory air hygiene of the standard operating theatre, which is ventilated by extractor fans over the sterilizers; by this method air is sucked into the theatre through doors, windows, and other apertures, carrying with it a representative selection of hospital and street flora. The need for a new style of operating theatre ventilated with filtered air under positive pressure was demonstrated by Cairns (1939), and more recently, by Girdlestone and Bourdillon (1951), and is now being recognized more widely. Such a theatre should be planned to incorporate other features which are likely to reduce the chances of contamination—for example, designed to minimize movements and personnel in the zone of operation (Gissane *et al.*, 1944). The frequency of wound contamination and infection at operations carried out in theatres of the old and new types is the subject of an extended investigation by Dr. Sevitt and myself in this hospital, to be reported later.

DISCUSSION AND CONCLUSION

Each of the measures found to have some effect in preventing the emergence or the transfer of antibiotic-resistant organisms makes, by itself, only a fractional contribution. Added together they contribute rather more, but still do not nearly solve the problem, which demands an extension and improvement of existing methods and the search for new ones. Elimination of the primary reservoirs of infection (places where pathogens breed) and of the targets for infection are obviously of the first importance. Sometimes—for example, in the primary excision and grafting of burns—both objects may be achieved by the same procedure. Some idea of the difficulty of setting up effective barriers is given by Rogers (1951), who found that cross-infection with infantile gastro-enteritis and the transfer of specific serological types of *Bact. coli* was not prevented by strict cubicle isolation. In open hospital wards, Anderson *et al.* (1954) have shown that the standard of nursing has little influence on the rate of cross-infection with these organisms. Sauer (1935), however, reported success in preventing cross-infection with gastro-enteritis at a special unit for premature infants by an elaborate series of barriers, including ultra-violet screens, special kitchens, and cubicle isolation. This experience suggests that our failures in preventing cross-infection may be due simply to insufficient standards of asepsis—such as might be expected, for example, in operating theatres where rubber gloves or masks were not used.

Whether such elaborate measures for preventing cross-infection (assuming that they work) are justified depends on the clinical hazards of infection in each particular field. In any case, however, it would be of the greatest value to have special units in which a maximum level of asepsis could be assessed for effectiveness in preventing different kinds of infection, and for guidance in planning of hospitals tomorrow. It is not enough (cf. Goodall, 1952) to attribute our failures to faulty nursing or to inadequate fulfilment of

the recommendations laid down in the memoranda of the Medical Research Council (1941, 1951) on control of hospital infection. Scrupulous observance of these recommendations may not, as we have seen, prevent some kinds of cross-infection. If the recommendations are to be saved from merely ritual observance—or uncritical disuse—they must be subjected to a more detailed assessment than has yet been possible.

Even without such elaborate special units, however, there is scope for the investigation of many ideas—for example, the admission of mothers as auxiliary nurses for their own children in hospital (Pickerill and Pickerill, 1954); the use of a disinfectant barrier to prevent contamination through soaked dressings (Lowbury and Hood, 1952); the use of rubber gloves for many duties in hospital wards; the use of chemotherapeutic agents for suppressing the skin carriage (Murray and Calman, 1955), and the nasal carriage (Moss *et al.*, 1948; Valentine and Hall-Smith, 1952) of *Staph. aureus*—methods which may cause some reduction in the cross-infection rate with that organism (Gould and Allan, 1954).

There is some danger that advances in surgery which were made possible by the arrival of antibiotics will be relinquished as the staphylococci surmount each new chemotherapeutic obstacle. The physical obstacles, such as air-conditioning, cannot be surmounted in this way; nor, apparently, can the older chemical obstacles—for example, disinfectants such as phenol and the cresols. Although our attention to-day is drawn to combined chemotherapy as the most hopeful weapon against the emergence of resistant forms, it is too early to assume that no substance will be discovered which is as safe as penicillin and as permanent in its effects against *Staph. aureus* as phenol, and perhaps hibitane.

Summary

The prevalence of antibiotic-resistant organisms—especially staphylococci—causing added infection of wounds in hospital patients has emphasized the limitations of chemotherapy and of hygiene applied in this field.

Emergence and spread of resistant organisms are considered in this paper as separate problems. To combat the former, efficient dosage and a combination of two or more agents has been advocated. In our hands, local application of neomycin and of "hibitane" has had some prophylactic effect against staphylococci in burns, so far not accompanied by the emergence of any resistant strains. Methods to control the spread of bacteria by air and by contact have been considerably developed in recent years, but more knowledge of their performance is needed. Some further improvements are suggested by existing data—for example, the general use of positive-pressure ventilation with filtered air for operating theatres and dressing stations. For the more complex task of limiting the transfer of infection in the ward, many changes (in hospital design and in nursing routine, for example) require investigation.

Studies on Fertility, edited by R. H. Harrison, is a collection of selected papers read to the Society for the Study of Fertility in 1954, augmented by "papers of high standing" which had not been read. This volume replaces the *Proceedings of the Society*, which had increased in size so rapidly as to become unwieldy. The papers in this present volume do not cover the whole field of fertility, but represent up-to-date opinion on such subjects as the "mechanotherapy of impotence" (i.e., splinting the penis), the management of pregnancy in previously infertile women, gynaecological coelioscopy, enzyme inhibitors in contraception, the aetiology of male subfertility, and testicular biopsy. *Studies on Fertility*, which costs £1 ls., is published by Blackwell Scientific Publications, 24-5, Broad Street, Oxford.

PATHOGENIC STAPHYLOCOCCI IN THE ENVIRONMENT OF THE NEWBORN INFANT

BY

Improved hygiene and the development of potent antibacterial agents have been responsible over recent years for a considerable reduction in the amount of neonatal infection, particularly infection of the alimentary and respiratory tracts. Staphylococcal infection of the newborn, especially in hospital, is, however, still a problem, and the marked tendency of the staphylococcus to acquire resistance to antibiotics has retarded its control and increased its relative importance.

The objects of the present investigation are to report and compare the carriage rates and antibiotic resistance of staphylococci in three maternity hospital units of different types; to compare these hospital results with corresponding data obtained from domiciliary confinements; to correlate staphylococcal carriage with clinical infection; and to study the mode of spread of the organism between mothers, babies, and hospital staff.

Materials and Methods

The hospital units concerned are (a) a maternity unit adapted from an old building, somewhat crowded and part of a general hospital (hospital W); (b) a newer and more spacious unit, also part of a general hospital, with better facilities for isolating infected patients (hospital E); and (c) a small self-contained maternity hospital with adequate accommodation situated in the country (hospital M). The period of the investigation was from March to July, 1952.

Altogether 608 vaginal swabs and 701 nasal swabs taken on admission from 770 mothers in these three hospital maternity units and 44 nasal and 44 vaginal swabs from mothers confined at home were examined for the presence of pathogenic staphylococci, and their sensitivity to four antibiotics and to sulphonamide was determined. Specimens taken from the offspring of these mothers included 683 conjunctival and 639 umbilical swabs, from a total of 774 babies. Eye swabs (E₄) were taken four days after delivery of the infant, since it has been shown that the carrier rate reaches its maximum about this time (Torrey and Reese, 1945). Umbilical swabs (U₈) were taken as soon as the cord had separated—that is, about the eighth day after birth. From the medical, nursing, and domestic staff attending these cases during the period of the survey, 245 nasal swabs were examined.

In order to ascertain whether mothers acquired pathogenic staphylococci while in hospital, 293 nasal and 297

vaginal swabs taken approximately eight days after admission were examined in addition to those taken on admission.

Swabs were plated out on nutrient agar within 24 hours and the plates incubated at 37° C. for 18 to 24 hours. The resulting growths were tested for coagulase production and if positive were tested by the disk technique of Gould and Bowie (1952), modified as described by Forfar *et al.* (1953), for sensitivity to chlortetracycline ("aureomycin"), chloramphenicol, penicillin, streptomycin, and "sulthiazole" (a soluble derivative of sulphathiazole). Four different possible results were recognized—3 (highly sensitive); 2 (moderately sensitive); 1 (slightly sensitive); 0 (resistant). The approximate relationships between these conventions and (1) the coefficient of resistance, and (2) the minimum inhibitory concentration, are given in the paper by Forfar *et al.* (1953). We used the drug-resistance pattern as a means of identifying or labelling an organism. Because of the margin of error in all sensitivity-testing techniques, however, the following methods were used in labelling organisms according to their reactions to the five drugs concerned:

(1) For the purpose of overall "resistance patterns" as given in Tables II-VI the organisms were labelled as either "sensitive" or "resistant." Thus grades 3 and 2 were grouped together as "sensitive" and grades 1 and 0 as "resistant."

(2) In comparing one individual organism with another, as is done in Table VIII, a difference of more than one grade of sensitivity was required in order to distinguish two strains as different. Thus a strain giving grades 3, 2, 3, 0, 3 for the respective drugs was considered to have the same sensitivity pattern as one giving grades 3, 2, 3, 0, 2, since only one degree of difference was present in respect of the last drug. A strain giving the pattern 3, 2, 3, 0, 1 would, however, be regarded as definitely different from the first-mentioned strain. This differentiation is made on the assumption that only in a very small proportion of strains could mutation occur in the short period during which specimens were taken from a mother and/or baby.

(3) Where comparison with the results of previous workers is involved, resistance rates include only those organisms giving complete *in vitro* resistance—that is grade 0.

While this method of labelling lacks the precision of serological and phage-typing methods, it does enable recognition of different strains to be achieved with a high degree of probability, although two strains giving the same pattern may not necessarily be identical. The disk-diffusion technique has, too, the advantage that it enables a large number of tests to be quickly performed, so that the numbers large enough to give statistically significant results may be readily obtained.

Where two percentages are compared, the difference between them is said to be significant when the observed difference is more than two and a half times the standard error of the difference.

Results

Carriage rates for coagulase-positive staphylococci are given in Table I for the three hospital units and for the domiciliary cases investigated. It will be seen that the carriage rate for the first-day vaginal swabs for the combined hospitals (3.5%) rose by the eighth day of stay in hospital to 10.8%. This is a statistically significant increase, but there is no corresponding rise in the maternal nasal carriage rate, nor is there any significant difference between the nasal carriage rates of mothers at home and in hospital.

The vaginal carriage rate of the mothers at the time of delivery is so low that vaginal contamination cannot be a significant source of infection of the infant.

Both the E₄ and U₈ staphylococcal carriage rates for babies born at home are significantly less than those for hospital-born babies. This is despite the fact that the carriage rate for the domiciliary nursing staff is the same high figure (55 to 56%) as that for the hospital W staff (where in fact the domiciliary nurses are accommodated) and shows that the domiciliary nursing staff did not pass on their staphylococci to any extent to babies born at home.

The highest carriage rate shown in Table I is the hospital staff nasal carrier rate (51% for the combined hospitals), but the U₈ rate approaches nearly to this level.

In Table II, for the combined hospitals, the antibiotic-resistance patterns of staphylococci from various sites on mother, baby, and nursing staff are shown. It will be noted that in parallel with the lower carriage rate for the mothers there is a lower incidence of drug resistance among the staphylococci carried by them. Among the staphylococci isolated from the babies and from the nursing staff penicillin resistance is of a high order. A fairly close resemblance is seen between the antibiotic-resistance patterns of staphylococci from the babies and staff, but there is an obvious difference between these staphylococci on the one hand and those of the mothers on the other.

Table III sets out the consolidated totals of coagulase-positive staphylococci isolated from mothers, from routine carriage swabs from babies (E₄, U₈), from clinical infections of babies, and from nursing staff subgrouped according to

TABLE I.—Carriage Rates for Coagulase-positive Staphylococci

Specimens		Hospital			Total	Domiciliary
		W	E	M		
1st-day swabs from mothers:						
Nasal	C.R. %	30.4	25.6	31.7	28.7	22.8

$\Sigma\chi^2$	379.1	16.87	323.67	102.75	112.2	7.084	8.12	8.96

their antibiotic resistance. In Table IV the χ^2 test has been applied to these figures, and in each case antibiotic resistance has been the character tested. The test has been applied to the group comprising mothers, babies (carriage), babies (clinical infections), and staff; to this group with the mothers omitted; and to the six possible pairings within the group. It will be seen that with the group comprising mothers, babies (carriage), babies (clinical infections), and staff high χ^2 values are obtained, and there is, therefore, a very low probability of similarity between the members of the group; whereas, when the mothers are left out, relatively low χ^2 values are obtained, hence there is a very much higher probability that the organisms from the group comprising babies (carriage), babies (clinical infections), and staff are similar. This is shown even more clearly when the summed χ^2 from mothers, babies (carriage), babies (clinical infections), and staff is compared with the summed χ^2 from babies (carriage), babies (clinical infections), and staff.

In other words, there is a very close similarity between those staphylococci carried on the baby, those isolated from clinical infections of the baby, and those carried by the staff, but no relationship between the mothers' staphylococci on the one hand, and those from the babies (carriage and clinical infections) and staff on the other. It is thus highly probable that there is a free interchange of staphylococci between the nursing staff and babies, and between one baby and another, but mothers seem not to be a significant source of infection to the infant.

This is further confirmed when the χ^2 test is applied to individual pairs—that is, mothers/babies (carriage), mothers/babies (clinical infections), mothers/staff, staff/babies (carriage), staff/babies (clinical infections), and babies (carriage)/babies (clinical infections). Again the high χ^2 values (and therefore low probability of similarity) obtained on comparing the mothers' organisms with those from the babies and nursing staff contrast with the low χ^2 values (and therefore high probability of similarity) obtained on comparing staff and babies (carriage and clinical infections), and babies (carriage) and babies (clinical infections).

Table V shows no significant difference in drug-resistance patterns between hospitals W, E, and M, but shows that domiciliary staphylococci gave a lower penicillin-resistance rate of 23% as compared with 65 to 76% for the hospitals.

TABLE V.—Comparison of Resistance Patterns in Hospitals W, E, and M, and in the Home (Pooling Hospital Results from Mothers' 8th-day Swabs, Babies' Swabs, and Staff Swabs; and All Domiciliary Swabs)

Hospital	% Coagulase-pos. Staph. Resistant to					Total Coag- pos. Staph.
	Sulphon- amide	Chlortetra- cycline	Chloram- phenicol	Peni- cillin	Strepto- mycin	
W	19.3	3.3	7.9	74.7	8.2	367
E	17.7	3.1	8.1	65.7	9.9	323
M	30.8	6.4	1.8	76.4	6.4	110
Total Home	20.2 23.5	3.6 0	7.1 0	71.3 23.5	8.6 11.8	800 17

Although this is not statistically significant, owing to the small numbers of *Staphylococcus pyogenes* isolated from domiciliary cases in the series, the difference is highly suggestive and reflects the well-known fact that staphylococcal penicillin-resistance rates are much lower among the general population than in hospitals.

Table VI compares the resistance patterns of babies' staphylococci (from E₄ and U₈ swabs) in the three units. Apart from a somewhat higher incidence of sulphonamide

TABLE VI.—Comparison of Resistance Patterns in Hospitals W, E, and M of Babies' Staphylococci (E₄ plus U₈)

Hospital	% Coagulase-pos. Staph. Resistant to					Total Coag- pos. Staph.
	Sulphon- amide	Chlortetra- cycline	Chloram- phenicol	Peni- cillin	Strepto- mycin	
W	20.7	4.0	9.7	77.6	11.0	227
E	22.1	2.0	7.7	77.6	12.8	204
M	38.3	8.8	1.5	86.8	7.4	68

resistance in hospital M than in hospitals W and E, no significant difference is seen between the figures for the three hospitals.

Table VII shows the incidence of septic eye and skin infections in the various hospitals and the combined incidence for the hospitals. There is no significant difference between the total infection rates in the three units, but among these infections eye infections occurred significantly more often in hospital M (92% of infections occurred in the eye) than in hospital W (52% of infections), while, correspondingly, skin sepsis was significantly lower in hospital M (8% of infections) than in hospital W (48% of infections). The proportion of clinical infections in which *Staph. pyogenes* was isolated was lower in hospital M (35%) than in hospital W (59%) or hospital E (50%).

The ratio *Staph. pyogenes* sepsis rate/*Staph. pyogenes* carriage rate was 1/4.6 for hospital W, 1/5.5 for hospital E, and 1/5.8 for hospital M, when E₄ and U₈ swabs and sepsis of the skin and conjunctivae are included. Although hospitals W and E showed similar ratios for eye-sepsis rate/eye-carriage rate and for skin-sepsis rate/umbilical-carriage rate, hospital M showed a relatively high ratio for the former and a relatively low ratio for the latter. Thus the rate of infection and the rate of carriage do not always run parallel to each other.

Table VIII shows the comparison in sensitivity patterns between staphylococci isolated from each member of 125 mother/baby pairs. In 34% of these pairs the two strains concerned had the same patterns of sensitivity to the five drugs used in the tests; that is to say, they could have been the same organism, though it does not necessarily follow that they were; in the remaining 66% the two strains had different sensitivity patterns and were therefore not the same. One can conclude from this that the majority of babies acquire staphylococci from a source other than their mothers. In view of the very much higher carriage rate on

TABLE VII.—Incidence and Bacteriology of Clinically Recognizable Infections in Babies

Hospital	Total Admissions to Baby Nursery During Period of Investigation	Clinical Infections, with Percentage of Total Admissions			Bacteriological Investigation of Clinical Infections, are of Number of Swabs Taken

TABLE VIII.—Comparison, by Sensitivity Patterns, of Coagulase-positive Staphylococci from Mother and Child, and of Strains From Two Sites in the Same Infant

Hospital	Where 2 Strains Had Same Sensitivity Pattern, i.e., Could be Same	Where 2 Strains Had Different Sensitivity Patterns, i.e., Strains Not Same
Mother/baby pairs where a coag.-pos. staph. was isolated from at least one swab from mother and baby	W E M Total	25 16 2 43 (34%)
Normal babies in whom a coag.-pos. staph. was isolated from both eye and umbilicus	W E M Total	15 19 7 41 (54%)
Babies in whom a coag- pos. staph. was iso- lated both from a septic lesion and from another clinically un- affected site	W E M Total	10 6 1 17 (49%)

baby than on mother, however, it may be that to an appreciable extent the mother acquires her staphylococci from her infant.

Table VIII also shows that, where organisms were isolated from two sites on the same baby, on only half of the occasions could these have been the same organism. This was equally true whether one of the sites was clinically infected or not. One should therefore not assume that a staphylococcus isolated, for example, from the skin is the same as that causing infection elsewhere in the body. Specimens for examination for drug sensitivity should be taken from each available locus and reported on separately.

Discussion

The coagulase-positive staphylococcal carriage rates for mothers' nasal swabs of 28.7% (first day) and 30.7% (eighth day) obtained in this series compare with the rates of 21% given by Torrey and Reese (1945), 28% by Parker and Kennedy (1949), 42.6% by Rountree and Barbour (1950), and 36% by Ludlam (1953). No significant increase occurred either in the carriage rate or the penicillin-resistance rate of staphylococci isolated from the nose between the first and eighth days of the mothers' stay in hospital. There was, however, a significant rise in the vaginal carriage rate during this period. The carriage rate in infants in hospital rose from presumably nil at birth to 35.3% by the fourth day of life (eye swabs), and to 40.1% by the eighth day (umbilical swabs). These are low figures compared with others previously published, yet a comparison with the figures for babies born at home (5% and 8.6% respectively for the fourth- and eighth-day specimens) demonstrates the great importance of the hospital environment in increasing the staphylococcal carriage rate of the newborn.

The low figures for carriage in babies born at home occurred in spite of the fact that they were attended by nurses from hospital W, who had the same high incidence of staphylococcal carriage as other hospital nurses. This shows that the limited contact occurring between domi-

ciliary nursing staff and the babies was relatively ineffective in spreading staphylococcal infection to these infants.

Other authors have given much higher figures for infant carriage of *Staph. pyogenes* after the fourth day of life—for example, 89% (Torrey and Reese, 1945), 100% (Cunliffe, 1949), 88.9% (Rountree and Barbour, 1950), and 75% (Barber *et al.*, 1953). We also gave a higher figure (60%) in a previous publication (Forfar *et al.*, 1953) for umbilical swabs from hospital W in 1951, and it may be that improved medical care and hygiene have contributed to this fall in staphylococcal carriage in infants. This decrease is not due to a reduction in numbers of staphylococci carried by the hospital staff, since their staphylococcal carriage rate has remained practically unchanged. Thus the present average figure of 51.3 for the combined hospitals compares with 64% given by Miles *et al.* (1944), 52% by Williams (1946), 58–68% by Barber *et al.* (1949), 54.5% by Rountree and Barbour (1950), 21–50% by Ludlam (1953), and 53% by Forfar *et al.* (1953).

On the other hand, the combined hospital rates for eye and skin sepsis in the present series (9.8% and 4.8% respectively) are high compared with some recently published figures—for example, 4.2% and 2.3% respectively given by Forfar *et al.* (1953), 9.2% and 3.6% by Barber *et al.* (1949), and 0.61% and 1.58% by Frazer (1948). It must be emphasized that the infections recorded in the present investigation were in the main trivial, and serious infection was entirely absent. The results were therefore similar in this respect to those of Barber *et al.* (1953), who reported high sepsis rates accompanied by an absence of serious infection. The apparent increase in the sepsis rates recorded in this series therefore reflects the increased care with which early mild infections were recognized and treated. We feel that early recognition and early and adequate treatment of all minor staphylococcal infection is an important factor in preventing more serious infection.

The incidence of complete penicillin resistance among hospital strains of *Staph. pyogenes* in the present series was 57.6%* for staff nasal swabs and 64.7%* for babies' fourth- and eighth-day swabs. The figure for nurses compares with 70 to 80% given by Barber *et al.* (1949), 64% by Rountree and Barbour (1950), 56% by Rountree and Barbour (1951), 75 to 85% by Ludlam (1953), and 30.7% by Forfar *et al.* (1953) for hospital W in 1951. The figure for babies compares with 90% given by Barber *et al.* (1953), and 64.4% by Forfar *et al.* (1953).

More than 90% of pathogenic staphylococci were still sensitive to chlortetracycline and chloramphenicol during the period of the present investigation, and almost as great a proportion were sensitive to streptomycin. The mean sulphonamide resistance percentage for all swabs was 16.8%, although in the case of hospital M babies the rate was as high as 38.3%.

Duncan and Walker (1942), Allison and Hobbs (1947), Parker and Kennedy (1949), Barber *et al.* (1949), and other authors, using serological and phage-typing methods, have shown that infection is usually conveyed in hospital maternity units from baby to baby, from staff to baby, or from blankets, dust, etc., to baby. This is borne out by the present investigation, since drug-resistance patterns

*Grade 0 only.

showed a considerable degree of uniformity among staphylococci from babies and staff, but no such uniformity between babies and staff on the one hand and mothers on the other.

The results for mother/baby pairs given in Table VIII are in keeping with the view that few infants are infected from their mothers. The actual proportion infected from this source must be much less even than the 34% of cases in which the two strains infecting mother and child could be the same. Some of these will have been different strains with the same sensitivity patterns, and even if they were identical there remains the likelihood that the mothers were infected from their babies and not vice versa.

The three maternity units W, E, and M were chosen because of the considerable differences between them—the crowded older buildings of hospital W contrasting with the more modern and spacious unit at hospital E and the separate maternity hospital M situated in the country. One would therefore have expected that staphylococcal carriage rates would have been higher in hospital W than in E or M, and that hospital W babies would have acquired more staphylococci from the nursing staff than in hospital E or M. In fact, however, staphylococcal carriage rates were at a similarly high level for the babies of all three units, and the resistance rates against the various drugs were similar for the staphylococci isolated from each of the three hospitals, with the exception of sulphonamide resistance, which occurred significantly more often in hospital M than in hospitals W and E (38.3% as against 20.7% and 22.1% respectively). Another point of similarity between the results from the three units was in respect of the ratio *Staph. pyogenes* sepsis rate/*Staph. pyogenes* carriage rate. Although hospital M showed differences where eye and skin sepsis/carriage ratios were examined individually, the overall ratio of 1/5.8 for hospital M compared with 1/5.5 for hospital E, and 1/4.6 for hospital W. There is thus no evidence in this investigation to show that the nature of the hospital buildings or their proximity or otherwise to other hospital departments had any effect on the spread of staphylococcal infection in the units concerned.

Summary

Over 51% of the members of the nursing, medical, and domestic staff in three Edinburgh maternity units were found to be carrying *Staph. pyogenes* in their anterior nares. Of these staphylococci, 58% were completely resistant to penicillin and nearly 20% were resistant to sulphonamide. Less than 10% were resistant to chloramphenicol, chlortetracycline, and streptomycin.

The staphylococcal carriage rates of the mothers admitted to, and babies delivered in, these units was determined. The mothers' vaginal carriage rate was 3.5% and their nasal carriage rate was 28.7%. Of these, only the vaginal carriage rate rose during an eight-day period.

The babies' eye carriage rate on the fourth day after delivery was 35.3% and the umbilical carriage rate on the eighth day was 40.1%. The corresponding carriage rates for babies born at home were 5% and 8.6%.

As between three different maternity units of different type there was little difference in the mothers, babies, and staff carriage rates.

There was a much higher incidence of penicillin-resistant strains among nurses and babies than among mothers, and among week-old babies born in hospital than among those born at home. Individual hospitals showed little difference in antibiotic-resistance rates.

A relatively high frequency of mild skin and conjunctival sepsis contrasted with a complete absence of serious infection in this series.

The great majority of infants acquired their staphylococci from sources other than their mothers, chiefly from the nursing staff and from other babies. Despite the fact that there was a high carriage rate among the nurses attending babies born at home the carriage rate on these babies remained low.

Where infants carried staphylococci on two different sites (eye and umbilicus), in approximately half the cases the staphylococci had different drug-sensitivity patterns.

On the clinical side we wish to thank the maternity nursing staffs of the Eastern and Western General Hospitals, Edinburgh, and Musselburgh Maternity Hospital for their wholehearted co-operation; the obstetricians of the units concerned; and the general practitioners who gave assistance, particularly Dr. E. V. Kuenssberg. We also wish to thank Dr. Lilli Stein for generous statistical advice and criticism. On the bacteriological side we wish to thank Professor T. J. Mackie and Dr. H. A. Wright for their advice and criticism, and the technical staff of the Department of Bacteriology of Edinburgh University.

MANAGEMENT AND TREATMENT OF PATIENTS WITH COAL-WORKERS' PNEUMOCONIOSIS

BY

J. C. GILSON, M.R.C.P.

AND

G. S. KILPATRICK, M.D., M.R.C.P.Ed.

Medical Research Council, Pneumoconiosis Research Unit,
Llandough Hospital, near Penarth, Glamorgan

Coal-workers' pneumoconiosis is an important industrial disease. In 1947 it was estimated that there were about 16,000 certified cases in South Wales and at least an equal number uncertified (Hugh-Jones and Fletcher, 1951). Since then an increasing awareness of the condition and more frequent radiological examinations have led to more cases being revealed in other parts of Great Britain. The number of new cases certified each year in South Wales rose steadily from 44 in 1931 to 5,224 in 1945, but declined to 1,079 in 1953. In the rest of Great Britain the number has been rising steadily, passing the figure for South Wales in 1951, to reach 2,987 by 1953 (Ministry of Fuel and Power, 1954). It is therefore likely that an increasing number of practitioners who have not met the condition before may be asked for advice about it by patients who are or have been miners. Although there is no specific therapy, the reassurance derived from a better understanding of the condition can be a real help, and in the more disabled case treatment of symptoms and complications is both possible and often quite effective.

Questions about re-employment and compensation are likely to arise. This article therefore includes an

outline of the present compensation arrangements and the scheme which enables a miner who is in receipt of disablement benefit to continue working underground under certain safeguards.

Pathogenesis of Coal-workers' Pneumoconiosis

Coal-workers' pneumoconiosis has two distinct but related forms. The first, simple pneumoconiosis, caused by the gradual accumulation of the fine dust (less than 10 μ diameter) in the lungs, is recognized radiologically by the characteristic minute opacities (0.5–1 mm.) which are often best seen in the early stages in the right upper and mid-zones. Its radiological severity is classified into three categories (1, 2, and 3) dependent principally on the profusion of the opacities (Cochrane *et al.*, 1951). The condition advances as such only if the miner continues to work in a dusty environment, but it makes the subject liable to the second form of the disease—complicated pneumoconiosis. In South Wales between 1 and 2% of men with simple pneumoconiosis (category 2 or over) develop complicated pneumoconiosis each year. The figure for other areas is not known, but the prevalence of complicated pneumoconiosis is almost certainly lower in most other coal-fields in this country. The condition is recognized radiologically by the appearance of additional larger localized opacities which correspond to the massive fibrosis found pathologically; it progresses whether or not dust exposure is continued, often develops after cessation of exposure to dust, and is much the more disabling form of the disease. The massive fibrosis is believed to be caused by tuberculosis modified by the presence of coal-dust—a hypothesis based on clinical, radiological, and pathological findings. Tubercle bacilli may be isolated from about 40% of cases at necropsy but in less than 10% of cases coming to hospital.

The prevention of serious disability from pneumoconiosis, therefore, depends both on reducing exposure to coal-dust to a level where simple pneumoconiosis does not occur to an appreciable extent during a working life, and on eliminating the risk of infection by tuberculosis. This can be achieved only by energetic measures to detect and treat all infectious cases both in miners and in the community in which they live (Rogan, 1954). By using full-size films and good radiographic technique it is possible to detect an early stage of simple pneumoconiosis (category 1) at which the risk of developing complicated pneumoconiosis is very small. Thus a system of periodic x-ray examinations (Cochrane *et al.*, 1951) could assist in preventing the more disabling form of the disease by detecting those men who were approaching the dangerous stage of the disease.

Coal-workers' pneumoconiosis is different both pathologically and in its natural history from the classical form of silicosis found in men who have worked in dusts containing a high proportion of silica.

Diagnosis

The symptoms of increasing breathlessness on exertion disproportionate to his age, cough, pain in the chest, and lassitude in a man who has worked in the mines for a number of years should raise the suspicion that he may have pneumoconiosis. The only pathognomonic feature is the expectoration of inky black sputum, but this is likely to occur only when complicated pneumoconiosis is well established.

Physical signs in the chest are of little help in establishing the diagnosis, which can be made with certainty only on the basis of the industrial history and the chest radiograph. The striking radiographs of well-established simple pneumoconiosis and the remarkable appearances of complicated pneumoconiosis may surprise physicians not familiar with the condition, and possibly lead to the assumption that patients are more seriously ill than is in fact the case. The typical formation of the opacities of complicated pneumoconiosis by a process of aggregation on a background of simple pneumoconiosis and their slow progression will usually differentiate the condition from carcinoma or tuberculosis. Extensive cavitation in the massive lesions of complicated pneumoconiosis is common but does not prove the existence of overt tuberculosis or even of an especially poor prognosis (Kilpatrick, Heppleston, and Fletcher, 1954).

Relationship of Radiographic Appearances and Age to Disability

Although simple pneumoconiosis is not, on the average, the cause of serious disability when large and unselected groups of miners are studied, there is of course a tendency for the general practitioner to see only those men who are becoming breathless to an extent which interferes with their work. Age is an important factor. Breathlessness of severe degree on account of simple pneumoconiosis is rare under the age of 50. Complicated pneumoconiosis may be a cause of serious disability at a much earlier age, but, even so, it is not infrequent, at least in South Wales, for men in the forties with quite advanced complicated pneumoconiosis to continue work without serious symptoms.

The term "pneumoconiosis" covers a wide range of conditions, from the man with the earliest detectable category of simple pneumoconiosis to the one with the whole lung destroyed by massive fibrosis. The miner is likely to be more familiar with the effects produced by the latter and may therefore be under a serious misapprehension about the gravity of his condition. An explanation to men with simple pneumoconiosis, who form the majority, that their lungs show evidence of dust accumulation but that it may cause them no more disability than the pigmented coal scars on their hands, often puts their condition in a new perspective. Coal-workers' pneumoconiosis at any stage is a slowly changing condition, and even quite seriously disabled men with complicated pneumoconiosis may be able to look forward to a number of years of useful life provided they find a job within their capacity.

In explaining the condition to men with category 1 simple pneumoconiosis we avoid using the word "pneumoconiosis." We think it is more helpful to tell the man that it is possible to guess by looking at his radiograph that he has worked in the mines and that some of the dust he has breathed has stayed in his lungs. This category can be diagnosed with reasonable certainty only on films of excellent technique. At this stage the miner is not liable to attack by complicated pneumoconiosis, and there is even some evidence that men with this category are less liable to develop infectious tuberculosis than miners with normal films (Cochrane, 1954). They can therefore hardly be said to have a "disease" on the radiological evidence. The earliest x-ray indication of dust retention in the lungs therefore occurs before the prognosis is adversely affected.

To men with category 2 and over, even if there are no symptoms, we think it is wise to explain the position

fully. If nothing is said about their chest radiograph, they will assume that it is normal, but at any time they may be diagnosed as having pneumoconiosis as a result of attending a mass miniature radiography unit or if they apply to the pneumoconiosis panel. A misunderstanding may then arise. The other reason for a full explanation is that under the Industrial Injuries Act any miner with diagnosable disease is eligible for some compensation even though his disability may be very slight.

It may be argued that to encourage a man with minimal disability to apply for compensation may have a bad psychological effect. In our experience this very rarely occurs if the position is fully explained.

Compensation

The various schemes for providing compensation for coal-miners with pneumoconiosis have gradually widened the circle of those eligible. Compensation for silicosis arising in coal-miners was started in 1928, but applied only to those who had worked in specified jobs. The Workmen's Compensation Act (W.C.A.) of 1943 extended the provisions to cover all types of job and forms of pneumoconiosis. Under this scheme the miner certified as having pneumoconiosis was awarded compensation, the amount of which depended on the degree of disability, assessed as either partial or total. He could either claim a weekly benefit or commute his claim for a lump sum. Miners receiving payments under this scheme (including those who commuted their claims) are not in general eligible for benefit under the present National Insurance Industrial Injuries Act (I.I.A.), 1946, which came into force on July 5, 1948, and applies to all miners employed then and since. Under this scheme a miner diagnosed as having pneumoconiosis is eligible for a disablement benefit, which is additional to the sickness benefit obtained under the National Insurance Acts.

In 1951 special arrangements were made to enable certain miners who had been suspended under the W.C.A. but who did not have overt tuberculosis to return to the mines. Those who return come under the I.I.A.

In considering a claim a pneumoconiosis panel* of the Ministry of National Insurance proceeds in two stages. A diagnosis is made first, based on the radiographs and industrial history, and if pneumoconiosis is diagnosed the second stage, assessment of disability, follows. Disability is expressed on a percentage basis and can be as low as 1%, but the payments are graded in steps of 10%. In reaching a decision on the percentage assessment, all the circumstances are taken into account, and, where necessary, pre-existing causes of disability or those unrelated to pneumoconiosis are offset to reach a fair estimate of the loss of faculty caused by pneumoconiosis. The disablement benefit starts at 6s. 9d. weekly for those of 1% to 10% (inclusive), and rises to 67s. 6d. for 100%.

The miner may also be entitled to supplementary weekly benefits which are (1) a special hardship allowance (27s. 6d.); (2) an unemployability supplement (40s.) (with additions for married men, and those with children); and (3) a constant attendance allowance (up to 60s.).† His basic disablement pension is supplemented by about one-third under the Colliery Workers' Supplementary Scheme—a contributory pension scheme supported jointly by the National Coal Board and the colliery workers.

Whereas under the W.C.A. a miner was debarred from returning underground and suffered a reduction of his weekly benefit according to subsequent wages if he obtained a job, under the I.I.A. his benefit is a life pension and is unaffected by his subsequent earnings, and he may if he wishes continue working underground. Most assessments are provisional

*There are ten panels at present, situated in Bristol, Cardiff, Edinburgh, Glasgow, London, Manchester, Newcastle-upon-Tyne, Sheffield, Stoke-on-Trent, and Swansea.

†The rates are those which will come into effect in May, 1955, under the National Insurance Act, 1954.

and miners are recalled for reassessment after a variable period, usually not exceeding three years. A miner who has tuberculosis or pneumoconiosis accompanied by overt tuberculosis may be compulsorily suspended. If the tuberculosis is active he will be given an assessment of 100%.

By a recent amendment of the regulations miners who have not worked in the mines since 1948 and who are not receiving payment under the W.C.A. may now apply for a certificate of partial or total disablement and if certified they may be eligible for supplementary benefits under the I.I.A.

In our experience the commonest misunderstandings which arise in the working of this scheme are as follows:

(1) Miners and others may have only a hazy idea of the meaning of the percentage assessments. Is it the amount of dust in the lungs? Is it a measure of the dust conditions in which the man may safely continue working underground? Is it the amount he is disabled? Therefore, it is hardly surprising that the man, to say nothing of his doctor, may have difficulty in appreciating the meaning of a 1% assessment. It is important that the miner should realize that the assessment is based on disability and that the x-ray film is used solely for establishing the diagnosis.

(2) The need to differentiate between the effects of more than one disease on disability may cause misunderstanding, and is perhaps commonest in men with, for example, hypertension or angina of effort, who may be totally disabled, but eligible only for, say, 40% assessment on account of pneumoconiosis. This problem also arises when a miner who has been assessed at a high percentage of disability in life dies of some cause quite unrelated to pneumoconiosis. A death claim may then be made by the widow and may be turned down. In some of these instances a discussion between the practitioner and the doctor at the pneumoconiosis panel might help to explain the situation to the relatives and avoid the perpetuation of a grievance.

(3) No precise level of radiographic abnormality for diagnosis of pneumoconiosis is laid down in the Act. Even if it were it has been well established (Fletcher and Oldham, 1949) that there is appreciable observer variability in reading films for pneumoconiosis, and thus a film near the borderline might be accepted as showing pneumoconiosis on one occasion and rejected on another. We have been impressed by how readily miners accept this idea of the inevitable uncertainty of reading some films. If a man is rejected at the first application he may apply again within three months, when the new film will be seen by two members of the panel who did not see the first film. To avoid advising men to go to the board when there is a high probability of their being rejected it seems in the best interests of all that consultants and practitioners seeing much of this disease should discover from the members of the local panel by informal discussion what level of abnormality is required for diagnosis. Variations in radiographic technique are an important factor in increasing disagreement in diagnosis. The use of automatic exposure controllers in the x-ray sets would help to reduce but would not eliminate this variation, as it is also due to variations in development technique.

(4) When a miner is recalled for reassessment of disability his benefit may be reduced. As most miners know that pneumoconiosis is not a condition which improves, this reduction may cause a real sense of grievance. In our experience downward assessments have usually resulted from the extreme difficulty of setting uniform standards of disability assessment when the I.I.A. first started. An explanation of this difficulty and of the possibility that assessment may have been made at the time of an acute chest infection is generally accepted by the miner as reasonable. A man may appeal (but in the case of a provisional assessment not normally under two years) and the case then goes to a tribunal.

Advice on Employment

Well-informed advice on problems of employment is of first importance to the miner with pneumoconiosis and is

often of greater value to him than anything else doctors can offer him. The opportunities open to him are now far better than they were under the W.C.A., and the figures for South Wales show the striking change since 1949. In that year there were 4,550 miners with pneumoconiosis unemployed on the Disabled Register; now there are 650.

The largest single factor has been the change of regulation which allows a miner to continue working underground. With the man's approval the pneumoconiosis medical panel informs the colliery manager of its findings, and provision is made to place the man in a job where conditions are "approved." The aim is, of course, to achieve these conditions for all places underground, and many more coal-faces are now "approved" than when the I.I.A. came into force.

The pneumoconiosis panel offers the miner advice on re-employment both at the time of his boarding and by letter. In 1953 75% of letters advised the men to continue in the industry under "approved" dust conditions; 12% recommended work on the surface in dust-free conditions, and about 6% advised leaving or remaining outside the industry; suspension on account of tuberculosis occurred in 2%. Thus a majority are advised to stay in the industry. By the end of 1953, of the 8,200 miners referred for employment under "approved" conditions in the mines, only a little over one-tenth rejected the advice. In over 80% arrangements were made for working in "approved" conditions (Ministry of Fuel and Power, 1954). These figures, however, do not show how many men had to move from better-paid jobs on the coal-face to other parts of the mine in order to work in "approved" conditions. At present the proportion who leave the coal-face varies considerably in different areas.

In the case of the moderately disabled man the combined effect of his disability and a wish to work out of the dust will often lead to his accepting a less strenuous and less remunerative job off the coal-face. The more difficult case is that of the younger man with heavy family financial commitments and only slight disability. If "approved" conditions can be ensured only by leaving the coal-face he may be unwilling to do this, as his small disablement benefit does not compensate for the large reduction in his weekly earnings. In these cases help may be obtained from the area or divisional medical officer of the Coal Board, who will know or can find out more about the dust conditions. Rapid improvements are now being made in the dust conditions, and in many instances face conditions which were recently not "approved" are now within these limits. In cases where difficulty is experienced in bringing one particular face within "approved" conditions the medical officer may be able to arrange employment on another face which is "approved" at the same pit, or in an adjacent one. In general it is usually to the man's financial advantage and not further damaging to his health* to stay in the mine, provided conditions are approved and the job is within his physical capacity. However, each case needs individual assessment, taking into account age, disability, financial and other commitments, x-ray category, and past and present conditions in the mine.

The case for recommending a change of job to one outside mining is strongest in the young man who has shown in serial films rapid progression of simple pneumoconiosis towards category 2, particularly if he is unmarried and there is a reasonable chance of his getting good employment elsewhere. These cases are, however, unlikely to be detected except where periodic x-ray examinations are made. It may also be wise to advise a young man with complicated pneumoconiosis which has shown rapid radiological progression but with little disability to look for another job while he is still young and to get, if possible, one which he can expect to continue even if he becomes short of breath. Those men who are on the Disabled Register at the Labour Exchange can get help in finding a job by discussion with the disablement resettlement officer. A meeting of the almoner, doctor, and D.R.O. can assist the latter to select the most suitable type of employment. It also brings a more personal interest in the man's re-employment.

The commonest and the most difficult cases are the miners of 50 and over, both with and without pneumoconiosis, who have become moderately or severely disabled. The mining industry at present provides employment for many of these men, but there comes a time when they are unable to get to and from the mine and are frequently off work with exacerbations of their chronic chest infections. A few are able to get jobs as caretakers and live near their place of work, but many others are unable to get any work within their capacity, and they fall out of employment at a relatively young age. The men in this group who have normal chest films or pneumoconiosis of a category less than that accepted for diagnosis under the Act, and who have spent many years working underground, not unnaturally sometimes feel they have been treated harshly in not being eligible for compensation. It seems reasonable to explain to them that their disability is not caused by a recognizable form of pneumoconiosis and that they might have developed equally severe breathlessness in any other occupation. It is not yet possible to state whether or not after excluding men with pneumoconiosis there is among miners and ex-miners an unduly high proportion with respiratory disability.

Treatment

Many of the miners seeking advice on account of breathlessness find their symptoms worst in the mornings, in cold weather, and also during bouts of chest infection, especially in the winter months. Alleviation of the distress at these times depends primarily on controlling bronchospasm and chest infection.

Bronchospasm

Bronchospasm is frequently precipitated by sudden changes of temperature—for example, going upstairs to a cold bedroom or bed. We have been impressed by the amount of relief men claim they receive from the equable temperature of the hospital ward without any specific therapy. Some men have gained appreciable relief by moving their bed to a warmer downstairs room and avoiding so far as possible any sudden changes of temperature.

Adrenaline is less dramatic in its effect in most of these men than in a typical asthmatic but is of real use given by injection or inhalation at the time of acute attacks. Many men also find that adrenaline and atropine compound spray (B.P.C.) administered through a hand spray is effective enough to make it worthwhile carrying the spray in their pocket. A hand spray can be prescribed under the National Health Service. In some men a lack of understanding of how to use the spray properly and how to keep it in working order prevents their getting the maximum benefit from this form of therapy. In our experience the more complex and usually more expensive proprietary inhalants rarely give materially greater benefit than the simple B.P.C. preparation.

Of the many other bronchodilator drugs recommended we have found isoprenaline sulphate (isopropylnoradrenaline), ephedrine, aminophylline, hyperduric adrenaline, and occasionally khellin most generally useful. It may take a while to find the dose and timing of the drug or combination of drugs which provide the greatest relief with the minimum side-effects. Patients who respond well to adrenaline or hyperduric adrenaline may be taught to give the injections themselves. They gain considerable benefit physically and psychologically from knowing that they have a powerful remedy at hand when in need. In a very severe attack of bronchospasm, aminophylline (0.25 g.) intravenously has in our experience been the most useful agent and is often dramatically effective, if rather short-lived in effect. The occasional severe case which has failed to respond to other forms of treatment may benefit from cortisone. Atropine is occasionally of use in those with profuse watery expectoration.

Acute Pulmonary Infections

These are a very common cause of increased breathlessness and bronchospasm in winter. The severity of the infection may not be obvious from the temperature chart or the

physical signs in the chest, but the sputum, at least after the first two or three days, will usually show a change of character, becoming more yellow or often black if the miner has complicated pneumoconiosis. Penicillin in large doses—two mega units of combined procaine and crystalline daily—combined with streptomycin, 1–2 g. daily, is usually effective, the sputum changing rapidly in character and the dyspnoea and bronchospasm becoming less severe even if no anti-spasmodic treatment is given at the same time. Because repeated attacks of chest infection are common in this disease we have avoided using chloramphenicol, while chlor-tetracycline ("aureomycin") and oxytetracycline ("terramycin") have been reserved for those cases which fail to respond to penicillin or streptomycin. A full account of the value of different antibiotics in acute chest infections has been given by Stuart-Harris (1953).

When the chemotherapy is stopped the sputum often rapidly reverts to its previous condition, but the bronchospasm and dyspnoea do not usually return, at least for a while, to their previous severity. The benefit seems greatest when chemotherapy has been continued for some period after the patient has apparently improved.

If recurrent chest infections could be prevented much distress and incapacity would be avoided, but no beneficial effect was detected in a trial of the prophylactic value of sulphonamides (Kilpatrick and Oldham, 1954). However, it is our impression that if patients are treated really effectively from the onset with sufficiently large doses of effective antibiotics, the period in bed and of convalescence is considerably reduced. Much may be gained, therefore, by encouraging those who can readily detect the onset of their attacks to seek treatment at the earliest stage.

In men with less obvious infection it is difficult to assess how much this contributes to their breathlessness, and it is therefore worth trying a period of intensive therapy for a week to ten days.

Cough and Sputum

It is usual for dyspnoea to precede cough in men with pneumoconiosis, but in the later stages cough may be very troublesome, particularly early in the morning. When there is much mucoid or purulent sputum, postural drainage, even in the absence of proved bronchiectasis, is of considerable value. If before going to sleep they empty their lungs so far as is possible by lying over the edge of the bed, some men can get a reasonable night's rest. The early-morning cup of tea or glass of hot water to which has been added the simple sodium chloride compound mixture (N.F.) may help to relieve the morning period of acute distress. Full doses of syrup of codeine phosphate are of use in treating an unproductive and irritating cough.

Expectoration of jet black or nearly black sputum indicates necrosis in the centres of the areas of massive fibrosis. The condition is likely to cause alarm but is not of serious import, as it seems to have little effect on the prognosis and certainly does not prove the onset of overt tuberculosis. Reassurance and a precautionary examination of the sputum for tubercle bacilli is all that is required. Small haemoptyses are as common as black sputum in men with complicated pneumoconiosis, and again do not necessarily indicate the presence of tuberculosis. Severe haemoptyses are rare. The presence of frankly malodorous sputum is also rare, and suggests some other underlying disease such as bronchiectasis or lung abscess.

Pain in the Chest

Pain in the chest is a common symptom, but its cause is often obscure. Localized intercostal pain and tenderness may be the principal complaints, which can usually be ameliorated by local radiant heat. The pains are often transient, disappearing in a few weeks or months whatever the treatment. Pleural friction is a fairly frequent physical sign but is often unassociated with pain. However, when persistent pain is also present local injury, such as a cough fracture of the rib, may be suspected. A more central pain or feeling of constriction may arise from cardiac ischaemia

or possibly pulmonary hypertension, both of which are common in men over the age of 55 with pneumoconiosis. Amylnitrite may be of therapeutic and diagnostic value. A marked coincidental increase of pain and breathlessness may be caused by a partial pneumothorax, which may be very difficult to diagnose without a chest film because of the extensive fibrosis and emphysema already present. Reassurance, and an explanation only, may cure the pain of a young man who has recently been told he has pneumoconiosis.

Breathing and General Exercises

During convalescence from an episode of chest infection general and breathing exercises are of help in re-establishing confidence by demonstrating to the man that he is capable of more activity than he supposed. To men who have lived an over-restricted existence since the diagnosis of their condition, exercises are of real benefit in getting back to a more normal life. Objective physiological evidence of improvement by breathing exercises is difficult to detect in pneumoconiosis, but many men claim improvement. Success depends more upon the enthusiasm and skill of the physiotherapist than in the particular set of exercises used.

Complications

Tuberculosis

Men with complicated pneumoconiosis who develop a positive sputum usually react poorly to chemotherapy and rarely survive more than two years (Kilpatrick, Heppleston, and Fletcher, 1954). As the lesions are almost always bilateral and extensive, surgery is of very limited use. It is possible that with initial treatment with streptomycin and P.A.S., followed by intermittent therapy over many years with P.A.S. and isoniazid, the outlook may be better. Young men with advancing complicated pneumoconiosis but a persistently negative sputum are a very difficult therapeutic problem. There is little evidence that antituberculous chemotherapy has any effect (Miall *et al.*, 1954), but long-term therapy over a number of years with isoniazid and P.A.S. while allowing them to continue working seems at present the most logical procedure. There are really no pointers to suggest that these men benefit in health by enforced idleness if they wish to work. As a protection to others, regular sputum examination is desirable.

Cor Pulmonale

In the terminal stages of complicated pneumoconiosis cor pulmonale is common and is often precipitated by an attack of chest infection. Rest in bed, an equable temperature, and large doses of antibiotics will often produce a dramatic improvement in the course of a few days. Mercurial diuretics, digitalis, and a salt-poor diet are beneficial, particularly where there is much oedema. In cases with a marked cyanosis and a very low urine output, aminophylline and oxygen have a useful potentiating effect on the mercurial diuretics.

After a period in bed and when their cardiac failure has been controlled, we encourage patients to be up and about as much as possible. There is usually greater risk of their becoming unnecessarily bedridden than of overexerting themselves.

Oxygen therapy has considerable use in this condition. Men with very severe and limited respiratory reserve get benefit both by relief of the cyanosis and by reduction of pulmonary ventilation. In our experience of these cases oxygen therapy rarely causes sufficient carbon dioxide retention to produce narcosis, so that it can usually be given without risk. Only in very severe and usually terminal attacks of cor pulmonale may it be necessary to use oxygen with caution. Some of the most disabled men also gain benefit from oxygen when up and about. The marked increase in their exercise ability while breathing oxygen suggests that a portable oxygen set might be of real value to them. For the present they can obtain the ordinary oxygen cylinder and mask for use in their homes under the

National Health Service. By taking oxygen after temporary exertion beyond their real capacity, such as going upstairs, they can shorten the period of acute respiratory distress. The cylinder is also useful for operating the nebulizer for the relief of bronchospasm.

Summary

Coal-workers' pneumoconiosis has two forms: simple pneumoconiosis, which is rarely a cause of severe disability except in elderly men; and complicated pneumoconiosis, which may cause severe disability after the age of about 35 and is a modified form of tuberculosis.

Under the present regulations men with either form are eligible for compensation. The number of new cases being certified annually in areas other than South Wales is increasing. The benefit paid is determined by the severity of disability and not by the degree of abnormality of the chest film. Miners receiving compensation may continue to work underground under dust-approved conditions if they wish.

Advice on the nature of the disease, compensation, and re-employment is of special importance in the management of these cases, as misunderstandings are apt to arise. These are discussed in some detail. There is need for more exchange of information between the doctors with whom a miner with pneumoconiosis is likely to consult.

Treatment of the acute pulmonary infections, bronchospasm, and cor pulmonale, and some of the principal symptoms in these cases, is briefly described.

We wish to express our thanks to Dr. J. C. McVittie, of the Ministry of Pensions and National Insurance, for help in preparing the section on compensation. We are grateful to Dr. J. M. Rogan, of the National Coal Board, and to our colleagues in the Pneumoconiosis Research Unit for their helpful criticisms.

In his annual report for 1954 Dr. J. F. WARIN, the principal school medical officer of the City of Oxford, describes the steps that are being taken to prevent food-poisoning at school canteens. About 200 people are employed in the school canteens in Oxford, and a full medical examination and a chest radiograph have been a condition of employment for the administrative staff for some time. There is a higher labour turn-over among the manual workers in the canteens, and before they are employed they are asked detailed questions about any intestinal illnesses they may have had in the past. If there are reasons for doubts about a prospective employee's freedom from transmissible disease, then a full medical examination is arranged and blood and stool specimens are sent to the laboratory. Manual workers have a chest radiograph as a condition of employment. Posters illustrating the prevention of food-poisoning are on display in the school canteens, and it is intended that members of the chief sanitary inspector's staff will give talks to canteen workers on this important subject. When selected groups of the population in Oxford were offered examination at the miniature camera unit last summer canteen workers were included. The response to this offer was 100%. No case of active tuberculosis was detected.

HAEMATEMESIS

WITH SPECIAL REFERENCE TO PEPTIC ULCER

BY

G. J. FRAENKEL, M.Ch., F.R.C.S.

Surgical Tutor, University of Oxford

AND

S. C. TRUELOVE, M.D., M.R.C.P.

Assistant Physician, Radcliffe Department of Clinical Medicine

(From the Radcliffe Infirmary, Oxford)

Haematemesis (including melaena) is one of the common emergencies met with in hospital practice. The most usual cause of the condition is chronic peptic ulcer, which is on the increase. At the present time the population is becoming increasingly loaded with middle-aged and elderly people, who are both more liable to suffer from chronic peptic ulcer and less able to survive blood loss than are young adults. For these reasons, the methods used in treatment must be kept under continuous review. We have therefore examined the experience of the Radcliffe Infirmary during a recent five-year period (1948–52 inclusive) and compared it with the findings of a similar study made for the previous decade (1938–47) by Lewin and Truelove (1949).

Data

The sources of data of this study are the in-patient notes of the Radcliffe Infirmary, which is the only general hospital taking in emergencies from the City of Oxford and a considerable rural area surrounding it. Hence the patients can reasonably be regarded as an unbiased sample. Case notes of all patients (other than children) presenting as emergencies because of haematemesis or melaena during the five-year period 1948–52 have been examined. Trivial cases in which there was no evidence of serious bleeding have been excluded.

In considering the fatal cases we have adopted the criteria of Avery Jones (1952) in excluding only those deaths due to unrelated diseases or to elective operation after recovery from the bleeding. We have included all other cases with serious complications, among them (1) patients who have haematemesis or melaena following a perforated peptic ulcer, a group excluded by Avery Jones (1947) because of their special nature; and (2) patients who were already in hospital because of a serious disease which terminated in severe gastrointestinal bleeding, sometimes diagnosed only at necropsy.

Results

During the five-year period of 1948–52 there were 540 emergency cases of haematemesis and melaena, compared with 305 during the previous ten years. During the five years under consideration the annual rate of admission for haematemesis and melaena increased steadily from 87 in 1948 to 142 in 1952, a change related to the increasing frequency of peptic ulcer. The cause of the bleeding was classified under the following headings: (1) chronic peptic ulcer (377), (2) acute peptic ulcer (84), (3) oesophageal varices (23), (4) carcinoma of the stomach (20), and (5) other causes (36). The criteria used were the same as those used previously by Lewin and Truelove (1949).

The miscellaneous collection of cases which we have grouped together under "other causes" were as follows: hereditary telangiectasia, 5 (4 admissions were of one patient); hiatus hernia, 5; unknown, 26. Of the unknown group, there was evidence later of a gastric or duodenal ulcer

in nine of the patients. In none of the others was any later diagnosis made to suggest the cause of the bleeding.

The fatality rate of the present series shows a sharp decline from that of the previous ten years. For the total series, the fatality rate has dropped from 19.0% to 8.3%. For the chronic ulcer group, which is the biggest and most

FIG. 1.—Whole series. Fatality rate by age groups.

FIG. 2.—Chronic ulcer group. Fatality rate by age groups.

of patients over 50 than the earlier, as shown in Table III. The lowered fatality rate is therefore not due to any favourable change in the age composition of the series. On the contrary, the circumstance that approximately two-thirds of all the patients were over the age of 50 is a striking feature of the present group.

TABLE I.—Fatality Rate from Haematemesis by Age. Total Series

Age Group	1938-47			1948-52		
	No. of Cases	Deaths	Fatality Rate	No. of Cases	Deaths	Fatality Rate
Under 30	26	0	0%	30	0	0%
30-39	42	3	7.1%	45	1	2.2%
40-49	67	5	7.5%	99	2	2.0%
50-59	84	19	22.6%	137	16	11.7%
60-69	56	18	32.1%	141	12	8.5%
Over 70	30	13	43.3%	88	14	15.9%
Total	305	58	19.0%	540	45	8.3%

TABLE II.—Fatality Rate from Haematemesis by Age. Chronic Ulcer Groups

Age Group	1938-47			1948-52		
	No. of Cases	Deaths	Fatality Rate	No. of Cases	Deaths	Fatality Rate
Under 30	18	0	0%	17	0	0%
30-39	30	2	6.6%	35	0	0%
40-49	44	4	9.1%	83	0	0%
50-59	59	15	25.4%	94	8	8.5%
60-69	41	13	31.7%	88	5	5.7%
Over 70	16	5	31.2%	60	8	13.3%
Total	208	39	18.8%	377	21	5.6%

TABLE III.—Percentage of Patients Over the Age of 50 in the Two Consecutive Series

Series	Whole Series	All Peptic Ulcers	Chronic Ulcers
I (1938-47)	55.7	54.4	55.8
II (1948-52)	67.8	65.3	64.2

Effect of Sex

Table IV shows the chronic ulcer group broken down into two main age groups and by sex. It will be seen that the difference in fatality in the two sexes is small, although women may be somewhat less prone to die. Another feature of interest is the different proportion of women in the two age groups. It will be seen that below 50 the male:female ratio is about 4:1, whereas above 50 it is less than 2:1. This is presumably related to the liability of women to develop chronic peptic ulcers after the menopause, although they are relatively free from them before. During these last five years the proportion of women in the over-50 age group is noticeably higher than it was in the earlier series, although the proportion of women in the under-50 age group is the same as it was before.

TABLE IV.—Fatality Rate by Age and Sex. Chronic Ulcer Group

Age Group	Men		Women	
	No. of Patients	Deaths	No. of Patients	Deaths
Under 50	107	0 (0.0%)	28	0 (0.0%)
Over 50	155	16 (10.3%)	87	5 (5.7%)
	262	16 (6.1%)	115	5 (4.3%)

Recurrent Bleeding

The most important single variable other than age which affects prognosis is the liability of a patient to continue to bleed freely or to have recurrent bleeding after admission to hospital, as has been particularly well demonstrated by Avery Jones. In this connexion it is worth mentioning that the proportion of patients who exhibited recurrent bleeding was closely similar in the two Radcliffe Infirmary series. In each series about one-third of the patients had a recurrent haematemesis or other evidence of continued bleeding after admission to hospital.

It is sometimes assumed that the longer an ulcer has existed the more likely it is to give rise to recurrent bleeding. In this series the length of ulcer history had no influence on liability to recurrent bleeding. In 101 patients with a history of chronic ulcer of less than five years the incidence of recurrent bleeding was 35%, while in 207 patients with a history of more than ten years the incidence was 32%.

Likewise, neither a history of previous haematemesis nor the age of the patient has any bearing on the liability to recurrent bleeding, as shown in Tables V and VI, and as previously found by Lewin and Truelove (1949).

TABLE V.—Incidence of Recurrent Bleeding in Patients With and Without a History of Previous Haematemesis. Chronic Ulcer Group

	No. of Patients	No. with Recurrent Bleeding
With previous bleeding	108	37 (34.2%)
No	256	84 (32.8%)

TABLE VI.—Incidence of Recurrent Bleeding in Two Main Age Groups. Chronic Ulcer Group

Age Group	No. of Patients	No. with Recurrent Bleeding
Under 50	135	41 (30.4%)
Over 50	229	80 (34.9%)

Treatment

It has been the practice in the Radcliffe Infirmary for patients with haematemesis to be admitted under the care of a physician and for initial treatment to be medical rather than surgical. About 7 out of every 10 patients in the peptic ulcer group made an uneventful recovery without evidence of recurrent bleeding on orthodox medical treatment—namely, rest, a bland diet, and blood transfusion when indicated. The proportion of patients who made an uneventful recovery on medical treatment is a little higher in

TABLE VII.—Proportion of Patients Making an Uneventful Recovery on Medical Treatment. Peptic Ulcer Group

Age Group	No. of Patients	No. Making Uneventful Recovery
Under 50	160	117 (73.1%)
Over 50	301	196 (65.2%)

the younger than in the older age groups, as shown in Table VII, but the difference is not marked.

Whereas in the previous ten years the part played by surgery was negligible, during the recent five years emergency surgery has often been used. Although there has been no rigid uniformity of policy among the various physicians and surgeons concerned, the usual course of action has been to employ medical treatment and to resort to surgery when there has been evidence of continued or recurrent bleeding and the presence of a peptic ulcer has been known or suspected. In all, 76 out of the 461 patients with chronic or acute peptic ulcer were treated by emergency partial gastrectomy—that is, 1 in 6. We have defined an emergency partial gastrectomy in this context as an operation done for the immediate arrest of dangerous bleeding. A partial gastrectomy carried out after bleeding had stopped for more than 24 hours but less than a week has been classed as an early elective operation; there were 38 such operations, or 1 in 12.

Following the 76 emergency operations there were 7 deaths (9.2%). None of these occurred in the 20 patients who were aged less than 50 years. Hence there were 7 deaths (12.5%) among the 56 patients over 50 years old. The operative fatality among patients over 50 was therefore considerable, but we must remember that the patients selected for emergency operation were those who would have had a high fatality rate with medical treatment, almost certainly much higher than occurred with surgery.

Of the 76 emergency operations, 66 were performed on patients in the chronic ulcer group, with 6 deaths (9.1%). The remaining 10 emergency operations were carried out for acute ulcer, and there was 1 death. Thus there is no obvious difference between the results of surgery in the acute and chronic ulcer groups.

It has already been noted that 20 of the emergency operations were carried out on patients under the age of 50. At the other end of the age scale, 14 emergency operations were carried out on patients over the age of 70 with 2 deaths, a fatality rate not appreciably different from the group between 50 and 70, as will be seen from Table VIII.

TABLE VIII.—Operative Fatality Rate in Relation to Age

Age Group	No. of Cases	No. of Deaths
Under 50	20	0
50-69	41	5 (12.2%)
Over 70	15	2 (13.3%)

It is of some interest that the only emergency operation done in the chronic ulcer group has been partial gastrectomy with excision of the ulcer. Before the start of the present series in 1948 other operations, such as ligation of vessels from within or without the stomach, cauterization, or oversewing of the ulcer had been practised. This change has been due to the individual choice of each surgeon, since uniform lines of treatment for the whole hospital by formal agreement of the staff do not exist at the Radcliffe Infirmary. The completeness of the change is therefore all the more striking.

Deaths

The total number of deaths in the chronic peptic ulcer group (377 admissions) was 21, but this includes 11 deaths which we regard as inevitable because there was some other grave disease in addition to the haematemesis. Many authors exclude such cases from their series. If we had done the same the fatality rate in this group of patients

would be 2.7% instead of the figure of 5.6% referred to in an earlier section. Brief details of the deaths are as follows:

Preventable (10 deaths).—Those deaths which occurred among patients without grave, unrelated, complicating diseases. Four of these patients died without surgical operation, and six died after emergency partial gastrectomy.

Inevitable (11 deaths).—Those deaths occurring in patients who suffered from a grave illness unrelated to the ulcer. In some of these cases the occurrence of massive bleeding was found only at necropsy. The nature of their complicating illnesses was as follows:

(1) Man aged 56. Admitted with coronary thrombosis. Arterial embolism of leg. Amputation and re-amputation. Collapsed and died suddenly. At necropsy, massive bleeding from a large benign gastric ulcer was found.

(2) Man aged 59. Admitted with acute appendicitis and general peritonitis. Developed severe recurrent haematemesis and was too ill for operation.

(3) Man aged 59. Admitted with haematemesis from chronic duodenal ulcer. Suffered from severe chronic tuberculous empyema with multiple sinuses and destruction of right lung.

(4) Woman aged 57. A severe chronic bronchitic admitted with bronchopneumonia and cardiac failure. Developed massive haematemesis from duodenal ulcer.

(5) Man aged 65. Admitted with carcinoma of gall-bladder with multiple metastases. Died suddenly. Necropsy showed two gastric ulcers and a duodenal ulcer with a large amount of fresh blood in stomach and small intestine.

(6) Man aged 68. Had previously had removal of carcinoma of rectum with local metastases. Was ill at home with diagnosis of carcinomatosis until admitted moribund. Died in three hours. Necropsy showed inhaled vomit, gross pyloric stenosis, and a duodenal ulcer which had bled.

(7) Man aged 70. Admitted for prostatectomy. On twelfth day had massive haematemesis and died in three hours in spite of transfusion. Necropsy showed large gastric ulcer which had eroded an artery.

(8) Man aged 75. Admitted with obstructive jaundice due to gallstones. Had suffered from intermittent attacks of jaundice with rigors for four years. Had haematemesis and quickly died. Necropsy showed two duodenal ulcers with fresh blood in intestine, cholelithiasis, and fibrosis of liver.

(9) Man aged 75. Admitted in coma due to metastases from carcinoma of the prostate which had been previously removed. Had recurrent haematemesis and died in four days. Necropsy showed bleeding chronic gastric ulcer and lobar pneumonia in addition to carcinomatosis.

(10) Man aged 81. Had a six-year history of hypertensive cardiac failure with auricular fibrillation. Admitted with haematemesis. Was in heart failure on admission. Had recurrent haematemesis and died on eleventh day. Necropsy showed two large chronic gastric ulcers, one of which had eroded an artery, and an enormous heart with generalized atheroma.

(11) Woman aged 71. Admitted with small intestinal obstruction due to carcinoma of ascending colon. Following a hemicolectomy, had severe recurrent haematemesis and died. Necropsy showed four chronic gastric ulcers.

Discussion

In the present series peptic ulcer was by far the most common cause of haematemesis, accounting for 85.4% of the admissions—that is, about 1 out of every 20. The next most common single cause was bleeding from oesophageal varices due to portal hypertension, which accounted for 4.3% of admissions. In almost all the latter patients the diagnosis was apparent on admission; in fact most of them were already under medical supervision for the underlying cause of their portal hypertension, and splenomegaly was almost invariable. Carcinoma of the stomach is also a fairly common cause of haematemesis, accounting for 3.7% of admissions; if the diagnosis is not obvious it may be confused with simple peptic ulcer, but the initial treatment is the same. The haemorrhagic disorders usually present other signs of the underlying disorder. Other causes are not common but are extremely diverse, and in some cases the diagnosis remains unknown. In such circumstances it is probably best to assume that the bleeding is from a peptic

ulcer, because the odds are in favour of this possibility even in the absence of a history of dyspepsia. Moreover, if the case is managed along lines suitable for peptic ulcer, little harm will usually be done if the source of bleeding proves to be some other lesion.

There is still no general agreement on the best course of treatment for haematemesis in patients with known or suspected peptic ulcer. Three schools of thought exist (Tanner, 1951; Avery Jones, 1952). The "conservative" school believes in treatment on purely medical lines with sedation, bland diet, correction of dehydration, and blood transfusion. Surgery is either not used or resorted to as a final desperate measure. Another group practises "selective surgery" (Tanner, 1950), carrying out emergency partial gastrectomy in those patients with peptic ulcer who are known to be poor risks with medical treatment. These are mostly patients over 50 with continued or recurrent bleeding after admission to hospital, as has been convincingly demonstrated by Avery Jones (1947). The third school of thought, often associated with the names of Finsterer and of Gordon-Taylor (1937), believes in "early surgery as the treatment of choice" (Finsterer, 1939) in all patients in whom there is a previous history suggestive of chronic peptic ulcer and in the absence of serious unrelated disease.

In connexion with these various approaches to treatment, it is of interest that the fatality rate from haematemesis in patients admitted to the Radcliffe Infirmary was much lower during the period covered by the present series (1948-52) than it was during the preceding decade. This fall in fatality has occurred in spite of a bigger proportion of elderly patients and with as big a proportion showing recurrent bleeding after admission. A number of improvements in medical care have doubtless assisted in this change, particularly improvements in blood transfusion and the development of antibiotics. However, we are satisfied that a major cause of the improvement has been the more frequent resort to surgery.

In general, the plan followed has been that of "selective surgery" as defined above, although a number of the patients who fulfilled the criteria for surgery were treated medically throughout, particularly at the beginning of the period under review. However, the age of the patient has not been regarded as an important factor in deciding against surgery. Twenty patients aged less than 50 were treated with emergency partial gastrectomy without a single fatality. It is often taught that emergency operation is inadvisable in patients aged over 70, but in this series there were 15 emergency operations on such patients, with only 2 deaths. The factor of age in deciding on operation is of importance only when there is genuine doubt whether operation is indicated. In such circumstances one can afford to await events if the patient is young, as he will probably survive a further haemorrhage, but if he is over 50 it is probably wiser to decide in favour of emergency surgery without delay.

The present series yields no direct evidence on the value of "early surgery as the treatment of choice" in all patients with known or suspected peptic ulcer. However, it may be relevant that 7 out of every 10 patients in the peptic ulcer group made an uneventful recovery on medical treatment. While early surgery might improve the expectation of the remaining 3 in every 10 who are fated to have recurrent bleeding after admission, it would expose all the peptic ulcer patients to a major operation at a time when they may not be in the best condition for it and when the majority would recover uneventfully from their present haemorrhage without surgery. However, the issue is not entirely straightforward, for many of the patients who are treated medically will need surgical treatment later or may have a further complication of the ulcer, so that a correct comparison of the two methods ("selective surgery" and "early surgery as the method of choice") should include a follow-up study. Even in the brief time between the admission of the patients of this series and the end of 1953 53 of the 258 patients

with chronic ulcer surviving their haematemesis without emergency operation have required surgical treatment in the Radcliffe Infirmary, in some cases because of emergencies due to the ulcer, such as another major bleed or a perforation.

Summary

During the period 1948-52 540 cases of haematemesis or melaena presented as emergencies in the Radcliffe Infirmary. The results of treatment have been compared with those obtained in the previous decade.

Peptic ulcer was the most common cause of bleeding, accounting for 17 out of every 20.

The overall fatality rate was 8.3%. For 377 patients with good evidence of chronic peptic ulcer the rate was 5.6%.

Among the chronic ulcer group, about 1 in 3 suffered from continued or recurrent bleeding after admission to hospital. The chance of recurrent bleeding occurring while still in hospital is not appreciably influenced by age, length of ulcer history, or a past history of haematemesis.

Of the peptic ulcer group, 7 out of every 10 made an uneventful recovery from bleeding on medical treatment. One in every 6 had an emergency partial gastrectomy for bleeding, with a fatality rate of 9.2%.

The scope of emergency surgery in the treatment of haematemesis has been discussed. Nine out of every 10 cases of haematemesis are likely to be due to peptic ulcer or gastric carcinoma, and surgery may be the wisest treatment in any of these who show evidence of continued or recurrent bleeding.

We wish to thank the physicians and surgeons of the Radcliffe Infirmary for permission to make this study. We are also grateful to Miss P. Coombes, the records officer, and Miss B. Merry and Mrs. M. Eastway of her staff, for their assistance.

"Maggots taken from a dead body are sometimes received with a request for identification and an opinion on their age, in case this may assist in fixing the time of death," writes J. A. Reid in Bulletin No. 7 from the Institute of Medical Research, Federation of Malaya. He explains that it is difficult to deduce precisely from maggots the time of the host's death because of the rapid decay in the Malayan climate. The presence of full-grown maggots of the flesh-fly suggests that death occurred at least three days before, of blow-fly maggots that it occurred at least six days before. But the victim may have had a fly-blown wound before death. The sequence in the processes of decay and the insects associated with them, the lapse of time between death and the laying of the first eggs, and the duration of the various larval stages of the different flies have not been fully worked out in Malaya; consequently the time of death cannot be very accurately gauged. In 1950, however, Dr. H. M. Nevin, a pathologist, examined some young maggots collected from the body of a woman shot by bandits in Penang, and Mr. Reid's identification of them as second-stage larvae of the blow-fly between 16 and 24 hours old agreed with police evidence that the woman had been killed less than 24 hours earlier. For forensic investigation, half the maggots collected from the body should be killed in boiling water and preserved in 70-80% alcohol to show their age at the time of collection, and the other half should be sent alive so that by breeding to maturity the adults may be used to check identification.

A CASE OF SYMPTOMATIC HAEMOLYTIC ANAEMIA IN PREGNANCY

BY

G. A. CRAIG, F.R.C.S.Ed., M.R.C.O.G.

AND

R. L. TURNER, M.B., B.Ch., B.A.O.

From St. Luke's Maternity Hospital, Bradford

This report describes a case of symptomatic haemolytic anaemia occurring during a young woman's first two pregnancies. She gave no previous history of jaundice or anaemia. The haemolytic process on both occasions followed the onset of gestation and ceased spontaneously after delivery.

In the older literature megaloblastic anaemia of pregnancy was often confused with haemolytic anaemia and pernicious anaemia, so the records are unreliable as regards the incidence of the disease. Within the last decade we could find few papers in the English literature specifically devoted to this complication of pregnancy. In our hospital the case described below was the only one which had occurred in over 12,000 pregnancies seen during the past five years. It would therefore appear to be rare.

First Pregnancy

A married woman aged 29 was first seen by one of us (G. A. C.) at St. Luke's Maternity Hospital in October, 1949. She was then in the last trimester of her first pregnancy. She gave a history of being quite well throughout that pregnancy until shortly before admission, when she felt sick and vomited, subsequent to which she became slightly jaundiced. She denied ever having been jaundiced or anaemic before in her life. There was no family history of haemolytic anaemia; her two sisters, both married, had had normal pregnancies. On examination the patient was found to be 32 weeks pregnant. She was clearly anaemic and jaundiced. Her liver and spleen were not enlarged and her body temperature was normal. No other clinical abnormality was found.

Investigations.—Haemoglobin, 8 g. per 100 ml.; red cells, 1,600,000 per c.mm.; reticulocytes, 25%. A marked polychromasia and scanty normoblasts were present in the peripheral film but no microspherocytes were seen. The red-cell-fragility test by the method of Creed gave a normal result. The total white cell count was 7,000 per c.mm., the differential count being normal. Platelets numbered 210,000 per c.mm. The sternal marrow showed a marked normoblastic hyperplasia. Blood chemistry: van den Bergh reaction—direct test negative, indirect test positive; serum bilirubin 3.2 mg. per 100 ml. Urine: bilirubin absent; haemoglobin absent; urobilinogen strongly positive.

A diagnosis of haemolytic anaemia was made. The patient was treated with folic acid and liver preparations, and was given blood transfusions, but did not respond to any of these. In fact, blood transfusion merely seemed to cause increased haemolysis. On December 14, after a surgical induction of labour, the patient delivered herself of a healthy female infant. Two weeks later her haemoglobin had risen for the first time since her admission to hospital, to 10.4 g. per 100 ml., and subsequently the haemolytic process rapidly ceased. The patient and her baby were seen three months after delivery and were then in good health. Laboratory examinations failed to give any evidence of haemolytic anaemia in either the mother or her baby. The mother's haemoglobin was then 15.6 g. per 100 ml.

Second Pregnancy

Clinical Features

The patient came under our care for the second time on December 8, 1952, being again pregnant. Her expected date of delivery was April 2, 1953. On inquiry she said she had been perfectly well since her last pregnancy, and had remained so during the early weeks of this one. In the two weeks prior to attending the antenatal clinic she had again noticed a slight jaundice accompanied by excessive tiredness.

Examination revealed a well-nourished woman aged 32. There was a slight icterus of the sclera and skin. No oedema was present. Her uterine enlargement corresponded to a 26-weeks pregnancy. Physical examination of her cardiovascular, central nervous, and respiratory systems showed no abnormality. Neither the spleen nor the liver was palpably enlarged. Her body temperature was normal.

Laboratory investigations, details of which are given below, showed that she had a recurrence of the haemolytic anaemia experienced during her first pregnancy. It was decided to allow the pregnancy to continue to term if her condition permitted, supporting her when necessary with blood transfusions.

Her progress continued fairly satisfactorily until March 12, when the maturity of her pregnancy was 37 weeks. On that date her haemoglobin level had fallen to 4 g. per 100 ml. Two pints (1,140 ml.) of whole blood was administered. This raised the haemoglobin level to 7.3 g. per 100 ml., but on March 14 it had fallen to 5.3 g. per 100 ml., and a cold agglutinin had appeared in her blood that temporarily rendered cross-matching difficult. As soon as this difficulty had been overcome a surgical induction of labour was performed. This was followed by the delivery of a normal live female child on March 15. The blood loss at delivery was normal.

Following delivery the haemolytic process persisted without apparent abatement for four weeks, and then gradually ceased. By May 20 it had stopped completely, so far as could be determined by laboratory tests.

The patient's clinical condition throughout the second pregnancy was much worse than during the first. The severity of the haemolytic process was evidently increasing with the parity. In view of this, sterilization was advised. For this purpose laparotomy was performed in the puerperium, when the patient was still showing some evidence of increased red-cell destruction.

At operation the abdominal organs, including the liver and the spleen, appeared normal. One ovary showed a number of small cysts, the other appeared atrophic. The genital organs were otherwise normal. Biopsy material was obtained from both ovaries, and a small inguinal lymph node was removed. Since the patient's discharge both she and her two children have been examined from time to time for the presence of haemolytic anaemia with negative results. The last examination of the patient, six months after delivery, showed haemoglobin 15 g. per 100 ml., reticulocytes less than 1%, serum bilirubin 0.8 mg. per 100 ml., and faecal urobilinogen 130 Ehrlich units per 100 g. of faeces. She was symptom-free and in good health.

Laboratory Investigations

Haemoglobin and Red Cells.—At her first attendance the patient's haemoglobin was 7.3 g. per 100 ml. Examination of the stained film showed a moderate degree of polychromasia. Normoblasts constituted 2% of the total nucleated cells present. No microspherocytes were seen, nor were any found in subsequent blood examinations. On February 12, 1953, the mean corpuscular volume was 114 cubic μ and the mean corpuscular haemoglobin concentration 30%. Reticulocyte counts when the haemolytic process was at its height varied from 20 to 32% of the total red-cell count, and normoblasts were found in every stained film examined during this period. The behaviour of the blood counts is given in Table I. The haemoglobin was estimated by the alkaline haematin method of King (1946).

TABLE I.—Chronological Record of Laboratory Studies

Date	R.B.C. mil./ c.mm.	Hb g. 100 ml.	Reticulo- cytes %	Leuco- cytes per c.mm.	Plate- lets per c.mm.	Serum Bilirubin mg. 100 ml.	Faecal Uro- bilinogen Ehrlich Units/ 100 g.
8.12.52	2.4	7.3	21	7,600	196,000	2.2	800

10.5.53	4.02	14.5	0.5	6,700	220,000	0.6	140
20.5.53	5.03						

Red-Cell Fragility.—The patient's red cells were examined, using the combined fragility test of Varadi (1951), on December 23, 1952, and February 24 and May 30, 1953, and no increase in fragility was demonstrated.

Faecal Urobilinogen.—The semi-quantitative method of Watson as described by Wintrobe (1951) was used. The results are summarized in Table I. The upper limit of normal by this method is 350 Ehrlich units per 100 g. of faeces.

Blood Chemistry.—No abnormality was found on estimating the serum proteins and blood urea. Schumm's test for methaemalbumin was negative. Haemoglobinaemia was never demonstrated. The direct van den Bergh reaction was negative, and the indirect strongly positive. Serum bilirubin estimations varied between 1.7 and 2.2 mg. per 100 ml. during pregnancy.

Fractional gastric analysis showed the presence of free hydrochloric acid.

Sternal Marrow.—This was examined on February 12. The myelogram (Table II) showed a richly cellular marrow. There was a marked normoblastic hyperplasia. Apart from the reduction in relative proportions the myeloid series appeared normal.

TABLE II.—The Myelogram

Proerythroblasts	4.0%
Early normoblasts	18.0%
Late and intermediate normoblasts	43.0%
Myeloblasts	0.5%
Premyelocytes	0.5%
Myelocytes	6.0%
Metamyelocytes	10.0%
Polymorphonuclear leucocytes	15.0%
Lymphocytes	1.0%
Normoblasts in mitosis	2.0%
Megakaryocytes	Present
Myeloid erythroid ratio	0.3:1

Leucocytes.—The total white cell counts varied from 5,000 to 10,300 per c.mm. Scanty myelocytes (under 1%) were present from time to time during pregnancy, otherwise the differential count showed no abnormality.

Platelet counts varied between 180,000 and 300,000 per c.mm.

Urine.—Urobilinogen was present in the urine in increased amounts during pregnancy. Its presence was demonstrated by the techniques described by Wintrobe (1951). Tests for haemoglobin, bilirubin, and haemosiderin were negative.

Coombs Test.—The direct and indirect tests were invariably negative during pregnancy and following the patient's recovery. The technique used was that described by Dacie (1950).

Circulating Haemolysins.—The patient's blood was examined, using the presumptive tests described by Wintrobe (1951), for the presence of cold and warm haemolysins on February 12, March 27, and April 20. They were not demonstrated.

In Vitro Erythrophagocytosis.—The method described by Zinkham and Diamond (1952) was used. The index was less than 0.1%—a normal result.

Cold Agglutinins.—On March 13, two days before delivery, a cold agglutinin in low titre (1/32) was noticed in the patient's blood. Its presence had not been detected previously and it disappeared within five days of its first appearance. It may have been due to the transfusion given on March 12.

Serology.—The patient was Group O, Rh positive; no atypical antibodies were present in her serum. The Kahn test was negative.

Baby's Cord Blood.—Blood Group A, Rh positive. No agglutinins active against the mother's cells in saline or albumin or by the Coombs technique were detected in the cord serum. The haemoglobin was 19.3 g. per 100 ml. No evidence of a haemolytic anaemia was found at birth or in subsequent examinations of the baby.

Histology of Biopsy Material.—One ovary showed the presence of multiple small follicular cysts; in the other a corpus albicans was present but no active follicles were seen. The inguinal lymph node showed fibrous scarring due to past attacks of lymphadenitis.

Discussion

O'Grady *et al.* (1953), in a short review of haemolytic anaemia in pregnancy, state: "Although pregnancy does not cause haemolytic anaemia it may be a precipitating factor." In our case, however, the intimate association of the anaemia with the patient's two pregnancies and its cessation following delivery suggest that gestation plays an important part in its causation. The mechanism of the increased red-cell destruction is obscure. The failure to demonstrate either autoagglutinins or haemolysins in the circulating blood indicates that abnormal antibody formation is not a factor. This is in keeping with the findings in cases of symptomatic haemolytic disease due to other causes (Allibone and Collins, 1951). Lescher (1942), in a review of eight cases of haemolytic anaemia in pregnancy, states that there is no evidence of the development of a haemolysin in either the maternal or the foetal structures. He also notes that neither nutrition nor infection seems to play any part in the abnormal haemolysis.

Whitby and Britton (1950) regard the haemolytic anaemia occurring during pregnancy as similar to Lederer's anaemia. Our case differs from the usual description given of the latter condition in that it ran a less fulminating course and, apart from the symptoms due to the low haemoglobin concentration *per se*, there was no constitutional upset. It did not respond dramatically to blood transfusion. The haemolysis, moreover, was not accompanied by pyrexia or leucocytosis.

The failure of the spleen to enlarge and the fact that the process ceased completely after delivery, in the absence of splenectomy, indicates that this organ does not play any dominant part in the production of the disease. The possibility that this was a case of congenital acholuric jaundice can be dismissed in view of the absence of spherocytosis, the negative Varadi test, and the lack of a familial or personal history of such a disease. As the patient belonged to Group O, red-cell-survival studies were not attempted. The very transient rise produced in the haemoglobin concentration by transfusions (see Table I) suggests that the normal transfused cells were eliminated as fast as the patient's own cells. It is unlikely, therefore, that the process was due to any intrinsic effect induced by pregnancy in her red-cell structure.

In this case the haemolytic process seems to be due to overactivity of the normal mechanisms for the removal of red cells from the blood stream. The nature of such mechanisms is at present obscure. It is known, however, that they are influenced by the sex hormones. Hyperhaemolysis has been demonstrated in normal women during the latter part of the menstrual cycle (Ashby, 1921; Berlin, 1951). These authors, while admitting the obscurity of the nature of this hyperhaemolysis, conclude that it is due to hormone influences; Berlin also believes that the spleen plays no part in its production, as he found it to persist after splenectomy. Presumably, during a normal pregnancy the hyperhaemolysis is inhibited, to prevent the increased concentration of sex hormones following gestation from causing a haemolytic anaemia. In our case the inhibitory mechanisms would appear to have failed.

Summary

A case of symptomatic haemolytic anaemia associated with pregnancy is described. The haemolytic process occurred during a young woman's first two pregnancies and ceased spontaneously on both occasions during the puerperium. Neither circulating haemolysins nor atypical agglutinins were demonstrated. The mechanism of the hyperhaemolysis was obscure. We suggest that it may be related to that occurring during the progestational phase of the normal menstrual cycle.

We are indebted to Dr. J. F. Wilkinson for advice and encouragement during the preparation of this paper.

ROSEOLA INFANTUM

13 CASES SEEN IN GENERAL PRACTICE

BY

E. L. McQUITTY, M.B., Ch.B.

Very little has been published in Britain on this relatively common condition, also known as exanthem subitum or sixth disease. The *British Medical Journal* (1950) draws attention to this "common but little-known infectious disease of young children which has received too little attention in the past."

Nearly all the published accounts of the disease come from the U.S.A., where Zahorsky, of St. Louis, first described it as a clinical entity and gave it the descriptive name in 1910. Up to 1940 he had seen about 300 cases in private practice (Zahorsky, 1940). Cases have been reported from all over the world, including Brazil, Formosa (Itagaki, 1933), Canada, Germany (Fischhof, 1936), South Africa (Witkin, 1937), Sweden, and Australia (Jackson, 1949). In Britain, only Schlesinger (1937) refers to a few cases seen in London.

The purpose of this paper is to show that, despite the paucity of references to it in the journals and textbooks, it arises quite frequently in general practice.

Age Incidence.—The disease affects infants between the ages of 6 months and 2 years. The youngest in Clemens's (1945) series of 80 cases was 5 months old, but he quotes one 2 months old. My youngest patient was 4½ weeks old.

Older children and adults have been involved in other series. The sexes are equally affected.

Aetiology.—Although the infective nature of the disease was accepted, proof was not established until Kempe *et al.* (1950) succeeded in transmitting the disease by injecting serum from an 18-months-old child in the pre-eruptive stage into a 6-months-old susceptible baby kept in isolation, who developed typical roseola infantum on the ninth day. In young apes these workers produced a fever without a rash after a similar period. While they consider the causal agent to be a virus, they have been unable to isolate it or to transmit it through any of the usual media. Hellström and Valquist (1951), at Upsala, have confirmed these findings in a larger series of 14 human cases.

Epidemiology.—Although most cases arise sporadically, epidemics have been reported, and the cases which I noted in my practice presented as a mild epidemic, although I can identify in recollection a number of sporadic cases over the years. American writers believe that it is endemic and almost universal in infancy, but that in favourable circumstances it appears in epidemic form. They find that the highest incidence is in the spring and to a less degree in the autumn.

Pathology.—No deaths have been reported. The blood changes seem to be important—they are a neutrophil leucopenia, appearing during the febrile stage and falling to a total white-cell count as low as 2,000 per c.mm. This process is reversed as soon as the rash appears, and the count returns to normal within a week. The incubation period is 5 to 15 days.

Clinical Course

The individual case presents on the following lines. A call is received to an infant who "has come out in a rash all over. He's been feverish for a few days, and I nearly sent for you yesterday, doctor. When I saw the rash to-day I thought it must be measles, but he seems better now." In fact, the child appears well apart from a rash in the form of discrete rose-coloured macules, most marked on the trunk but spreading on to the thighs and upper arms, up to the neck and often behind the ears. In severe rashes some coalescence may occur.

If the case is seen earlier the child has a fever extending over three to five days, the temperature rising to 101–102° F. (38.3–38.9° C.) or higher, with symptoms of inflammation and congestion of the nose and throat, and frequently of the tympanic membranes. He is restless, may refuse feeds, and is obviously unwell. Examination of the fauces shows redness of the tonsils and pharynx, and of one or both ear-drums. A cough may be present without signs in the chest. With the appearance of the rash the child rapidly improves, the catarrhal signs disappear, and normal lustre returns to the ear-drums. Posterior cervical and occipital lymph-node enlargement can nearly always be found: in my experience this is more obvious when the rash is severe, especially on the neck and behind the ears. The glands in the groins and armpits do not become palpable. All signs disappear in a day or two in most cases, but occasionally congestion of the nose or Eustachian tubes persists and frank otitis media may develop (as in one of the present series).

Clemens (1945), in a series of 80 cases, reports a pre-eruptive enanthem in 87%: this took the form of erythematous specks and streaks on the soft palate which preceded the typical exanthem by 48 hours and coincided with the period of maximum tubotympanitis and faucial congestion. I noted this in one case, but would be inclined to dismiss it as part of the general congestion of the mucous membrane of the palate.

Differential Diagnosis

In a clear-cut case the disease which is most like roseola infantum is rubella. In that condition the pyrexia and malaise coincide with the rash and are usually less pronounced. There is not the three to five days' pre-eruptive

fever and malaise, with a dramatic return to normality invariably found with roseola. In rubella the rash is usually marked on the face, as opposed to roseola infantum, in which the face escapes, apart from a few faint rosy macules on the forehead. The absence of cases of rubella among older children and adults suggests the correct diagnosis.

Scarlet fever may be suspected. The absence of circumoral pallor, strawberry tongue, tonsillar adenitis, and the rapid resolution of the rash in roseola infantum, together with the age incidence, will help to exclude it.

The prodromal rash of measles, or the early stage of the eruption with a post-auricular rash, may also be suggested. Again, this doubt is soon resolved by the absence of Koplik's spots and the course of the illness.

Since I have recognized the disease in practice I am certain that many rashes which were previously dismissed to the parents as "teething" or "stomach upset" or "drug rash" have in fact been roseola. The story of restlessness, fever, and sweating may suggest miliaria, but the rash is quite different. There are, too, the blood changes I have already mentioned.

Complications

Although most observers say that recovery is always complete, Zahorsky reports several cases of suppurative otitis media and rhinitis following the illness, and one case in the present series developed an acute catarrhal otitis media three days after defervescence.

Jackson (1949), in Australia, had two cases in which convulsions occurred in the feverish stage: no changes were found in the C.S.F., and he believes them to have been due to the pyrexia.

It has been suggested that deaths in convulsions may occur before the rash has had time to appear; this is obviously difficult to prove.

Details of Cases

Case	Age in Years	Sex	Date of Rash	Comments
1	3½	M	15/1/54	Cough and cold preceding; cleared rapidly afterwards. Post-auricular glands enlarged
2	10/12	M	23.1.54	Feverish preceding rash—normal afterwards. Lives in adjoining street to Case 1
3	10/12	F	23.1/54	Feverish preceding rash—normal afterwards
4	10/12	F	23.1/54	Typical roseola—had been to same Christmas party as Case 3, on 16/1/54
5	11/12	M	27/1/54	Had tonsillitis 10 days previously—apparent recurrence 3–4 days before rash, but subsided with rash
6	4½/52	F	27.1/54	Adopted sister of Case 1. Cough and nasal catarrh. ? Pain on swallowing; fauces red. Better after eruption
7	11/12	F	4/2/54	Fever preceding—no cough or cold. Better after rash
8	11/12	M	15/2/54	Fever and tonsillar infection preceding eruption. Fine macular rash with some coalescence. Occipital glands enlarged. Brother aged 4 years remained well
9	19/12	M	17.3.54	Rash to-day after 4 days' malaise. Now well
10	23/12	M	21/3/54	Feverish beforehand. Both T.M. very red. Ear infection seemed to be settling when seen again 2 days after rash, but flared up as typical acute catarrhal otitis media after another 48 hours
11	12/12	F	26.3.54	Typical rash with preceding fever
12	4/12	M	27.4.54	
13	9/12	F	25.8.54	Typical rash on trunk—preceded by fretfulness and diarrhoea, which stopped when rash appeared

Present Series

In the brief description of individual cases which follows I have included only the comments which I jotted down in my visiting diary. In view of the youth of the patients and the invariable recovery I did not feel justified in taking blood samples to establish a leucopenia followed by a return to normal. However, during the period discussed, no cases of measles were notified to the medical officer of health and none of my partners in a practice of over 10,000

patients saw any cases of rubella. None of the older members of the families developed rubella, although I watched particularly for it. Cases 1 and 6 demonstrated the infectivity and incubation period. Case 1 was an adopted son aged 3½ years, who developed the rash two days after his adopted sister, aged 18 days, was introduced into the house from a maternity home outside the area. She developed the rash 12 days later. In all cases the rash was typical of roseola infantum. The last patient, whose illness occurred at a much later date, lived out in the country. The mother told me that two babies of about the same age, in near-by cottages, had had a similar rash and fever, but I did not see these cases.

Summary and Conclusion

Roseola infantum is a distinct entity with characteristic age incidence, epidemiology, signs, and symptoms which should be more frequently diagnosed.

It has been obscured in the past by a tendency to dismiss unusual rashes in infants as teething, sweat rash, drug sensitivity, or even "slight measles" or "mild scarlet fever," or, more excusably, German measles.

The alternative name of exanthem subitum—the unexpected rash—should not excuse our failure to think of it in any case of unexplained fever in the critical age groups. I personally prefer the more descriptive name originally bestowed by Zahorsky. Its recognition may prevent the unnecessary use of antibiotics or other drugs, and will certainly give reassurance to anxious parents.

Treatment has not been mentioned, as this is purely symptomatic unless the rare suppurative complications arise.

The ways in which the two great Asian countries of India and Japan have struggled with their problems of excessive population are reviewed by P. E. P. in "Population Policies in India and Japan" (Planning Broadsheet No. 378). In India the need to feed adequately from domestic sources a population which increases by five million a year has been met by an imaginative series of five-year-plans covering industry, agriculture, and public services. In these, birth control is integrated with a family service including sex education and marriage guidance. In 1951 Dr. Abraham Stone, for W.H.O., organized controlled experiments in the rhythm method, which is in some respects consonant with Indian thought and custom, but the results were disappointing. The Indian Government, however, accepted most of the recommendations of the Family Planning Research and Programme Committee for encouraging clinics, research, and the setting up of voluntary as well as government agencies. In Japan only American financial aid has in recent years buttressed the nation's economy against collapse, says the report. Between 1945 and 1953 Japan's population increased by 15 million. In 1948 a Eugenic Protection Law facilitated the termination of pregnancy for physical and economic reasons, so that now over a million abortions are procured each year; abortion replaces infanticide, the traditional method of population control. Last August, however, the Japanese Minister of Welfare's Advisory Council on Population Problems announced that birth control was preferable to abortion and advocated government sponsored clinics. But these recommendations have not yet been adopted as the official policy.

MITRAL VALVOTOMY FOR DEXTROCARDIA WITH MITRAL STENOSIS

A CASE REPORT

BY

P. KOSHY, M.D.

Clinical Assistant, Department of Thoracic Surgery

From the Departments of Medicine and Thoracic Surgery, Christian Medical College and Hospital, Vellore, South India

Rheumatic valvular disease in dextrocardia with situs inversus is said to be rare. Bleyer and Saphir (1953) have reviewed the literature on five hitherto published cases, and reported a sixth. According to them, Owen is credited with the first case report of mitral stenosis in dextrocardia with situs inversus, but since he could not definitely establish the aetiological factor for the mitral stenosis the authors did not include it in the review. Of the six cases reported, two were cases of aortic valvular affection, three of mitral stenosis with insufficiency, and one a case in which both mitral and aortic valves were involved.

The purpose of this paper is to report a seventh case of rheumatic heart disease in a case of dextrocardia with situs inversus, producing pure mitral stenosis, and to record the successful performance of mitral valvotomy on such a case. So far as we are aware, this is the first case of surgical correction of mitral stenosis in dextrocardia to be reported.

Case Report

An Indian labourer aged 19 was admitted to the medical wards of the Christian Medical College Hospital, Vellore, on November 18, 1953. His only complaint was progressively increasing breathlessness with effort, of three years' duration. Until 1950 he could cycle five miles at a stretch, besides carrying on his job of unloading bags of tobacco. But from that time he has felt increasing dyspnoea. In 1952 he had to rest after walking half a mile. Three months prior to admission he was so incapacitated that he voluntarily left his employment. He had no history suggestive of definite rheumatic fever or of nocturnal cough or dyspnoea. He had blood-stained sputum once, two years previously. The family history had nothing significant.

Physical examination showed him to be physically somewhat underdeveloped, moderately anaemic, with no cyanosis and without any clubbing of fingers or toes. His temperature was 98.6° F. (37° C.), pulse 86 a minute, regular, and of normal tension and volume. His respiratory rate was 20 a minute and his blood pressure 110/70. There was no visible venous pulsation in the neck or obvious deformity of the chest. The apical impulse was visible and palpable in the fifth right intercostal space, in the mid-clavicular line. A well-marked presystolic thrill could be felt over the systolic impulse. Auscultation revealed, close to the apex on the right side, a loud first sound, a normal second sound, and a slow rumbling crescendo presystolic murmur in the same area. There was reduplication of the second sound in the pulmonary area, but the reduplication disappeared on deep inspiration—indicating that it was probably due to the opening snap (Mounsey, 1953). The

opening snap of the mitral valve was definitely well heard in this patient, just internal to the right nipple. Examination of the lungs revealed no abnormal physical signs. The liver and spleen were not palpable. There was no peripheral oedema. The central nervous system was normal.

His exercise tolerance was as follows: he was comfortable while walking on level ground for a distance of about 50 yards, but became uncomfortable if he tried to do more, and became acutely distressed on running. He was not able to do any work comfortably. He was classified as Grade 2 on the basis of the criteria laid down by Baker et al. (1952). Fluoroscopy revealed no obvious cardiac enlargement, but the pulmonary artery was somewhat prominent, and the left atrium was moderately enlarged, as observed by barium swallow. There was moderate enlargement of the right ventricle, but no enlargement of the left ventricle. Systolic expansion of the left atrium and calcification of the mitral valve were not visualized on fluoroscopy.

The electrocardiogram showed the standard Lead I to be a mirror image of Lead I in a normal individual, with inversion of all the complexes, which is characteristic of dextrocardia. aVR showed an RS pattern and an upward T wave, which suggests that it is facing the left ventricle in a vertical heart. aVL resembles an aVR tracing of a normally placed heart, showing a downward P and T, and this is pathognomonic of dextrocardia (with situs inversus) (Goldberger, 1950). Chest leads were taken on the right side of the chest as would normally be done on the left chest, and were designated VR₁, VR₂, VR₃, and VR₄. The R wave in VR₁ is suggestive of right ventricular hypertrophy.

The mitral configuration in a dextrocardiac was well seen in a skiagram. It was also noticed that the barium was flowing into a stomach which was placed in the right hypochondrium, thus confirming the diagnosis of situs inversus.

An angiocardigram was done with the patient in the right posterior oblique position. The study of films at 8 and 11 seconds after injection showed an enlarged well-defined left atrium remaining opacified during that period. The small left ventricle remained poorly filled. Cardiac catheterization studies were not done, as the patient was not co-operative.

A diagnosis of mitral stenosis (grade II) in a dextrocardiac, with moderate incapacity of a progressive nature, was made, and as no obvious contraindications to operation were present he was submitted to a mitral valvotomy.

The operation was carried out on December 9 by one of us (T. T.), with endotracheal anaesthesia administered by Dr. K. Blott. The patient was placed on his left side and the thoracic cage was exposed by a right postero-lateral incision. The fifth rib was resected and the pleura was entered through the fifth rib bed. On opening the pericardium it was found that the heart was smaller than normal. The left auricle seemed to be somewhat dilated and there was no adequate ventricular filling. The auricular appendage was nearly 3.5 cm. long, and narrow, and its base was only about 2 cm. broad. It was felt that only the little finger could possibly enter the small auricular appendage. It was accordingly introduced through an opening, controlled both by a purse-string suture and by a Brock clamp. A tight mitral opening, not more than 0.5 cm. in diameter, was felt. A satisfactory commissurotomy was achieved. The finger was withdrawn and the auricular opening repaired. Histological examination of the auricular appendage revealed typical Aschoff bodies, thus establishing the aetiology of acquired mitral stenosis.

A post-operative follow-up study, about four months after operation, revealed that the patient's general condition was better. Whereas he could walk only 50 yards in comfort before operation, he now could walk about a mile. On physical examination the findings were more or less the same, the presystolic murmur being present as before. But there was a significant diminution in the intensity of the opening snap. The pulmonary second sound was reduced

in its intensity. His blood pressure was 108/70. The lungs were clear. He could now be classified as grade I.

Comment

The diagnosis of dextrocardia with mitral stenosis was well established from physical findings, electrocardiographic studies, and angiocardiology. The aetiology of mitral stenosis was only presumptive before operation, but was established beyond doubt from histological study of the atrial wall.

Dextrocardia of the mirror type with situs inversus is probably not as rare as is commonly believed; but unless the condition is associated with other congenital cardiac anomalies or cardiac disease no symptoms are produced. These symptoms, when they do appear, are those of the associated abnormality and not due to the dextrocardia *per se*. The signs in the heart are, of course, found on the right chest instead of on the left.

It is claimed by some workers that the condition is common in white persons. It is worth noting, however, that the case reported prior to this was in a negro (Bleyer and Saphir, 1953), and our case is in an Indian.

Summary

A case of pure mitral stenosis due to rheumatic infection in a true dextrocardiac (with situs inversus) is described.

The successful performance of valvotomy in such a case is reported.

IDIOPATHIC PULMONARY HAEMOSIDEROSIS IN A YOUNG ADULT

BY

N. A. J. HAMER, M.B., M.R.C.P.
Captain, R.A.M.C.

(From the British Military Hospital, Singapore)

Idiopathic pulmonary haemosiderosis is being recognized with increasing frequency in recent years. Most of the cases described are in children, and the mortality rate is high. Considered in retrospect, the clinical picture is remarkably uniform, but early diagnosis may be difficult. Several cases of milder forms of the condition in young adults have been reported. In these the outlook is generally good and long remissions may occur. A further adult case is presented in this article.

Case Report

A National Service man aged 19 was first admitted to hospital in October, 1948, when aged 13, with a three-weeks history of intermittent frontal headache, pallor, and weakness. He described about six similar episodes since an attack of chicken-pox a few months previously. There was some dyspnoea on exertion. For four weeks he had been coughing up moderate amounts of brownish-red sputum. Oral iron therapy had had no apparent effect on the pallor. He had four sisters and nine brothers, all well except a brother with pulmonary tuberculosis. There had been no previous illness of significance.

On examination he was quiet and intelligent, and gave a clear story. He was very pale and listless. There were

no signs of cardiac failure or jaundice, and no haemorrhagic manifestations. His tongue was normal. There were no enlarged lymph nodes and the spleen could not be felt, but a sharp rubbery liver edge was palpable 1 in. (2.5 cm.) below the costal margin. The pulse rate was 110 per minute and the blood pressure 120/80 mm. Hg. The heart and chest were normal, as was the central nervous system.

He was transfused immediately after admission to hospital. The haemoglobin level after transfusion was 9 g.%. This rose to 11 g.% after two weeks, and remained at this level until discharge one week later. No iron therapy was given at this time. The E.S.R. and the leucocyte count were normal. No urobilinogen was found in the urine.

The patient did not attend for observation, but was readmitted with severe anaemia six months after leaving hospital. Dark-red sputum was produced during most of the time between the admissions to hospital. There were no new physical signs. The haemoglobin value was 4.1 g.%. The red cells showed anisocytosis and were poorly filled with haemoglobin. The icteric index was 8 units, and no urobilinogen was found in the urine. A red-cell fragility test showed haemolysis from 0.56% to 0.32% saline, almost the same as a control.

After a week, treatment with oral iron was started and the haemoglobin level rose rapidly, reaching 12.4 g.% after four weeks, when the patient was discharged. During this period the chest was x-rayed, but no abnormality was reported. He remained completely free of symptoms from July, 1949, until December, 1953, a period of 4½ years.

In December, 1953, the cough with reddish-brown sputum returned. This attack lasted six weeks. There were several minor recurrences during the next few months. He began his national service in October, 1953, and at the end of April, 1954, he arrived in Singapore; the haemoptyses appeared again a few days later. After three weeks he reported sick and a radiograph of the chest showed miliary mottling of the lung fields.

On admission to hospital his only symptom was a mild frontal headache on exertion. Apart from a slight sternal depression no abnormalities were found on examination. The mucosae were of good colour and there was no cyanosis or jaundice. The mouth and tongue were normal. There was no finger-clubbing. No lymph nodes were enlarged, and the spleen and liver were not palpable.

Investigations.—Several blobs of dark-brown sputum with a little mucus were produced each day. On microscopy numerous macrophages containing haemosiderin granules were seen, and a very few red blood cells. No acid-fast bacilli were found on direct examination or culture of six specimens. X-ray examination of the chest showed a normal cardiac shadow, confirmed on screening. There was diffuse mottling throughout the lung fields, maximal in the middle zones. There was no suggestion of a clear centre in any of the markings. Blood picture: Hb, 14.5 g.%; red cells, 5,000,000 per c.mm.; P.C.V., 45%; E.S.R., 36 mm. in the first hour (Wintrobe). Absolute values: M.C.V., 90 cubic μ ; M.C.H., 29 γ ; M.C.H.C., 32%. Reticulocyte count, 2.5%; leucocyte count, normal; platelet count, 200,000 per c.mm.; bleeding-time, 2 minutes; clotting-time, 4 minutes; prothrombin time, 15 seconds (equal to control). Capillary fragility test, negative. The indirect Coombs test and trypsin cell test showed no antibodies. Cold agglutination was negative at 1 in 4. Red-cell fragility showed haemolysis from 0.52% to 0.28% saline. Blood W.R. and Kahn test were negative; serum bilirubin, 0.5 mg. per 100 ml. on two occasions; serum proteins, 7.5 g.% (albumin 5.5 g.%, globulin 2 g.%). An E.C.G. was normal. The urine was normal on repeated tests, and no urobilinogen was present. The Mantoux test was negative to 1 in 10,000, but positive to 1 in 1,000 O.T. X-ray films of the skull, hands, long bones, and abdomen were normal.

During three months' observation there has been little change in the clinical condition. Daily haemoptyses continue, but the haemoglobin has remained between 13.3 and

14.6 g.%. The reticulocyte count has varied from 2.5 to 0.7%. No iron has been given during this period.

On the first few days in hospital there was a mild evening pyrexia up to 100° F. (37.8° C.), but this quickly disappeared. Slight headache recurs from time to time.

Aetiology

The basic pathological process in idiopathic pulmonary haemosiderosis is repeated intrapulmonary haemorrhage, resulting in deposition of haemosiderin in the lungs.

Pulmonary haemosiderosis also occurs after prolonged pulmonary congestion in mitral stenosis and in chronic left ventricular failure (Lendrum, 1950), and the pathological effects on the lungs are similar to the idiopathic forms. According to Hastings-James (1952), haemosiderosis may follow any form of pulmonary haemorrhage repeated over long periods. In the idiopathic form, however, fresh blood in the sputum is most unusual. It is probable that in these cases haemorrhage occurs diffusely into the alveoli themselves, haemosiderin is formed, and is engulfed by macrophages before the material is produced as sputum. The mechanism differs from the secondary types of pulmonary haemosiderosis in which there is focal bleeding followed by widespread absorption of the pigment.

Three main causative factors have been postulated as the possible fundamental lesions in idiopathic pulmonary haemosiderosis:

Defects in Pulmonary Arterioles and Elastic Tissue.—The extensive changes in the elastic tissue of the lungs seen in most cases at necropsy suggested that a defect in the elastic fibres of the pulmonary arterioles might be the primary lesion in pulmonary haemosiderosis. However, the necropsy assessment of elastic tissue change is difficult owing to the varying effect of distension (Nancekievill, 1949), and it is possible that some of the appearances seen were due to distortion. In some cases with only a short history before death there is no evidence of defect in the elastic tissues. On the whole it appears that these changes are the result, rather than the cause, of haemosiderosis, and the degree of elastic-tissue damage is roughly proportional to the duration and intensity of the disease.

Functional Changes in Pulmonary Capillaries.—Even those cases with a short history and no change in the elastic tissues show capillary stasis at necropsy. It is possible that dilatation of the capillaries in the pulmonary interstitial tissue and changes in the permeability of the capillary walls may lead to diapedesis of red blood cells and subsequent haemosiderosis. Recurrent haemorrhages will initiate fibrosis and destruction of elastic tissue.

Haemolytic Anaemia.—The haematological picture is of recurrent loss of red blood cells in the absence of external haemorrhage, associated with a compensatory increase in erythropoiesis. There is no evidence of decreased stability of the red blood cells or of failure of the blood-clotting mechanism. Cold auto-agglutinins are present in some cases in the acute attack. Wyllie *et al.* (1948) suggest that this is a secondary antibody response to red blood cells destroyed within the body. A positive Coombs test has also been found on occasion. Few cases have been examined in detail for circulating haemolysins, but in one case the haemolytic activity of the serum at body temperature was increased (Wiesmann *et al.*, 1953), and in another the life span of the patient's red blood cells on transfusion was shorter than normal (Jonsson *et al.*, 1951). If a haemolytic process is responsible for idiopathic pulmonary haemosiderosis, it is difficult to see why the lesions should be restricted to the lungs, unless the physiological conditions in the pulmonary capillaries increase the activity of the haemolysin.

From the present evidence it seems most likely that the fundamental lesion in idiopathic pulmonary haemosiderosis is a change in permeability of the pulmonary capillaries. This results in intrapulmonary bleeding, which produces fibrosis and elastic-tissue damage. Erythrocyte destruction within the body may cause the production of antibodies.

Discussion

The occurrence of idiopathic pulmonary haemosiderosis in adult life is rare. Kerley (1951) gives a brief description of five adult cases, and Cliff (1953) describes the case of a man who first had symptoms at the age of 20. After two acute attacks he was under observation for three years, and during this time had no symptoms or anaemia, but haemoptyses continued. This closely resembles the present case.

It seems likely, as Kerley (1951) suggests, that there is a mild form of the disease which persists for many years and may be found in young adults. These subjects may have typical recurrent attacks of severe anaemia in the later years of childhood or young adult life, and later settle down to a steady state with recurrent minor haemoptyses but no anaemia. Similar cases will probably be discovered more frequently with the increasing use of mass miniature radiography, and idiopathic pulmonary haemosiderosis must be considered in the differential diagnosis of miliary x-ray shadows in the chest of a symptomless young adult. Radiological changes may persist for several years after the anaemia and haemoptyses have disappeared. A diagnosis of Lederer's anaemia was made in the present case during the first acute attack. Some cases previously included in this group, which remained well after transfusion, may well be in fact idiopathic pulmonary haemosiderosis.

The diagnosis in the early stages is often difficult, as there may be no radiological changes at first. Walton and Williams (1951) found none for 18 months in their case, and in the patient described in the present article a chest x-ray film was reported as normal during the acute phase of the disease. Young people with anaemia of obscure origin should have sputum or gastric washings examined for macrophages containing haemosiderin. If x-ray changes are present lung puncture must be considered, to confirm the diagnosis. This is not without hazard, as the widespread destruction of elastic tissue that occurs greatly decreases the retractility of the lung, and may possibly prolong bleeding if a large vessel is damaged. It was thought to be inadvisable in the present case.

Summary

A case of idiopathic pulmonary haemosiderosis is described, and the aetiology of the condition is discussed.

The existence of a milder form of idiopathic pulmonary haemosiderosis in young adults is brought to notice.

It is suggested that the disease be more often considered in the differential diagnosis of miliary shadows in the chest x-ray film and of obscure anaemia in young people.

My thanks are due to Brigadier D. Bluett, O.B.E., for permission to publish this article.

The Ministry of Health has sent a memorandum to hospital authorities (H.M.(55)35) explaining that notifications of patients diagnosed in hospital as suffering from tuberculosis should usually be sent to the medical officer of health of the district in which the patient normally lives. Where, in the case of long-stay patients, the hospital itself can reasonably be regarded as the patient's place of residence, the notification should be sent to the medical officer of health of the district in which the hospital is situated.

A CASE OF LARGE DIVERTICULUM OF THE EUSTACHIAN TUBE

BY

MAHMOUD KAMAL MUFTIC, M.D., D.E.N.T.

AND

SALLAHEDDIN DERWISH LOUTFI, M.B., B.Ch.
D.E.R.

Middle Euphrat Hospital in Kuffa (Iraq)

Welin (1941a, 1941b, 1948) and Diamant (1941) have demonstrated, by lipiodol injection, the existence of small diverticula in the petrous part of the Eustachian tube, but no other diverticula in the bony portion have been described. The cartilaginous portion is closely related to the antero-medial aspect of the petrous part of temporal bone, and in radiographs is seen to project from the base of the skull. No diverticula have been reported in this portion of the tube. While stenosis of the pharyngeal orifice and hypertrophy of the pharyngeal tonsil might cause stasis in the pharyngeal part of the tube, this would hardly be sufficient to produce pouches in the cartilage; it would more probably lead to perforation of the drum or to the forcing of secretions into the attic or the mastoid cells. Diverticulum formation in the cartilaginous part must therefore be extremely rare, and it is for this reason that a large diverticulum at this site is reported.

Case Report

A man aged 27, with no relevant past history, began his present illness in December, 1953, without any previous malady except a severe coryza. It started with pain in the region of the angle of the left mandible and styloid process,

Lateral view of diverticulum after injection of lipiodol.

aggravated by clenching the jaw, and deafness in the left ear. Two weeks later a copious aural discharge compelled him to consult an otologist. After local and general treatment the discharge diminished slightly, but the pain remained. At that time he complained of crepitation and bubbling in his ear, especially after swallowing and mastication, deafness, and post-nasal discharge. The discharge was abundant at night, irrespective of the side on which he lay.

In September, 1954, we saw him for the first time. His left ear showed a small perforation of Shrapnell's membrane, a mucopurulent discharge, and granulations in the middle ear. The right ear, the nose, and the throat appeared normal. A plain radiograph showed slight opacity of the mastoid cells on the left side, but no abnormality of the petrous bone or the styloid process. Through the perforation 2 ml. of 40% lipiodol was injected, the patient reclining

on the opposite side while his head was rotated so as to fill the epitympanic cavities. A lateral radiograph (see Fig.) now showed retention of lipiodol in two air cells of the petrous bone and a large pouch directly below the base of the skull, in the position of the cartilaginous portion of the Eustachian tube. The lateral oblique view showed that the diverticulum projected postero-anteriorly, and that it was cylindrical in shape. Its volume was about 0.5 ml., and it arose from the lower part of the tube, 3-4 mm. from the pharyngeal opening.

Radical surgery was obviously indicated, and the operation was performed a few days later. With a Hautant transmastoidal approach, the antero-medial aspect of the tympanic cavity was exposed and the granulations were removed. The orifice and isthmus of the Eustachian tube were then enlarged, and the diverticulum was identified without difficulty. Its mucopurulent contents were aspirated and its walls curetted and cauterized. The wound was drained and closed, 250 mg. of oxytetracycline being left in the tympanic cavity. The drain was removed on the fifth day and the wound healed by first intention. The aural discharge dried up, and the pain, crepitation, and post-nasal discharge had all disappeared by the tenth day. The drum perforation was still under treatment at the time of writing, and had nearly closed.

Discussion

It seems most unlikely in this case that the pouch was congenital, as such anomalies are not found in cartilage. A more acceptable theory is that it was the result of degeneration and an inflammatory process secondary to obstruction of the pharyngeal orifice, the perforation of the drum being due to the same cause. Once the diverticulum had formed it became a focus of chronic infection, probably due to the most destructive organism of the middle ear, *Bacillus mucosus capsulatus*. The presence of previously existing air cells can be ruled out, as cartilage never contains them. The subacute course of the infection and the absence of calcification and caseous material in the cartilage are against a tuberculous origin. Once the diverticulum had been obliterated and normal drainage of the tube established, the symptoms disappeared.

Summary

A single large diverticulum of the cartilaginous portion of the Eustachian tube is described. This condition has apparently not been previously reported. The symptoms of pain, aural and post-nasal discharge, and crepitation in the ear were cured after surgical treatment. The aetiology of the condition is discussed.

Our thanks are due to the Director of the hospital, Dr. Abdoul Rassoul Haddad, for his encouragement and help during the preparation of this article.

MIGRAINE AS A SEQUEL TO INFECTION BY L. ICTEROHAEMORRHAGIAE

BY

J. B. ATKINS, B.M.

H.M. Medical Inspector of Mines, Cardiff

Of recent years migraine has been attributed to a bewildering assortment of causes, ranging from heredity (Friedman and Wilson, 1947), through allergy (Crowe, 1946), and personality (Alvarez, 1947), to the comprehensive list drawn up by von Storch (1947). The estimate of Scott (1941) that "much has been written and little has been established as to the aetiology of migraine" seems largely true to-day.

The following observations, which were made in the course of a follow-up study of former cases of Weil's disease in the South Wales coalfield (Atkins *et al.*, to be published), seem worthy of record even at the risk of further complicating the subject.

Method of Study

During 1953 all earlier cases of serologically proved Weil's disease which were known not to have been immediately fatal were traced. Fifty-eight such cases were known to have occurred in the area of the coalfield, but five of the patients were found to have left the area and three had died by 1953. Fifty cases therefore remained for study, and in all but one the specific agglutination reaction remained positive at a titre of 1 in 100 or more in 1953. Each man was questioned about his health both before and after his attack of Weil's disease and clinically examined; in addition to general questions designed to elicit anything thought worth mention by the patient, the questionnaire included specific questions about various symptoms, one of which was headache.

Although estimates are available of the prevalence of migraine among the general population of the United States, it was thought worth while to make use of a control group of South Wales miners known to be serologically negative for *L. icterohaemorrhagiae*. These were also questioned about their experience of headache, and it is hoped that variation in the interpretation of answers, as well as in the definition of migraine, was avoided by the observer's use of similarly phrased questions for both groups.

The definition of migraine which has been adopted is based on that of von Storch, quoted by Marshall (1949). This requires that, to qualify as migrainous, headaches should be recurrent, though not necessarily hemispheric; and they should be accompanied by at least one of the following features: associated visual symptoms—classically scintillating scotomata; temporary gastro-intestinal symptoms—usually nausea or vomiting; or hereditary migraine diathesis, occasionally with an epileptic history. Since the follow-up study had not been designed to investigate the aetiology of migraine, information on the last alternative criterion of von Storch is not available. The diagnosis therefore rests here on a history of recurrent headache with either scotomata or gastro-intestinal disturbance, or both; it can perhaps be said that these criteria are thus more strict than those of von Storch. It may be that opportunity will later occur to study the hereditary factor.

Prevalence of Migraine

Among the 50 men in the control series, 6 (12%) described headaches satisfying the above criteria. This represents a prevalence greater than was to be expected from estimates in America (Scott, 1941; Friedman and Wilson, 1947), where about 7% of the population are said to be affected—the more so as females are said to be two or three times as

often affected as males, and the control series here comprised males only. This point may be borne in mind when considering the prevalence observed in the former cases of Weil's disease.

Among the latter there were 24 men who suffered from migraine by the same criteria—a prevalence of 48%, or nearly half the cases. This difference of prevalence in former cases of Weil's disease and the controls is highly significant ($\chi^2 = 15.4$, $n = 1$, $P < 0.001$). It is clear that had comparison been made with American estimates of prevalence among the general population, instead of with the control series, the prevalence among former cases of Weil's disease would have seemed even more striking.

The prevalence of migraine among former cases of Weil's disease of different ages at the time of their infection is shown in Table I. As the period elapsing since infection might also have influenced the prevalence of migraine, these cases are also broken down into their quinquennia of infection.

TABLE I.—Age at Infection with *L. icterohaemorrhagiae*, and Date of Infection by Quinquennia, of Men in South Wales Surviving Attack. (Numbers Subject to Migraine in Parentheses)

Ages	1935-9	1940-4	1945-9	1950-	Total
11-20	—	—	3 (2)	1 (1)	4 (3)
21-30	5 (3)	5 (3)	3 (1)	1 (1)	14 (8)
31-40	5 (1)	2 (1)	5 (3)	1	13 (5)
41-50	3 (1)	6 (3)	3 (1)	1	13 (5)
51-60	—	2 (2)	4 (1)	—	6 (3)
Total	13 (5)	15 (9)	18 (8)	4 (2)	50 (24)

It will be seen that migraine occurs fairly evenly among these different categories, there being no tendency for a rising prevalence with age. This fact is of importance in establishing the validity of the control series; for this was unavoidably deficient in men above the age of 50, and contained a disproportionate number of middle-aged men (Table II). It seems likely that this lack of correspondence in age composition of the two series has not overestimated the difference in prevalence of migraine between them.

TABLE II.—Ages, in 1953, of Former Cases of Weil's Disease and of Controls. (Numbers Subject to Migraine Shown in Parentheses)

Age	Former Cases	Controls
11-20	1 (1)	0 (0)
21-30	4 (3)	6 (1)
31-40	10 (5)	17 (1)
41-50	12 (5)	22 (3)
51-60	13 (6)	5 (1)
61-70	10 (4)	0 (0)
Total	50 (24)	50 (6)

As might be expected, both the frequency and the severity of attacks were described in most of the former cases of Weil's disease as diminishing with the passage of years, the course of the disorder being similar to that generally seen in ordinary migraine sufferers. On the other hand, as mentioned above, it originated in those of 45 and over nearly as frequently as in those infected at an earlier age.

Among the 24 cases in the Weil's disease group there were 4 individuals whose migraine preceded their infection. The influence of this infection upon established migraine varied, but only one man described aggravation. Subtracting these cases, it will be seen that migraine appeared in 20 cases (40% of those infected) as a sequel to this specific infection, and during convalescence in most cases.

Least suggestion between one case and another might have led to distortion of histories, upon which alone the diagnosis of migraine must be made, care was taken to keep the men separate at the time of interview. Moreover, since Weil's disease had occurred mainly in relatively closed communities, it was possible to analyse results for each of these geographical groups separately. The results of such analysis show

similar prevalence of migraine in each of the four main widely separated areas of the coalfield where cases have occurred.

Allied Vasomotor Disturbances

In view of modern concepts of migraine as a localized cerebral vasomotor disturbance allied to Ménière's disease (Atkinson, 1943) it may be of interest to record the following observations.

Among the 50 men there were eight who described giddy attacks dating from their infection, but none had associated tinnitus or gross deafness for conversational speech. Only one of these had a diastolic blood pressure of over 100 mm. Hg (mean of three readings at rest). All but two of them were migraine sufferers, though the precise chronological relationship between headaches and giddiness was not investigated. Vertigo was thus associated with headache in a quarter of the cases of migraine.

No cases of epilepsy or its equivalents were found among the 50 cases, nor was a family history of such forthcoming in any of them.

In six cases there was complaint of numbness, tingling, and clumsiness of the fingers and hands, often on waking, and usually more severe in cold weather, since the specific infection; but facilities for proper investigation of these phenomena were lacking. A further patient complained of frequent attacks of "cramp" in the legs and hands since his infection.

Significant hypertension, as judged by a mean resting diastolic pressure of over 100 mm. Hg (there were no cases with signs of failure), was found in 6 of the 24 migraine sufferers. Of these, four were over 50 years of age and the youngest was aged 39 at the time of examination. Among the 26 free from migraine only two had significant hypertension. In addition, before this follow-up study was begun, one former patient had died of a stroke at the age of 65, another of cardiac failure following hypertension aged 52, but it is not known whether either of these men suffered from migraine during life.

Discussion

Such a prevalence of hypertension in men of these ages might be found perhaps in 50 men drawn from the general population. However, this finding of hypertension in a quarter of the cases of migraine may be in accord with the views of Gardner *et al.* (1940) that migraine sufferers may become hypertensive in middle life.

The finding of so large a number of cases of migraine among this series, small as it was, does seem to indicate a probable causal relationship between infection with *L. icterohaemorrhagiae* and migraine. There exist other areas of Britain where this infection is not uncommon, and which offer opportunity for confirmation of this point.

It seems that, if such a causal relationship is established, existing views of the aetiology of migraine may need some modification. Such specific infection is not mentioned in the comprehensive list of causes drawn up by von Storch (1947), nor in the secondary "trigger mechanisms" listed by Friedman and Wilson (1947). Moreover, the latter's insistence upon a primary inherited susceptibility to migraine would appear untenable in the face of such a prevalence as the 48% reported above, even though family histories have been neglected in this study.

It seems possible that migraine may result from the meningitis which is so often a feature of infection with *L. icterohaemorrhagiae*. This would account for the occurrence of vasomotor disturbances in other regions, if those were also established as a significant sequel to the infection. It may be that follow-up investigation of other types of meningeal infection would throw light on this possibility.

The onset of migraine regardless of age in this series underlines the possibility of this diagnosis being correct even in those presenting symptoms late in life. In areas where infection with *L. icterohaemorrhagiae* occurs it would certainly seem wise to test the appropriate agglutination reac-

tions before submitting the patient to such procedures as cerebral arteriography.

Summary

The health of 50 men who had formerly been infected with *L. icterohaemorrhagiae* has been studied.

The prevalence among them of cases of hypertension, and of symptoms suggesting various types of vasomotor disturbance, is recorded. Of these former cases of Weil's disease 48% suffered from migraine. In a control group the prevalence of this disorder was 12%. The difference is of high statistical significance.

The literature on the aetiology of migraine is briefly reviewed and discussed in the light of these findings.

Thanks are due to the miners who so readily co-operated in this study; and to Dr. J. C. Broom, of the Wellcome Research Laboratories, and Dr. R. W. S. Harvey, of the Public Health Laboratories, Cardiff, for performing agglutination reactions in these cases and, with Dr. C. R. E. Freezer, of Church Village Hospital, for help in planning the follow-up of them.

Medical Memoranda

Thyroid Enlargement and the Crico-thyroid Muscle

The importance of the crico-thyroid muscle has not been stressed in any textbook dealing with diseases of the thyroid gland and the operations carried out for the cure of these diseases. The muscle takes origin from the anterior part of the cricoid cartilage and runs upwards and backwards in two parts—an oblique part inserted into the lower border of the thyroid cartilage in front of the oblique line, and the horizontal part inserted into the inferior cornu and the lower border behind the oblique line. The nerve supply is the external branch of the superior laryngeal nerve, which comes from the vagus. The nerve runs superficial to the inferior constrictor of the pharynx but deep to the sterno-thyroid muscle; both these muscles are attached to the oblique line on the thyroid cartilage. The diagram makes these details clear.

- 1, Crico-thyroid muscle.
2, Superior laryngeal nerve.
3, Internal laryngeal nerve.
4, External laryngeal nerve.
5, Inferior constrictor muscle.
6, Sterno-thyroid muscle.
7, Oblique line.

The function of the crico-thyroid muscle is to tense the vocal cords. Damage to the muscle or its nerve will produce a voice which is incapable of varying its pitch. It can be described as a monotone voice at about F, middle register.

The patients complain that they are unable to sing or alter the pitch of the voice; also, the voice gets tired easily. It is not

husky, but is slightly tremulous. There is no difficulty in breathing. The trouble can arise before any operation on the thyroid gland, especially in a very large thyroid with an isthmus spreading out over the cricoid and lower part of the thyroid, from direct pressure on the muscle or its nerve. The muscle or nerve may be damaged, or even removed, during the freeing of a large isthmus from the underlying structures. There is a third possibility—that the nerve or muscle may be strangled by fibrous tissue following operation, especially if a clot under the infrahyoid muscle has been allowed to organize.

The treatment of a pre-operative case is careful partial thyroidectomy, to give the muscle or nerve a chance of recovering. There is no useful treatment for a post-operative case. From the above remarks it is clear that before partial thyroidectomy the patient's voice should be carefully studied, and if abnormal an examination by a competent laryngologist should be carried out. I feel that when confronted with the crico-thyroid syndrome after operation many surgeons with a limited experience of thyroid surgery have wrongly assumed that the recurrent nerve has been damaged.

Two patients of mine illustrate the mild trouble resulting from crico-thyroid inefficiency. Both had a very large thyroid, with a husky voice, and had some difficulty in breathing. One was a school mistress in a primary school, the other a local manager of an insurance company. After partial thyroidectomy the latter had complete restoration of his voice, while the first had a crico-thyroid syndrome four years later. She has some difficulty in talking to her classes for more than half an hour, but she agrees with me that lectures and talks lasting more than half an hour are rarely appreciated by the audience.

Many people in this country are incapable of altering the pitch of the voice; also many have no appreciation of pitch alteration in a voice or musical instrument. It seems that the former suffer from some congenital trouble in the crico-thyroid, just as the latter suffer from internal ear trouble.

Consulting Surgeon, Cardiff United Hospitals.

Ruptured Uterus with Survival of Extrauterine Twin

The following unusual case is thought to be worthy of record.

CASE REPORT

A native woman was admitted to the Zomba African Hospital at 5 p.m. on October 17, 1952. She stated that she had been in labour 32 hours. About midnight on the 16th-17th, during strong contractions with no advance, the pains seemed to cease, being replaced by a continuous pain in the abdomen, especially in the flanks. She was a slim woman in the early thirties, a 2-para. There had been no trouble with the previous labours, although the babies had been large.

On admission she was seen by the sister, who reported that urine had been passed just before examination. The sister carried out a vaginal examination. The vulva was oedematous. What appeared to be a rectocele could be seen in the vaginal orifice. The vertex was felt in mid-cavity. No os could be felt, but the head seemed to be covered by a layer of tissue almost corresponding to a thin well-taken-up cervix. The sister thought this membrane to be part of the "rectocele," although she could not understand why she was unable to pass her fingers between it and the head at a higher level. There was no vaginal bleeding.

The patient was seen by me an hour later. She was ill, but her condition was fair and she was not unduly shocked. The abdomen was distended and tender. There was a visible tumour rising above the pubes, so resembling a distended bladder that I could not accept the African midwife's assurance that the patient had again passed urine, and catheterized her myself. The catheter entered easily, with-

drawing a little urine with no effect on the tumour. It thus became evident that this was the uterus. Above it, foetal parts lay immediately under the abdominal wall. Ruptured uterus was confidently diagnosed, no further vaginal examination being performed. In view of the prominence of the uterus and absence of external bleeding it was expected that the body of the child had passed out of a posterior rent, leaving the head jammed in the pelvis.

After anti-shock therapy, and with intravenous saline running, the abdomen was opened. There was a moderate amount of blood in the peritoneal cavity. A transverse anterior tear of the lower segment of a well-contracted uterus was seen with a T extension through the cervix into the vagina. A small full-term dead foetus was removed from the abdomen complete with placenta and membranes. It was then noticed that there was a large tumour behind the uterus responsible for pushing it forward. This proved to be the back of a second child lying in the occipito-anterior position with the head well down in the pelvis, in an apparently unruptured amnion. The amnion was slit and the child delivered. To our amazement it was alive and cried immediately. The membranes had to be peeled from the rectosigmoid, the left broad ligament, posterior surface of the uterus, the sides of the pelvic cavity, and coils of small intestine, within a mass of fibrinous peritoneal adhesions. The placenta, however, was not adherent. Its amniotic surface was normal, but the decidua surface was covered over by a membrane except along a narrow pedicle, not more than 3 cm. wide, through which the vessels ran into its substance.

It is to be regretted that the origin of the pedicle was not accurately noted owing to the presence of oozing and the necessity for haste. The impression was that it arose from the mesosigmoid, but it may have been from the region of the left broad ligament, which is more likely. It was the only impediment to easy removal of the placenta. Subtotal hysterectomy was performed, with repair of the cervix and vaginal vault. The patient stood the operation well. One pint (570 ml.) of blood was given next morning, and she made a smooth recovery. The baby, a female, was normal in all respects and weighed 5 lb. 2 oz. (2.3 kg.). It was seen at intervals up to three months after leaving hospital and was thriving. Thereafter, as commonly happens in African practice, mother and child were lost sight of.

COMMENT

The probable course of events was that the twin, surviving from a tubal rupture, developed with the head in the pelvis. When labour began, its head prevented entry into the pelvis of the presenting part of the intrauterine twin, with consequent rupture of the overstretched anterior aspect of the lower segment. The abnormal appearance of the placenta of the extrauterine gestation is difficult to explain, except on the basis that at the time of tubal rupture the decidua contact of the foetus with the tube was not entirely lost, and as it grew the placenta was gradually drawn out from the tube *pari passu* with repair and reperitonization of the rent, the process also continuing over the decidua surface, finally forming a pedicle of the remaining contact.

It is a remarkable coincidence that two days later another full-time extrauterine child was delivered alive in this small hospital dealing with about 500 births in a year and with no previous records of such an occurrence. In this case the mother was unfortunately lost owing to severe persistent bleeding from the placental site as a result of possibly unwise separation of its attachments to the viscera, from the shock of which she failed to recover. The infant was a female weighing 4 lb. 2 oz. (1.9 kg.) also without obvious abnormality. It was also thriving on discharge from hospital.

This report is published by permission of the Director of Medical Services, Nyasaland.

Lately Senior Surgical Specialist, Nyasaland.

Reviews

REPRINTING OF A CLASSIC

Atlas of Congenital Cardiac Disease. By Maude E. Abbott, B.A., M.D., F.R.C.P. (Canada). (Pp. 62+x; illustrated. \$5.) New York: American Heart Association. 1936, reprinted August, 1954.

This reprinting of Maude Abbott's well-known monograph will bring great joy to many. When this book was reviewed in these pages on its first appearance in 1936 it was stated that it "must be included among the few modern medical publications destined to become classics." This prediction has proved to be amply justified, for it has been almost impossible to obtain a copy, and many first-class libraries have also been without one. The American Heart Association is to be congratulated, not only on its action in publishing this facsimile, but on the excellence and accuracy of its production. Everyone interested in congenital heart disease from its present manifold aspects will now be able to acquire a copy, and libraries will be able to correct their deficiency. However, those who want the book will have to hurry, as only 1,500 copies have been printed. One would have thought that several times this number will be needed, and we must hope that other impressions will follow.

The *Atlas* is, as is well known, based on a study and analysis of 1,000 cases of congenital heart disease, its statistical analysis being often quoted. It contains an excellent presentation of the development and comparative anatomy of the heart as a basis for the clinical and morbid anatomical presentations, which are profusely and well illustrated, even for to-day with our better radiography and electrocardiography and the revelations of angiocardiology. It is a pity that the author was never able to do what she states in the preface was her intention—namely, to produce a further volume.

The book has only one drawback—its large, awkward size, which makes it difficult to handle and very difficult to find shelf room for. It would have been so much better if it had originally been produced only half the size. No change, of course, was possible in this facsimile.

RUSSELL BROCK.

ENZYME ACTION

A Symposium on the Mechanism of Enzyme Action. Sponsored by the McCollum-Pratt Institute of the Johns Hopkins University. Edited by William D. McElroy and Bentley Glass. (Pp. 819+xvi; illustrated. 88s.) Baltimore: Johns Hopkins Press. 1954.

This volume records the proceedings of a symposium held at the Johns Hopkins University in June, 1953. The papers, with a record of the relevant discussions, are grouped into five main sections: I. Protein configuration and biological activity. II. Kinetics of enzyme-catalysed reactions. III. The function of metals in enzyme catalysis. IV. The mechanism of electron and hydrogen transport. V. The function of enzymes in group transfer. As is natural, Section V is the longest, taking up rather more than one-third of the whole volume. The book concludes with a masterly summary by Bentley Glass of the facts and ideas discussed, which amounts to 65 pages (approximately 8%).

In a hydrolytic reaction the elements of water are added across a chemical linkage to produce its fission. In group-transfer reactions an organic molecule plays the role of the water in a hydrolytic reaction, and as a result synthetic process of great importance can occur. In such group-transfer reactions the enzyme molecule itself enters as a reactant, apparently with the function of preserving energy that might otherwise be lost during the chemical exchanges. The reactions to be studied in detail are therefore often somewhat complex, but an excellent account of most of them is given in Section V of this book.

The book will appeal to the expert, and for the expert it is extremely readable—indeed, absorbingly so. Dr. Fritz

Lipmann, Nobel Laureate in Medicine, puts forward an interestingly new idea about the possible mechanism of protein biosynthesis, a subject of first-rate importance in the study of tissue growth. The accounts of the discussions are good, and are occasionally longer and possibly more interesting than some of the papers themselves.

The volume is well produced, and an adequate index greatly enhances its value. This book of 819 pages, formidable to the non-expert in its size and content, is an indication of the exuberance of biochemical research in the United States—an exuberance which gives birth to an ephemeral volume of such impressiveness. That such exuberance must assist directly or indirectly in the elucidation of many outstanding problems in medicine cannot seriously be doubted.

F. G. YOUNG.

DISEASES OF THE SPLEEN

La Rate et ses Maladies. By Gabriel Gelin. Preface by Professeur Agrégé Jean Bernard. (Pp. 299; illustrated. 2,200 fr.) Paris: Masson et Cie. 1954.

This book on the spleen and its diseases is one of a series by different authors, published by Masson, which now includes "The Spleen as a Reservoir" (1930), "Functional Exploration of the Spleen" (1933), "The Spleen in Haematological Pathology" (1936), "Splenic Puncture" (1936), and "Hypersplenism" (1953). Apart from the work of Barcroft and Knisely on the splenic circulation, no fundamental discoveries in the physiology and pathology of the spleen have been made over this period, and the preoccupation of the French school of haematology with the spleen is to be explained by the frequency of various forms of tropical splenomegaly in their North African possessions and by the occurrence of Cooley's anaemia, with its characteristic splenomegaly, throughout the Mediterranean basin.

The approach of these various monographs is clinical and morbid-anatomical rather than experimental or quantitative, and the present book consists of a series of essays or reviews, each chapter being complete in itself. The main subjects discussed are the structure and function of the spleen, hypersplenism, the parasitic splenomegalies, tuberculosis of the spleen, myeloid metaplasia of the spleen, Gaucher's and Niemann-Pick's diseases, tumours of the spleen, and the various syndromes associated with hypertension and thrombophlebitis of the portal and splenic veins. The material is clearly presented and up to date. The feature of the book of particular value to English readers will be the bibliographies, which are of a richness unusual in French publications and which embrace the Continental as well as the Anglo-American literature. There are, in fact, over 2,300 references. As in many French books, there is a table of contents but no index.

L. J. WITTS.

PSYCHOPHYSIOLOGICAL MEDICINE

Psychophysiologic Medicine. By Eugene Ziskind, M.D. Foreword by John C. Whitehorn, M.D. (Pp. 370. 52s. 6d.) London: Henry Kimpton. 1954.

The application of the methods of medical science to the problems of psychiatry has meant much to the sick in mind, and it is now the turn of mental science to repay some of its debt to medicine by throwing light on those disorders which, while manifest in physical signs and symptoms, have their aetiology to a greater or less degree in psychological maladjustment. Psychological medicine, however, has developed a method of approach of its own which requires a considerable mental effort on the part of the physician if he is to learn enough of it to apply to the psychosomatic aspects of his practice. In order to do this he may have to reverse the process of specialization which threatens to restrict the field of interest of the general physician, and to study the human factors explored by his psychiatric colleague. Dr. Ziskind is an experienced teacher of clinical psychiatry who has maintained contact with the advancing front of medicine. He has paused in his life's work to

write what is, in effect, an intelligent physician's guide to psychological medicine.

Without pandering unduly to the busy doctor's demand for information which will produce quick results, he has tried to thin out the jungle of psychiatric literature and to preserve the more useful and permanent growths. In the first two parts he introduces the reader to simplified principles of psychopathology with which few but the followers of militant and exclusive schools of thought will quarrel. He then shows in some detail how psychiatric methods of clinical investigation can be applied to psychosomatic illness. This is followed by chapters on differential diagnosis, social factors, psychotherapy, and on psychiatric emergencies.

After giving an account of the methods of psychiatry as applied to general medicine, the author proceeds, for the benefit of those whose interest he has aroused, to give a general review of psychological medicine which includes outlines of the contributions made by the principal schools. This section is thoroughly up-to-date and notably free from strong bias. There is also a sound guide to further reading which will be of value to those embarking on a fuller study of the subject. As the book proceeds, the fruits of the author's experience and teaching become evident, and his account of the simple adaptive mechanisms found in the medical patient is readable and clear. Finally he abandons the role of a reporter and ends with a critique of the evidence that certain diseases—asthma, peptic ulcer, essential hypertension, and ulcerative colitis—which have been rather freely labelled as psychosomatic, are in fact of this nature. Here careful arrangement of the conflicting testimony of the psychologizers who have overreached themselves contributes strongly to the author's argument that the evidence is in the main insufficient. This subject serves as a text upon which he bases an exposition of some of the loose thinking and plausible writing which have appeared since psychopathology has been trying to engorge and digest the general adaptation syndrome. It may be that Dr. Ziskind has found a formula for making applied psychology palatable to physicians.

The style of writing is a little bare and technical for British readers, and the pattern of medical practice in the Western United States a little unfamiliar, but the book gives a clarifying account of the psychosomatic approach. In a foreword Dr. Whitehorn, of the Johns Hopkins Hospital, whose own outlook is mainly psychoanalytic, indicates that the author's presentation of this subject may not be seriously irritating either to the busy physician or to the majority of psychiatrists. Rather long for continuous reading in the study, it is well designed for the night-stop bag or the bedside. The price is such that many physicians will prefer to borrow rather than to own this book.

ALEXANDER KENNEDY.

THE STORY OF INFECTIOUS DISEASES

Pomp and Pestilence. Infectious Disease, its Origins and Conquest. By Ronald Hare, M.D. (Pp. 224. 12s. 6d.) London: Victor Gollancz Ltd. 1954.

Medical history has no official status in the training of the doctor, and it is left to individual teachers to indicate, if they please, the great importance of disease on the course of human history, whether it be syphilis or apoplexy or madness in some powerful king or dictator, or great plagues destroying armies and civilizations.

Professor Hare's small book tells the story of the development of parasitic infections in man, and indicates the way in which some of the major pestilences—smallpox, typhus, plague, cholera, dysentery, and in our own time influenza—have had greater victories than kings or conquerors. He goes on to say how many of the infections have been overcome by community or individual effort, but ends on a pessimistic note regarding the effects of the control of infection in allowing growth of populations in backward countries more quickly than there will be the wherewithal to feed them.

The writing of medical history requires much general reading, and the author shows that he has delved well into the literature. He gives at the end various explanatory notes and numerous references for further reading. Let us hope that teachers of bacteriology and others will recommend this book to their students as being at least as important as the orthodox textbook.

R. CRUICKSHANK.

PRISONERS OF THE JAPANESE

Operation Rangoon Jail. By Colonel K. P. MacKenzie, R.A.M.C. (ret.). Foreword by Brigadier J. G. Smyth, V.C., M.C., M.P. (Pp. 201; illustrated. 15s.) London: Christopher Johnson. 1954.

"War," as General Sherman once said, "is hell," and one of its worst manifestations is imprisonment at the mercy of a sadistic enemy. Colonel MacKenzie, who was over 50 at the time, suffered this fate in Rangoon jail at the hands of the Japanese, and he has here set down the plain tale of his sufferings. It is a moving story. Deprived of every amenity, half starved, forced to do menial work though physically unfit, punished brutally for trivialities—in fact, treated as outcasts—Colonel MacKenzie and his 500 fellow-prisoners kept up their morale through three long years and finally won through. On the Colonel's fifty-fifth birthday the Scots in the party organized a parade and inspection in his honour—a magnificent effort. The Colonel addressed them in a humorous manner: "I have never seen a finer body of men. You haven't a decent pair of boots or socks amongst you. I have reason to believe, however, that this is not altogether your fault."

The author can be scathing, as when he comments on the fact that his guardians in Rangoon aped the European, but succeeded only in "being a tenth-rate caricature of a third-rate Continental comedian giving an impression of an Englishman."

The Japanese in Rangoon did not recognize the Geneva Convention, and no Red Cross parcels came through to the prisoners. Even worse was their attempt to break the spirit of their prisoners. In a memorandum given to each prisoner occurred this passage: "Though you might think it enough to lay down your arms, we should never admit those who are not obedient in their thoughts or spirit as a true surrender." Colonel MacKenzie writes, "Perhaps this work of mine will cause some to think again." It has caused at least one person to do so.

ZACHARY COPE.

HAEMATOLOGICAL TECHNIQUE

Haematological Technique for Medical Laboratory Technicians and Medical Students. By F. M. Darmady, M.A., M.D. (Camb.), F.R.C.P., and S. G. T. Davenport, F.I.M.L.T. (Pp. 197+viii; 4 coloured plates, 25 figures. 18s.) London: J. and A. Churchill, Ltd. 1954.

This book was written "for medical laboratory technicians and medical students," but satisfies the needs of neither. The description of technique is too sketchy for the proper training of technicians; for example, the three pages devoted to various methods of visual haemoglobinometry by dilution methods give no description of matching technique. A fourth page describes the expensive and relatively inaccurate M.R.C. grey-wedge photometer, yet there is no description of the photoelectric methods that are the routine in most laboratories. Blood grouping, which constitutes half the work of haematological laboratories, is not mentioned at all.

The sections on clinical haematology are perhaps adequate for technicians—although much space is given to rarities—but are quite inadequate for medical students, who should be taught to think primarily in terms of the whole patient, not of laboratory findings.

Besides some grave errors of fact (iron absorption is ascribed to the gastric mucosa) the book contains a number of errors in technical procedures, suggesting careless revision of the text.

MARTIN HYNES.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 23 1955

VACCINE AGAINST POLIOMYELITIS

Seldom has an item of scientific news aroused such intense and universal interest as last week's announcement of the successful outcome of the field trials with a poliomyelitis vaccine developed by Dr. Jonas E. Salk and his staff at the University of Michigan. The results, assessed under the expert guidance of Dr. Thomas Francis, jun., were released by the National Foundation for Infantile Paralysis to coincide with the tenth anniversary of the death of President Roosevelt and have been acclaimed as an outstanding achievement. The complete report is not yet available, and only limited accounts have appeared in Britain.¹

Ten years ago there seemed to be little prospect of immunization against poliomyelitis in the immediate future. Previous attempts in the 1930s with vaccines prepared from monkey nervous tissue were abandoned as unsafe.² But latterly the whole outlook changed and a new era in poliomyelitis research started. Four salient points previously reviewed in this *Journal*³⁻⁴ are worth emphasizing now. First and foremost came the discovery by J. F. Enders, T. F. Weller, and F. C. Robbins that poliomyelitis virus could be grown in tissue culture of non-nervous tissue and with it a complete change in experimental methods and outlook.⁵ Secondly, the existence of three distinct strains of virus was definitely established.⁶ In the same year I. M. Morgan showed that in vaccinated monkeys resistance could be correlated with the level of serum antibody.⁷ And lastly it became increasingly clear that the old idea of poliomyelitis as a neurotropic infection was no longer tenable. Following the work of D. M. Horstmann

and others⁸ and D. Bodian,⁹ a new concept of the pathogenesis developed with viraemia as an essential precursor to infection of the central nervous system. On this basis it seemed logical to prevent paralysis by stimulating the production of antibody in the blood stream.

Rapid progress was made in tissue-culture methods.¹⁰ It became clear that high concentrations of virus could be produced in tissue cultures of monkey kidney in a simple medium with a low protein content. Salk developed an experimental vaccine containing a mineral-oil adjuvant, and with it some degree of immunogenic activity was established.¹¹ A number of changes were made before the vaccine used last year was completed. The mineral-oil adjuvant was omitted and the process of inactivation with formaldehyde was changed.¹²⁻¹³ A team of Canadian and British scientists played a substantial part in the preparation of this vaccine at the Connaught Laboratories in Toronto, where methods of mass production had been worked out.¹⁴ The crude vaccine containing live virus was shipped to the U.S.A., where it was inactivated and tested. A leading member of the Anglo-Canadian team is now in charge of vaccine production by a pharmaceutical firm in Britain.

In the U.S.A. field trials last year 440,000 school-children in forty-four States were vaccinated, the children receiving three injections of 1.0 ml. vaccine over a period of five weeks. About half as many were injected with 1.0 ml. of the uninfected culture fluid; a further 1,830,000 schoolchildren served as additional controls.¹⁵ The final figures are not yet available, but Dr. Francis is reported to have stated that the vaccine had proved to be 80-90% effective in preventing paralytic poliomyelitis.¹⁶

Unquestionably this is a tremendous achievement and will become a landmark in preventive medicine. But at the same time it would be unfortunate if, in the first burst of enthusiasm, it was thought to be the final answer to poliomyelitis. Last year's trial established two main facts: the formolized vaccine was safe, and it produced an immune response. What has not been established yet, for obvious reasons, is the duration of the immunity. The question arises whether immunity produced in this way will interfere with reinfection, the natural method by which immunity is maintained, and, if not, how often booster inoculations will be necessary. The possibility of toxic effects from repeated injections with monkey tissue must be considered. Many problems on the general effect of formolized vaccine still remain unanswered, such as improved methods of preparation, quantitative assay, and the timing of vaccinations. At the same time research must go on with alternative

methods of developing an attenuated poliomyelitis vaccine along the lines suggested by A. B. Sabin¹⁷ and H. J. Cox.¹⁸ P. Lépine, of the Pasteur Institute, Paris, has also developed a vaccine which is soon to be tested,¹⁹ and a description of the vaccine manufactured by the Behringwerke in Marburg has already been published.²⁰

These are some of the points being studied in Great Britain. In 1954 the Medical Research Council appointed a committee of experts to advise on laboratory research, and valuable assistance in this direction has been given by the National Fund for Poliomyelitis Research. Vaccination centres have been established in which the serological response in children will be studied. A number of vaccines will be used, including those produced in Britain, attention being paid to the immune response in children from different age groups, with variation in the timing of the three injections. A follow-up of some of these children will be made so that the antibody levels can be studied over a long period. These are important questions, well suited to British research methods; they should be answered before mass immunization is attempted.

HOSPITAL CROSS-INFECTION

Twice in the last twenty years a well-founded hope that the prevention of sepsis could be achieved has been disappointed. For some years the sulphonamides served well for not only the treatment but the prevention of haemolytic streptococcal infections, but during the war resistant strains began to appear on which these compounds had no effect. The advent of penicillin did indeed solve this particular problem, because the haemolytic streptococcus cannot develop resistance to this antibiotic, and has been so suppressed by its use that hospital epidemics of this infection are now almost unknown.¹ It is remarkable that the once most dangerous form of communicable sepsis should now be the most trivial in its consequences if treated in any reasonable way. But penicillin was also confidently expected to deal equally effectively with staphylococci, and at first it did so: now it often fails for this purpose, as may most of the other antibiotics which have followed it. Staphylococci are among the most resourceful of all bacteria: they can acquire resistance to almost any chemotherapeutic agent, and they have a great capacity for epidemic spread and for prolonged survival in any closed environment.

After the use of penicillin had been general for some years it began to be recognized that strains

resistant to it had become established in hospitals, and particularly in surgical and maternity units. A majority of the staff of such units became nasal carriers of a resistant strain, which was sometimes transmitted to patients, causing infections which were usually, but not always, of minor severity. So much more attention has been concentrated lately on this form of cross-infection than in the past that we may be seeing things which escaped attention before, but it is at least a tenable proposition that minor staphylococcal sepsis is actually commoner than it used to be, in spite both of antibiotics and of improved aseptic technique. This is the conclusion reached by Howe,² who gives figures for the incidence of sepsis, usually staphylococcal, in clean operation wounds in the general wards of the Massachusetts Memorial Hospital. Between 1949 and 1953 there was a steady rise from 1.99 to 7.22%, and Howe suggests that these resistant strains—a small and highly selected fraction of the staphylococcal population of ten or more years ago—may be endowed with an epidemic propensity greater than that of the sensitive strains whose place they have taken. Whether or not the increase in such infections is real and general, the situation as seen by anyone who has studied it certainly gives no grounds for complacency.

Two papers in this issue of the *Journal* present the problem as seen in each of the two types of clinical unit in which staphylococcal cross-infection has been most troublesome. Drs. P. N. Edmunds, T. F. Elias-Jones, J. O. Forfar, and C. L. Balf describe at page 990 an epidemiological study pursued in three maternity hospitals in Edinburgh, and in the domiciliary practice of midwifery in that city. Nasal and vaginal swabs were taken from mothers on admission and eight days later, and eye and umbilical swabs from infants on the fourth and eighth day respectively. Pathogenic staphylococci recovered from these sources and from nasal swabs from the nursing staff, of whom slightly over half were carriers, were submitted to sensitivity tests to antibiotics and to a sulphonamide. The results of these tests were the basis for subdividing staphylococci into types. Although this method is not ideal, it serves two purposes at once, and two strains with clearly different sensitivities must be different in identity: the converse, of course, is not necessarily true. The percentages of babies in hospital whose eyes and umbilical stumps yielded pathogenic staphylococci were 35 and 40 respectively. The corresponding figures for those born at home were only 5 and 8.6, despite the fact that these families were attended by nurses from one of the hospitals. The antibiotic resistance patterns of the hospital babies' staphylococci corresponded with

those in the nurses, and bore no relation to those of organisms from mothers. The mothers, indeed, seem to have played a singularly passive role; they usually neither acquired the prevalent organism nor communicated to their babies such staphylococci as they possessed themselves. Actual infections in babies were fairly frequent but of a minor nature. The authors do not mention breast infections in mothers—a more serious manifestation of this form of sepsis which may develop either in the ward or after the mother has left it. The conclusion that babies acquire their staphylococci directly or indirectly from nurses seems inescapable, and accords with the results of earlier studies. What we need to know is why more than half of the staff of such a unit so often become nasal carriers of a staphylococcus which is usually resistant to penicillin. No complete answer to this question has yet been given.

The same problem as it affects a surgical unit—and one doing specialized work in which the liability to sepsis is exceptionally high—is discussed in the paper by Dr. E. J. L. Lowbury in the opening pages of this issue. A series of different applications has been used successively in the Burns Unit of the Birmingham Accident Hospital for the prevention of staphylococcal sepsis. Penicillin failed owing to the appearance of resistant strains, as in turn did chlor-tetracycline and erythromycin, although each succeeded for a time. Dibromopropamide and staphylococcal phage became useless for the same reason (the former was also locally toxic). The latest policy is to combine penicillin with another agent to which resistance is less readily developed, and the two chosen have been neomycin and "hibitane." Both combinations have greatly reduced the frequency of colonization of burns by staphylococci, and no strain resistant to either of the new agents has been recovered. Apparently resistance to hibi-tane cannot be induced, even *in vitro*: to neomycin it can, but the resistant variant is a small-colony form of reduced virulence which might well be eliminated *in vivo*. It is not clear how much of this success was attributable to the penicillin in the combined treatment, and the new agents might well be tried alone—as appears to have been contemplated—or themselves combined.

Dr. Lowbury also reviews at some length the general problem of the erection of barriers to the spread of bacteria in hospitals. There are several new methods available, mainly directed to air hygiene, and the positive pressure ventilation of operating theatres and of rooms used for dressings will no

doubt come to be regarded as essential. Nevertheless "it is now common knowledge that the classical methods for controlling cross-infection—barrier nursing, cubicle isolation, aseptic techniques—are quite inadequate for the exclusion of resistant staphylococci from susceptible sites of hospital patients." If the deductions of Howe, quoted earlier, are correct, it is then indeed true that "the dilemma of hospital infection has been complicated rather than solved by chemotherapy."

MEASLES

The graphs of infectious diseases published in this *Journal* have recently been showing a weekly incidence in England and Wales of between twenty and thirty thousand cases of measles: deaths in the 160 great towns of England have numbered not more than one or two per week. The figures for deaths and the figures for cases are not derived from the same sources or areas and a death rate based on them would be inaccurate, but it is obvious that the present epidemic is one of very low mortality and very high infectivity. This has been the pattern of the disease during the sulphonamide and antibiotic era, and, if mortality alone were considered, it might be concluded that the disease is no longer of great importance. But, especially in younger children, the illness is still often very acute and recovery may depend on skilled nursing and powerful drugs.

The diagnosis of measles in the eruptive stage is usually easy: Koplik's spots are almost always still present on the first day of the rash and frequently on the second day too; their recognition ends all doubts when the rash is a little atypical. Sometimes the rash on the first day is quite discrete and the individual macules are small and pink. If the cervical glands are slightly enlarged, as they often are in measles, the resemblance to rubella is close, and failure to recognize Koplik's spots at this stage is a frequent cause of mistaken diagnosis. By the second day these rashes change to the florid semi-confluent dusky rashes of measles and the diagnosis becomes obvious. A less common cause of difficulty at this stage is the scanty coarse rash sometimes seen in the more "septic" types of scarlet fever: there is little evidence of punctation, the rash consisting of fairly large macules, scanty on the trunk but more numerous on the limbs, especially around the elbows and knees. The fauces in these cases are usually acutely inflamed and covered with exudate, the tongue is stripped, and the cervical glands are

enlarged and tender. The diagnosis can usually be made on careful clinical examination, but sometimes a white-cell count is necessary. A polymorph leucocytosis will be found in scarlet fever; in measles the count is nearer normal, with an increase in Türk cells and a decrease in small lymphocytes. Croup is a common symptom in the pre-eruptive stage of measles, when it is so desirable to diagnose and isolate the case: Koplik's spots can usually be seen and the disease diagnosed two or three days before the rash appears.

Bronchopneumonia is the commonest complication. Its presence can scarcely be missed, but it is often diagnosed when not present, especially in the first day or two of the rash. A child at this stage may have a temperature of 103–105° F. (39.4–40.6° C.) and there may be some moist sounds in the chest. But most cases of measles have moist sounds in the chest in the eruptive stage, and often the early, rather alarming temperature falls to normal within twenty-four hours without any treatment. A child with bronchopneumonia is a very distressed child, with grunting respiration, often a little cyanosed, frequently very restless, sometimes with slight neck stiffness, often with twitchings. It is desirable to try to make an accurate diagnosis in these cases, often not easy, rather than to administer antibiotics to every case with a high temperature and a few moist sounds. Most cases of measles recover with no specific treatment. Haemolytic streptococci are common causes of the bronchopneumonia of measles, and penicillin should always be given first: one injection of 100,000 units followed by oral doses of 300,000 units every four hours will give therapeutic serum levels. The routine use of penicillin to prevent complications of measles has been recommended, but careful observation of the individual patient is sounder and certainly more economic practice. In ward or institutional outbreaks, where cross-infection with secondary organisms may be expected, some such routine may be justified.

Otitis media is a fairly common complication of measles. It should be looked for with the auriscope and treated in the early stage with sulphonamides or penicillin, when it will usually resolve. Prophylaxis by routine drugs has been advocated for this complication too, but there is little to justify it. Enteritis occasionally accompanies the eruptive stage of the disease, especially in babies. It is usually non-specific in character and subsides in a day or two; no antibiotic treatment should be given unless the condition fails to settle, and only then if a specific organism is isolated. Encephalitis is the rarest and

most serious complication: there is no specific therapy. Cortisone has been advocated, but no convincing results have been published. Gamma globulin has been given in large doses, but the results have been disappointing; nor has concentrated plasma injected intravenously given much benefit. The only reassuring feature is that often the prognosis is not so grave as the symptoms suggest, and apparently complete recovery may occur after several weeks of coma. Patients with the paralytic type, if they recover, usually do so completely.

Measles is an acute and sometimes a serious disease. The onset of complications should be detected by careful observation of the patient, and treatment prescribed early. Indiscriminate dosing with antibiotics for a disease capable of causing twenty thousand cases a week has nothing to recommend it.

HYPNOTISM

There will be a warm welcome among medical men and women for the report on the "Medical Use of Hypnotism" which was approved at last week's Council meeting of the British Medical Association (see *Supplement*, page 190). The subcommittee of the Psychological Medicine Group Committee of the B.M.A.—under the chairmanship of Professor T. Ferguson Rodger—is to be congratulated on producing not only a very readable report but also one which is much to the point. For the past hundred years there has been an abundance of evidence that psychological and physiological changes could be produced by hypnotism which were worth study on their own account, and also that such changes might be of great service in the treatment of patients. Nevertheless, the profession as a whole has kept aloof, and the feeling has persisted that hypnotism was not respectable. There were sufficient reasons why this should be so. The mechanism of hypnosis could not be satisfactorily explained by any current theory on either a psychological or a physiological basis, while the observations which could be made often partook of the startling and spectacular; the patients who would naturally be selected for hypnotic treatment would consist largely of those suffering from what were often regarded as "imaginary" ailments; the practitioners of the art included a large proportion of charlatans and showmen with whom medical men would dislike being associated; and, finally, the actual method of treatment seemed to entail an element of wilful deception—for example, in persuading the patient of something which was not yet true—which doctors would regard with some repugnance.

Nevertheless medical interest in hypnotism has returned again and again, especially when stimulated by the widespread occurrence of acute neurotic illness. Such a wave of interest developed after the first

world war, though not after the last war, presumably because other methods of treatment—such as continuous narcosis and drug-aided abreaction—served the same purpose as hypnotism. However, public recognition of the need to curb the use of hypnotism as a spectacle has once more turned the spotlight in that direction, and the B.M.A. properly decided that the time had come to redefine the medical attitude. If, as the subcommittee recommends, the use of hypnotism is to be confined to those who will be governed by medical standards and ethics, the way will be thrown open to doctors to give the subject the attention it deserves.

The report lays great stress on the need for research, and, first among the subheadings, mention is made of neurophysiological and psychological observation under controlled conditions. In the final paragraph it is recommended that work of this kind should be sponsored by university departments and research foundations. Both of these points are of cardinal importance. Hypnotism has its physiological and its psychological aspects, and its central problems lie in the nebulous and difficult border country between the two disciplinary fields. In its operation there appears to be an interaction of psyche and soma which it is impossible to explain, in any satisfying way, with the aid of current concepts. Fundamental scientific work will require, and will be likely to lead to, new ideas, which may well prove to be of a revolutionary kind. For these reasons it is greatly to be hoped that fully trained research workers will be attracted to the investigation of hypnotism, and that they will be provided with all the facilities they need. Work with animals, in which the phenomena of hypnotism can be observed in a relatively simple form, should not be neglected. It will only be when we know and understand a great deal more about hypnotism than we do now that we shall be able to make the best use of its therapeutic potentialities. Meanwhile, even with our present inadequate theoretical understanding, it should be fairly easy to carry out, as the report recommends, the statistical investigation of its uses in treatment. Anaesthesia is one of the most obvious and important fields of study; and another would be among such common though varied disorders as stammers and tics, migraine, disturbances of sleep, and so on. The report rightly rejects the idea of there being a special "gift" for hypnosis, but doctors will undoubtedly vary in their aptitude for this as for every other form of specialized work. Those who feel the call to use hypnotism in therapy, and have the opportunity to do so, will hardly object if scrutiny is made, by statistical methods, of the results they obtain.

In 1831 the French Royal Academy of Sciences affirmed their belief that with hypnotism a new field of physiological science had been opened up; and this view has now been reaffirmed. It is to be hoped that the scientists will at last make use of their opportunity, and find out just how much, or how little, this field contains.

THE DISEASED DISK

Clinical interest in the "disk syndrome" and the diagnosis of it have increased in recent years, yet it remains a subject of some mystery and unfamiliarity. We are told¹ that H. von Luschka observed posterior prolapse of the intervertebral disk so long ago as 1859, but it remained until G. Schmorl's detailed study² of the spine in routine necropsies in Dresden during 1927 to 1931 for any proper assessment of the nature and the frequency of pathological lesions in these structures. Schmorl's work, part of which was also described by O. A. Beadle in a Medical Research Council report,³ established a number of different types of change in the contour of the intervertebral disk. When the bone tissue adjacent to its upper and lower surfaces becomes weakened, the disk tissue can expand diffusely, resulting in the "ballooned" intervertebral disk of advanced osteoporosis or osteomalacia. Under other—incompletely understood—circumstances, the nucleus pulposus may herniate through its fibrous capsule into the cancellous bone of the vertebral body; in fact in Schmorl's material this change (forming the lesions we now describe as "Schmorl's nodes") had occurred in 38% of adult spines. Finally, and of greatest clinical importance, posterior herniation of the nucleus pulposus into the spinal canal may occur. In Schmorl's series this posterior herniation was present in 15% of adult spines, and occurred most frequently in the lower dorsal and upper lumbar regions. These processes of diffuse expansion and herniation of the intervertebral disks result from the semi-fluid nature of the normal nucleus pulposus, the considerable compression to which these structures are subjected by the stresses of weight-bearing, and the osmotic factors⁴ which are responsible for their residual turgescence under resting conditions. Although intervertebral disks can undergo certain degenerative changes, including calcification, it is of interest that they can become herniated without any histological abnormality being present—or even developing—in the herniated tissue.

While Schmorl's studies were progressing, clinical awareness was developing of the sensory and motor changes resulting from compression of nerve roots by the same posterior herniation of intervertebral disk tissue into the spinal canal. The accounts of W. E. Dandy⁵ and of W. J. Mixter and J. S. Barr⁶ were illuminating, though back in 1911 G. S. Middleton and J. H. Teacher⁷ had described a case where paraplegia had resulted from "rupture" of an intervertebral disk during muscular effort. It became apparent that the

"cartilaginous" masses sometimes observed at operation in the spinal canal were prolapsed intervertebral disk tissue and not tumours, and that clinical symptoms of sciatica from nerve root compression were commonly produced by such lesions in the lower lumbar region. More recently it has become clear from the work of B. Stookey⁸ and of others that symptoms referable to the arm and neck are occasionally produced by lesions in the cervical region of the spine. From the absence of clinical manifestations it would appear that the herniations observed by Schmorl and others in the dorsal and upper lumbar region do not usually produce nerve compression. The general accounts of J. R. Armstrong⁹ and of R. G. Spurling¹⁰ summarize the clinical aspects of the "lumbar disk syndrome" and discuss in some detail the problems of clinical recognition and treatment.

As to disk herniation in the cervical region, evidence has recently been brought forward in an important paper by W. G. P. Mair and P. Druckman¹¹ to confirm the idea that compression of the anterior spinal artery, with the secondary production of ischaemic damage in affected parts of the spinal cord, may play a large part in the production of symptoms. Such a mechanism is not possible in the lumbar region, where the clinically frequent sites of disk protrusion (L.4, L.5) are some distance caudal to the lower end of the spinal cord.

PORTAL VENOUS PRESSURE

By means of hepatic vein catheterization the portal venous pressure may be assessed indirectly. The technique is to block a hepatic vein by wedging the tip of the catheter into it and then to record the resulting pressure.¹ Investigations on man at laparotomy and on animals have shown that the pressure recorded in the blocked hepatic vein closely parallels that recorded directly in the portal vein.² The principle is similar to that used in assessing pulmonary venous pressure from measurements of the pressure in a blocked pulmonary arteriole—the so-called pulmonary capillary pressure.³

The pressure recorded in a blocked hepatic vein has been shown by this technique to be greater than normal in patients with cirrhosis of the liver, indicating the presence of portal hypertension.^{4,5} By this technique also it is possible to distinguish between intrahepatic portal hypertension in portal cirrhosis and extrahepatic portal hypertension resulting from portal venous thrombosis or congenital vascular anomalies, since in the extrahepatic group the blocked hepatic venous pressure is not raised. When vascular surgery for the relief of portal hypertension is considered, this test may therefore be of practical value in confirming the diagnosis of portal hypertension and in distinguishing the site of portal venous obstruction. It may also help in assessing the efficacy of the shunt after porto-caval anastomosis has been performed, if catheterization repeated after operation shows a significant fall in portal venous pressure.

MEDICINE ON TELEVISION

As the honorary secretaries of B.M.A. Divisions well know, it requires prodigious efforts to gather together more than two or three dozen doctors at a local meeting. Whether they would turn out in greater number to watch medical television programmes in a closed circuit remains to be seen. Meanwhile, such "telecasts" in the U.S.A. and Canada are drawing audiences of 20,000 doctors and upwards. Last week, for instance, Dr. Thomas Francis, jun., and Dr. Jonas Salk spoke about the new poliomyelitis vaccine (see p. 1016) on a television programme sponsored by the National Foundation for Infantile Paralysis. In 63 cities in North America medical audiences—comprising, it is reported,¹ 54,000 doctors—met in halls specially equipped to receive the programme, which, being transmitted in a closed circuit, could not be picked up on ordinary domestic television screens. Earlier this year "two of the world's greatest medical extravaganzas"² had already been staged, the first on the management of coronary thrombosis and the second on the management and elimination of streptococcal infections. The importance attached to these programmes can be judged from the fact that the first—produced and sponsored by Smith, Kline, and French under the aegis of the American Medical Association and local and State medical societies—was introduced to the medical profession by the President of the United States. The second closed-circuit transmission was sponsored jointly by the American Academy of General Practice and Wyeth Laboratories. Presumably the three programmes already produced this year will be the forerunners of many more, and perhaps of similar programmes in Britain. Commenting on the value of these "ethereal pageants" (or "videoclinics"), the *New England Journal of Medicine*³ takes a cautious line and wonders whether the money might not be better spent on other educational needs. While there may be a place for the occasional "super" production designed for an audience of thousands of doctors, the small medical meeting, with its free and easy atmosphere and often keen discussion, is certainly not to be despised either for its educational or for its social advantages.

The Queen has approved the appointment of Professor G. W. Pickering as Regius Professor of Medicine at Oxford. Professor Pickering has been director of the medical unit at St. Mary's Hospital, London, since 1939, and he will take up his new appointment next year.

The Council of the British Medical Association has approved a proposal to award the Gold Medal of the Association to Sir Henry Simpson Newland, a past-president of the Royal Australasian College of Surgeons and of the Federal Council of the B.M.A. in Australia, in recognition of his outstanding services to the Association and to the profession.

EMERGENCIES IN GENERAL PRACTICE

BARBITURATE AND ASPIRIN POISONING

BY

T. J. THOMSON, M.B., F.R.F.P.S., M.R.C.P.

AND

STANLEY ALSTEAD, M.D., F.R.C.P., F.R.F.P.S.

(From the Department of Materia Medica and Therapeutics, University of Glasgow, and Stobhill General Hospital, Glasgow)

The summons, "Come at once: Mr. Smith has poisoned himself," may be the prelude to a medical emergency. How to deal with it depends to a large extent on circumstances of time and place. For example, Mr. Smith is, in fact, an employee of a general hospital, and, being on duty when the incident occurred, he is already on his way to a well-staffed and well-equipped medical ward. On the other hand, Mr. Smith may be a crofter 20 miles from the doctor's house and 100 miles from the nearest hospital. Most cases of poisoning, however, are seen in town practices, and it is against this background that the general practitioner is called upon to deal with the emergency.

The management of such a patient is likely to make excessive demands on the time and resources of the doctor who has innumerable commitments. It is therefore in the best interests of all concerned that steps should be taken to have the patient removed to hospital if the journey is not likely to prejudice his chance of recovery. However, even if transfer is practicable, the immediate treatment given by the general practitioner is infinitely more important than anything that can be done some hours later.

If the patient survives it will often be because the doctor or the relatives did the right thing at the outset; if, in the hospital ward, elaborate methods of resuscitation are needed it may well be because the simple forms of treatment were neglected while the patient was still at home. The general management is the same in nearly all the common types of drug poisoning, including acute intoxication by barbiturates and aspirin.

Removal of the Poison

The relative who telephones for the doctor must be told how to give first aid. This consists in making the patient vomit. If the patient is conscious—even though drowsiness is developing—vomiting can nearly always be induced by boldly thrusting a finger down the patient's throat. The vomitus should be collected in a clean pail for examination later. After vomiting has occurred the patient should be made to drink two cupfuls of warm water and then digital stimulation of the fauces should be repeated. This simple procedure carried out three or four times is invaluable. It is much more rapid and reliable than the use of reflex emetics; among these are common salt (a dessertspoonful in a tumblerful of tepid water) and mustard (a teaspoonful mixed into a thin paste with cold water and then diluted with tepid water to make a tumblerful); ipecacuanha wine (tinct. ipecac. B.P.—a tablespoonful) is even less reliable, and salts of the heavy metals (copper sulphate, zinc sulphate, etc.) should not be used because they are likely to damage the stomach and may even poison the patient, especially when they fail to cause vomiting.

The most reliable of all the drugs used as emetics is apomorphine hydrochloride. It acts centrally, but it is apt to fail if the brain is depressed by narcotics and other drugs such as barbiturates and salicylates, and for this reason the

administration of this drug to the comatose patient is a waste of time. On first seeing the patient the doctor will decide whether it is worth while to give apomorphine. If there is reasonable likelihood of success—as judged by the degree of consciousness and the state of the corneal reflex—a dose of 6 mg. (1/10 gr.) should be given intravenously at once. It usually acts within two minutes, but if given subcutaneously it may take five minutes. Emesis is more likely to occur if the patient is sitting or standing, rather than lying down (B. Isaacs, personal communication). Occasionally circulatory collapse occurs following the use of apomorphine. Further, when vomiting is induced in a patient already ill from poisoning, special care is needed to prevent aspiration of vomitus. These, however, are hazards which must be accepted when dealing with this kind of emergency.

No matter what may be the outcome of treatment with emetics the stomach must be washed out. And even when it seems virtually certain that the poison has passed into the intestine gastric lavage should not be omitted; experience shows that when suicide is attempted by rapidly swallowing a large number of tablets, many of them may become impacted at the lower end of the oesophagus and remain there until they are removed by the physician—or by the pathologist at necropsy.

Gastric Lavage

It is reasonable to assume that when the general practitioner accepts responsibility for the treatment of a patient suffering from poisoning he has had considerable experience

of the routine procedure of washing out the stomach. The stomach tube proper (not to be confused with Ryle's tube), the glass connexion, the main length of rubber tubing, and the funnel are shown in the diagram. The total length of tubing should be about 5 ft. (1.5 m.) and its diameter rather less than $\frac{1}{2}$ in. (1 cm.). There should be two or three apertures in the side of the tube near the tip to minimize the risk of blocking by debris in the stomach. A suitable funnel which is readily available has a diameter of $4\frac{1}{2}$ in. (11.5 cm.). If the stomach tube is first dipped into water no other lubrication will be needed. The rounded end of the

Gastric lavage. Note position of the head.

rounded end of the tube is guided to the back of the pharynx, taking care to avoid the trachea, and is passed down the oesophagus. It is convenient to mark the tube 20 in. (50 cm.) from the tip: when this mark passes the lips it may be assumed that the free end of the tube is lying in the stomach an inch or two beyond the cardiac orifice. The doctor's poisons bag should also contain a smaller stomach tube and accessories suitable for use in children. The prone position of the patient minimizes the risk of inhalation of gastric contents in the event of regurgitation of fluid alongside the tube. About one gallon (4.5 litres) of tepid water is needed for lavage. In cases of barbiturate poisoning sodium bicarbonate should not be used, as it promotes conversion of insoluble barbiturates to their soluble sodium salts. The stomach is emptied repeatedly by siphonage. Not more than half a pint (300 ml.) should be poured into the funnel at a time, because large volumes of fluid rapidly entering the stomach tend to drive the gastric contents through the pylorus. The washings should be set aside for analysis. The biochemist's problem is made easier if the first few ounces of the vomitus or stomach washings is kept separate for examination; the rest of the material—much more bulky and dilute—can be sent in a separate vessel.

Before withdrawing the tube a solution of magnesium sulphate (two tablespoonfuls of the crystals in half a pint (300 ml.) of warm water) should be run into the stomach and left there. This hinders the absorption of water from the intestine, and if the toxæmia has not resulted in intestinal stasis a liquid motion may be passed within a couple of hours; bowel activity can be further assisted by giving a simple enema. Drastic purgation is undesirable because it exposes the patient to the hazards of dehydration; and where easily absorbed drugs are concerned purgation is unlikely to be an important method of elimination after the first few hours have elapsed.

General Supportive Measures

Once the poison has entered the body tissues there is little or nothing to be done to prevent its characteristic action. Nevertheless, much remains to be done for the unconscious patient: he requires food and water, otherwise there will be serious metabolic complications; he must be protected from bacteria which are capable of invading many parts of the body; and he must be saved, if possible, from the dangers which threaten life when the vital centres in the medulla are depressed, with consequent respiratory failure and signs of anoxia, and cardiovascular paresis with falling blood pressure. The services of experienced nurses are indispensable: the hygiene of the mouth, the skin, and the bladder calls for special care, and charting of all treatment is highly desirable. Recognition of these requirements underlines the importance of early admission to hospital. When this is impossible, the general practitioner is obliged to make such arrangements as may be practicable to provide some of the amenities of a hospital. The problems are complex, and in trying to solve them the close collaboration of the district nurse, the medical officer of health, and the ambulance service will be invaluable.

Four or five pints (2.5 litres) of fluid may be required daily. The intragastric drip is the best method for giving fluid and nourishment. With the patient in the supine position a Ryle's tube, lubricated with water, is directed into one nostril, pointing the tip backwards but not upwards. If it passes down the oesophagus, then when the single mark on the tube reaches the nostril the free end should be in the stomach. A few drops of water are passed through the tube to exclude the possibility that it is lying in the respiratory tract. After administering milk or other fluids the tube should be occluded with a spring clip, pressure forceps, or spigot and fixed to the side of the face with adhesive tape. If, however, intra-gastric administration is impracticable, fluid should be given parenterally—glucose solution (5%) or 5% glucose in normal saline intravenously. Water can be given by rectal drip. This method, however, is not unreservedly recommended: trouble may arise from block-

ing of the tube, or it may be pulled out inadvertently while the patient is being moved in the course of routine nursing care.

The daily intake of fluid varies according to such factors as the degree of dehydration and the activity of the skin, but the amount should suffice to ensure an adequate daily output of urine (say 1.5 litres). The onset of infection, especially at the bases of the lungs, must be anticipated by giving soluble penicillin intramuscularly—500,000 units followed by 100,000 units six-hourly. Incontinence of urine is inevitable and calls for the insertion of a self-retaining catheter; infection of the urinary tract, which almost invariably supervenes, necessitates the prophylactic administration of small doses of a sulphonamide—sulphadimidine 0.5 g. four-hourly injected through gastric drip tube.

Barbiturate Poisoning

In barbiturate poisoning respiratory failure is the chief danger. Serious prognostic signs are profound coma and the absence of poison in the gastric washings. Also, there may have been long delay in starting treatment. In such cases respiratory failure is almost certain to occur and this provides an urgent indication for transfer to hospital. The doctor should travel in the ambulance with the patient and be prepared to give artificial respiration *en route* if necessary. He should never leave the patient until his colleagues in the hospital have assumed responsibility; this is important, because in barbiturate poisoning respiratory failure often comes on suddenly.

In hospital the anaesthetist should be invited to supervise oxygen therapy and prepare appropriate apparatus to maintain a free airway and a satisfactory respiratory rhythm. Oxygen should be given without waiting for signs of anoxæmia, such as cyanosis of the extremities and the lobes of the ears. It is best administered by means of the B.L.B. mask or a special polythene bag at the rate of 6 to 8 litres a minute. If breathing becomes shallow artificial respiration must be started at once. The choice of method lies with the anaesthetist: bag ventilation of the lungs may be achieved manually or by a machine which ensures mechanical compression of the bag. The circumstances may warrant transferring the patient to the Drinker respirator and calling on a specially trained nursing staff. Artificial respiration and adequate oxygenation may maintain life until most of the barbiturate in the tissues has been either excreted or destroyed. The patient then gradually emerges from coma and normal breathing is resumed.

This phase of treatment, however, can often be shortened by giving analeptics. The two drugs most widely used are amphetamine sulphate and picrotoxin. Amphetamine sulphate is a safer drug than picrotoxin. The initial dose is 50 mg. intravenously, and this may be repeated after one hour if there is no obvious improvement—judged by recovery of the corneal reflex. If recovery is incomplete further doses of 25 mg. are given hourly. In severe cases a total dosage of 0.5 to 1 g. is not unusual. Picrotoxin is injected intravenously in 0.3% aqueous solution. The initial dose is 6 mg. (2 ml.), and this is followed by doses of 3 mg. (1 ml.) every three minutes until there is evidence of return of consciousness; but administration should not be pursued after slight twitching of the muscles occurs—for example, flickering of the eyelids. At this point caution is indicated: no more should be given for about 15 minutes, and then only if the twitching has ceased and the patient is relapsing into coma. If too much is injected there is a risk of causing convulsions, and these may be so persistent that intravenous injection of sodium thiopentone (0.1 to 0.5 g.) may be required to control them.

Interesting reports* have recently appeared on the actions of a new barbiturate antagonist called "NP 13" (β -methyl-ethylglutarimide), but it would be premature at the moment to offer an assessment of its value in general practice.

Aspirin Poisoning

The toxicity of aspirin is much less than that of the barbiturates. If the patient's stomach can be washed out within an hour of his swallowing the tablets the chances of serious constitutional upset are negligible. Absorption of a large quantity of aspirin usually produces an acidotic state with noisy hyperpnoea. This is easily identified as a sign of acute salicylism because of the other characteristic manifestations—tinnitus, deafness, congestion of the skin, sweating, mental confusion, and muscular twitchings.

The acidosis of aspirin poisoning is best treated by giving Ringer-lactate solution *B.P.* intravenously. One pint (570 ml.) can be given in the first hour, a second pint in the next two hours, and thereafter one pint every four hours. This relieves the acidosis without exposing the patient to the risk of developing alkalosis. At the same time, if the patient is co-operative and can tolerate fluids by mouth he should be encouraged to drink water, tea, and coffee. Two teaspoonfuls of baking soda, in divided doses, can be given during the first two or three hours of treatment.

"The Bleeder," by Dr. R. G. Macfarlane.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

THE FUNCTION OF HISTAMINE**REPORT OF A SYMPOSIUM IN LONDON**

On April 6 and 7 the Ciba Foundation held a symposium on histamine in honour of Sir Henry Dale, O.M., F.R.S., whose work with Laidlaw, and later Richards, laid the foundations of our knowledge of this substance. In conjunction with this symposium, on the preceding two days, April 4 and 5, the Physiological Society and the British Pharmacological Society held another symposium on histamine. This was at the Wellcome Foundation, London, and our correspondent's impressions of it are given below.

[FROM A SPECIAL CORRESPONDENT]

What is the function of histamine in man? No doubt the desire to find this out was one of the main reasons for the large attendance of scientists of different disciplines and from various countries at the recent symposium in London, arranged by the Physiological Society and the British Pharmacological Society.

Gastric Secretion

However, it is likely that most of the scientists were disappointed in their quest, for only C. F. CODE (Rochester) had sufficient of both knowledge and courage to claim for histamine a definite role in normal bodily function and to defend his claim against considerable criticism. Code holds that histamine is the normal direct stimulus for the secretion of gastric juice, and that all other stimuli—nervous or humoral—exert their effect by activating this histamine mechanism. His case is based on the local high concentrations of histamine found in the stomach and duodenum, on the presence of histamine in gastric juice in amounts closely correlated to the volume and acidity of the juice itself, and, of course, on the fact that injected histamine provokes gastric secretion. Support

for Code's conclusions was also to be found in the comments of R. A. GREGORY (Liverpool), who has shown that histamine potentiators will increase gastric secretion in response to a number of different stimuli.

Nerve Transmission and Vasomotor Control

No other definite claim for a physiological function of histamine was put forward. There was, on the other hand, quite a lot of evidence about what histamine does not do. U. S. VON EULER (Stockholm) drew attention to the large amounts of histamine found in some peripheral nerves, especially in post-ganglionic sympathetic nerves (adrenergic), but no explanation for its presence there was offered. Section of such nerves is followed sometimes, though not always, by a reduction in the histamine content of the organ they supply; but no experiments on the effect of tetanic stimulation of these nerves on their histamine content have been carried out. One is consequently unable to judge whether the histamine is actually present in the nerve fibres themselves or not, and, if it is so located, whether it plays a part in nervous transmission. R. F. WHELAN (Belfast), from studies of blood-flow under a variety of experimental conditions, came to the conclusion—based solely on evidence of resistance to block by antihistamines (always a doubtful criterion)—that there is no evidence that histamine plays any part in vasomotor control.

Allergy and Anaphylaxis

W. L. M. PERRY (London) discussed the role of histamine in skin allergies and thought that histamine was not involved in the direct pathway leading from the antigen-antibody reaction to the skin lesion. He suggested, however, that the fraction of skin histamine located in mast cells might have a defensive action in causing oedema and thus diluting and washing out foreign materials; and that the fact that large amounts of histamine in mast cells are found in the skins of only those animal species which do not easily form fixed-tissue antibodies in the skin might be because this histamine is a substitute for the antibody defence mechanism.

H. O. SCHILD (London) reviewed the role of histamine in anaphylaxis. Large amounts of histamine are known to be released during an anaphylactic reaction, both *in vivo* and *in vitro*; but Schild pointed out that other substances are also formed. This point was taken up by several others, notably by D. F. HAWKINS (London), who showed that, in anaphylaxis in the isolated smooth muscle of bronchi, a slow-reacting substance is released as well as histamine; and by W. E. BROCKLEHURST (London), whose demonstration of the release by the specific antigen of a similar substance from both sensitized guinea-pig lung and from human asthmatic lung was coupled with evidence of its power to contract human bronchial muscle. All these contributions suggest that histamine may not be the most important or the most direct cause of the symptoms of anaphylaxis and allergy in man; and Brocklehurst's work especially may have considerable importance in our understanding of the nature of asthma and the well-known failure of antihistamines in the treatment and prevention of asthmatic attacks.

Thus, on balance, there was a general concurrence of opinion that histamine is of less importance than previously thought in anaphylaxis and in allergies of various kinds; and that there is as yet no evidence that it has any physiological function in the peripheral nervous or vascular systems—a depressingly negative series of conclusions.

Patterns of Histamine Distribution

We may not have much idea why histamine is present in the body; we may know only an increasing number of things with which it appears to have little to do; we do know, however, a very considerable amount about where it is, how it gets there, and how it is released and excreted,

and it was in dealing with these aspects of the problem that this symposium was most successful. W. FELDBERG (London), in an opening review of the distribution of histamine in various species and various tissues, brought vague impression to vivid realization of the almost incredible diversity in the patterns of histamine distribution. Why should rabbit liver contain twenty or more times the concentration of histamine found in guinea-pig liver? Why should ox lung contain ten times more histamine than rat lung? Why should there be a high local concentration of histamine in the skin of the ear, nose, feet, and nipples of the guinea-pig? And why should rat skin have more than ten times the histamine content of guinea-pig skin? These are the questions that come spontaneously to mind, bringing with them no clear answer. Nearly all tissues contain some histamine, and the universal presence of small amounts does not occasion much speculation; its formation may well be associated with the metabolism of all types of cell. It is the strikingly high local concentrations, varying in locality from species to species, that cry out for a teleological explanation.

Role of the Mast Cell

G. B. WEST (Dundee) reminded us of the role of the mast cell. His work with Riley has established the extraordinary concentration of histamine in those cells (1 in 1,000 or more). Riley and West have demonstrated convincing correlations between tissue contents of histamine and of mast cells respectively, and offer this as one major factor in accounting for the diversity in histamine distribution. But, so long as the function of the mast cells themselves remains obscure, acceptance of these workers' views does not help in deciding the functional significance of the diversity. F. C. MACINTOSH (Montreal) continued the story of the location of histamine in the mast cells by reviewing the evidence which suggests that histamine is held in their characteristic metachromatic granules. These granules, which behave in many respects like mitochondria, can be separated by differential centrifugation, and histamine can be released from them by a variety of physiological and chemical stimuli, but not by specific antigens.

Since antigen-antibody reactions almost certainly do liberate histamine from intact mast cells, as pointed out for skin by W. L. M. PERRY, it may be that such reactions produce a change at the membrane of the mast cell, this change being responsible for the release of histamine from the granules. A similar mechanism for the release of histamine was postulated by B. N. HALPERN (Paris) to account for the action of the large-molecule histamine liberators (dextran and polyvinyl-pyrrolidone) which must produce their effects without entering tissue cells, the membrane of which would be wholly impermeable to them.

W. T. BERALDO (São Paulo) produced further evidence of the correlation between mast cell populations in tissues and their histamine contents before and after depletion by histamine liberators. He found one striking discrepancy, however, in the high local concentration of histamine found in the stomach and duodenum of the rat; this histamine is not released by histamine liberators and there are few mast cells in this region. It might be reasonable to suppose that this particular histamine is specifically concerned with gastric secretion.

Release of Histamine

W. D. M. PATON (London) reviewed the various classes of substance which release histamine and discussed possible mechanisms by which they might act. The list of substances known to release histamine is now formidable, and includes, apart from specific antigens, compounds which cause tissue damage, proteolytic enzymes, surface-active agents, large molecular compounds such as dextran, and dibasic and monobasic histamine liberators. J. L. MONGAR (London) described the various ways in which histamine-releasing activity can be estimated, and in this connexion

H. O. J. COLLIER (London) put forward some evidence to suggest that, in screening drugs for subsequent use in man, it is safer to test for histamine liberation by intradermal injection into a human volunteer than to rely on laboratory tests on animals.

M. ROCHA E SILVA (São Paulo) discussed the release of histamine by naturally occurring substances. He reviewed current thinking about anaphylatoxin and discussed the release of histamine by trypsin.

The whole question of the method or methods of release proved a controversial one. On the one hand, G. UNGAR (New York) presented his recent work on the activation of proteases by the antigen-antibody reaction, the resulting proteolytic activity going in parallel with histamine release, and C. G. HAINING (Birmingham) found that histamine release by dextran sulphate also ran parallel to protease activation. On the other hand, F. C. MCINTIRE (Chicago) pointed out that most tissue histamine could be released by boiling water, and all of it by cold extraction with basic lead acetate; trypsin did not release any additional histamine. McIntire considers that this is proof that the binding of histamine must be relatively loose and that the proteolytic activity cannot be necessary for its release. In view of the diversity of tissues and species which served as test objects this controversy may well be one of those in which there is much to be said on both sides.

Destruction of Histamine in the Body

The fate of histamine was another subject which provoked some controversial opinions. R. W. SCHAYER (Chicago), in reviewing his own recent and elegant experimental results, obtained using C^{14} -labelled histidine, showed that histamine is excreted in three forms. The first of them, he suggests, is the result of breakdown of histamine by diamino-oxidase to the riboside of imidazole acetic acid; the second, the result of breakdown by an unknown methylating enzyme, is methylimidazole acetic acid; and the third is free histamine mixed, perhaps, with N-methyl histamine. J. H. GADDUM (Edinburgh) disposed of acetyl-histamine, found in the urine sometimes in considerable quantities, as being of importance only in so far as it confused the picture of histamine metabolism as a whole.

G. KAHLSON (Lund) discussed the significance of histaminase in the body, and among other matters suggested that the exceptionally high histaminase content of the placenta is a defence mechanism to protect both the uterus and the foetus from histamine produced by the mother. E. A. ZELLER (Chicago) mentioned difficulties encountered in the nomenclature of the histamine-destroying enzymes, criticizing that used by R. KAPFELER-ADLER (Edinburgh), who did not, however, rise to the bait but dealt instead with the potentiating effect of oestrogens on histaminase activity, suggesting that determination of the latter might serve as a useful clinical test for hormonal imbalance in pregnancy.

Conclusion

One left with the feeling that, although there are still few known physiological functions of histamine, we are beginning to have a clearer idea of its dynamics and that perhaps further clarity in this respect may help to solve the teleological problem.

Sir HENRY DALE, who presided over the final session, confessed to embarrassment that a chance observation many years previously should have had such influence on the interests and endeavours of so many people. Few would agree that he has cause for embarrassment. All who attended must be grateful to him and to Dr. W. FELDBERG and Professor F. C. MACINTOSH, the chairmen of the two other sessions; to the Physiological Society and the British Pharmacological Society, who organized the symposium; and to the Wellcome Foundation, our most hospitable hosts for the occasion.

MEDICAL ASPECTS OF ATHLETICS

A meeting of the Harveian Society of London, with Mr. A. DICKSON WRIGHT presiding, was held on April 13 for a discussion on the medical aspects of athletics.

The Role of the Doctor

Sir ADOLPHE ABRAHAMS said that the criticism was made that the doctor could not be much of an authority on athletics because his preoccupation was with diseased not with healthy people. Superficially that was true, but only superficially. The doctor had played a great part in athletic training; he had rescued it from its extraordinary former state when athletes were advised to eat huge quantities of half-raw meat and to reduce their liquid consumption until they became dehydrated. As for injuries in athletics, in major injuries the general principles of surgery obtained, but minor injuries were a different matter. The athlete regarded himself as a privileged person. The ordinary patient might be satisfied to get away with a 10% disability, but the athlete expected complete restoration and in the shortest time. On the medical side much was said formerly about the dangers which schoolboys incurred by strenuous exercise and about the "athlete's heart." To-day he doubted whether any authority would agree that there was such a thing as a "strained heart" in the case of a healthy heart. A word should be said in warning against taking any violent exercise while in a pyrexial condition. In the case of poliomyelitis the danger was serious. All vital processes were affected by a rise in temperature—an engine worked best when hot—but there were dangers above a certain temperature limit. He had always protested against marathon races being run in the heat of the day.

In conclusion he paid a tribute to the work of British physiologists. Nearly 40 years ago Professor F. A. Bainbridge wrote his book on *The Physiology of Muscular Exercise*. It had been re-written and edited by others since then, but the basic principles there set out remained for all time. Such names as Joseph Barcroft, Martin Flack, A. V. Hill, and many others proved that this country was a pioneer in this field.

The Needs of the Runner

Dr. ROGER BANNISTER declared that athletes were essentially hypochondriacs, almost superstitious about health, and likely to consider themselves and their training methods much too seriously. These matters had been dealt with empirically in the past, and he did not think that physiology had yet got to the state at which it could make accurate predictions of a man's achievements. Dr. Bannister went on to speak in detail of three types of runners—the sprinter, the middle-distance runner, and the marathon runner. The sprinter was in a situation in which he was unable to make full use of the existing supplies of oxygen in the air, and was dependent on the extent of his lactic acid tolerance. His speed of movement was limited also by muscle viscosity, an innate property which could be influenced little, if at all, by training. The sprinter could by taking thought improve by a fraction his starting time and bring about an improved tolerance to some extent by practice, but an improvement of, say, 1% in his performance would barely be reflected in present methods of timing.

With middle-distance runners the problem was different. They could greatly improve their oxygen uptake by training. The oxygen uptake depended on many factors: cardiac output, ventilation rate, speed of diffusion in the lung, and the rate of oxygen uptake in the muscles themselves. If it were made possible for such a runner to breathe a higher percentage of oxygen there was no doubt that all distance records would be broken. Dr. Bannister showed diagrammatic curves which had been worked out to illustrate, in the example given, how subjects breathing

ordinary air reached breaking point within six or eight minutes, whereas others, subjected to the same strain but breathing a higher percentage of oxygen, were able to carry on for 16 minutes, and in some cases much longer. Whether it was practicable to breathe oxygen in high concentrations while running a race it was difficult to say. If it were, no middle-distance records would be beyond the runner's grasp, but whether this was desirable in what was after all only a sport was highly questionable.

The same phenomenon of oxygen lack was met with in mountain climbers, although there, of course, the trouble arose from deficiency of oxygen in the outside air. But in climbers at altitude the same mental changes and changes in vision and consciousness occurred as in distance runners. The problem of the distance runner was one of distribution of effort with a view to maximum economy. At certain parts of the race he might save oxygen and use it advantageously at others. As for the marathon runner, here the essential limiting factor might be not oxygen uptake but exhaustion of the carbohydrate reserves of the body. In conclusion Dr. Bannister said that the various physiological studies were undoubtedly a help to athletics, but the main thing was the athlete's enjoyment of his performance irrespective of the standard.

Dangerous Games

Sir ARTHUR PORRITT said that sport and medicine had always been linked together even from distant times, as was suggested by such hackneyed phrases as *Mens sana in corpore sano*. The problem of medicine in athletics was twofold. There was first the therapeutic problem, which had both its physical and its psychological components, and then the research problem, which was immensely stimulating. How many athletes in that company when running had had a "stitch," and who could explain it? What was the position of young women in regard to athletics from the gynaecological point of view? These and many other questions remained. In view of the number of people in this country who went in for some form of sport, sport medicine was as much a social service as industrial medicine. One had only to think of the vast number of work days and school days lost owing to injuries sustained in playing games. But the only people who took an interest in such matters were the insurance companies.

Games from the point of view of liability to injury fell into three categories: hazardous, medium risky, and safe. The most hazardous was rugby, 10% of whose players received injuries; the corresponding figure in soccer was 8%. Other hazardous sports were polo and lacrosse. Medium-risk sports included boxing and hockey. Safe sports were swimming, athletics, golf, tennis, and so forth, in which the players did not come into bodily contact. Sir Arthur Porritt concluded his remarks by describing the varied work of the sports doctor.

HUMAN REACTIONS TO DANGER

In an address to the Alfred Adler Medical Society on April 7 in London, Professor ALEXANDER KENNEDY, President of the Society, spoke on "Human Reactions to Danger." He described his observations on the effects of training on individuals already known to be capable of efficient performance under conditions of danger and stress, and their actual responses in the field.

It was always the hope of Science, he said, after the initial period of observation and record, to reduce a problem to as simple a form as possible and to put any preliminary conclusions to the test of experiment. Situations involving fear and danger were of particular interest to

Adlerians, as they represented the struggle to adapt to circumstance in its simplest form. In observing the natural experiments seen in time of war or where man chose to pit himself against the forces of nature in sport and in the pursuit of knowledge, it was essential to record events as they occurred, and not in terms of any preconceived theory. In studying psychological reactions and the subjective aspects of physiological changes it was necessary to minimize the effects of interpretation on the part both of the observed and of the observer. The hesitation to discuss fear and personal aims in warfare was at least as great as the inhibitions about descriptions of sexual matters in the normal citizen. In the constitutionally well-endowed, operating at their peak of efficiency, however, stress sometimes produced clear insights which were expressed in almost poetic language. The accounts given by trained observers of their own sensations and thoughts under stress were of value, if they retained their objectivity.

Professor Kennedy said that his work was based on the behaviour of individuals who had been examined in some detail previously, when not under stress. While most of the observations were made in time of war, he had found that the observation of athletes in training for major events also contributed useful material.

Survival Value of Fear

The general concept of danger and the emotion of fear had survival value. Foolhardiness was as pathological as neurotic breakdown. Individuals varied very greatly in their capacity to realize their full potential under stress, whether this was a matter of making the instantaneous decisions necessary in combat, or of straining the organism to a calculated degree of cardiac decompensation in athletics. Certain short-term mental mechanisms were employed to ensure, firstly that the individual prepared himself for danger, and secondly that under stress he simplified his mental operations in the interests of efficiency. Many of the features of breakdown showed as inefficient caricatures of these protective mechanisms.

The response to danger was a psychosomatic one in which the whole organism was involved, and variations in the individual response to the same situation were dependent on the previous make-up and on the efficiency of preparation. In both spheres there were alarm or short-term reactions and training or long-term reactions. Cannon had shown the way to understanding the immediate physiological responses, and Selye's work had great bearing on training and the building up of resistance to stress.

Professor Kennedy said that his own results indicated that the psychological responses showed a similar division into emergency and training responses. "Wind-up" or tension served a useful preparatory purpose, as did the mental mechanisms which concentrated the attention on essentials and allowed calculated risks to be taken instantly and without retrospect. He gave illustrations of the purpose of diversion, humour, anger, loyalty, and the reversion to simple and almost childish values in the interests of efficiency at the critical moments, and of the great vulnerability of the highly trained if compensatory mechanisms were upset by the unexpected. He also described the effects of drugs such as adrenaline, noradrenaline, amphetamines, and A.C.T.H. on the alarm and training reactions. Their actions had thrown a great deal of light on the optimum length of training as opposed to practice, on staleness in athletes, and on the relative place of thought and effort in preparation for stress.

Very simple theoretical conclusions could be drawn from these observations which, he thought, had a bearing on the more complicated stresses of adaptation to life and work in a civilized community. They might be of assistance in understanding the ways in which normal individuals adapted themselves to less acute stresses and how that adaptation might be threatened.

THE DOCTOR'S APPROACH TO PAINTING EXHIBITION OF THE MEDICAL ART SOCIETY

A professional artist reviews below the thirteenth exhibition* of paintings and drawings by members of the Medical Art Society.

This year's exhibition at Walker's Galleries shows the high standard of the Medical Art Society. The Society consists entirely of doctors who are also amateur painters, and it is interesting to see how painting is for them an escape from their daily lives. For instance, their professional life is largely concerned with people; yet these are almost wholly absent from the paintings. The subjects are generally remote rural scenes or deserted seascapes. Doctors work in houses or hospitals, but these pictures are mainly painted in the open air. There are few concerned with the objects and places of the doctor's work.

In general the paintings are objective and cheerful impressions of places visited in moments of relaxation. There is no hint of the anxieties of the everyday life of the doctor. This is strange, for the professional painter is often attracted to hospitals for material. Barbara Hepworth, for example, exhibited recently a collection of drawings of operations; and most painters are constantly using their immediate surroundings and the people near them as subjects for pictures.

As a profession, doctors have eyes trained to observe detail carefully, active and cultivated minds, and hands sensitive and deft. This is apparent in the paintings. The materials, whether oil, pastel, or water-colour, are skilfully handled; and observation is acute. Compositions are also well-planned, space and depth being admirably suggested.

Another interesting feature of the exhibition is that there is no apparent sign of influence by the dominant figures of contemporary painting. There seems to be no interest in the sources where Picasso and Klee, Sutherland and Moore, find their inspiration. The Medical Art Society seem to be escaping from the Atom Age and space travel in the same way as they are escaping from their clinics and operating theatres. This is not a wholly bad state, as it leaves the painter an open mind to record the facts in front of him without striving to fit them into a preconceived idiom—a fault so often found in the professional student of painting.

Landscapes and Still Life

The work in this exhibition is mostly a personal record of places, things, and people seen by the painter. Only occasionally is an echo of another painter's work to be found in such a picture as No. 37 by R. A. BEAVER (London), which reminds one a little of the work of Lowry, though Lowry's paintings have Midland industrial areas as their settings. R. A. Beaver has admirably adapted the style to portray a particular part of London. His other painting, *Cold Hampstead*, though different in style, also achieves this. Both are most interesting compositions.

No. 47, *Station Approach*, by A. B. HEWLETT (London), is also a painting that reminds one of another artist, in this case Charles Ginner, and the influence may be quite unconscious. The meticulous observation used by both painters excludes a feeling of light and shade and heightens the grey leaden atmosphere of this very English scene. To capture the character and "feel" of a particular scene is surely the object of all landscape painting; Claude and Turner were both masters in this way. A show of virtuosity in painting windswept clouds and sea foam can never compensate for a lack of atmosphere. That is why *South Downs*, No. 172, by R. OGIER WARD (London), is a good painting; it achieves the character of a particular place at a particular time and in this contains more than others which are executed with greater skill. Another painting

* The exhibition is on show at Walker's Galleries, 118, New Bond Street, London, until April 30 (hours 10 a.m. to 5 p.m.; Saturdays 10 a.m. to 1 p.m.).

which successfully creates a quite different atmosphere is No. 22, *Fortaleza de Sao Joao de Estoril*. FRANK FORTY (London) has achieved this by precisely opposite means to those used by A. B. Hewlett in No. 47. By selecting the minimum of shapes and colours and presenting them with complete simplicity, he obtains a feeling of sunlight and immense heat.

Three modest but successful landscapes are No. 43, *Amalfi*, and No. 52, *Yarmouth, Isle of Wight*, by D. N. MATTHEWS (London), and No. 65, *Barges on a Canal*, by C. VER HEYDEN DE LANCEY (Jersey). In No. 52 it is interesting to see how the painter has taken a mass of small boats and a large area of landscape and reduced them to a beautifully ordered composition.

The few still lifes differed greatly in character. No. 56, by NORMAN ASHTON (London), has its roots in Flemish painting. It shows an interest in the surface qualities of the different objects, which are skilfully represented. The cabbage was plainly a savoy. N. NEWMAN'S (London) interest in still life is quite different. It is in colour and form rather than surface texture. His painting, No. 82, has made full use of rich colour. Next to this painting is another still life by A. PHILLIPS (London); this has a most interesting composition and is sensitively handled.

In this exhibition of amateurs' paintings there are very few that are completely unsophisticated and unhampered by knowledge of academic painting. Exceptions are the three paintings by S. LEONARD SIMPSON (London), Nos. 85, 100, and 184, which have a directness of vision and are charmingly painted, especially No. 100, *Play Time*, which is really delightful.

Water-colours and Drawings

The water-colour paintings and the drawings are on the whole a little unadventurous, relying too much on the traditional and academic handling of this very difficult medium. No. 155, *St. Mawes, February*, by T. HOLMES SELLORS (London), and No. 149, *November in Barking Park*, by G. H. ROSE, are two paintings that use the medium well and imaginatively to express the season at which they were painted. No. 131, *Colherne Road*, by ISABEL WILSON (London), and No. 142, *From the Kitchen Window*, by CONSTANCE APPLETON (Inverness), are two other paintings fresh in technique and interesting in detail.

Among the drawings there are six portrait heads drawn with considerable skill. These are much more successful than the painted portraits. No. 116, by RENÉ MICHELMORE (London), has a fine feeling for the character of the little girl portrayed. The sculptured head in bronze, No. 19, by DAVID I. FINER (Kent), is also an accomplished piece of work having great solidity.

Final Impressions

The exhibition leaves one with the impression that, although the intelligence and skill of the medical profession can readily master the craft of painting, most doctors are reluctant to treat painting as more than a relaxation. If the painters had tried to communicate something of their special experience as doctors the exhibition could have had deeper significance.

And again, most doctors must be acquainted with art-therapy as used in tuberculosis and mental hospitals to reveal the buried thoughts and problems of their patients. It seems a little strange, therefore, that some of the exhibitors were not tempted to use the methods of art-therapy in their own painting.

A new half-yearly journal, *Veterinary Reviews and Annotations*, issued by the Commonwealth Bureau of Animal Health, Weybridge, has commenced publication. It consists of reviews of topical veterinary subjects and is obtainable from the Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks, price 25s. per annum. The first issue discusses intestinal diseases of young calves, parasites of poultry, and euthanasia for animals.

Correspondence

Management of Brain Abscess

SIR,—I felt sure that Mr. Walpole Lewin's article on this topic (*Journal*, March 12, p. 631) would provoke an otological protest about the route via which such abscesses should be approached, and my friend Maxwell Ellis (*Journal*, April 2, p. 848) has not disappointed me. It is perfectly true that in well-established cases where the brain abscess already is well localized simple drainage via the mastoid has often proved to be entirely satisfactory. But this presupposes a mastoidectomy, which may in fact not be needed in the early stage, if at all.

Otogenic brain abscess can arise in relation with acute or chronic otitis. In both cases the condition which may kill the patient is the intracranial complication, and this must take pride of place in regard to treatment. The underlying ear condition must have whatever treatment it merits, irrespective of the complication, but this should not be undertaken until the dangerous factor is controlled. In the acute case the chances are that adequate antibiotics will cure it without operation, or if operation be needed this can be done at leisure. In the chronic case otologists should not be stampeded into doing radical operations until the optimum moment, which will be determined by friendly consultation. We otologists should be invited to see these cases, and we should expect that our opinion on what should be done should carry weight, but in the last analysis our contribution should be secondary to that of the neurosurgeons.

If an otologist is faced with the possibility of doing something in a hurry for such patients miles away from neurosurgical help, he would do well to learn the simple technique of making a burrhole and needling the abscess. Close association with a neurosurgical unit for 18 years has made me realize that the best results are in fact obtained when the neurosurgeon operates through a clean field. Maxwell Ellis is fighting a gallant rearguard action, but I fancy he has reached the last ditch.—I am, etc.,

Oxford.

RONALD MACBETH.

Salicylates and Anticoagulant Therapy

SIR,—I was interested to read Dr. M. H. Singer's letter (*Journal*, April 2, p. 851). I would refer him to my paper on "Aspirin in the Treatment of Vascular Diseases," the correspondence preceding it, and a leading article¹ on the subject, all in the *Lancet*. There is also a paper by Lovibond² in the proceedings of the British Cardiac Society.

For the past five years aspirin in suspension has been used at the Torbay Hospital as a routine treatment for coronary thrombosis, pulmonary embolism, and thrombophlebitis. It is widely used in this area by many doctors who prefer it to the better-known anticoagulants for domiciliary use, for it is not only a safe anticoagulant but it often relieves anginal pain as effectively as nitroglycerol. I have not yet had time to assess the results during this five-year period, but I hope to do so shortly. The fact that so simple and ancient a remedy has maintained its popularity in this area for five years speaks well for its value.—I am, etc.,

Torquay.

PAUL C. GIBSON.

Doctors and the Press

SIR,—I had not intended to enter this correspondence, but the letter of Dr. Alfred Byrne, Medical Correspondent of the *Manchester Guardian* (*Journal*, March 26, p. 791), requires a certain amount of annotation, for it attempts to suggest that Press attention was of benefit to the mother of the Nigerian twins.

Before the operation on the children, and for a couple of weeks after it, their mother showed the greatest possible emotional disturbance at the very mention of the word reporter and insisted on not meeting any. Furthermore, at one point in this period she had to be persuaded not to withdraw her permission for operation and not to return to Africa with the children unseparated; discussion in the Press of the prognosis had led her to believe that the operation could not succeed. She was particularly upset not only at attempts to obtain unofficial photographs of the babies through the ward windows, but was even alarmed for the survivor's safety when the official flashlight photographs were taken. She particularly refused to receive those persistent representatives of certain Sunday newspapers who insisted on bargaining with each other in attempts to buy an "exclusive interview" for large sums of money. Mrs. Davies's permission for interview was not "forthcoming." After a couple of weeks had passed, when she was convalescent from her anxiety and grief, she was persuaded by me to attend an official interview with a representative number of reporters, and I have no doubt it was this occasion to which Dr. Byrne refers as "a lengthy interview." This interview was trying. Nevertheless, the mother of the twins, who is a gentle, kind, and courteous person with a short memory for evil things, told the collected reporters, when directly interrogated, that she had found them all nice except two. This exception number would have been much larger if she had not enjoyed special protection. On balance, Press attention was harmful to the mother of these children, and if access to her had been freer it might have been harmful in an extreme and long-standing degree.

The distribution of news to the Press had to be meagre rather than "adroit," because even before the children arrived in England their identity had been disclosed to the public. Intimate anatomical and pathological details cannot be supplied about an individual whose identity is known unless that individual or his or her guardian gives permission, which in this case was not obtainable. Dr. Byrne refers to the "large business house which had a finger in the pie." The use of this last term nearly always implies rancour, which in this connexion is not dissipated by Dr. Byrne's failure to mention that the company in question, the United Africa Company, had not only been officially responsible, without any wish for publicity or profit, for bringing the mother, the twins, and a nurse to England, but was regarded by the lady in question as her protector, and its Press representative her nearest friend, adviser, and confidant in this country. The Press representative of that company, Mr. Dennis Buckle, handled the whole situation extremely "adroitly" in my opinion, and the actions of the company were uniformly responsible, honourable, and humane.

Dr. Byrne mentions an article in a weekly magazine and appears to be resentful also about its appearance. I would refer him to the article again and he will find that no part, internal or external, of either baby appears in any part of the illustrations except for one picture which had already appeared in the public press; in the illustrations shown none of the doctors concerned could be identified by his closest friend; no fact appeared in the article which had not previously appeared, or at least been deducible from facts previously published, officially or unofficially, in the public press. Some of these facts had appeared exclusively in the *Manchester Guardian*.

The help of the Public Relations Officer of the British Medical Association, Mr. John Pringle, was refused in the case of the recent twins because the relatives of the twins had made secrecy an absolute condition. To my mind, if a doctor has given his word specifically not to disclose some particular secret he is not at liberty to disclose it in any circumstances. I think any man of honour would agree with this principle even in a non-medical connexion. Dr. Byrne quotes Mr. Pringle in writing that, if the help of the British Medical Association had been accepted, the two cases of the twins would "have had the courteous co-operation of all but the less reputable elements of the Press." The answer to this argument is implicit in the last six words. It is precisely the less reputable elements of the Press whose attention most people hope to escape. The only way to escape it is to achieve secrecy. Although we have since been told by a person of responsibility in newspaper work

that secrecy in such cases is unobtainable because of the wide network of paid Press informers throughout all the hospitals of the land, secrecy was in fact obtained in the case of the recent twins, at least for the period covering their investigation and operation.—I am, etc.,

London, W. 12.

IAN AIRD.

Winter Coughs

SIR,—Apropos of your leading article on winter coughs (*Journal*, March 12, p. 651) in which you rather tend to depreciate paregoric, may I remind you of your own annotation (*Journal*, September 30, 1944, p. 441) wherein you summarize the experimental results of some Canadian workers, which I in turn may sum up in brief by quoting Quincy's¹ opinion—that is, that opium procures a truce with the cough and so provides opportunity for the other ingredients to rarefy and thin the viscid cohesions in the vessels, etc.? Certainly Boyd and MacLachlan² show most clearly that paregoric, especially when matured by keeping, increases the respiratory tract secretion of experimental animals, in the case of albino rats by as much as 300%.—I am, etc.,

South Molton, Devon.

R. A. NASH.

Night Cramps

SIR,—Night cramps have, during the last few years, rather interested me, as I have seen about a dozen cases of this unfortunate complaint in general practice, and in each instance the patient has merely mentioned it *en passant*, as "one of those things." Quinine tablets have given relief in a number of cases, but in none have I found anything to compare with mephenesin elixir given last thing at night *in water*, since taken neat it does cause a burning sensation.

I have actually been able to experiment on my own family, since my wife had paralytic poliomyelitis four years ago and, although she has only very slight residual weakness in one leg, when she is tired this one leg is very liable to cramp at night especially when lying in certain positions. Mephenesin was given by me over a period of three months and the terrifying cramps were definitely improved. I also found that, if one can elicit which muscles are cramped, putting the limb in the opposite position by forcing it against the affected muscle—that is, flexing forcibly the leg at the knee when the quadriceps are in spasm—will break the attack. I have endeavoured to teach my patients a little basic anatomy so that they may gain relief from this manoeuvre should mephenesin not be 100% efficient.—I am, etc.,

London, W. 6.

DAVID JACKSON.

The Metric System

SIR,—We are all intellectually convinced that advantages would accrue if we could convert our system of weights and measures and our mental concepts to a metric system. Not everyone is convinced that the benefits would be worth the not inconsiderable effort of making the change. Clinicians all require to be familiar with both systems, but most people have two distinct mental compartments for things like body-weight, which are kept in the British unit compartment, and those like doses of sulphonamides, which live in the metric compartment. The two mental compartments are usually highly exclusive: any transference requires a complicated administrative process reminiscent of a civil service office. Who, for example, could quote the usual dose of sulphaguanidine in grains or his own height in metres without recourse to paper and pencil if not to a reference table?

One of the many ways in which this schizophrenic thinking inhibits good work is in prescribing fluid or electrolyte replacement. The tradition of ordering "a pint of 5% glucose-saline" or "a pint of blood and a pint of half-

strength saline" dies hard. It is based on rule-of-thumb therapy which clinicians have learned by experience to be appropriate in certain conditions, but it is rarely the result of logical thinking. The importance of reasonable precision in adjustment of body fluids is becoming increasingly apparent. Most who have some years of experience behind them can think back to patients whose death was probably due to imbalance of their internal body fluids. There is no doubt that the only satisfactory way to record concentrations of these ionic solutes of the body and the amounts lost in excreta and effluents is in milli-equivalents per litre. To calculate how much should be put back when transfusion solutions are marked in per cent by weight and in ounces and pints is most laborious; it is usually not attempted or is thrown back to the "lab. man." Let anyone who is in doubt calculate how many ounces of 5% sodium lactate and of half-strength saline are required to make good a deficit of 47 mEq. sodium and 32 mEq. chloride, and if he is still in doubt let him make the necessary adjustment if it is also necessary to give 15 mEq. potassium as KCl. If people could be persuaded to accept transfusion fluids marked in mEq./litre of each ion and the volumes in litres and half-litres the necessary calculation could be done mentally in ten seconds. The arithmetic required under the present system is such that the majority refuse to attempt it and continue to give fluid by "blind experience." There are those who would maintain that blind experience is an oxymoron and that they can get on well without milli-equivalents and analyses of body fluids; similar statements have been made about antiseptics, x-rays, and anaesthetic machines. There are many cases where plasma and urine analyses are unnecessary, but there are also many cases where they would have led to life-saving measures.

The obvious conclusion is to have transfusion fluids marked in both systems for the present. The intelligent use of such fluids would be greatly promoted, the not inconsiderable danger of mistakes in calculation would be eliminated, and lives would be saved.—I am, etc.,

Glasgow, C.4.

JAS. C. EATON.

Chicken-pox Quarantine

SIR,—Most of us will agree with Dr. M. Curwen (*Journal*, March 19, p. 727) and Dr. J. F. Warin (*Journal*, April 9, p. 908) that too much fuss is made about chicken-pox in schools. Certainly the adult with, for example, painful herpes ophthalmicus, complicated perhaps with iritis, may find it difficult to be grateful to the school doctor for the zeal with which he prevented him from acquiring immunity at the expense of a trivial illness involving a few days in bed. On the other hand, severe cases of chicken-pox do exceptionally occur, and if one were to connive at the infection of a child who subsequently developed chicken-pox complicated by encephalitis one would scarcely feel very happy about it nor would one's medico-legal position be very secure.

I agree that the segregation period for chicken-pox is also very much over-done. For many years in hospital I have worked on the assumption that as soon as the last lesion has well scabbed the risk of transmission is negligible, and it has so far never let me down. This period usually coincides with Dr. Warin's "five or six days after the appearance of the rash," though occasionally if there are several crops it may take a little longer.—I am, etc.,

Isleworth, Middlesex.

G. E. BREEN.

SIR,—Recent correspondence in the *Journal* on the subject of chicken-pox prompts me to report the following case.

On January 31, 1955, I was asked to see a girl of 8 years, whom I found to be suffering from chicken-pox. Her mother was on that actual date due for delivery of another child, and as she was quite positive that she had had the disease in infancy the arrangements made for home confinement were allowed to stand. The baby, a girl, was born spontaneously on February 2, but ten days later the

remaining child, a boy aged 2 years, developed typical chicken-pox. On February 17 the baby, now aged 15 days, developed a similar rash, which responded well to treatment with an ichthyol-calamine lotion, and had cleared away completely by early March.

From those textbooks which I have been able to consult I find that chicken-pox is a distinct rarity in the neonatal period. I would be interested to learn if any readers have seen other cases as young as mine.—I am, etc.,

Glasgow, N.2.

NEIL McDUGALL.

Ban on Heroin

SIR,—The relief of severe pain, especially in those dying of incurable malignant disease, is surely the moral duty of every doctor. If therefore heroin is required, as it certainly is, for those patients who have become resistant to the less potent analgesics, then no effort should be spared to ensure its legitimate supply, regardless of the administrative inconvenience it may cause a government.—I am, etc.,

Ipswich.

JAMES WIGDAHL.

SIR,—We were astonished to learn from Dr. A. H. Douthwaite's letter (*Journal*, April 9, p. 907) that the Government has decided to ban heroin. We would like to add our protest. Quite apart from the usefulness of the drug, it seems to us an intolerable interference with our liberties, which should not be borne by the medical profession without objection.—We are, etc.,

Winchester.

F. C. HEATLEY.
H. J. BLISS.
G. H. FISHER.

Hypodermic Injection Technique

SIR,—Being to-day mainly concerned with the immunization of young children against diphtheria and whooping-cough, I would like to comment on Dr. K. D. Salzmann's letter (*Journal*, April 9, p. 909). I have for a long time applied his principle without, I admit, defining, as he has so ably done, the factors responsible for its undoubted success. All my injections are given in the deltoid region, and the very great majority are subcutaneous. When inoculating babies and very young children, and especially when the victim insists on watching what is going on, I find that stroking the skin gently two or three times with the back of the needle before inserting the point often allays suspicion. Yet more important, having punctured the skin—the critical point in the operation—I hold the syringe absolutely still for a second or two before pressing the piston, using meanwhile every available device for distracting the child's attention. Incidentally, a slight protrusion and side-to-side movement of the tip of one's tongue will often so astonish the patient that a ml. more or less no longer matters. A No. 20 needle is an ideal weapon of attack; and it must be remembered that adsorbed antigens with a mineral carrier cause, *per se*, more pain on injection than do the newer suspended vaccines.—I am, etc.,

Cross-in-Hand, Sussex.

H. L. DUKE.

Hot-water Bottle Burns

SIR,—Yet another case of burning by hot-water bottles has been recorded in your columns (*Journal*, April 2, p. 856). It seems reasonable to call for a critical review of the use of hot-water bottles, at least in the care of the severely injured.

Recent work has shown that it is more important to prevent further loss of heat from a shocked patient than to add heat. When the circulation of the skin is depressed the heat added to it from without tends to accumulate and cause a rise in temperature which may reach locally lethal levels. Some years ago Sheehan¹ reported the case of a woman who died following obstetric shock. A hot-water bottle had been applied to her side, and although its temperature was not very high the underlying tissues, including the surface of the liver, were found at necropsy

to have been partly cooked. Even in a fully conscious patient the pain of a burn quickly passes away after the full thickness of the skin has been destroyed. If the burning agent remains after the pain has disappeared a very serious burn can result.

These facts leave no doubt that deliberate warming of patients should be completely abandoned and that reliance should be placed upon reducing loss of heat by careful wrapping in blankets; even in the freezing conditions of the Italian campaign during the war this was found adequate. The old campaigner's advice about having as many blankets under the patient as over is particularly important in this connexion.—I am, etc.,

Birmingham, 15.

Castration of Sex Offenders

SIR.—It is an axiom of moral philosophy that the moral law must be supreme. Expressed more explicitly, this means that if an action is condemned by the moral law then no reasoning, medical, sociological, or scientific, can justify that action.

A few years ago the Church of England Moral Welfare Council issued a booklet on sterilization,¹ in which it stated there appear to be no circumstances in which it would be legitimate for the State to exercise the right of punitive sterilization. The reasoning behind this statement is fully set out in the booklet. It further pointed out that as regards therapeutic sterilization properly so-called (to be distinguished from operations necessary to the welfare of the body as a whole which involve sterilization as an indirect effect—for example, hysterectomy), the rule is that an operation is only morally justified when it is the only means of securing the welfare of the body as a whole. In the cases quoted from the Danish experience, vasectomy or castration were not the only means of treating the delinquents.

As far as practising Anglicans are concerned, procedures such as the Danish castration one you commented on in your leading article (*Journal*, April 9, p. 897) can be of only academic interest.—I am, etc.,

Bath.

J. H. WHITTLES.

A Simple Method of Performing Bronchography

SIR,—Standard methods of bronchography are apt to cause great discomfort to the nervous patient, and the following method, dispensing almost entirely with local analgesia, has been carried out at the London Chest Hospital, Country Branch, in the past few months on a series of adults with excellent results. If the patients are producing copious sputum postural drainage is instituted under the guidance of a physiotherapist for several days prior to the investigation. As most of the patients have been tuberculous, with upper lobe bronchiectasis and little sputum, this has seldom been required. It has not been found necessary to provide antibiotic cover—for example, penicillin—and sensitivity tests have been discarded, as there is no release of iodine or iodides from the opaque medium used. Methylpentynol, two 250-mg. capsules, and atropine, 1/100 gr. (0.65 mg.), are given half an hour in advance, and have been satisfactory as a premedication.

The method of endotracheal intubation is used with the patient sitting up, and a Jacques No. 9 E.G. rubber catheter, smeared with 2% lignocaine ointment, is inserted into the right or left nostril according to patency. When it reaches the level of the posterior nares the patient is asked to put out his tongue, which is covered with a gauze swab. He is then instructed to pull his tongue forwards and downwards with either hand, and at the same time to protrude his chin forwards and slightly upwards. The catheter is slowly pushed onwards and the tip drops naturally into the larynx and trachea, causing a momentary tendency to cough, which soon passes. The basal and apical lower segments are filled by injecting 4–6 ml. of "dionosil oily" into the tube, after shaking the bottle, with the patient sitting up and leaning

backwards and to the side to be filled, and with the shoulders rotated towards the same side. The middle or lingular segments are filled with a further 3–5 ml. while the patient bends forward and to the side to be filled, with the opposite shoulder raised and tilted forwards. The upper lobe is filled with the patient lying on his side with the head supported on two pillows to prevent the medium from running backwards up the trachea, using another 6 ml. Each of these three positions is maintained for one minute. X-ray films are then taken in full inspiration with the patient recumbent in the lateral or oblique and antero-posterior positions. It has been customary with tuberculous patients only to carry out bronchograms on one side at a time.

It will be noted that no local analgesic, apart from the 2% lignocaine ointment smeared on the catheter, is used throughout the investigation, the latter being used mainly for its lubricant value. This reduces the time factor so that it is possible to complete the bronchogram in an average time of 15 minutes, including developing the films. Toxic reactions to local analgesia are thus avoided, and the patient is able to eat his next meal without fear of food going "down the wrong way." Careful spraying of local analgesic into the back of the mouth and into the larynx has been found to be time-consuming and completely unnecessary. Indeed, it provokes coughing and laryngeal spasm so that it may not be possible to pass the tube beyond the patient's cords at all, and adds considerably to his discomfort. With this method laryngeal irritation is avoided and the tube slips easily into the trachea in a matter of seconds. Also it is of such a diameter that it is unlikely to be coughed up.

Patients subjected to this method of bronchography, and who have had bronchograms by other methods, have all been impressed by the small amount of discomfort caused and by the speed of the investigation. I would like to thank Mr. L. H. Porter, Chief Radiographer at the London Chest Hospital, Country Branch, Arlesey, Beds, for his co-operation with me in this work.—I am, etc.,

Frimley, Hants.

JOHN C. BARKER.

Recovery from Chronic Lymphocytic Leukaemia

SIR,—May I add another case of 10-year recovery from lymphocytic leukaemia to those noted by Dr. Max Schott (*Journal*, April 9, p. 877)? In 1933 I was asked to see a well-known American aged 73 who was suffering from a mild attack of bronchitis. After a few days his general condition deteriorated and I noticed a few enlarged lymph nodes in various parts of his body. A blood count showed a typical lymphatic leukaemia. I told his wife a former nurse—that he was suffering from something more serious than bronchitis. She replied: "Oh, has his leukaemia come back?" She then told me that her husband had been desperately ill for many weeks in 1923 with leukaemia, and indeed had been ill for some six months before making a complete recovery. He was very ill for some weeks, under my care, but finally insisted on making the attempt to return home. He died at sea. On her return home his widow sent me the report on his 1923 illness, by Dr. Gutmann,¹ of New Brunswick.—I am, etc.,

Buxton.

F. A. BEARN.

Tropical Pulmonary Eosinophilia

SIR.—I have read Dr. James A. McFadzean's account (*Journal*, March 26, p. 771) with great interest, and wish to record my findings during 1943–4 at the Indian Military Hospital, Bangalore. During that period five cases of pulmonary eosinophilia were diagnosed and confirmed by the Army medical specialist. The signs and symptoms were as those described by Dr. McFadzean, and the x-ray findings in all cases were similar. The lungs showed a general woolly appearance, in fact one would mistake the x-ray for pulmonary tuberculosis. Treatment in those days was with N.A.B. and the response was very satisfactory, the whole condition clearing in about 12 weeks.

Two of the above cases were invalided from the Army, even though they showed great improvement, but psychological and malingering elements predominated, hence the reason for invaliding from the Army. The N.A.B. treatment was started at that time, as we had very good results

from N.A.B. in two cases of asthma. The course was bi-weekly injections starting with 0.15 g. and increasing to 0.45 g. The condition cleared, showing an x-ray of the lungs with clear fields, and W.B.C. within normal limits. In all cases the predominant signs were a very high W.B.C. count and the very typical x-ray findings.—I am, etc.,

Bagdad, Iraq.

Cancer Education

SIR,—The letters of Mr. Malcolm Donaldson and Dr. W. A. Ball (*Journal*, April 2, p. 849) criticizing our article (*Journal*, March 12, p. 627) call for brief replies. Mr. Donaldson is distressed by our "appalling" mistake in not mentioning and emphasizing "cancer." We admire his own pioneer work in the field of cancer education, and wish him all success. However, had we adopted his method our task would have been much more difficult than it was, and the problem of recalling patients for follow-up examination after doubtful or suspicious findings would in many cases have been insuperable. When the pioneers, such as Mr. Donaldson, have done their own important educational task on a really large scale, it may be possible to talk freely of cancer at medical overhauls. But that day has not yet come, at least in this district.

Dr. Ball's thesis, of a psychological-hormonal upset caused by our campaign and leading to an increase in cancer, is interesting, but not supported by figures. We have analysed the number of cancer cases in the practice (excluding the skin) over the last seven years, and there is no obvious effect of our campaign in the numbers recorded. In fact, there was a temporary increase that began six months before the outset of our investigation. It might well be that an intensive educational campaign would be accompanied by an increased incidence of recorded cancer, but this would more probably be accounted for by an ageing population, improvement in diagnosis and certification, etc. Such factors would at least have to be ruled out first.—We are, etc.,

J. WALTER.

Sheffield, 10.

E. C. ATKINSON.

Post-puerperal Recurrent Depression

SIR,—I have been interested in Dr. R. Greene's comments (*Journal*, April 9, p. 909) on my article (*Journal*, March 12, p. 637). It was not my intention to review the entire literature on the premenstrual tension syndrome. In the patients whom I described a state of chronic ill-health had existed since a childbirth some years earlier, with symptoms which were by no means confined to the premenstrual or ovulatory phases of the menstrual cycle. On the basis of the history I am much more inclined to look on these patients as suffering from a sequela of puerperal depression. The main practical point, however, is the profound alteration which has occurred at the puerperium in these women and which has persisted chronically. They and their families do not enjoy three weeks of normality every month as occurs in the premenstrual syndrome in its typical form. The history is so characteristic that I do feel most strongly that the post-puerperal group deserves separate consideration.

Dr. Greene and Dr. Dalton¹ have noted that, "in all cases in which the [premenstrual] syndrome had existed before pregnancy, the attacks occurred with increased severity at the first menstruation after childbirth . . . 15 dated the onset of regular attacks from childbirth. In severe cases, childbirth was followed by increasing weight and lethargy in addition to the premenstrual syndrome" (my italics). Clearly I should have referred to these observations, and I apologize to Dr. Greene and Dr. Dalton for not doing so.

In addition I should like to cite an interesting paper by Dr. Joan Malleon² in which an attempt is made to find a common factor linking premenstrual disturbance, menopausal upset, puerperal depression, and involutional melancholia. Under the heading of puerperal depression, she writes: "It is commonly found that, if menstruation returns

before the psychosis is resolved, exacerbations occur repeatedly in the premenstrual phase." This is much nearer to what I intended to convey, but again I must stress that symptoms are not confined to the premenstrual phase.—I am, etc.,

Birmingham.

The "Nape" Naevus

SIR,—In this corner of Berkshire we have never heard of the Sturge-Weber-Kalischer syndrome, but we frequently see a nape naevus on newly born infants. Any midwife will tell Drs. J. Shafar and A. Doig (*Journal*, April 9, p. 913)—and I pass this information on to them—that it is caused by an affectionate peck from the stork who delivers the child before taking final leave of its charge.—I am, etc.,

Streatley, Berks.

J. R. B. DIXEY.

SIR,—Drs. J. Shafar and A. Doig (*Journal*, April 9, p. 913) have found that a superficial vascular naevus in the nuchal region is much commoner than most doctors had supposed, and that its presence is not generally associated with other congenital abnormalities. Its situation over the upper (cephalic) level of the spinal cord may perhaps be compared to the presence of so-called "mongolian" pigmentary naevi in the sacro-gluteal region at the lower (caudal) end of the spinal cord. Another type of superficial naevus near the lower end of the spinal cord is the multiple angiokeratoma (haemangiokeratoma) of the scrotum. This latter must, I think, be regarded as a mild local form of the rare condition of "angiokeratoma corporis diffusum," which, according to J. H. Price,¹ may possibly constitute part of a very rare inborn metabolic lipid storage disease.—I am, etc.,

Low Back Pain Treated by Manipulation

SIR,—The recent article on "Low Back Pain Treated by Manipulation" (Dr. A. B. Coyer and Dr. I. H. M. Curwen) (*Journal*, March 19, p. 705) comes opportunely at a time when there is considerable discussion on this form of treatment in the correspondence columns of the *Journal*.

Controlled clinical experiments are unfortunately rare in physical medicine. When studying a controversial form of treatment for a symptom complex rather than a definitive diagnosis the standard of "control" needs to be of the highest order, and it is unfortunate that we are not convinced of the validity of the design of this particular experiment. Tegner¹ has said: "We should be aware that the classical attack of lumbago usually clears up of itself in the majority of cases after a comparatively short period, and we should not blindly accept the disappearance of symptoms to be the result of whatever treatment has been ordered. Long before we knew about prolapse of the intervertebral disk we treated lumbago and sciatica with considerable success. And what is more, many sufferers from these conditions were treated successfully and safely with rest and analgesics alone, and the patients got better. Such facts cry aloud for proper controlled experiment in our evaluation of the results of the treatment we prescribe."

The snares of "historical controls" have been forcibly emphasized,² and the "controls" for this series can hardly be called more than "historical." The key to clinical investigations must lie in the criteria for diagnosis, and the more detailed the criteria the more comparable will be the groups of patients. In this series no diagnoses are recorded, and detailed criteria for selection are not specified. For example, it is stated that 50% of the patients manipulated were free of signs and symptoms at the end of one week compared with 27% of the controls. This is an impressive result, but it would have been more logical to compare the patients with limitation of straight-leg raising. If this is done we find that 20 of 39 (51%) patients with limitation of straight-leg raising were free of signs and symptoms at the end of one

week compared with 10 of 26 (38%) of similar controls (much less impressive, but more logical). The Chi-square test applied to these figures gives $\chi^2 \approx 1.1$, and $P < 0.2$. The difference between the groups is not statistically significant. Limitation of straight-leg raising may be used to separate between two clinically distinguishable types of patient with low backache or sciatica.³ Thus in this series under discussion three clinically distinct groups of patients are being lumped together (those with a severely limited S.L.R., those with slightly limited S.L.R., and those with no limitation of S.L.R.). Is the thesis held that these clinically separate and probably pathologically different groups are all amenable equally to one form of treatment?

Many cases of derangements of intervertebral joints, and lesions of the supporting ligaments of the spine, may give rise to referred sciatica.⁴⁻⁶ These cases have been excluded, for no patients with radiation below the buttock were selected. There has been no selection, for example, according to mode of onset, surely most important in relation to reaction to treatment. Although site of pain, presence of congenital defects, and recurrences and other factors have been recorded these have not been separately analysed, so the unwary reader is led to the conclusion that, having excluded "rarer and more serious causes," manipulation is the treatment of choice whatever the diagnosis. As many cases of derangement and prolapse are excluded, as indicated above, then what was the pathological lesion in most of the patients in this series? It is felt that many may have been postural defects, muscular lesions and similar disabilities in which rest and sedation were in fact contraindicated.

Without a detailed analysis allowing for the study of strictly comparable groups of patients, this series does not help in the elucidation of the part that manipulation has to play in the relief of backache.—We are, etc.,

P. J. R. NICHOLS.

Boxing Injuries

SIR,—I hasten to reassure Dr. H. Simon (*Journal*, April 2, p. 853) about albuminuria in boxers. I have frequently examined the urine of boxers after training and sparring in the gymnasium without any exchange of blows, and have found albumin and sometimes blood present. The urine becomes clear in three to four hours. Albuminuria and haematuria are quite frequent after violent physical exercise and leave no after effects. All boxers under the control of the London Amateur Boxing Association have their urine tested in their routine examination on joining a club.—I am, etc.,

London, W.1.

J. L. BLONSTEIN.

Oxygenation by Needle Puncture in Asphyxia

SIR,—In connexion with Mr. N. A. Jory's article on "Acute Respiratory Obstruction" (*Journal*, March 26, p. 781) I would like to suggest the following method of giving oxygen as possibly being a useful measure in the treatment of some of the cases discussed.

The method consists in the administration of oxygen via a fine cannula, such as is used in "lipiodol" bronchography, which is passed through the crico-thyroid membrane. The cannula is attached by a suitable mount to the delivery tube from an oxygen cylinder. Dr. G. M. Willey and I have demonstrated that this method is quite adequate to restore quickly full oxygenation in anoxaemia during general anaesthesia.

In passing the trocar and cannula through the crico-thyroid membrane the use of a tenotome for skin-puncture makes the procedure easier, as the skin in this region may be very tough. When the cannula has been inserted, the preliminary passage of a fine polythene tube well down into the trachea will indicate that the end of the cannula is free within the lumen of the trachea, thereby obviating the risk of surgical emphysema. Indeed, oxygen may be

administered through the fine polythene tube introduced in this manner, but not of course so freely as through the lipiodol cannula itself. I have found Forestier's trocar and cannula suitable for the purpose.

Apart from laryngeal obstruction, the method might very well be found useful in cases of drowning and coal-gas poisoning, and the polythene tubing method of administering oxygen in cases of clinical anoxaemia. A convenient pack containing a baby oxygen cylinder, trocar and cannula and fine polythene tubing, etc., could easily be assembled for first-aid work.—I am, etc.,

London, W.1.

Fluoridation of Water Supplies

SIR,—I have been interested in this subject for some years, and it is extremely difficult to be certain that it is quite safe for every individual to have 1 p.p.m. of fluoride added to the water supply in an endeavour to reduce the incidence of dental decay.

It is surprising that, in the midst of the discussions in connexion with the improvement of the dental condition of schoolchildren, little is said of the great need for improved oral hygiene. The oral condition of many of our schoolchildren is really alarming, and an intensive campaign to encourage the use of the tooth-brush would be a valuable and safe contribution towards a very considerable reduction in dental caries and improved oral health. Local authorities might well direct their energies in this direction as a first step.—I am, etc.,

Dundee.

DAVID A. FINLAYSON.

SIR,—The Delaney Committee, which investigated this matter in 1952, correctly stated in its report¹ to the U.S. Congress: "It is safe to say that fluoridation is mass medication without parallel in the history of medicine." Even if its effects were less controversial than they appear to be, it is clear that this method of wholesale, indiscriminate administration of what is undoubtedly a highly toxic substance is improper, and constitutes a complete break with the medical tradition of individual care and responsibility.—I am, etc.,

London, W.1.

Speaking Up

SIR,—In reply to Dr. J. Hamilton McIlroy's letter (*Journal*, April 2, p. 853) on the subject of the inaudibility of medical lecturers, I would like to suggest the following "prescription" which I found written in large letters in a pulpit in a Methodist church in Halifax: "Speak up, the deaf aid is not working."—I am, etc.,

London, S.E.1.

D. G. BATES.

Hazards of Electric Razors

SIR,—Dr. A. S. Porter's letter (*Journal*, April 2, p. 854) mentions a condition to which referral is surely overdue in your columns. That modern, and otherwise invaluable, instrument, the electric razor, is an undoubted potential cause of sneezing attacks in the morning and of painful snippets of hair in the eye.

Most of the trouble is due to its use whilst lying supine in bed, a device adopted by poor risers not only to keep the legs warm but to save having to clean out the appliance after use. So far as the eyes are concerned, they can be covered with spectacles; the nostrils can likewise be packed loosely with cotton-wool; but, in any case, the tendency is for a recumbent shave to drag on in time, with the weight of the appliance resting heavily upon the cheek of the same side as the dominant hand. This leads to a further hazard of the electric razor, which is traumatic neuritis of one or more of the cutaneous sensory filaments where they

cross bone to reach the temporal fossa. The vulnerable sites appear to be either far forward over the malar bone, where injury leads to pain in screwing up the eye; or again just above the mandibular point, where the condition might have to be distinguished from temporal arteritis.—I am, etc.,

Richmond.

JOHN DANCY.

Natural Childbirth

SIR.—I was sorry to read of Mrs. Constance Lynn's painful and disappointing experience (*Journal*, April 2, p. 851), but, for fear that it should prove discouraging to others, I should like to put it in perspective, comparing it with my own experience in dealing with some 4,000 deliveries at Stonefield Maternity Home (Blackheath) over the period 1920-54. From the first my late partner and I worked for "natural childbirth," and in the last 20 years developed our methods considerably and along very similar lines to those used by Dr. Dick Read. We had a unique opportunity of observing, for the antenatal work, the delivery, and the puerperium were conducted under our own roof, and we remained in touch with most of the mothers for a year and often longer.

Results were most encouraging. A large proportion of our later patients suffered no more pain than they were able to bear without distress; labours tended to be short and without fatigue with its risk of haemorrhage and shock. Our forceps rate dropped from about 12% to 3%. We used pethidine freely, and occasionally gas and air as well. But perhaps the most striking result was the great happiness of many women during the birth. We never promised a painless birth, and I always impressed on my patients that the physical effort of the second stage was probably greater than any they had ever been asked to make. We found the presence of husbands in this stage to be a great encouragement. (One of them, after a long journey, fainted, but his wife immediately rose to the occasion and encouraged him so that five minutes later he was able to witness the birth.) While sympathizing with the disappointment of Mrs. Lynn and "quite a few recent mothers" of her acquaintance, I submit that her claim to "give a true and tried viewpoint" is not justified.

Dr. Dick Read and I, and many others whose enthusiasm has been kindled by results, realize that we are up against a fearful attitude of mind in the expectant mother, which has existed for centuries, and which tends to be both hereditary and infectious, so we cannot expect 100% success in 30 years' work; but even so, the successes we do achieve provide our patients, their husbands, the doctor, and the nurse with the happiest moments of our lives.—I am, etc.,

Bristol, 9.

CYRIL V. PINK.

SIR.—For evidence of better results from preparation for natural childbirth I would refer those interested to an article by Dr. Henderson in the *New Zealand Medical Journal* in which 300 cases are compared. The 150 prepared cases show fewer complications and shorter duration of labour. Indeed, it is this very shortening of labour of which some doctors complain, saying that women have been so relaxed that the attendants were unaware that full dilatation had occurred.

Commenting on Mrs. Constance Lynn's letter (*Journal*, April 2, p. 851), I would suggest that too much enthusiasm is often followed by a sense of guilt over personal failure to achieve perfection, and that post-partum depression is a common state for which women should also be prepared. These personal reactions do not lessen the validity of Dr. G. D. Read's theories. High morale during pregnancy is certainly preferable to "a disease of nine months' duration," which was an earlier definition of pregnancy. Many women I know in New Zealand are greatly indebted to Dr. Read for a changed attitude, and some keen mothers have established a Wellington Parents' Centre in order to propagate the principles.

Dr. Dick Read has not deleted the word "labour" from the experience of childbirth, but has emphasized the sequence of fear-tension-pain which is an incontrovertible fact, and remains of lasting significance.—I am, etc.,

London, S.E.5.

Chlorpromazine

SIR.—Few will doubt the wisdom of the cautionary note sounded by the leading article (*Journal*, February 5, p. 338) which stressed the desirability of using chlorpromazine with caution.

The reason for this communication is to record the use of chlorpromazine in a few cases of intractable vomiting in whooping-cough. Few conditions can be more frustrating to treat, and frequently alarming to observe, in general practice. The results when chlorpromazine is used are dramatically gratifying, both to patient and parents. Its use for the condition, so far as I am aware, does not appear in the literature of the drug. My first case, in a child aged 3 years, required 10 mg. to control a situation that had led to ketosis and dehydration. The youngest case, aged 7 months, responded to 5 mg. My instructions to parents are to repeat the dose twice daily if required. Repeated doses to prevent recurrences have been only exceptionally required. In this clinical situation, and with the dose described, nothing but benefit to the patient has resulted, and with no insidious sequelae.—I am, etc.,

London, S.E.13.

HOWARD REEVE.

Advertising by Post

SIR.—Like many of your readers I was at one time plagued by unsolicited and unwanted trade advertisements. I have largely overcome the problem, but it was a long battle. I started by sending to each firm in turn a brief but bold request asking for my name and all my addresses, past and present, to be removed from the mailing lists (except for any list devoted to my particular specialty—namely, radiological diagnosis). My postage expenses were high, particularly as it was soon apparent that in many cases my requests were not being heeded. Perhaps the manufacturers have a similar problem, that of receiving unsolicited and unwanted correspondence, and maybe my letters were going straight into the waste-paper basket. Be that as it may, I did obtain a response in these cases by returning the literature in its original envelope with the flap stuck, addressed back to the sender, and without any stamp. I saw no reason why I should be put to postage expenditure in respect of literature which I had never requested in the first place.

Mr. James H. Clayton (*Journal*, April 2, p. 854) states that "many manufacturers are constantly adopting more original techniques of getting their information over to the doctor in the hope that such will be amongst the favoured proportion singled out for detailed study." One of these methods is to use plain envelopes. These may be sealed at ordinary postal rates. They are more difficult to sort out from one's own mail. I have even had advertisements in envelopes marked "Personal" and containing only the trade circulars. This I regard as an impertinence, and I would have no hesitation at all in asking for a visit from the manufacturers' representative so that I may tell him in person that I do not wish to hear from his firm. At present more than nine-tenths of the mail which I receive is mail which interests me personally, and it does get read properly. There is therefore very little risk of important personal letters getting mixed up in a large pile of highly coloured glossy literature destined for the waste-paper basket.—I am, etc.,

Worcester.

ANTHONY A. VICKERS.

SIR.—While I agree with Dr. Claud C. M. Watson (*Journal*, April 2, p. 854) that the representatives of the manufacturers are always most polite, I cannot agree that they are unnecessary. In the course of years I have learnt a good deal from these representatives and only wish that they came more often.

I receive about twenty advertisements a week. Having looked to see what the drugs advertised are for, I then look for the price. If it is not there the advertisement goes into the waste-paper basket without more ado. I always doubt the excuse proffered by the manufacturers—namely, that it is not possible to give the price, as it is liable to frequent fluctuations. Could not the profession take it that any price quoted was the price at the time of going to press?

I deplore the complete lack of dignity of many advertisements. Is it necessary to send to a "learned profession" circulars clad in all colours of the rainbow and armed with cupid's armamentarium?—I am, etc.,

Exeter.

F. E. GRAHAM-BONNALIE.

SIR.—None of your correspondents has drawn attention to one great inconvenience caused by all these unsolicited free samples and circulars. Many doctors live at the beginning of a postal round and are therefore called out of bed at an early hour to receive these things. This, to me, seems an intolerable abuse, but doubtless the advertising firms would state that arrangements could be made with the post office for later delivery. This is undoubtedly true, but how many of us know this? I have only just found it out after 17 years in practice.—I am, etc.,

Reading.

P. W. F. MCILVENNA.

Treatment of Vaginal Discharges

SIR.—May one of the "well-meaning travellers" to whom Dr. Elizabeth Gourlay refers (*Journal*, April 9, p. 912) be permitted to reply?

I think that it is true to say that very few, if any, firms claim to have found cures for vaginitis or any other condition. Initially treatments are suggested and trials carried out by practising specialists, where possible under controlled conditions. It is the duty of a traveller (or, as some of us style ourselves, medical representative) to pass on this information to as large a number of medical men as possible, and of their employers to market the products in an as efficient and economical form as possible.

During the course of some years' experience as a traveller, the products of my company have met with both praise and criticism, and it has always been my endeavour to present the doctors who grant me the privilege of an interview with a balanced view. When I meet with criticism I make a point of asking a number of other doctors whether they have had similar experiences, and by so doing sometimes get somewhere near the truth. A traveller's existence can only be justified by his products doing the job for which their manufacturers claim they are suitable.

The cynical observation, sometimes made to us, that we are all only concerned with £ s. d., is untenable, for the medical profession is the most discerning of all professions, and unless results are forthcoming all the travellers (no matter how well-meaning) and all the publicity in the world will avail us nothing.—I am, etc.,

Chichester.

C. H. J. BISHOP.

Fibrositis

SIR.—Whatever fibrositis may mean, it is surely a matter of common observation that repeated local chilling may produce symptoms resembling those of grossly excessive use of a muscle or muscle group. Presumably the symptoms are in each case due to circulatory disturbance and with this a piling up of waste products.

I remember a patient whose constant pain in the side ceased when he was advised to discontinue sitting in a direct line from window to fire. A case quoted in the *Journal* many years ago described pain in the point of the shoulder of a lorry driver, relieved by providing a washleather lining to the shoulder of the coat. The windscreen was too narrow to keep the draught off the extremity of the shoulder. In his case many treatments and investigations had led nowhere. Faulty posture, possibly due to badly

designed equipment, is a common cause of pain. I can remember backaches caused by the club chair, the feather bed, and the bucket seat of cars; also from a scullery sink too low for the housewife to use while erect.

A short haircut or a shampoo followed by inadequate drying of the hair sometimes gives me a headache. As cold without short hair, as when gardening without a hat, does the same thing, I wonder if a postural explanation is entirely adequate. It seems doubtful. But the neck pain of shorthand-typists occurs without cold and is surely postural, aggravated particularly by looking at work on the table and then at the typewriter at another level.—I am, etc.,

Hitchin, Herts.

G. C. PETHER.

Bleaching of Hair by Chloroquine

SIR.—Chloroquine is now widely used in the treatment of chronic discoid lupus erythematosus, because it appears to be at least as effective as mepacrine without producing discoloration of the skin. Numerous toxic effects, mostly reversible, are described, but bleaching of the hair is one not widely known in this country; awareness of this seems desirable, as it might cause embarrassment. Aiving *et al.*¹ studied the toxic effects of chloroquine given over long periods to inmates of a penitentiary; 300 mg. daily followed by 500 mg. weekly for a year bleached the hair of all blondes studied. Tye *et al.*² treated 48 patients suffering from lupus erythematosus with a loading dose followed by 250 mg. daily; in one redhead and one blonde the hair "was made lighter." The following case is of interest.

A married woman had suffered from very extensive chronic scaly lupus erythematosus of the whole face for 13 years; during six years I had given all the usual treatments, including mepacrine, without much benefit. On May 8, 1954, I started "nivaquine," one tablet daily (200 mg. of chloroquine sulphate); this brought about considerable improvement, but not complete clearing, so on June 26 the dose was increased to two tablets daily. On July 17 the eruption was clearer than it had ever been; a month later I went on holiday, and in my absence the dose was continued at this level until September 10, when I observed that the eyebrows were white and the scalp hair, normally a medium brown, was white for its proximal 20 mm. The patient told me that during a recent holiday the sunshine, instead of bronzing her as usual, had caused severe erythema not followed by pigmentation. Chloroquine was stopped on September 10; by September 25 the lupus was obviously active again. On October 23 her eyebrows had regained their usual colour. The scalp hairs showed normal pigmentation of their proximal 10-15 mm. separated by white bands of 25 mm. from the distal normal portions. This appearance was much more evident under Wood's light, the bleached areas showing a bluish-white fluorescence, as did a tablet of nivaquine suspended in water. At this time the patient asked for nivaquine to be resumed, as she considered the white hair more attractive than the lupus. Accordingly one tablet daily was given and continued until the present time (March 29).

The eruption is at present almost completely controlled. The bleached areas are still evident in the distal portions of the longer scalp hairs, and these still fluoresce, although the proximal portions do not do so.—I am, etc.,

London, S.E.5.

Society for Endocrinology

SIR.—Dr. P. M. F. Bishop's article on "The Development of British Endocrinology" (*Journal*, April 9, p. 865) was interesting and valuable as a record of events in this field. For the sake of accuracy I think I should point out that Dr. Bishop has overlooked a factual error. The two present secretaries of the Society for Endocrinology are, in fact, Professor C. H. Gray and myself. This statement does not, of course, in any way alter the intention of Dr. Bishop in referring to Professors Gray and MacLagan in the way that he does.—I am, etc.,

London, S.E.1.

F. T. G. PRINTY.

Obituary

A. D. SHARP, C.B., C.M.G., M.D., F.R.C.S.Ed.

The death occurred at Leeds on March 18 of Colonel A. D. Sharp, consulting ear, nose, and throat surgeon to the Leeds Public Dispensary and to Dewsbury Infirmary. He was 84 years of age.

Born at Keith, Banffshire, on November 6, 1870, Alexander Dunstan Sharp received his medical training in Edinburgh and took the Scottish triple qualification in 1900, being awarded four medals and three prizes during the course of his student career. After qualification he held the appointments of resident surgeon and house-surgeon to the ear, nose, and throat department at Edinburgh Royal Infirmary and resident physician at the Royal Maternity Hospital, Edinburgh. In 1901-2 he was on active service in the South African war as a surgeon with the 1st battalion of the King's Royal Rifles, being awarded the medal and four clasps. Sharp was elected F.R.C.S.Ed. in 1903, and in the following year he obtained the Brussels M.D. with distinction. After postgraduate study in London and in several European capitals he was appointed honorary aural surgeon to the Leeds Public Dispensary in 1906, an appointment which he was to hold for the next 43 years. He also became honorary aural surgeon to Dewsbury Infirmary, the Leeds Education Committee, and to Noble's Isle of Man Hospital, Douglas. Always keenly interested in the Volunteer movement, he was commissioned in the Leeds detachment of the R.A.M.C. in 1905, and on the outbreak of the first world war in 1914 held the rank of major. Later in the same year he was promoted lieutenant-colonel with command of the 1st West Riding Field Ambulance, taking the unit to France with the 49th West Riding Division in 1915. He was appointed A.D.M.S. of the division in 1916, by which time he had attained the rank of full colonel, and held the position until 1925. For his war services he was four times mentioned in dispatches, being appointed C.M.G. in 1916 and C.B. two years later. The honour of Commander of the Military Order of Aviz of Portugal was conferred on him in 1919, and in 1926 he received the Médaille de la Reconnaissance Française. He was awarded the Territorial Decoration in 1921, and from 1922 to 1927 was an Honorary Surgeon to King George V. A member of the British Medical Association for many years, he was chairman of the Leeds Division in 1928-9.

In 1909 he married Miss Amelia Sutcliffe, a medical graduate of Edinburgh University, and she survives him together with two sons and one daughter, to whom we extend our sympathy in their loss. One son is consulting aural surgeon to Charing Cross Hospital and to the Hospital for Sick Children, Great Ormond Street, and the other a barrister-at-law practising on the North-Eastern circuit.—G. A.

Mr. GEORGE SEED writes: For nearly half a century the name of Alexander Sharp has been prominent among medical circles in the West Riding of Yorkshire. He studied laryngology in Edinburgh and in the main European cities, and was the only ear, nose, and throat surgeon, until his retirement in 1949, at the Leeds Public Dispensary. This hospital, situated in the centre of Leeds, serves a densely populated area, and Colonel Sharp visited and operated at

the hospital daily for many years, in addition to having a busy consulting practice. His out-patient clinics were huge and his operating sessions long. His commanding figure combined with his striking personality, and kindly disposition, were well known in the hospital. In spite of his training, Colonel Sharp was a strictly conservative surgeon, disliking any radical measures. He was one of the last physician-laryngologists, preferring nasal medication to drastic surgery. Many house-surgeons will remember his kindness. He was a keen supporter of the Leeds and West Riding Medico-Chirurgical Society and the section meetings of the Royal Society of Medicine.

Dr. W. D. CHAPMAN died at his home at Windermere, where he had lived for over half a century, on October 20, 1954, at the age of 83. William Daniel Chapman was born at Wanstead, Essex, on March 27, 1871, the son of Captain W. D. Chapman, of the Madras Staff Corps, and was educated at Trent College and at Corpus Christi College, Cambridge, receiving his clinical training at the London Hospital. He qualified M.R.C.S., L.R.C.P. in 1899, and took the M.B., B.Chir. degrees four years later. At Windermere, where he settled in practice, he soon entered into all aspects of the life of the district. He took an active interest in the work of the Windermere District Nursing Association and of the Windermere Lecture Association, being chairman of both bodies for many years, and of the Nurse Cavell Home, of which he was a trustee. From 1934 to 1949 he was a member of the urban district council, vice-chairman in 1947, and chairman of the health committee over a long period. It was the work of the council's library committee, perhaps, which gave him the greatest pleasure after his retirement from practice, and he continued to serve on it, as a co-opted member, for some time after he had resigned from the council. He was also a justice of the peace. A member of the British Medical Association for over 50 years, he was president of the old North Lancashire and South Westmorland Branch in 1922-3. Although he retired from practice some 20 years ago he continued to live at Windermere, and there to enjoy the lovely countryside and the companionship of old friends. For recreation he enjoyed a round of golf—he was a skilful player—and did not give up the game until some three years ago. In 1904 he married Miss Norah Moss, by whom he had two sons and one daughter, and in 1930 Miss Edith Barton, who survives him, together with the children of the first marriage.

Lieutenant-Colonel J. S. DUNNE died in hospital at Winchester on March 4 at the age of 77. After his retirement from the R.A.M.C., in which he had a distinguished career, he was for some years county director of the Hertfordshire Branch of the British Red Cross Society, and for a short time before the outbreak of the last war he was county A.R.P. controller. James Stuart Dunne was born at Edenderry, King's County, on November 2, 1877. He studied medicine in Dublin, taking the Irish conjoint diploma in 1905. In the same year he became a Fellow of the Royal College of Surgeons in Ireland, being awarded the gold medal for operative surgery and silver medals for theoretical surgery and midwifery. He then entered the R.A.M.C. and went to India as medical officer with the Royal Irish Regiment, being placed in charge of a cantonment hospital. Returning to the United Kingdom, he became medical officer at Woolwich, where he claimed to have the largest midwifery practice in the country. On the outbreak of the first world war in 1914 Dunne went to France with the Dragoon Guards, and later the same year was awarded the D.S.O. for heroism in the following circumstances: "During a German attack on the night of October 31, near Messines, he established a dressing station just behind the trenches, and was the means of saving many lives, he himself going several times into the trenches to

Medico-Legal

ACTION AGAINST HONG KONG DOCTORS FAILS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On February 11, 1955, in the Supreme Court of Hong Kong the trial was concluded before the Acting Chief Justice, Mr. Justice T. J. Gould, and a jury, of an action brought by Mr. Joseph Leslie Quie, a merchant, against three Government doctors for negligence in connexion with his certification as of unsound mind and his detention in a mental hospital. The defendants were Professor A. J. S. McFadzean, of Queen Mary Hospital, Dr. P. M. Yap, of the Mental Hospital, and Dr. S. H. Moore, of the Colonial Medical Department. Mr. Quie claimed \$130,831.88 general and \$119,168.12 special damages.

The plaintiff's case was that on March 12, 1952, Professor McFadzean was called in by his doctor, Dr. Yang, to examine him in consultation, and confirmed that he was suffering from cirrhosis of the liver. On the professor's advice he went into Queen Mary Hospital next day to try a new treatment, which he was told would last for two or three weeks, and there he was seen by Dr. Yap. On the evening of March 14 he was told that Professor McFadzean wished to examine him at the Matilda Hospital, and he went into the ambulance in his dressing-gown. He was taken to the Mental Hospital, seen by Dr. Yap, detained there in spite of his protests, and put in a padded cell. Some hours later he was moved to a private room. The diagnosis was manic elation, and Dr. Yap said in evidence that the patient seemed to have the appearance of an advanced chronic alcoholic or a person with general paralysis of the insane.

On March 19 Mr. Quie agreed to stay as a voluntary patient, but on March 22 gave seven days' notice that he wished to be released. Dr. Yap persuaded him to stay for a full three weeks, to which he agreed. On March 28 Dr. Yap applied under s.7 of the Mental Hospital Ordinance for an order that Mr. Quie should be conveyed to the Mental Hospital and detained for observation, and Dr. Moore signed the order, and on March 31 signed a certificate that he was of unsound mind.

On April 26, after a visit on April 10 from his lawyers, Mr. Quie was let out of the mental hospital and flew to England. There he was treated as a voluntary patient at St. Andrew's Hospital, Northampton, until May 20, and was discharged with a certificate that he was not certifiable as of unsound mind.

Mr. Quie's case that Professor McFadzean, Dr. Yap, and Dr. Moore had been negligent was supported by the expert evidence of Dr. Ellis Stungo, of London, who gave evidence that he had practised as a psychiatrist during 25 of the 29 years he had been qualified. He had seen Mr. Quie in England on July 23, 1952, and later, and said that not only was he not certifiable as insane, but that his certification and detention had been made on wholly inadequate grounds.

The case for the defendants was that not only had Professor McFadzean, Dr. Yap, and Dr. Moore exercised proper care and done their best in diagnosing Mr. Quie's condition, but also that their diagnosis had been correct and was supported by all the information which they had received in answer to the proper inquiries which they had made. Dr. Desmond Curran, senior consultant psychiatrist of St. George's Hospital, was called as expert witness for the defence, being flown from London for the purpose at the Hong Kong Government's expense. In his opinion, Professor McFadzean would have laid himself open to the severest criticism if he had not acted as he did. Dr. Curran used very strong expressions about some of the definitions given by Dr. Stungo in his evidence on behalf of the plaintiff, and declined to withdraw them when invited to do so by the plaintiff's counsel.

attend to wounded men who could not be moved." He was also mentioned in dispatches. Promoted to major in 1917, he was employed as embarkation staff officer at Le Havre towards the end of the war, and, after the Armistice in 1918, at Marseilles. From then until he retired under the age limit in 1932 he spent a good deal of time abroad. For three years he worked as a senior medical officer in Turkey, and later he was in charge of military hospitals at Cairo and Alexandria, being also senior medical officer for Northern Egypt. He attained the rank of lieutenant-colonel in 1930, and returned to England in the following year to become director of the surgical division at Woolwich. After his retirement from the R.A.M.C., Dunne settled, first at Welwyn Garden City, and later at Digswell, both in Hertfordshire, where his work for the British Red Cross Society was greatly appreciated. When the second world war broke out in 1939 he was recalled to the Army and was a member of a medical board from then until he left Hertfordshire towards the end of 1951 to live in permanent, but all too short, retirement at Whitchurch, in Hampshire. He married Catharine, daughter of Admiral Sir William Henderson, in 1920.

By the death of Dr. ROBERT McLAREN on March 14, at the age of 83, less than a year after the death of his brother, Dr. JOHN McLAREN, on July 16 last year, at the age of 89, Edinburgh has lost two examples of a fast-disappearing race of beloved general practitioners. The brothers lived lives based on the solid foundation of their religion; both at one time sang in church choirs; and in later life John McLaren was the senior elder of Christ's Kirk at the Tron for many years, while Robert McLaren became a well-beloved pillar of the Methodist Church at the Central Halls, Edinburgh. John McLaren graduated M.B., C.M. at Edinburgh University in 1889 and Robert McLaren took the Scottish triple qualification in 1900. Eventually both engaged in general practice in Edinburgh, each in his own practice, from which Robert McLaren retired in 1946. John McLaren became a district medical officer under the old parish council and was also medical officer for the Trinity Pensioners, while Robert McLaren was medical officer to the Edinburgh Skin Dispensary for 43 years, and during the first world war served in the R.A.M.C., both in this country and in Salonika. In their practices the brothers were more than just doctors. They were the friends and confidants of their patients, and their presence and personalities will be sadly missed. We may not meet their like again.—J. G. S.

Dr. HARRY SUGARÉ writes: I can fully bear out Dr. Walter Pagel's remarks (March 26, p. 793) about Professor MAX NEUBURGER's privations after the first world war. On the back of a large visiting-card dated April 11, 1921, was written in English, "I am sorry that I don't possess a photograph of myself, and under the present conditions it costs too much, but I send you enclosed a very good copy and hope you will be satisfied with it." The excellent copy, with his characteristic signature, was taken from a scientific magazine.

Dr. ROBERT CHISHOLM died after a short illness on April 1 at the age of 80. Born in Assam, India, on March 10, 1875, Robert Chisholm studied medicine at Edinburgh and qualified by taking the Scottish triple qualification in 1902. He first practised in Pelton Fell, Co. Durham, where he gained a varied experience in a mining community. In 1915 he moved to Cambridge, where he was in practice until an accident forced him to give up medical work in 1920. Since then he had spent his retirement at Bedford, where he was a councillor, serving on the public assistance committee, and at Mill Hill, London. He had been a member of the B.M.A. for over 50 years.

A memorial service for the late Mr. R. DAVIES-COLLEY, who died on April 16, will be held in Guy's Hospital Chapel on Wednesday, April 27, at 1.45 p.m.

In his summing-up, Mr. Justice Gould said that the jury had to decide whether the defendants were negligent in expressing the belief that Mr. Quie was of unsound mind. Had they exercised reasonable care in making inquiries and in coming to their conclusions as a result of their examination of Mr. Quie and the information they had received? It was for the jury to consider whether these three medical men, not one of whom had any financial interest in the matter, had been negligent or acted in bad faith in this matter or not.

The jury, after an absence of one hour, returned unanimous verdicts in favour of the three doctors.

FINED FOR FORGERY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Reginald Morgan Ford, of Bedminster, Bristol, after obtaining a Swedish diploma in chiropody and physiotherapy, set up in practice as a physiotherapist in Bristol. He then entered Bristol University as a medical student, but a year later was expelled for breaches of discipline. He thereupon erased the central portion of a letter he had received from the General Medical Council, and inserted in its place a paragraph saying that he was a graduate in medicine and held the Bristol University degrees of M.B. and Ch.B.

Armed with this letter Ford got employment with several local doctors, and finally became locumtenent to Dr. W. B. Williams, of Knowle, during an illness. It was only when Dr. Williams decided to keep him on as assistant and wrote to the Bristol Executive Council that it was discovered that Ford's name was not on the *Medical Register*. Ford at first asserted that his name had been left out by mistake, but when taxed a second time by Dr. Williams admitted the truth.

Ford was indicted at Bristol Quarter Sessions for forging a letter from the chief clerk to the General Medical Council purporting to show that he was a qualified doctor. Sentencing him to a fine of £100, the Recorder said that it was an exceptional case with startling mitigating features. Ford had possessed sufficient skill to satisfy those who had become his patients, and had been careful during his employment as assistant not in any way to abuse the professional position he had wrongly assumed. Apart from the bad example, he did not appear to have done any harm. He was given three months in which to pay the fine.

OPERATION ON WRONG KNEE

Damages of £40 and costs were awarded to a 5-year-old boy by Judge Allan Walmsley at Blackpool county court on March 30 for pain and suffering caused after a surgical registrar at Blackpool Victoria Hospital had operated by mistake on the wrong knee to remove a broken needle. The boy, Anthony John Sargeant, of Newcastle-under-Lyme, was awarded damages against the Blackpool and Fylde Hospital Management Committee.

The plaintiff's case was that he was admitted to the hospital with a piece of broken sewing-machine needle in his left knee. The surgeon, Mr. F. Galea, was apparently misled by the little boy and operated on the right knee. The mistake was realized, and after another operation the needle was removed from the other knee. There was no complaint of permanent disability to the right knee, but negligence was admitted by the hospital.

The boy's mother said the surgeon had told her he had made an incision into the boy's right knee because the boy insisted that that was where pain was. Later she took the boy to her own doctor, and on both wounds there was yellow pus. He could only walk stiff-legged. After visiting the doctor on about six occasions the boy was discharged. Following the first visit the doctor told her to keep the boy off his feet for fourteen days. She admitted that when the stitches were removed at the hospital there was no sign of sepsis on either of the wounds.

¹ *Bristol Evening News*, April 4, 1955.

Mr. William Lamont, consultant orthopaedic surgeon, said that having examined the boy he was not satisfied that the knee had been septic, because the sores on the knees were not thick and did not indicate previous infection. The scars would always be visible but not noticeable. Mr. Lamont added that the needle had penetrated just under the surface of the skin. A 1½-in. (3.8-cm.) incision was necessary to remove it, but it was not necessary to cut beyond ½ in. (1.2 cm.) deep.

Summing up, Judge Walmsley said the boy must have suffered additional pain by having a second operation and must have suffered handicap in moving about and playing. He also had the further handicap of a second scar. There appeared to have been a clerical error at the hospital which had an effect on the mistake. The judge stressed, however, that the mistake should not reflect on the surgeon's professional skill or competence, but he should have examined the radiograph with more "scrutinious care."

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Mr. Galea.

DANGEROUS DRIVING CONVICTION

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Defending himself on summonses² for dangerous driving contrary to s. 11 of the Road Traffic Act, 1930, and for exceeding the 30 m.p.h. speed limit, Dr. P. J. Moriarty, of Bradford, suggested to the magistrates that as he was driving a midwife in his car to an urgent case his car had become an ambulance and that accordingly he was privileged under the Highway Code to exceed the speed limit like the police, firemen, and ambulance drivers. The evidence was that Dr. Moriarty had received an urgent evening call and was taking a district midwife with him to the case. His car was followed by two police officers along a road at 35 to 47 m.p.h. through two lots of traffic lights into another road, where it overtook two lines of traffic in some places and went through traffic lights at a road junction with its headlights flashing at 40 m.p.h., so that a woman who was crossing the road had to run to avoid being knocked down. After the clerk to the justices had pointed out that any privileges which police, firemen, or ambulance drivers might have under the Highway Code must be exercised consistently with safe driving, the chairman said that he disagreed with the suggestion that Dr. Moriarty's car had become for the time being an ambulance. The case of dangerous driving was found proved and a fine of £25 imposed, and a further fine of £5 was imposed for exceeding the speed limit.

Dr. Moriarty indicated that he would consider an appeal.

Universities and Colleges

UNIVERSITY OF OXFORD

The Gotch Memorial Prize for 1955 has been awarded to George Jamieson Ross McHardy, B.A., of Brasenose College.

UNIVERSITY OF CAMBRIDGE

In Congregation on January 22 the following medical degrees were conferred:

M.B., B.Chir.—J. T. N. Williams, J. H. C. Hunt, J. B. Pond, J. D. Ellis, *R. A. Carpenter, *P. A. Eckstein.
M.B.—J. N. Godlee, *P. J. D. Kirk, *I. McL. Flowers, *T. D. Carter, L. H. Blonstein, G. J. M. Milton-Thompson, C. B. Mortimer, G. C. Spackman, *A. H. Labrum, *J. N. Bodger, *C. F. Ridley, J. W. Blaxill, L. H. Hurrell, J. N. Rea, *D. H. Cameron, *R. Schram, Claudia M. B. Grigson.

*By proxy.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following candidates have been awarded the Diploma in Gynaecology and Obstetrics:

S. K. Chattopadhyay, N. J. Choksey, Rosalie J. Gollan, Sister Mary Hyacinthe, M. A. J. Khan, E. S. Linton, S. Malhotra, P. O'Shea, H. B. Perera, Olga M. Rampersaud, A. Rosin, B. Saha, Ma Khin Aye Si, Eunice S. Simon, M. El K. A. Tarshouby.

² *Yorkshire Observer*, March 26, 1955.

UNIVERSITY OF LONDON

Mr. A. C. H. Bell has been appointed part-time Director of the Department of Obstetrics and Gynaecology at the Westminster Medical School from October 1, 1954.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *University College Hospital Medical School*: Dr. R. E. Bonham Carter (Children's Diseases); Dr. R. W. Cope (Anaesthetics); Mr. B. J. Harries (Surgery); Dr. R. F. Tredgold (Mental Diseases (Psychological Medicine)). *King's College Hospital Medical School*: Dr. B. S. Cardell (Pathology). *Westminster Medical School*: Mr. C. E. Drew and Mr. J. P. Reidy (Surgery); Dr. R. D. Tonkin (Medicine).

Dr. P. D. Samman has been granted probationary recognition as a teacher of dermatology at Westminster Medical School for two years from February, 1955.

UNIVERSITY OF MANCHESTER

The following candidates have satisfied the examiners at the examination indicated:

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Part II: H. L. English, P. A. L. Scott, B. F. Whitehead. Part I: L. Grimshaw, E. Howarth, D. F. Potter, K. E. Schmidt, Mrs. Irene Waga.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

CH.M.—L. F. Tinckler.
DIPLOMA IN RADIOLOGY (RADIODIAGNOSIS).—Part I: R. S. Miller, F. P. Peach, V. Rogers, M. C. Winter.
DIPLOMA IN RADIOLOGY (RADIOTHERAPY).—Part I: B. Lall, S. H. M. Zaidi.

UNIVERSITY OF LEEDS

Dr. J. R. Fountain has been appointed Senior Registrar and Tutor in General Medicine and Mr. F. G. Smiddy Senior Registrar and Tutor in General Surgery at the United Leeds Hospitals for an initial period from a date to be decided until March 31, 1956.

UNIVERSITY OF SHEFFIELD

Dr. W. Whitaker has been appointed full-time Senior Lecturer in Medicine and Mr. D. H. Randall and Mr. D. J. Robertson part-time Clinical Teachers in Surgery.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on January 13, with Sir Harry Platt, President, in the chair, the deaths of Sir Arthur Keith (Past Conservator of the Museum and Master of the Buckston Browne Farm) and Mr. R. J. Willan (Past Member of Council) were reported and the Council unanimously adopted resolutions of condolence.

A Moynihan Lectureship was awarded to Professor H. Olivecrona, of Stockholm.

Diplomas of Fellowship of the Faculty of Anaesthetists were granted to Sheila McC. Wilson and A. H. Kasasian.

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN LARYNGOLOGY AND OTOLGY.—S. E. M. Bates, C. Chowdhary, A. R. N. Dhanji, D. A. T. Farrar, G. F. Fennell, A. N. Griffith, G. M. Homan, B. Jha, M. S. Khan, P. M. Kothary, M. V. Kurian, J. T. Lees, J. A. M. Martin, N. G. McGuire, J. R. Purvis, D. Russell, J. R. Samuel, S. D. Sethi, T. M. Srinivasan, M. M. Wain, W. M. K. Wijetunga.

DIPLOMA IN ANAESTHETICS.—Catherine K. Adam, R. D. Allan, H. B. Aronson, A. C. Ashton, L. M. V. Attygalle, P. S. Barclay, K. W. Baruch, K. Biss, J. A. Blundell, Janet C. Brash, June E. Brett, H. D. Browne, Mavis Buck, Fodda B. K. Burnell, Anthea M. Bushby, P. R. Chaik, Peggy J. Clark-Roberts, Sheila R. Clarke, J. A. Cluver, I. McL. Cochran, A. R. Cohen, Phyllis Connor, C. M. Conway, H. M. C. Corfield, L. G. B. Cumpston, P. N. Cunliffe, Muriel D. Dauby, Margaret C. D. Daniel, W. R. Daniel, E. J. D'Arcy, J. Davenport, J. W. Desmond, J. D. Dickson, Maria T. D'Ocon Asensi, B. A. Dowdell, H. D. Doyle, Winifred B. Drew, Beatrice M. Evans, Rosemary A. Faulk, L. Feldman, P. Flintan, B. G. Francis, J. E. S. Gould, Elizabeth Green, J. Greenan, N. R. Gupta, S. J. Halkett, I. M. Hallack, G. G. Harrison, H. I. Heffernan, R. S. T. Hey, J. R. E. Jenkins, E. G. R. Jones, K. Kennedy, A. R. Kerr, A. Kilpatrick, D. W. King, M. Lauchlan, Lucy T. Lee, Heather J. Loper, Dorothy J. Lucas, G. F. Lynam, I. Macphail, Esme D. Martin, P. M. Mehta, Catherine H. McK. Mellen, Morag J. R. Miller, W. More, B. D. Morison, Annie Mortell, S. M. MacD. O'Brien-Moran, Helen B. O'Hea, R. H. Oram, Buddug Phillips, A. P. Poole, Freda E. Prince-White, T. C. Probyn, K. R. Rama Rao, Stella J. E. Randall, M. V. Rao, J. T. Russell, Yvonne K. Russell, D. K. Sen, Margaret H. N. Smith, B. Solomon, Jean P. Spalding, H. Stable, H. W. Stanley, A. Thorogood, J. N. Thorpe, F. Turrettini, C. H. van Hasselt, I. R. Verner, N. A. Vincent, Betty R. Warltier, A. N. E. Watt, R. P. Wise, W. S. Wren, T. M. Young.

DIPLOMA IN OPHTHALMOLOGY.—C. Chowdhary.
DIPLOMA IN MEDICAL RADIOLOGY.—J. W. Logan.
DIPLOMA IN CHILD HEALTH.—J. A. Kay.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 2 (No. 13) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases during First Quarter in England and Wales

After the very poor summer of 1954 the popular belief was that resistance to disease might be lowered and a large amount of sickness result in the winter. The vital statistics of the fourth quarter did not support this theory, and the notifications of infectious diseases during the first quarter of this year also fail to support such a hypothesis.

During the first quarter of 1955 in England and Wales the notifications of scarlet fever and diphtheria reached record low levels. The notifications of diphtheria were only 1/120 of those in the first quarter of 1938. The notifications of acute poliomyelitis were the lowest for any first quarter since the disease appeared in epidemic form in 1947. The incidence of measles was slightly lower than usual in a year of epidemic incidence, but this was due to the fact that the maximum appeared about a month later than usual, and the epidemic will probably reach the same size as those in 1951 and 1953. Deaths from influenza have followed the pattern of recent years of a diminishing peak in the epidemic year. Dysentery provided the only exception to a low or moderate incidence, and the number of notifications from this cause reached a record high level. The numbers of notifications of infectious diseases for the first quarters of the past five years are as follows:

	1951	1952	1953	1954	1955
England and Wales:					
Scarlet fever	12,088	18,013	20,550	15,868	9,121
Whooping-cough	66,865	35,042	34,207	28,985	25,020
Measles	311,709	64,596	350,836	23,340	251,486
Acute poliomyelitis	339	288	345	332	208
Diphtheria	572	456	264	246	173
Meningococcal infections	662	562	595	515	499
Dysentery	13,995	6,936	4,449	10,808	14,551
Acute pneumonia	26,536	12,960	20,005	10,507	13,430
Enteric fever	149	126	123	244	113
Great Towns:					
Influenza deaths	7,448	496	2,995	398	1,181

Infectious Diseases

The only variations of note in the trends of the notifications of infectious diseases in England and Wales during the week ending April 2 were increases of 3,642 for measles, from 28,682 to 32,324, 66 for acute pneumonia, from 984 to 1,050, and 54 for dysentery, from 1,815 to 1,869.

With the exception of the 1953 epidemic the number of notifications of measles was the largest since this disease was made notifiable. The largest rises in the incidence of measles during the week were 766 in London, from 3,337 to 4,103, 496 in Warwickshire, from 2,910 to 3,406, 424 in Middlesex, from 1,574 to 1,998, 233 in Buckinghamshire, from 272 to 505, 256 in Derbyshire, from 814 to 1,070, 175 in Southampton county, from 373 to 548, 157 in Durham, from 841 to 998, 152 in Sussex from 277 to 429, 144 in Glamorganshire, from 376 to 520, 142 in Kent, from 1,081 to 1,223, 128 in Worcestershire, from 364 to 492, 111 in Gloucestershire, from 279 to 390, 109 in Staffordshire, from 1,017 to 1,126, and 109 in Wiltshire, from 137 to 246, while the only large fall was 102 in Surrey, from 1,393 to 1,291. 822 cases of scarlet fever, 7 more than in the preceding week, were notified, and the largest rise was 25 in Essex, from 40 to 65. 1,849 cases of whooping-cough, 18 fewer than in the preceding week, were notified, and the largest fluctuations were a rise of 47 in Warwickshire, from 83 to 130, and a fall of 32 in Cheshire, from 73 to 41. 9 cases of diphtheria were notified, being 2 fewer than in the previous week; 2 cases of diphtheria were notified in Birmingham C.B. and in Manchester C.B. The rise in the number of notifications of paratyphoid fever from 4 to 12 was due to cases scattered throughout 11 counties.

6 cases of acute poliomyelitis were notified. These were 1 fewer for paralytic and 3 fewer for non-paralytic cases than in the preceding week. 3 of the 6 cases were notified in London (Holborn 2).

The number of notifications of dysentery was the largest ever recorded. The chief centres of infection were Lancashire 624 (Blackpool C.B. 135, Oldham C.B. 113, Blackburn C.B. 69, Manchester C.B. 63, St. Helens C.B. 40, Chadderton U.D. 33, Middleton M.B. 25, Royton U.D. 22, Liverpool C.B. 19, Lytham St. Anne's M.B. 16, St. Helens C.B. 14, Kirkham U.D. 13, Failsworth U.D. 11), Durham 241 (Seaham U.D. 72, Darlington R.D. 49, Easington R.D. 30, South Shields C.B. 22, Felling U.D. 20, Stanley U.D. 17, Gateshead C.B. 16), Yorkshire West Riding 144 (Huddersfield C.B. 41, Leeds C.B. 35, Castleford U.D. 20, Sheffield C.B. 13), Northumberland 130 (Newcastle-upon-Tyne C.B. 30, Whitley Bay M.B. 27, Bedlingtonshire U.D. 23, Blyth M.B. 20), London 120 (Shoreditch 23, Hackney 20, Islington 20, Southwark 10), Leicestershire 77 (Leicester C.B. 60), Norfolk 66 (Norwich C.B. 39), Yorkshire North Riding 49 (Middlesbrough C.B. 46), Surrey 46 (Carshalton U.D. 16, Woking U.D. 11), Warwickshire 45 (Nuneaton M.B. 27, Birmingham C.B. 12), Cheshire 39 (Stockport C.B. 26), Southampton county 25 (Droxford R.D. 14), Lincolnshire 25 (Scunthorpe M.B. 21), and Nottinghamshire 24.

In Scotland an increasing incidence of dysentery has been recorded during recent weeks. 417 cases, an increase of 83 on the preceding week, were notified during the week. The largest returns were Glasgow 176, Dundee 50, Lanark county 47, Edinburgh 33, and Stirling county 32.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 665, whooping-cough 1,310, diphtheria 5, measles 26,833, acute pneumonia 872, acute poliomyelitis 7, dysentery 1,454, paratyphoid 13, and typhoid fever 4.

Medical News

Medical Illustration.—In the Old Library at B.M.A. House the Medical Artists' Association of Great Britain has staged a small exhibition of its members' work. There are paintings and drawings of operations and dissections, suitable for the illustration of books or papers; visual records of endoscopic and ophthalmoscopic appearances; models in resins and wax; composite panels illustrating clinical syndromes; slides; and other aids to the medical teacher. The work is of a remarkably high quality. Opening the exhibition on April 15, Sir CECIL WAKELEY, the association's honorary president, said he was keen to see the medical artist become established as an essential member of the staff of every hospital in the country, especially the teaching hospitals. Illustrations before and after operation were invaluable, he said; more so, in some cases, than pages of medical notes. The exhibition will remain open until April 30 from 10 a.m. to 5 p.m. (on Wednesday until 8 p.m.). A list of members of the Medical Artists' Association is available at the exhibition, giving their addresses and appointments. This should prove most useful to medical authors and teachers.

Royal Northern Hospital.—In place of the old North London Medical and Chirurgical Society, it is intended to hold open monthly meetings for postgraduates and general practitioners at the Royal Northern Hospital, Holloway. These meetings will usually be held at 2.30 p.m. on the last Thursday of the month, and their chief aim will be discussion of clinical subjects by both hospital staff and general practitioners. The first meeting will be held at 2.30 p.m. on April 28 (in St. David's Wing) when Dr. J. F. BUCHAN will speak on "The Relief of Pain by Physical Methods" followed by a demonstration and discussion. Local general practitioners are particularly welcome.

Grey Turner Lectures.—Sir ZACHARY COPE will deliver the first annual Grey Turner Lecture at Newcastle-upon-Tyne on May 19. His subject will be "Some Early Medical Museums." The Grey Turner lectures are endowed by a bequest to King's College, University of Durham, by the late Professor George Grey Turner, and in accordance with his wishes their subject will be some aspect of the history of surgery. Before the lecture, at 5 p.m., a memorial plaque to Professor Grey Turner will be unveiled in the Royal Victoria Infirmary.

Hunterian Society's Gold Medal Essays.—The winner of last year's gold medal, for an essay on the "Management of the Climacteric in General Practice," is Dr. PHILIP HOPKINS, of Hampstead. He will receive the medal at the annual meeting of the society at the Talbot Restaurant, London, on April 25. The subject for the 1955 essay is "Headache," and the competition is open to all general practitioners. Further details from Mr. R. S. MURLEY, 95, Harley Street, London, W.1.

Ames Awards in Gastroenterology.—The American College of Gastroenterology and the Ames Company of Elkhart, Indiana, announce prizes of \$250, \$100, and \$50, with a year's free subscription to the *American Journal of Gastroenterology*, for the best papers submitted before September 1 on original work in gastroenterology. The competition is open to any doctor irrespective of nationality. Further details may be obtained from the American College of Gastroenterology, 33, West 60th Street, New York, 23.

Honorary Freeman of Barbers' Company.—At a meeting of the Court of the Worshipful Company of Barbers of London at Tallow Chandlers' Hall on April 5, the Master, Sir CECIL WAKELEY, admitted Sir JAMES PATERSON ROSS as an Honorary Freeman.

Dr. Charles Hill, the new Postmaster-General, was sworn a member of the Privy Council on April 12.

Helms Trophy for Dr. Bannister.—On April 12 Dr. ROGER BANNISTER was presented with the Helms Trophy of the Helms Athletic Foundation of America, as being Europe's leading athlete in 1954. The presentation was made in London by Mr. HAROLD ABRAHAMS, honorary treasurer of the British Amateur Athletic Board. It commemorates the first mile under 4 minutes (3 minutes 59.4 seconds at Oxford on May 6, 1954) and the mile of 3 minutes 58.8 seconds in the British Empire Games.

Sir Cecil Wakeley received the honorary D.Sc. of Delhi University last month. He is the first member of the medical profession to have this honour.

Professor Ian Aird will deliver the Edward Starr Judd Memorial lecture at Minnesota University on May 26. He will then conduct short postgraduate courses in surgery at Minneapolis and Vancouver, and engage in a lecture tour of Western Canada and the United States. He expects to leave England on May 23 and return on July 7.

Dr. Wilfrid Sheldon, physician-paediatrician to the Queen, is on a lecture tour in Cyprus and Turkey arranged by the British Council. The tour ends on May 6.

COMING EVENTS

The Montreal Conference.—"Medical Aspects of Traffic Accidents," May 4 and 5. Invitations and details from Dr. HAROLD ELLIOTT, Queen Mary Veterans Hospital, 4565, Queen Mary Road, Montreal.

International Hospital Federation.—The Ninth International Hospital Congress will be held at Lucerne from May 29 to June 3. The central theme will be "The Mental Well-being of Patients in the General Hospital." Details from the Federation, 10, Old Jewry, London, E.C.2.

Canadian Neurological Society.—The seventh annual meeting will be held in Toronto, June 16-19. Visiting physicians and scientists are welcome at scientific sessions. Details from office of the secretary, 730, Medical Arts Building, Toronto.

NEW ISSUES

Annals of the Rheumatic Diseases.—The new issue (Vol. 14, No. 1) is now available. The contents include:

HEBERDEN ORATION. Robert M. Stecher.
CARDIAC CHANGES IN RHEUMATOID ARTHRITIS. Nils Egelius, Olie Göhle, Eric Jonsson, and Fredrik Wahlgren.
HUMAN SKIN COLLAGEN FROM DIFFERENT AGE GROUPS BEFORE AND AFTER COLLAGENASE DIGESTION. Madeline E. Keoch.
RHEUMATOID ARTHRITIS: DYE RETENTION STUDIES AND COMPARISON OF DYE AND RADIOACTIVELY LABELLED RED CELL METHODS FOR MEASUREMENT OF BLOOD VOLUME. Allan St. John Dixon, Savitri Ramcharan, and Marion W. Ropes.
NATURE OF ANEMIA IN RHEUMATOID ARTHRITIS. I. METABOLISM OF IRON. L. M. H. Roy, W. R. M. Alexander, and J. J. R. Duthie.
ACTION OF HYPOPHYSAL GROWTH AND THYROTROPIC HORMONES IN THYROIDECTOMIZED RATS. E. Salgado.
ANKYLOSING SPONDYLITIS. F. Dudley Hart. With an Appendix by N. F. MacLagan.
THERAPY OF "FELTY'S SYNDROME." Philip Ellman, Leon Cadkowitz, and J. Stanley Elwood.
A SIMPLE POSTURE METER. R. Harris.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Heart Journal.—The next issue (Vol. 12, No. 2) is now available. The contents include:

PATENT DUCTUS ARTERIOSUS WITH PULMONARY HYPERTENSION. William Whitaker, Donald Heath, and James W. Brown.
CALIBRATION OF AN ELECTRONIC PHONOCARDIOGRAPH. By A. W. Sloan and J. R. Greer.
THE EARLY DIASTOLIC SOUND OF CONSTRICTIVE PERICARDITIS. Patrick Mounsey.
THE RESTING HYPERVENTILATION OF CONGENITAL HEART DISEASE. R. J. Shephard.
THE BLOOD FLOW IN THE RIGHT ATRIUM AND SUPERIOR VENA CAVA IN TRICUSPID INCOMPETENCE. Otar Müller and John Shillingford.
A PHOTOMETRIC METHOD FOR ESTIMATING THE OXYGEN SATURATION OF SMALL BLOOD SAMPLES. L. Molyneux and E. A. Pask.
SOME VARIATIONS IN THE SHAPE OF THE PRESSURE CURVE IN THE HUMAN RIGHT VENTRICLE. Peter Harris.
SECONDARY TUMOURS OF THE HEART AND PERICARDIUM. Robert B. Goudie.
THE ELECTROCARDIOGRAM IN PRIMARY ENDOCARDIAL FIBROELASTOSIS. Peter Vlad, Richard D. Rowe, and John D. Keith.
AORTIC VALVULAR STENOSIS WITH COARCTATION OF THE AORTA. D. E. Smith and M. B. Matthews.
THROMBOSIS OF THE MAIN PULMONARY ARTERIES. Oscar Magidson and George Jacobson.
THE INTRACARDIAC ELECTROGRAM AS AN AID IN CARDIAC CATHETERIZATION. D. Emslie-Smith.
THE ATRIAL PRESSURE TRACING IN CONGENITAL HEART DISEASE. R. J. Shephard.
THE RESULTS OF VALVOTOMY FOR SIMPLE PULMONARY STENOSIS. Maurice Campbell and Sir Russell Brock.
UPPER ATRIO-VENTRICULAR NODAL BEATS PRECIPITATED BY VENTRICULAR EXTRASYSTOLES WITH RETROGRADE CONDUCTION. A. Schott.
PATENT DUCTUS ARTERIOSUS WITH AN ABNORMAL AORTIC VALVE. R. E. Bonham-Carter, C. H. M. Walker, R. Daley, M. B. Matthews, and W. E. Medd.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, April 23

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Queen's Head Hotel, Maidstone, 3 p.m., eighth annual general meeting.

Monday, April 25

● HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, E.C.4, 7 for 7.30 p.m., annual general (dinner) meeting. Professor E. N. da C. Andrade, F.R.S.: Isotopes.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., Second Lettsomian Lecture by Dr. J. G. Scadding: Treatment of Pulmonary Tuberculosis.
NATIONAL SPASTICS SOCIETY.—At Old Council Hall, Bromley Road, Beckenham, 8 p.m., Dr. and Mrs. K. Bobath: Working Methods of Treatment in the Field of Cerebral Palsy.

Tuesday, April 26

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Professor R. J. Lasi: Form and Structure of Muscles.
ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 6 p.m., Dr. J. N. Morris: Some Hypotheses on Coronary Artery Disease.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., neurological demonstration by Dr. B. G. Parsons-Smith.

Wednesday, April 27

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Queen Elizabeth Hospital, Birmingham, 8 p.m., clinical meeting.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., short papers and discussion: Some Obstetric Problems in General Practice. Short papers by Dr. Dorothy M. Parkin: The Rh Factor; Dr. Helen Payling Wright: Thrombosis; Miss Josephine Barnes: Toxicemia.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., Third Lettsomian Lecture by Dr. J. G. Scadding: Treatment of Pulmonary Tuberculosis.
OSLER CLUB OF LONDON.—At 1, Wimpole Street, W., 8.15 p.m., meeting in honour of Anthele Brillat-Savarin (born April 1, 1755). J. I. M. Jones, D.Sc.: Savour, Science, and Brillat-Savarin. Discussion, Professor S. J. Cowell and Mr. L. R. Ring.
ROYAL SOCIETY OF ARTS.—2.30 p.m., Peter Le Neve Foster Lecture by Sir Basil Henriques, J.P.: Detection and Prevention of Anti-social Behaviour in Young Persons.
ST. MARLYBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. A. F. McGlashan: Principles in Psychotherapy.
SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP.—At the Town Hall, Bournemouth, 10 a.m., joint meeting with Royal Sanitary Institute. Subject: Contribution of Processing Techniques to the Nutritional Value of Food. Professor J. Yudkin: Normal Processing Techniques; Dr. A. J. Amos, Ph.D.: Fortification.

Thursday, April 28

HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Professor G. J. Romanes: Motor Cells of the Spinal Cord.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. I. R. Maric: Common Skin Diseases.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Professor R. J. Dubos (Rockefeller Institute for Medical Research): Micro-environment of Inflammation or Metchnikoff Revisited.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. R. G. Taylor: Brown-Séquard Syndrome following Trauma.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor W. T. Cooke: Nutritional and Metabolic Factors in the Aetiology and Treatment of Regional Ileitis.
ROYAL SOCIETY.—4.30 p.m., Bakerian Lecture by Professor M. L. E. Oliphant, F.R.S. (Australia): Acceleration of Charged Particles to Very High Energies.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. W. Feldberg: A New Experimental Approach to the Pharmacology of the Central Nervous System.
SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Netherne Hospital, Coudson, Surrey, 8 p.m., clinical meeting. Papers by Dr. I. C. White, Dr. J. P. S. Robertson, and Dr. R. K. Freudenberg.

Friday, April 29

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, 3 p.m., Dr. J. D. Spillane: Neurology in General Practice.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—3.30 p.m., Mr. J. C. Ballantyne: Use of Hearing-aids.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At 11, Chandos Street, W., 7.30 p.m., short papers by Surgeon Lieutenant P. R. Oliver, R.N., Dr. G. W. Czomka, and Dr. R. S. Morton.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. I. M. Jackson: Ectopic Gestation.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Dr. S. E. Dicker: Renal Clearances in Mammalian Kidneys.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Carter.—On April 7, 1955, to June, wife of Dr. J. K. Carter, Redhill County Hospital, Surrey, a daughter—Heather.
Clarke.—On April 14, 1955, at Gosforth, Newcastle-upon-Tyne, to Catherine, wife of Mr. Patrick Clarke, F.R.C.S., a son.
MacLeod.—On April 14, 1955, at Nuffield House, Guy's Hospital, London, S.E., to Joan, wife of Dr. Ian S. MacLeod, a son—Hamish.
Turner Warwick.—On March 25, 1955, to Margaret (formerly Harvey Moore), M.R.C.P., wife of Richard Trevor Turner Warwick, F.R.C.S., M.R.C.P., a sister for Gillian—Lynne Frances.
Vowles.—On April 9, 1955, at Cardiff, to Mary, wife of Mr. Keith Vowles, M.B., F.R.C.S., a daughter—Susan Jane.
Wilkinson.—On April 12, 1955, at St. Mary's Hospital, Paddington, London, W., to Patricia (formerly Pipet), wife of Dr. A. P. H. Wilkinson, a brother for Timothy and Robia—Nicholas Simon John.

MARRIAGES

Davis—Liddle.—On April 2, 1955, at Beverley Minster, Yorks, Leslie Russell Davis, M.D., of the Royal Free Hospital, London, W.C., to Margaret Jean Liddle, S.R.N., of Cottingham, Yorkshire.
Trigg—Jordan.—On April 16, 1955, at St. Barnabas' Church, Dulwich Village, London, S.E., Kenneth H. Trigg, M.B., B.S., of Surbiton, Surrey, to Sylvia Jordan, M.B., B.S., of Herne Hill, London, S.E.

DEATHS

Barbour.—On April 12, 1955, at 97, Alleen Park, Dulwich, London, S.E., Thomas Barbour, M.B., Ch.B., D.P.H., aged 75.
Mitchell.—On April 9, 1955, at The Mount, Topcliffe, near Thirsk, Yorks, Talbot Carter Mitchell, M.R.C.S., L.R.C.P., aged 78.
Roche.—On April 7, 1955, Alfred Reginald Roche, M.C., M.R.C.S., L.R.C.P., of 13, North Park Avenue, Leeds, Yorks, aged 79.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Prognosis after One Epileptic Child

Q.—A young couple have an epileptic child aged 2½ years. Contraceptive measures have failed, and the wife is now pregnant. They are fearful that a second child will also be epileptic. The wife's mother had fits as a child and after the menopause. Can one reassure them that the chances of a second child being epileptic are very faint, and that another pregnancy is really desirable?

A.—In this case there is a chance of approximately one in twenty that the second child will in due course develop epilepsy like the elder sib, as it is to be assumed that the epilepsy in the cases of the elder child and the grandmother was "idiopathic" or cryptogenic. However, if the epileptic child only developed the trouble after possible or probable damage to the brain—for example, birth injury or a febrile illness—then there would be no increased tendency for the second sib to be epileptic too, and the probability which obtains for the general population—that is, approximately 1 in 200—would hold.

Clearly, the parents can be emphatically reassured, as at the worst there is only a small chance that the second child will not be normal.

Hereditary Factors in Endogenous Depression

Q.—To what extent is endogenous depression hereditary? A patient of mine wishes to marry a man whose mother suffers from attacks of endogenous depression about twice a year, when she gets so agitated that she has to retire to a mental home for several weeks. It is not known whether other members of the family have suffered from mental disorders. The son appears quite normal.

A.—The hereditary factor in the predisposition to endogenous depression is quite strong. If any single gene can be held responsible, it would probably be an irregular dominant. If a parent is liable to recurrent manic or depressive states of such severity as to require hospital treatment, then one in five (approximately) of the children can be expected to show signs of a similar disposition. However, more often than not the mood swings in the child will never be so severe as to need treatment in hospital.

In the case quoted a great deal depends on the present age of the son. If he is still in his early twenties, then his present normality does not preclude the possibility that he will develop a cyclothymic temperament, and still less the possibility that he may one day have an endogenous depression. Even then, however, the chances are rather remote that he will develop the very disabling pattern of recurrence shown by the mother. If the son is well into the thirties, and shows no sign of a tendency to spontaneous mood swings, it is exceedingly improbable that he will have anything worse than one or two isolated depressive illnesses late on in life; and the chances are about 9 to 1 that he will go through the rest of his life without trouble.

Persons with a tendency to endogenous mood swings very rarely indeed become chronic psychiatric invalids. If they have an illness, they nearly always get over it satisfactorily, and rarely have difficulty in maintaining their social level. Numbers of them are socially more than averagely successful, and as a class they tend to be rather easy to get on with.

The inquirer's patient should feel no very great apprehension in deciding to marry the man described, unless he also shows defects of character or personality of other kinds.

Provocative Androgen in the Acid Phosphatase Test

Q.—Can you give me any details about a test for determining the acid phosphatase level in cases with a doubtful positive result by the ordinary methods? I believe this test is concerned with giving a provocative dose of testosterone to activate the output of acid phosphatase by the prostate in cases of carcinoma.

A.—Under physiological conditions, no acid phosphatase can be detected in the plasma, but in the presence of a carcinoma of the prostate, and especially when there is metastasis to bone, this enzyme passes into the blood stream, and its detection has proved a valuable diagnostic aid. The administration of androgen in these cases increases the plasma acid phosphatase level, and so could be used as a provocative test where doubt exists; the administration of oestrogens diminishes the plasma level.

Toxic Hazards of Aniline and Benzene Compounds

Q.—What routine supervision should be given to workers dealing with aniline and benzene compounds with a view to the prevention and early detection of toxic effects?

A.—Under the Chemical Works Regulations (1922) all persons engaged in any "nitro" or "amido" process (which includes the nitro- and amide (amino) compounds of benzene) shall be examined by a doctor once a month (or at other such intervals as may be prescribed) (Reg. 30(c)), and the results entered in a health register. Other provisions of these regulations are that no person under 18 years of age should be employed in such a process (Reg. 24); that protective clothing, such as overalls and protective footwear, shall be provided—the overalls to be washed or renewed at least once a week (Reg. 25). A cloakroom has also to be provided for the working and other clothes, as well as storage space for the protective clothing (Reg. 26). So that meals shall not be taken in the workroom a mess room must be provided for the workers (Reg. 27), and not only must good washing facilities be provided (Reg. 28) but also bathing accommodation, with hot and cold water, with soap and towels (Reg. 29). A bath register must be kept containing a list of all people employed in contact with the chemicals, and the date on which each person takes a bath must be entered. By regulation all persons employed in the processes must carefully wash the hands and face before taking food or leaving the factory.

These regulations recognized that aniline (aminobenzene) and most of the nitro-compounds of benzene (e.g., nitrobenzene) are absorbed by the unbroken skin, as well as the fact that most of them are volatile and the vapours can be inhaled. In general, therefore, preventive measures should consist in keeping the chemicals off the skin, and, if splashes on the skin do occur, their rapid removal by washing in cold water. Exhaust ventilation should be applied to the processes to keep the vapours out of the air of the workroom.

The compounds of benzene are numerous, but aniline and nitrobenzene can be taken as good examples. Both are tissue asphyxiants and narcotics, and the common early presenting sign of poisoning is cyanosis of the skin, due to the formation of methaemoglobinemia. This sign may be detected by an experienced foreman, who should be instructed to send a cyanosed worker immediately to the doctor. Further information about the signs and symptoms of poisoning can be obtained from the standard textbooks on industrial toxicology. Aniline poisoning is notifiable under the Factories Act.

Stramonium Leaves and Smoker's Cough

Q.—Would the addition of stramonium leaves to tobacco benefit smoker's cough?

A.—The addition of stramonium leaves to tobacco would certainly not benefit smoker's cough. Stramonium leaves contain both hyoscyamine and hyoscyne, and these substances

greatly diminish or arrest ciliary movement. This movement normally removes the tarry deposits from tobacco smoke which are formed in the bronchioles. The tar is transported from the respiratory passages into the oesophagus. The cough probably arises from the irritation caused by the tarry deposits, and would be made worse if the removal of these deposits were impeded.

Circumcision and Sexual Satisfaction

Q.—I have heard it said on various occasions, sometimes by men and sometimes by women, that women prefer coitus with a circumcised male because he takes longer to reach orgasm than one who is uncircumcised. Is this a statement of fact or merely an expression of opinion?

A.—This is a belief rather than a fact, but it is one which has been firmly held by certain races from earliest times. Ancient as well as modern literature contains accounts of women who, after failing to satisfy their sexual desires elsewhere, turned ultimately to a man who had been circumcised. The idea is widely accepted and discussed amongst the more primitive peoples to-day.

It is said that removal of the prepuce results in the glans penis becoming less sensitive to touch, and more stimulus is therefore required to produce an emission. The coital act is thus prolonged, and this tends to ensure that the woman always reaches orgasm. The same objective can be achieved by other means, so that the reputation enjoyed by circumcision is traditional rather than proved, and it remains to be shown that any success which a circumcised lover may have is "based not on artistry but on anatomy" (R. L. Dickinson). It may be added that ejaculation is not dependent only on the tactile sensitivity of the glans, and it is not uncommon to hear circumcised men complaining of premature ejaculation.

Circumcision does not necessarily make the act more pleasurable for the male, but the men of Eastern races tend in any case to set great store on mere prolongation of coitus—with or without the interests of the female partner in mind. Some authorities hold that this is the original motive for ritual circumcision as practised by certain primitive communities.

Plastic Ring Pessaries

Q.—What advantages have plastic ring pessaries over vulcanite and rubber ones?

A.—Although they can be moulded by heat, the only plastic rings of which the writer has knowledge are rigid in use and therefore a little more difficult to insert than pliable rubber or rubber-covered pessaries. Their great advantage is that they do not irritate the vaginal wall, so the patient remains free from offensive odour and discharge. They therefore require changing only at relatively infrequent intervals, and douching is usually unnecessary. They are not, of course, free from the risk of producing pressure necrosis. Vulcanite pessaries are also much less irritating than rubber-covered ones, although they may not be quite so good in this respect as those made of plastic material.

All ring pessaries, irrespective of their material, are only efficient if the perineum is strong enough to hold them. As a rule, they support the uterus better than the vaginal walls.

Nylon Toothbrushes

Q.—Are toothbrushes made from nylon or other synthetic fibres better than those made of bristle? What are their advantages and disadvantages?

A.—Toothbrushes made from nylon or synthetic fibres usually have a longer life than those made of natural bristle. The pattern of wear is also different, as nylon fibres tend to bend, producing a splayed brush (particularly if used with hot water), whereas natural bristle tends to break.

The main disadvantage of nylon toothbrushes is that most are too hard and are liable to damage the gums and teeth. Natural bristle brushes may be hard at first, but soften rapidly with use. As an alternative soft nylon brushes are now available and would appear to clean the teeth and gums adequately without causing damage. However, there is some evidence¹ that brushes made from natural bristles are more efficient cleansers. Unfortunately the supply of first-quality bristle available in this country is at present limited, as this grows on the backs of Siberian hogs.

NOTES AND COMMENTS

Wet Clothes.—Colonel L. W. HARRISON (London, S.W.1) writes: Your expert's answer on this subject ("Any Questions?", April 9, p. 923) reminds me of an experience during the South African War of 1899-2 which may help to supplement his remarks usefully. For many months during that war I trekked with an infantry battalion, and on very many days we marched through a steady drizzle in which the soldiers' clothes were wet through. To my surprise at first, the soldiers kept their greatcoats rolled—in those days they carried them "banderole"—that is, rolled and supported on one shoulder whilst hanging diagonally across the body—and they did not put them on until the rain had ceased, in the evening. How they had learnt the tip I did not know. Perhaps it was from some Scot who had condescended to soldier with this "Manchester" battalion; perhaps it had been handed down in the regiment from experience in earlier campaigns. Your expert says, "The more clothing worn, within limits, the warmer the skin." The words "within limits" should be emphasized. For the three years I was in South Africa, during the war and immediately thereafter, except for three days in Lydenburg and two days in Johannesburg, I slept under tent or bivouac, mostly the latter, and in the cold season it was at first a problem to keep warm: it was quite usual then to find the water in one's hand-basin frozen pretty hard. At first I piled on clothing and seemed to become colder and colder, so one night I took off my greatcoat and laid it loosely over me, having concluded that the tightness of the clothing was responsible for the feeling of chilliness. The experiment was a success, and I learnt thereby that for warmth the clothing should not be too tight. In spite of the many days spent in saturated clothing nobody in my medical charge caught cold, so far as I knew.

A Commonwealth Tour.—Mr. D. D. BROWNE (Wangaratta, Victoria, Australia) writes: Mr. A. Lawrence Abel (*Journal*, December 25, 1954, p. 1540) refers to Wangaratta as a town of 16,000 people that has doubled in five years. Actually, the population is a little over 10,000 and has increased 64% in the last seven years. He refers to Dr. Phillips as the local senior surgeon with two partners, and as a member of the Commonwealth B.M.A. Council. None of these statements is correct. . . . In Dr. Phillip's own interest and in justice to his fellow practitioners in this town and surrounding country, among whom your *Journal* circulates, it seems fair to ask that these errors be corrected.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

Correction.—In Dr. A. T. Mennie's letter on tetracycline (*Journal*, April 16, p. 973) the statement in the last paragraph that "tetracycline produces fewer side-effects . . ." should have read that "tetracycline produces fewer side-effects."

ACHROMYCIN*

TETRACYCLINE

offers wider scope in general practice . . .

available in many dosage forms

ACHROMYCIN tetracycline, Lederle's newest broad-spectrum antibiotic, is now derestricted and can be prescribed on E.C. 10. It is available in many convenient therapeutic presentations enabling the practitioner to select the most appropriate form that best suits the needs of the patient. All these dosage forms embody the striking advantages of ACHROMYCIN . . . widest range of antibacterial action, higher solubility and diffusion in body tissues, lowest incidence of side effects. These advantages mean greater comfort for the patient, quicker response and greater economy in prescribing. ACHROMYCIN is well tolerated by patients of all ages in all its dosage forms. Average adult dose of ACHROMYCIN, like that of Aureomycin† chlortetracycline—from which it is derived—is 1 GRAM DAILY.

ACHROMYCIN FOR GREATER COMFORT, POTENCY AND ECONOMY

Capsules 50 mg.—Vials of 25 and 100.
250 mg.—Vials of 16, bottles of 100.
Tablets 50 mg.—Vials of 25 and 100.
250 mg.—Vials of 16, bottles of 100.
Intramuscular. Vials of 100 mg.
Intravenous. Vials of 250 mg. and 500 mg.
Ointment 3%. Tubes of ½ oz. and 1 oz.
Ophthalmic Ointment 1%. Six tubes of ½ oz.

Oral Suspension. Cherry-flavoured—Bottles of 1 oz.
Pediatric Drops. Cherry-flavoured—Bottles of 10 cc.
Soluble Tablets. 50 mg. Bottles of 100.
Spersoids.* Dispersible powder—Jars of 36 Gm. and 75 Gm.

* Regd. Trade Mark. † Trade Mark.

In Coma or Delirium

In Toxicity (with psychoses)

In Psychoses

from Barbiturates, Narcotics, Alcohol

from Acute infections
e.g. Influenza, Pneumonia

from Prolonged ill health
Multiple operations, Chronic stress

PARENTROVITE

The following are some of the conditions for which PARENTROVITE is being found effective: Acute alcoholic psychoses, including delirium tremens; Coma or delirium from drugs e.g. barbiturates; Collapse after continuous narcosis; Drug withdrawal symptoms; Post-operative confusional psychoses; Psychiatric reactions to prolonged ill-health; Toxic syndrome of and sequelae to influenza and pneumonia.

In all these conditions there is disturbance of intracellular glucose metabolism in the brain calling for massive doses of the VITAMIN B COMPLEX and VITAMIN C given by the most rapid and effective route.

Adequate dosage can be given by slow intravenous injection or, diluted with normal saline by intravenous drip. Ampoules are also available for intramuscular injection.

Available in boxes of 3 pairs and in hospital packs. Notes on the formulae, rationale and dosage may be obtained on request.

THE CHANGING FACE OF MEDICINE*

BY

CLIFFORD KENNEDY, M.B., Ch.B., F.R.C.Sed., F.R.C.O.G.

Consulting Obstetrician and Gynaecologist, Royal Infirmary, Edinburgh

To the layman reading his daily paper, and in particular the ponderous and often pontifical pronouncements of our politicians, must come the belief that he lives in an era when all is well with medicine. I wonder if he is right. Why so often is the medical father of to-day relieved when his son, sometimes perhaps with a little persuasion, chooses a different career? The reason is that in this age of rapid transformation medicine has not escaped. The foundations upon which our work was built have been rudely shaken, and I sometimes wonder whether the structure above is beginning to totter. I would like to draw attention to several of the factors which I think may be playing their part in this change so far as it affects specialist practice, for I would not presume to speak of the worries which attend the general practitioner. Some of the causes are naturally of our own making; others have been thrust upon us through this new health service under which we work. I propose to treat my subject under four main headings: (1) undergraduate training; (2) registrar appointments and training; (3) changes in consultant practice; and (4) the law and medicine.

1. Undergraduate Training

It is always a good thing to raise the standard of anything, and with that end in view the course in medicine has been increased to one of six years. This step—I think an unnecessary one—might have been excusable had the extra year been devoted to clinical study rather than to the basic sciences. It was thought that by giving more time to the subjects at the beginning of the medical course the boy or girl in the last year of school might benefit from a broader education at that stage. The opposite result has, however, obtained, in so far as the schoolmaster, hearing of this additional year spent on the basic sciences at the university, has got the idea that still more attention should be given to those subjects at school, and as a result the whole idea has been nullified. It was interesting to hear some two years ago, from one vitally concerned in this change at the University of Edinburgh, an admission that a mistake had been made and that this further year of study should have been devoted to the end of the course rather than the beginning, and yet this mistake is apparently allowed to be perpetuated indefinitely.

I think it is true to say that Edinburgh, unlike some medical schools in the south, has always laid stress on

providing the undergraduate with a solid foundation of theory on which to build his clinical study. There may be great value in this—indeed, it may be the correct approach and the best method of ensuring a sound training. But are we satisfied that this is not being overdone, that the medical undergraduate course is not too intense, too overcrowded? With increasing knowledge and an ever-widening research it is inevitable that there is nowadays more to learn; but, even allowing for this, there is sometimes the feeling that there is too much teaching, too much spoon-feeding, and that more good might derive from a less concentrated course of lectures and tutorials which would leave the student a little precious time to think for himself. Again, I would say there is an element of danger in instruction which lays too much emphasis on diagnosis made by the "back-room boys of medicine." How often, on asking a simple clinical question requiring an equally simple and straightforward clinical answer, are we advised, in a pitying sort of way, to have some fantastic biochemical investigation carried out; or, if it be a question of the head going through the pelvic brim, to have the patient x-rayed! It is singularly unfortunate that an assessment of the patient by the bedside appears nowadays to be deemed less essential and is becoming more carefree and haphazard. At the end of university training there is an invaluable year in hospital and then two years in the Services, when the mind of the doctor, so far as things medical are concerned, might in the average case be a complete vacuum. Postgraduate courses are nowadays popular and are an essential stimulant to the general practitioner, who, overburdened by the trivialities of present-day routine—trivialities encouraged by the attitude of the Welfare State mentality—has little time to keep abreast with advances in his subject. It is a sad reflection, though, that so many young men take those courses simply because during two years of Service life they have forgotten much of the teaching of their undergraduate days.

2. Registrar Appointments and Training

Suppose now that one of those doctors, finished with his National Service, wishes to specialize in obstetrics and gynaecology. At this stage he does three things. Assuming that he has done six months' medicine and six months' surgery in his year in hospital following graduation, he now spends another two years as house-surgeon in obstetrics and gynaecology. Then he becomes a registrar, and finally he prepares for the special examinations which are necessary. This last phase of

*The Presidential Address read to the Edinburgh Obstetrical Society on November 10, 1954.

specialization takes up another five or six years at least, so from the day he started medicine he will have spent some fifteen years in preparing for his specialty. But his programme is not yet complete—there is often a dreary wait before a suitable and congenial consultant post offers; indeed, the wait may prove too long and he may eventually be offered, and forced to accept on economic grounds, some junior post where he may carry out efficiently and conscientiously the work of a consultant without being granted the title. Is there any other profession which calls for such a prolonged period of preparation and apprenticeship? I wonder whether the layman, still reading about the improved status of the specialist, realizes all this.

Some will say, "But look—nowadays the resident appointments are associated with more adequate remuneration than in the past," and will remind me that, as compared with the honorarium of £25, raised ultimately to £40, which a clinical tutor of my time received in the gynaecological wards of the Edinburgh Royal Infirmary, his counterpart, the registrar of to-day, receives a princely salary and his financial position is secure so long as he holds his appointment. I wonder if this security is altogether a good thing and whether registrar appointments should be whole-time.

In the old days a clinical tutor's hospital appointment was part-time. To close the financial gap between starvation and a moderate degree of comfort he gave private tuition to the Fellowship candidate, to the final-year student, and on occasion even to the nurse. He might also conduct special classes for the various examinations. It was his privilege to assist his chief in private, and in addition he began to get the occasional private case himself, very often the obstetric patient unable to afford the fee of a more senior man. From all this the clinical tutor derived much benefit and a much wider experience. To-day the registrar appointment is whole-time; an introduction to private practice is therefore not possible, and even the assisting of his chief outside of hospital has on occasion been questioned.

The present-day system breeds a mentality whose horizon is bounded by the hospital walls. There is little awareness of the world outside, and the young registrar often has little or no desire to go through the monotonous routine of private tuition. The whole approach has tended to become more lethargic and more lackadaisical. The younger folk may not approve of this observation, but it is true nevertheless. They are losing some of the greatest thrills which we who were fortunate enough to work under another system experienced: the enormous satisfaction of making headway—financial headway, to take it at its lowest value, for I would not underrate the importance of that for one moment; making headway, then, by our own initiative, ability, and "private enterprise." There is no doubt whatever that almost any nationalized industry which lacks competition to keep it on its toes goes downhill—one does not need to look far to see that—and medicine will be no exception if a whole-time salaried service comes to pass. Already there is a levelling-up process taking place whereby the unsuccessful specialist of the past, through his hospital remuneration and the decline in private practice, will be on almost equal terms with his more able and more capable colleague. Once that happens and there is no real reward for merit, something will have gone out of the profession.

Now, I consider this to be of tremendous importance to the future of medicine. There is no doubt that a section of our politicians wish private practice to die out, and the quicker the better. They want instead a whole-time salaried State service. To my mind this would be a disaster of the first magnitude for the doctors and for the country. Rather should an active and virile private practice in friendly rivalry with the Health Service be our safeguard. I am quite sure that this system of whole-time registrar appointments, in so far as it denies the right to carry out, and finally kills any desire to take part in, private practice, is playing into the

hands of the politicians. There is, too, another point. Whereas the clinical tutor of bygone days had his introduction to private practice during his five years of appointment, and therefore had something to fall back on when his tutorship expired and before he gained a position on the honorary staff, the registrar of to-day has no such introduction, and may well find himself in dire straits in the gap between.

May I digress for a moment to venture comment on the question of research, upon which ever-increasing stress is being laid. It is well known that nowadays, when applicants for a specialist post are being considered, first importance is given to any research that the individual may have carried out and the number of publications to which his name may be attached. Indeed, it is the advice of the senior consultants to the very junior that they must write and write and keep on writing if they want their application to be successful. It sometimes, nay quite frequently, matters naught, when the candidates are being discussed, whether the research was of practical worth, of particular brilliance, or, on the other hand, of no value whatever; it counts for nothing that, to many members of a varied appointing body, the publications might as well have been written in a foreign language with which they have become somewhat out of touch. The articles may be so much rubbish—they often are; the important point is that one very special candidate may have written more or is thought to be potentially a more likely research worker than another, and he is invariably the successful applicant. There is no doubt whatever that that is the position to-day, and it applies to most specialties. We have come to a pretty pass when such a situation can obtain that a first-rate clinician and a sound and experienced operator may be passed over just because he has not put pen to paper as often as another.

It must be obvious to the meanest intelligence that everyone who makes the decision to specialize is not destined to carry out original work or even to be a low-grade author. It has been said that a man should be given a taste for research before he is thirty or it may be difficult to get him started. This may be the grand ideal, but in actual fact the trainee of that age has already an overloaded plate and there may be no more space left for the non-essential trimmings. Do not therefore be too ready to condemn the young man as lazy; do not damn him just because he cannot write something "original." Let him work out his salvation in other ways—he will if he is given a sympathetic chance. Surely there is a place for both types in the scheme of things—the clinician and the research worker. After all, the main function of the average physician, surgeon, or gynaecologist is to alleviate suffering and heal the sick so far as lies in his power, and I would maintain that this should be the first concern of the vast majority. It seems rather dreadful that we have in these days to remind ourselves from time to time of our primary role. It is sad that in this present age of experiment we are sometimes apt to lose sight of the fundamentals of our calling.

3. The Changes in Consultant Practice

Now let us look for a moment at those of consultant status. Partly because of a changing outlook and partly as the result of this new system under which we work, we have been, as a class, divided and subdivided, and it is all-important to bear this in mind in the years to come if we are to present a solid front on matters of policy and on the improvement of the National Health Service. Most important of all, it would appear to me, is the chasm—unfortunately an ever-widening chasm—which divides whole-time and part-time appointments. I do not propose to discuss the relative merits of those appointments, for obvious reasons. Each has its own peculiar advantages. Let us all recognize those advantages and leave it at that—that would be the solution, but I am afraid it is not quite so easy. A year or two ago sarcastic, and indeed bitter, criticism was levelled at the part-time consultant. It is, of course, inevitable that we should criticize one another, but let such criticism not be tainted, let it be free of rancour.

In discussing this question with a general practitioner a month or two ago I was rather surprised when he said there would soon be a place for the general practitioner in the teaching of the undergraduate. He believed that if the whole-time specialist idea were to go on growing there would come a time when no consultant had contact with the patient outside of hospital, and something would be lost to teaching on that account. I sometimes wonder whether the influence of the whole-time teacher is not a little responsible for the too academic outlook of the present-day undergraduate. I am quite certain of this: the more we lose touch with the general practitioner—and the whole-time is doing that now—the more will something vital depart from a valuable relationship. We need each other, we should get to know each other, and we should wish to help each other without hindrance of any kind.

We are divided again into four groups according to whether we have one of three grades of merit award or none at all. Following a letter to the *British Medical Journal** from Mr. John Simons on the subject of merit awards and stating that there was "considerable disquiet," Lord Moran replied in the same *Journal*† that this was "diametrically opposed to our experience." He describes in that letter the machinery involved in this labelling process—how, to begin with, in some areas small bodies advised the Awards Committee, and in other areas, notably "some of the London teaching hospitals," the task of recommendation was handled, at the request of the staff, by some of the senior members, who reported directly to the Awards Committee.

"There was a feeling that it was not fair to ask those who had been given this difficult task to submit their conclusions, which were obviously of a confidential nature, in open committee to perhaps as many as thirty members, for they were asked not merely to submit a list of names to fill vacancies; it was necessary to supply the Awards Committee with the reasons which had led to the choice of those names. And it was found that many consultants were not prepared to furnish these reasons save to the Awards Committee, where they could feel assured that the confidential nature of their report would be respected."

Lord Moran goes on to say that the "master principle" which has guided them from the beginning in their selection for awards has been to tap as many sources of information as possible. "So only," he continues, "can we hope to eliminate prejudice and attain to some degree of accurate appraisal." He speaks of the successful working of the awards system, asks the question whether he is entitled to make any such claim, and concludes his letter thus: "It is indeed a remarkable achievement, which has its roots in the good sense of our people—an achievement, I think, beyond the reach of more selfish countries." It did not occasion much surprise to find in the next few weeks replies of very contrary opinion to this letter in both the *British Medical Journal* and the *Lancet*.

Cloaked in such diabolical secrecy as those awards are, it is often difficult to get at the truth, and, not unnaturally, the wildest rumours run riot, but enough is known to say that wrongful decisions have been made. There are three questions I would ask Lord Moran: (1) Is the original percentage of awards in the three grades being adhered to? (2) What is the number of consultants in the teaching schools of England and Scotland, and how many awards in each grade have been given to the men in those schools? (3) What is the number of consultants in the teaching schools of London, and how many awards in each grade have been given to the men in those schools? The answer to those three questions would be more than interesting. The suggestion is often made that certain regions—and now I refer particularly to the larger medical schools—have been dealt with more generously than others, implying that the standard of the specialists and of medicine in one area is infinitely

superior to that in another. This I do not accept. We have no grouse whatever against the individual who is deemed worthy of a top-class award either by himself or by his fellows—let him have it by all means and good luck to him; our grouse is against a system which works so ineffectively and, so often, quite unfairly. The problem of improving this system is indeed a difficult one, because it is often impossible to get at the truth; the individual is afraid to complain—he feels that by so doing he makes his colleagues aware that he is a disappointed man; he is afraid also that by open complaint he may prejudice his chances for the future. Our national reserve and upbringing are no doubt responsible for the feeling that it is bad form to discuss this subject labelled "confidential," and so we tend to keep quiet about it. Silence therefore has been wrongly taken as approval of, and acquiescence in, the whole idea. It is unfortunate that it should be so. There is indeed grave disquiet in regard to the mechanism by which the awards are made, and unless we air our grievance openly and in a sufficiently large body there is little chance of having this part of our house put in order.

I gather that in Scotland there is a committee with representatives from different regions and from different specialties. Their opinions go to headquarters in London, where, I suppose, the recommendations are confirmed or rejected. Now, I would ask, what does the surgeon or physician on the committee know of the relative merits of one obstetrician as against another? The answer is, very little or nothing at all. They therefore have to be guided by their obstetric colleague, for I believe there is only one on the committee, and what can he know about the relative merits of his colleagues in regions far removed from his own? Again the answer is, very little or nothing at all. This whole question—a very vital question to most of us, for it affects not only our annual income but, what is more important, our pension—therefore is decided on hearsay and vague impressions—surely a Gilbertian situation.

What is the solution to all this? So far as I see it there are three alternatives. The first is that the whole scheme, born of unimaginative and insensitive mortal, be cast out and the money saved added to the consultants' ordinary salaries. I don't suppose that this is possible. The second is that a merit award should really be a merit award, and given from time to time—on the basis of an annual award—for particularly good work done in a single year. As things are at present, a man who has been given a top or even a second grade merit award is apt for the remainder of his active professional life to sit back and lose any desire to repeat his epic performance. The third possibility is that the mechanism by which these awards are made be radically changed. This could be done in many ways, but here is one method which, I think, is worthy of attention. Considering Scotland only, I would suggest that every year two or three representatives from each specialty in each of the four teaching schools be chosen. In obstetrics, for example, that would mean eight or twelve consultants, as senior as possible, getting together annually. They would discuss the various candidates in their own specialty and forward to the committee the names suggested. The claims from the various specialties could then be settled on a seniority basis. If the present Scottish committee is to remain, with important function, then there should be more than one representative for the major specialties. This enormous and onerous task is quite outside the capability and compass of one individual no matter how extraordinary he may be.

4. The Law and Medicine

I am quite prepared for criticism of, and even open disagreement with, much that I have said. I would be surprised, however, were there not unanimous approval of my final remarks, for an exposition of the changing face of medicine would not be complete without mention of the changed relationship between doctor and patient and between patient and hospital.

* June 26, 1954, *Supplement*, p. 359.

† July 17, 1954, *Supplement*, p. 69.

The compensation payments made by National Health Hospital Authorities, largely resulting from claims for damages by patients, have risen from £7,560 in the period July, 1948–March, 1949, to £152,590 in 1953. This startling information was given in the House of Commons in answer to a question asking how much money the Ministry of Health had paid each year “in damages for neglect or inefficient medical or nursing treatment.” Commenting on the figures, the questioner went on: “Is this not further evidence that the Health Service under State control breaks down when individuals are relieved of personal responsibility?” That question, of course, comes from a man who has no knowledge and less understanding of the doctor's worries and anxieties for his patient which are part of his heritage and his tradition. It is good to know that the Minister of Health replied: “Personally I both resent and repudiate that,” and continued that he was certain that there had been absolutely no deterioration in care since the start of the National Health Service. Why then, if this be true—and I am sure it is—do we find headlines in the daily press featuring with ever-increasing frequency the actions brought by patients against the surgeon or against the hospital? I would say the main reasons are three in number.

(1) Free legal aid enables the individual to bring an action without risk of financial loss. If he loses his action the expense is borne by the State; if he wins he stands to gain. There is therefore no deterrent, and he probably gives little thought to the possible effect of such an action on the future of the unfortunate doctor. For, make no mistake, even should he lose his action and the doctor be vindicated, some of the mud which has been flung is liable to stick.

(2) There is the idea, all too prevalent, that nowadays it is the Government—the State if you like—that is being sued, not the doctor, for after all the doctor is merely the servant. This may in part be true, and where some doubt exists the jury may well take the line of reasoning that the State is wealthy and can well afford to pay the poor claimant something. What the jury, and, I fear, sometimes the more learned judge, are apt to leave out of reckoning is that the State is big enough to surmount and quickly forget such unpleasantness, but the poor doctor is damned for all time.

(3) In this present age, and in every walk of life, there is prevalent a desire to get something for nothing. One can hardly blame the man in the street for this, for such an outlook is being bred and fostered by the ideas behind the Welfare State, giving rise to a new mentality.

These are the factors which are responsible for this never-ending litigation. We must therefore ask ourselves, “What is the effect of all this?” and “What is the solution?” The effect is seen at all levels of hospital staff appointment from the most junior to the most senior. The young resident is often unwilling to undertake the responsibility of a casualty department because he is only too well aware of the pitfalls and dangers which may crowd the very beginning of his medical adventure. His more senior colleague, the anaesthetist, is burdened down by the fear of “death on the table,” and anaesthetics suffer as a result. The surgeon finds that he is loath to undertake the “risky” case. In former days he would have gone ahead and in all probability done enough to make the last days of a patient's life more comfortable and more bearable. Now he is apt to adopt the attitude that as “something may happen” it would be safer to do nothing at all, and he sends the patient home to end his or her days in misery and pain. There is no doubt that this is happening to-day; I have done it myself. Again, he feels that by making a wide resection to eradicate disease and cure the patient some important structure may be subjected to trauma. And so he pulls up short; his work is rendered incomplete and the disease remains. On occasion in the old days there was a spirit of adventure about some surgical operation: some new procedure “came off” and a great advance was made. Now the surgeon may be unwilling to take this risk: he has to think of his own safety too. The advance of medical science will never be

stopped, but initiative is being stifled, and the advance may well be slowed down if the surgeon is forced to work under the continual threat of retribution.

The solution is more difficult. The first essential is mutual trust and confidence between patient and doctor. The second is a change of outlook on this matter by the legal profession. The law has not been very helpful or sympathetic to us in those trying years, and expert evidence by eminent medical men would appear sometimes to have counted for nothing. The judgment has sometimes seemed harsh and bitter. A different attitude from our legal friends is of first importance, and I would go so far as to submit that many cases should be flung out at the beginning and never allowed to be heard in open court.

In a letter to *The Times* of October 26, 1954, S. Cochrane Shanks, President of the Medical Defence Union, stated that the number of claims for alleged medical negligence submitted to them in 1953 had increased by 80% as compared with 1947. He goes on:

“Of the total claims during this period only one-third were justified, in that the union settled without going to court or lost the action in the courts. In the remaining two-thirds the plaintiff either abandoned the claim or lost it in the courts. Of the cases coming to court the same ratio obtains: the union successfully defended two-thirds and lost one-third.

“It is evident from the above figures that many of these claims are unjustified, and as the plaintiff is now legally aided in about 80% of all cases the successful defendant is usually unable to recover any of his costs. In two recent cases, successfully defended by the Medical Defence Union, the union's costs exceeded £10,000, none of which was recoverable. The legal aid scheme makes proper and desirable provision for the impecunious plaintiff, but the question arises whether it should not be extended to cover the taxed costs of a successful defendant when the plaintiff is legally aided. Alternatively, there might be adopted in England the practice which already obtains in Scotland of allowing a prospective defendant, through his solicitor, to submit evidence as to why a certificate of legal aid should not be granted to the plaintiff. . . .

“All three defence societies accept it as their duty to pay proper compensation for real negligence on the part of their members. Equally they feel concerned at the drain on their funds, and even more so at the damage to the good name of their members, by unjustified claims and legal actions.”

In a magnificent article* on this subject Bryan McFarland, Professor of Orthopaedic Surgery at Liverpool University, has written:

“No one is suggesting that the doctors should be immune from criticism or protected from retribution when they have erred. No one is suggesting that an injured person should be denied the right to proper compensation. What is suggested is that the machinery for settling these issues should be such that the doctor should only be put ‘on the spot’ if in the minds of responsible members of the legal and medical professions he has been negligent.

“It would not be difficult, for instance, for the merits of a case to be judged by a tribunal such as deals with appeals under the National Insurance Scheme—a tribunal nominated by high authority and consisting of two medical men with a lawyer as chairman. If such a tribunal were to decide that there was a case to answer then the doctor should have to answer it. If on the other hand it was thought that no particular doctor had been negligent but that the hospital system or arrangements or staffing as a whole had behaved inadequately, then the hospital would have to answer. If it was thought that the damage resulted from something ‘going wrong’ in which no negligence was involved, then neither doctor nor hospital would have to answer.”

* *Liverpool Daily Post*, May 6, 1954.

This solution might not be acceptable to the law, but I feel sure the medical profession would welcome such a compromise.

I have but touched the fringe of the subject. One could ask whether, with the enormous cost to the country which this new service entails, the patient has benefited in the essentials of treatment; whether the vast administrative wheel, which often grinds so slowly, might be made smaller and yet more effective; whether the endless committees, which force the public-spirited to spend almost as much time in the train as in the hospital, are so necessary; and whether great power and influence vested in the hands of a few satisfies our democratic ideals. Those are but a few of the problems.

It has fallen to our generation to work out and put into practice this new regime in medicine. Changes, whether we like them or not, are taking place around us all the time and we have to make the best of them: but, with the highest ideals ever before us, let us see that it is the best. Let there be honesty and frankness among us and let us frown on intrigue—for there is much of that in medicine at the present day—and cast it out. Let gentle suasion never steer us away from a true sense of values, and, above all, let us never forget that our first aim should be to heal and cure the sick.

YOUTH LOOKS AT GENERAL PRACTICE*

BY

C. P. D. GRANT, M.B., Ch.B.
Glasgow

It might be of interest to the profession to know what a recently qualified doctor, and therefore one without specialist training and with only a short experience as a practitioner, thinks of some aspects of general practice to-day. The views I express are my own and not necessarily those of the younger generation as a whole. Furthermore, if any of my comments appear unduly critical of those older and wiser than myself, they are in no way intended as an impertinence, and I hope will not be so regarded.

The student of to-day working for his “finals,” and faced with a compulsory year in hospital followed by two years' National Service, probably does not give much thought to general practice, though he may well be thinking of it rather vaguely as a future career. In fact I would suggest that many final-year students and “neo-graduates” rather tend to have a leaning towards some specialty. This is not unnatural, since the training is almost entirely in the hands of specialists, and this despite the fact that many of the students are destined to become general practitioners. The year of compulsory internship may accentuate any specialist leaning, as by now the young doctor is even more closely bound by the hospital tie. However, it is not easy to become a consultant these days, and, if a man is contemplating taking a wife, it is difficult to marry on a resident's or S.H.O.'s salary. Furthermore, the thought of the high failure rate in the F.R.C.S., M.R.C.P., and other specialist examinations may deter him from pursuing his choice. So, rather unwillingly perhaps, he plunges into the unknown and looks for a job in practice, leaving behind him, probably for good, the world

*An address given to the Southern Medical Society of Glasgow on November 25, 1954.

of starched aprons and white coats. His idea of what is involved is, more than likely, rather vague, since he has had no specific training for general practice. I myself had had the advantage of being reared in a medical household, but despite this my knowledge of the job to be tackled was far from clear. I cannot say I was very enthusiastic. I had been told by friends with some slight experience that all was not well. The hospital swallowed all the clinical interest. The hours were long and tedious, and the day was spent coping with queues of “not-so-very-sick” but demanding people out to see what they could get for nothing. And so, by now not quite so confident, I crossed the threshold with a background of three residencies and National Service completed.

Initial Difficulties

What were my initial difficulties and worries?

First, I think, would my knowledge be sufficient? I had no idea what measles looked like, or mumps. When I was a resident there had always been someone else to take the ultimate responsibility of the patient. Now it was to be my turn. How would I fare? What on earth would I prescribe? I realized with horror I could not really write a prescription. I imagined that I would meet with much more of the hospital type of illness than I actually did. However, with this kind of illness I found that my knowledge was sufficient; but when it came to bronchitis, influenza, childish febrile conditions, rheumatism, tonsillitis, old age and its problems, and so on, I discovered I was not so clever. Their mysteries were all contained in a closed book which had to be opened and studied closely page by page, and yet this was to be the bulk of my everyday work.

Prescribing turned out to be easier than I had anticipated. The local chemist proved a great help, and there was always the *National Formulary*. However, the temptation to prescribe proprietaries with their easily remembered names was the severest trial. Furthermore, the persistent pestering of the drug firms via the post and the traveller would break down the ideals of all but the very righteous. Nowadays there seems to be no need to write an old-fashioned prescription at all: there usually turns out to be a proprietary equivalent, which is supposed to be as cheap and equally efficacious. At least, so say the manufacturers' travellers.

Restrictions Imposed by the N.H.S.

My early reaction to the volume of trivial complaints brought to me was. This is not medicine at all: a fourth-year medical student could cope. There seemed to be so many people to be seen that even when one had separated the wheat from the chaff there was not time to deal properly with the wheat.

The cessation of clinical control of patients removed to hospital under the National Health Service seemed to me a great loss. On the other hand, it was often not a bad thing to be relieved of the responsibility and worry, allowing one to concentrate on the ordinary run of everyday work. The fact that it was found necessary to refer to hospital anyone requiring even a simple diagnostic investigation proved a great irritation to the late house officer who had so recently himself had the power to order many of these investigations. And the delay in waiting for out-patient appointments was most frustrating. Often weeks would elapse before the answer to a clinical problem arrived by post on one's desk.

In many cases it appeared to me superfluous for the hospital officer to enter into the picture at all. He merely seemed to act as a middleman anyway. Why should I personally not have more direct access to such investigations as “x-ray chest,” “straight x-ray abdomen,” blood counts, and minor biochemical and pathological investigations? More important still, it appeared to me that the patient must think that, because he has been sent to hospital for all but the very trivial, the G.P. is only good for this. I

am sure this has done much to lower the general practitioner's standing in the public eye. This is borne out by the fact that even when the general practitioner may himself wish to carry out certain investigations or try out this or that treatment, patients are often better pleased if sent direct to see "the Professor." They demand specialist opinion and x-rays as a right for which they have paid.

The fact that the numbers the G.P. must care for in order to earn a living wage to-day inevitably result in crowded surgeries does not help either. The G.P. with a large list, who has to cope with a multitude of trivial complaints, will have to resist very strongly the temptation to refer to hospital; the easiest way to satisfy a hungry public is to pass the clinical buck. The system seems designed to undermine incentive and initiative. It is too easy to cultivate a *laissez-faire* attitude of "we are paid anyway." Loss of interest in the practice of clinical medicine as such may soon follow, and the way is wide open for the habit of practising slovenly medicine. The G.P. can very easily degenerate into a rather apathetic kind of sorting clerk, doing very slipshod work. What a system!

In this connexion it might be interesting to quote a passage from a letter I received recently from a friend now in practice in Canada. "After working for eighteen months with a socialized medical scheme run by . . . Corporation," he writes, "I quit . . . due to the fact that I felt I was on a large treadmill which went round faster the harder you climbed. I knew that if I did not get out I would lapse into the easy-going way some of the older men had developed over the years—namely, they are company patients. They do not expect exotic medicine. I had enough drive and belief in medicine to feel I could not go on this way. I tried hard to do good work, but woke up one morning to the terrible sensation of defeat, knowing I was slipping. So I got out into private practice, where I am much happier." The tragedy is that he might well have been talking about National Health Service practice in Britain to-day. Here, however, we have no such escape into private practice.

A Comparison

I should like to say a word about Canadian practice, which I had the good fortune to see for myself a year or two ago. A New World general practitioner would be aghast if he were asked to work under our system. To him it is fundamental to the practice of good medicine that he personally looks after his patients in hospital and supervises the various investigations which may be necessary. He often works from a rented office in what is called a Medical Arts Building—rather similar to the health centre envisaged in this country. His consulting-rooms are almost invariably more elaborate than ours. He normally employs a nurse, and often also a laboratory technician who is frequently trained to do x-ray work and electrocardiography as well. But the Canadian is remunerated on a basis of fee for services rendered, which makes all this possible. Unfortunately, from the patient's point of view an illness is a very expensive calamity, even though the type of service is of a very high order. More important than this is the fact that, if he is to give the patient of his best, he must keep up to date with medical advances. In this country, with the attitude tending towards hospital referral for all but the trivial, there is no such pressing need. This, I feel, inevitably lowers the standard of general medical practice, and incidentally the prestige of the practitioner.

Learning the Job

But I have wandered from my story, which was beginning to show how general practice was not all it might be. After a few months I paused to reflect. I had had to work harder than I had ever done before, mentally and physically (all my patients seem to live in a top flat). I had had to learn to control a temper, which I had not realized existed, when malingers wanted certificates and ignorant people called

me out needlessly in the small hours. Although in partnership practice, and despite the fact that I was seeing people all day, I felt rather lonely. I longed to be back in the hospital atmosphere.

However, by this time I was beginning to learn a little about my new job—such things as how to get a home help and how to diagnose measles before the spots came. Then very gradually, just when I was getting rather despondent, it began to dawn on me that there was more to general practice than met the eye. The drama of the operating theatre and the brilliant diagnosis of difficult cases was not my province at all. Here was to be found a different type of satisfaction where, as Osler said, "your heart will be exercised equally with your head." The sea of faces which initially presented in the waiting-room was, at the outset, very like that met with in any hospital out-patient department, but gradually the faces began to take on a familiar pattern and to develop personalities. I began to see that my job was mainly people—people as personalities, as human beings, who had families and worries; girls who got married and had babies. More time went by, and by now I had quite a family of babies, the oldest of whom was nearly two and a half.

Again I paused to reflect. My hospital outlook was beginning to recede. I had almost forgotten such things as the 17-ketosteroids. Instead I had learned a great deal about people, how to handle them, how to reassure them, and how to talk to them in simple language. It appalled me to see how much social conditions had to do with illness—such things as overcrowding and living with in-laws. I had learned that most working-class patients expect a bottle and are not content with advice only; that an illness must be labelled, confidently (whether the label is right or wrong does not always seem to matter); that the stethoscope still has a magic power psychologically despite its many failings in the light of modern x-ray technique and the remark of a specialist overheard recently that there are two methods of examining the chest—percussion and x-ray.

By now I realized I was beginning to learn a little about how to be a general practitioner. I began to appreciate the full meaning of Osler's words when he said, "The practice of medicine is an art, not a trade; a calling, not a business." In fact, by this time, somewhat to my own surprise, I began to like general practice.

The Personal Touch

We are living in a scientific age. Medicine has not escaped, but sometimes I feel we get carried away by mechanical devices and forget that primarily our job is people. Fortunately I realized that I was interested in people, which was just as well, because without that interest I should be lost. Something else struck me rather forcibly: in hospital I had been a cog in a machine; now I was very largely my own master. Furthermore, so far as my patients were concerned, and despite their readiness and willingness to be sent to hospital, I was still *their doctor*. All this I found very satisfying. But for all this new-found satisfaction I still missed hospital. It did not seem natural to one who had spent nearly six years therein that its doors should now be closed. It seemed to me nonsensical that, once the choice of general practice or a specialty had been made, the decision should be binding and irreversible. Unfortunately to-day there is a widening gap between hospital staff and general practitioners. This, I feel, is a great pity, but not unnatural since they now really do two very different kinds of job. It apparently takes years and years to train a specialist these days. Furthermore, there is a feeling current that hospital work is very arduous. Be that as it may, much of hospital work is routine and does not need very advanced or specialized knowledge. It does not seem unreasonable to suggest that G.P.s should be attached to hospitals as clinical assistants doing much of the work at present done by registrars. This would add greatly to the interest of the G.P.s concerned, and incidentally might go a long way towards solving the present registrar problem.

I should like here to say a word or two about present-day hospital staff. Many of them, bubbling over with scientific facts, tend to lack the human touch. Too often they think of their patients as cases rather than as people. The patient of to-day frequently complains that he is told nothing in hospital. Perhaps it is just as well for the nursing staff or the G.P. to be left to explain some things, but it would appear to have gone too far when the patient recently discharged from hospital has to ask his G.P. what was removed at operation and why. Incidentally it adds to the confusion of the practitioner, not to mention the patient, when the hospital letter is not forthcoming for a further week.

In my opinion the trainee consultant, as well as mastering his specialty, must also learn how to handle people. I feel that he can best learn this in general practice; only there can he appreciate the individual as a whole. Goodness knows, the medical training is long enough to-day. But for all this, I cannot help thinking that it would be a good idea to make a period in practice as essential a qualification to the aspiring consultant as the year in hospital is to the prospective general practitioner.

Midwifery and Obstetrics

Midwifery used to be so much the concern of the family doctor. Nowadays, for social and other reasons, more mothers are opting to be confined in hospital and the average practitioner is doing less and less midwifery. In one way this is not a bad thing, for equipment is at hand for dealing with any emergency that may arise. However, there is at present in Glasgow a regulation in force which I would like to quote without further comment: "Unless a woman attends an antenatal or local authority clinic she cannot have an assurance that she will get a hospital bed." I do not see why G.P.s should not look after their own antenatal patients if they should so desire, even those women who intend to have a hospital confinement. It would greatly add to the practitioner's interest and provide an admirable opportunity for establishing a good doctor-patient relationship. The mother, too, would generally rather attend her own doctor than an impersonal clinic, but is afraid to do so because she may not get into hospital. In any event, the general practitioner is the one who has to deal with an antenatal emergency when it arises, not the clinic.

Our Patients

And now what about our patients themselves? I have found the vast majority very considerate and appreciative of what is done for them; but then I am fortunate to be dealing with a decent working-class type of patient, most of them ex-panel patients, those for whom the service should have been primarily designed. Ex-private patients tend to be somewhat demanding. The fact that they can read a clinical thermometer more readily and have a telephone in their house may sometimes be a nuisance. They are more prone to call one out needlessly on a wet night than those who have to find three pennies and go and brave the storm to find a public call-box. Broadly speaking, the younger generation take very little responsibility on their own shoulders and often tend to call the doctor at the least provocation. They have no idea of the cost of drugs and hospital investigations and could not care less. Their elders, on the other hand, frequently apologize for sending and often wait longer than they should before doing so.

There is no doubt that the established young general practitioner in partnership practice to-day has a much easier time of it than had his predecessors. His nights are less frequently disturbed, mainly because there is now less domiciliary midwifery, and his off-duty time is much more regular with the inception of the rota system. Finally he has a secure, pensionable job. So far as his patients are concerned, there is greater continuity of care and incidentally of clinical records, since patients are now on a list and do not often change their doctor. There is no longer

a financial barrier between patient and doctor, who can prescribe freely without fear that the patient may not be able to afford his treatment. But at the same time removal of this barrier lets in the malingers and neurotics—the pests, the 10% hard core of every doctor's list who are never far away from the surgery door.

I would like to stress that there is a very real danger that the young practitioner, excluded from the hospital and committed to his desk by the system, may become apathetic, especially since it no longer seems to be worth while building up a good class of practice: one only ends up with more trouble and less money. The politicians seem to be doing their best to discourage private practice, which to many doctors and patients is a far more satisfactory method of rendering service, despite the fact that it is often more wearing and not necessarily any more lucrative. I feel that private practice provides an opportunity for rewarding incentive and initiative, and is good for one inasmuch as it keeps one on one's toes and guards against the development of slovenly habits. The next step may well be that of a State-salaried service. This would indeed be a tragedy.

Teaching General Practice

But to revert to the student. What should he be taught about general practice? I think that the training of the general practitioner is largely a postgraduate affair; but the student must be taught more about practice than at present, if only to encourage greater numbers to enter this field and with more enthusiasm. A series of lectures by general practitioners interspersed throughout the final two student years might maintain a proper balance, because too often the specialist teacher tends to exaggerate the importance of his own subject.

What, then, are the prerequisites for entering general practice? First, knowledge; the student should concentrate on seeing as much as he possibly can in the out-patient department, because never again will he meet such a wealth of clinical material. If time permits, and he does not want to get married, he should hold three house appointments, possibly in medicine, surgery, and obstetrics and gynaecology. If he can find time to do a bit of dermatology and casualty work, so much the better. Secondly—and this is very important—he must have a liking for people, particularly children.

If the young general practitioner refers everything in sight to hospital, then naturally the aura of omniscience which surrounds the hospital officer in the public eye will be magnified. The status of the general practitioner is still what he himself makes it. Despite its many present-day failings, general practice remains a branch of medicine in which is to be found a great deal of satisfaction. I believe that, taken seriously and practised conscientiously, it is the most difficult specialty of all.

Plans for reorganizing medical teaching departments on more modern lines are set out in part 5, *Medical Sciences*, of Volume III of the Unesco series *Inventories of Apparatus and Materials for Teaching Science*. Prepared jointly with W.H.O., the book is chiefly intended for use in new medical schools. It contains lists of equipment needed for the instruction of medical students in anatomy, bacteriology, biochemistry, histology, morbid anatomy (pathology), pharmacology, physiology, and preventive and social medicine (hygiene and public health), and gives rough indications of prices. Each list is preceded by a short discussion of teaching methods with special reference to the organization of practical work. The English edition may be obtained through the national distributors of Unesco publications or the Sales and Distribution Division of Unesco, Paris. The price is 15s. 6d.

DECOMPRESSION TREATMENT OF WHOOPIING-COUGH

A CLINICAL SURVEY OF 903 CASES

BY

H. STANLEY BANKS, M.D., F.R.C.P.

Late Senior Physician, Park Hospital, London

Weekly or twice-weekly clinic sessions for the treatment of whooping-cough by low air-pressure in a decompression chamber have been held in this hospital since May, 1949, except for short periods when the prevalence of the disease was very low. The chamber was purchased from the Royal Air Force by the Ministry of Health in 1948, was conveyed to its present site by the London County Council, and was reconditioned and refitted by the Lewisham Group Hospital Management Committee. At that time considerable public interest had been aroused in high flying and decompression treatment, and, by request, I published a brief preliminary account of it with illustrations of the chamber in action (Banks, 1949).

Selection and Examination of Patients

During the five and a half years 903 patients were treated, but the results could be assessed in only 782, of whom 686 were out-patients and 96 in-patients. The out-patients were sent by their doctors by arrangement with the Emergency Bed Service, and in accordance with a simple plan. Patients were generally accepted only if they had been coughing for about three weeks or more, and the doctor was asked to instruct the parent to take to the clinic a record of the number of coughs, whoops, and vomits observed during the 48 hours before attendance. Every case was personally interviewed and examined by me or by my colleague Dr. L. J. M. Laurent. The history was checked and the estimated day of disease recorded. The record of coughs and vomits of food day and night for two days was verified; particulars of appetite, activity, lethargy, fretfulness, or loss of weight were noted; and the parent was asked whether she thought the condition was stationary, improving, or getting worse. The faeces, tympanic membranes, and chest were examined, the temperature was taken, any cyanosis or tachypnoea was noted, and in a very large proportion of cases the chest was radiographed.

I soon learned to reject the more acutely ill cases, especially those with pyrexia, or cyanosis, or with more than a minimal degree of pulmonary collapse as shown radiographically, usually by shadows filling the cardiophrenic angles. The cases deemed too ill for decompression were either admitted to hospital or sent home with a letter to the doctor advising rest in bed and, if necessary, treatment later for pulmonary collapse. Minimal atelectasis in a bright, active, afebrile child was not regarded as a contraindication, nor were rhonchi and other signs of bronchitis without fever.

Decompression Treatment

The selected cases, up to six or eight at a time, went into the chamber accompanied by a nurse or ward orderly, or by the parent in the case of some infants or a young frightened child. In cold weather the children were kept warm by hot bottles and blankets, the chamber itself having been pre-heated by an electric radiator. Picture books and toys were provided and stories were read to the younger children, usually until they fell asleep lulled by the hum of the motor. Oxygen was laid on inside the chamber, but was used only once in five and a half years. A telephone connected the occupants of the chamber with the porter-operator, who watched them through a porthole window during the whole

course of the treatment. The pressure of air in the chamber was reduced progressively for about 20 minutes until the equivalent of a height of 12,000 feet (3,660 metres) was reached. This low pressure was maintained for 45 minutes, and then gradually increased during the 20 to 25 minutes "descent." The treatment thus lasted about 90 minutes. Some pain in the ears and deafness were commonly experienced during the "descent" and for a short time thereafter. In this routine a hitch occurred only on two occasions, once when a woman in the chamber became hysterical, and once when the motor failed. In both cases "ground level" was regained without incident.

Assessment of Results

A form was provided upon which the parent or ward staff was asked to record the time and character of each cough and food vomit during a period of 48 hours commencing one week after the treatment; in addition they were asked to report in a few words their impressions of the progress or otherwise of the child from the date of treatment until the date of the report. The completed forms were sent to me generally about the tenth day after decompression. They were delayed for two weeks or so in a small proportion and occasionally a reminder had to be sent out after about two weeks. The factual report on coughs and vomits, and the mother's or ward sister's statement of her impressions of the result of the treatment, taken in conjunction with the recorded data before treatment and the stage of the disease, formed the basis upon which the assessment of the results was made. The factual report on coughs and vomits was usually far better done by the parent than by the ward staff, although the "summing up" by the ward staff after a week was quite good. A feature of this work, however, was the obvious care taken by most of the parents to produce an accurate factual record of coughs and vomits for the 48-hour period. Sometimes the statement of their impressions seemed unduly optimistic in view of the factual report, and in such cases it was treated with reserve.

The assessment of the results on this basis was usually not difficult. It was made by me personally in the great majority of cases, and by Dr. Laurent in my absence. Our marking was conservative and showed almost complete agreement. A sample series of 462 cases was assessed by Dr. Laurent independently, without knowledge of the marking which had already been given by me. His marking turned out to be the same as mine except in 14 cases—a difference of assessment of only 3% between two observers working independently.

The following classification of results was adopted:

XX=Improvement marked and rapid in four to seven days or less, with virtual cessation of the paroxysmal cough.

X=Improvement more gradual over seven to ten days, but probably significant.

X-=Improvement likely to be attributable to the natural progress of the disease at that stage.

O=No improvement in 10 days.

OO=Worse. (Cases excepted in which increased cough and expectoration was limited to 24-48 hours; this was not uncommon.)

TABLE I.—Cases Treated but Not Assessed

	1949	1950	1951	1952	1953	1954	Total
Disease too mild	1	7	7	6	5	—	26
" " acute	2	5	1	1	—	—	9
" " early*	—	8	1	1	2	1	13
No report	—	12	9	12	25	15	73
Total	3	32	18	20	32	16	121

* Less than 2½ weeks of disease.

Cases Excluded from Assessment (Table I)

Mild Cases.—Twenty-six cases, though treated, were so mild that no accurate assessment of the result was possible.

Acutely Ill Cases.—Nine cases with mild pyrexia or cyanosis and atelectasis were treated by decompression

experimentally in the first year or two. Such cases were thereafter excluded, as this was found to be wrong practice.

Early Cases.—Decompression is a physical treatment which cannot be expected to stem the advance of the disease in the first two and a half to three weeks. Although there was an occasional apparent exception to this rule the assessment of results probably gained in precision by the exclusion of the 13 cases treated at a stage of the disease earlier than two and a half weeks.

No Report.—Seventy-three treated cases had to be excluded because no report on the results was received.

Results

Effect on Cough, Vomiting, and General Conditions.—Table II indicates that marked rapid improvement with virtual cessation of paroxysmal cough (XX) occurred in

TABLE II.—Cases Treated by Decompression and Assessed Results

* See text.

28.2% of the assessed cases, and slower but probably significant improvement (X) in a further 34.1%; while in 37.7% the treatment appeared to have no effect.

Effect on Vomiting.—A particularly valuable sequel to the treatment in many cases was the relief of vomiting (Table III). Among the 427 children who were vomiting

TABLE III.—Cases Vomiting Food (more than once daily)

	1949	1950	1951	1952	1953	1954	Total	%
Vomiting stopped	18	84	60	33	30	21	246	57.7
reduced	10	30	22	7	10	6	85	20.0
unre-	—	—	—	—	—	—	—	—
lieved	9	34	22	12	15	4	96	22.3
Total	37	148	104	52	55	31	427	100.0

food more than once daily just before treatment, the vomiting stopped fairly abruptly in 57.7%, was reduced in a further 20%, and was unrelieved in 22.3%. This was something for which the parents were especially grateful.

Influence of Sex.—Table IV shows the sex incidence of the assessed cases. There is a considerable preponderance of females, as in all statistics of whooping-cough. This

TABLE IV.—Sex Incidence of Assessed Cases

	1949	1950	1951	1952	1953	1954	Total
Males	36	112	80	41	44	28	341
Females	38	136	106	58	63	40	441

is an unexplained feature of the disease. The assessed results showed no relation to sex. To category XX, 26% males and 28.5% females were assigned; and to category X; 37.5% males and 30.8% females.

Influence of Age.—Table V shows that 63 of the assessed cases were infants under 12 months, 454 were children aged

TABLE V.—Age Groups of Assessed Cases

Age:	Under 1 Year	1-4	5-9	10-15	15+	Total
No. of cases	63	454	244	7	14	782

1-4 years, 244 were 5-9 years, 7 were 10-15 years, and 14 were over 15 years. Table VI suggests that results may be best in the age group 5-9 years, with 34.4% assessed as XX and 36% assessed as X. Results in the 1-4 years group were about average, while those in infants under 12 months

were possibly slightly inferior (19% assessed as XX and 35% as X); the number in this group, however, was rather small for comparison. Most observers have concluded that the results of decompression treatment are independent of

TABLE VI.—Results in Relation to Age

Assessment	Under 1 Year		1-4		5-9		10-15	15+
	Cases	%	Cases	%	Cases	%	Cases	Cases
XX	12	19	117	25.8	84	34.4	—	2
X	22	35	156	34.1	87	36	2	6
X-	15	—	85	—	37	—	—	2
O and OO	14	—	96	—	36	—	5	4
	63		454		244		7	14

age, but there is a suggestion in Table VI that results in babies and adults may not be quite so good as in children aged 1-9 years and especially in those aged 5-9 years.

Second Decompression.—Although the figures are small, Table VII suggests that a second treatment did not often yield good results when the first treatment failed, except,

TABLE VII.—Results After a Second Decompression Treatment

Assessment:	XX	X	X-	O and OO	Total
All cases	5	6	8	5	24
First decompression too early	2	2	1	1	6
Net No. of second decompression cases	3	4	7	4	18

perhaps, when the first treatment was given too early (before two and a half weeks of the disease). When the latter subgroup was excluded, a second decompression yielded results only about half as good as the average for all cases.

Results of Other Observers

Treatment of whooping-cough by high flying began in Strasbourg in 1927, when air pilots took children in the paroxysmal stage up to a height of 10,000 feet (3,050 metres). From 1937 to 1939 small-scale trials were carried out in Strasbourg, Switzerland, Germany, Holland, Poland, Spain, Uruguay, Chile, and a very few in England. Not all were favourable. In 1943 open aeroplanes were used in Strasbourg and Switzerland, a dangerous practice which was soon abandoned. Matter (1946) reported on high-flying treatment in 100 patients between the ages of 2 months and 40 years. He concluded that cases over three weeks from onset of the disease profited most, that vomiting stopped in one to two days, appetite returned, sleep improved, and convalescence was shortened.

Baldy and Richou (1946), employing the decompression chamber in Paris, treated 275 children and 21 adults, of whom, however, only 128 were followed up for 21 days. Of the latter group, 22% were reported as practically cured in less than five days, 51% frankly improved, and 4% had paroxysms and vomiting temporarily aggravated. They concluded that the third to fourth week of the disease was the best time for treatment and that repetition of the treatment did not materially increase successes. Contraindications to the treatment were fever, respiratory and cardiac complications, epistaxis and other haemorrhage, acute nasopharyngeal or ear infections, hernia, surgical emphysema, and malnutrition (conditions which I have grouped together generally as the "acutely ill patient").

Lauener and Maeder (1942), in Berne, treated 256 cases by flights to a height of 12,000 ft. (3,660 metres), each lasting one and a half hours. They reported "abrupt cure" after one flight in 57 (22.8%) and slower cure over about eight days in 80 (32%). They also took 24 cases up the Jungfrau to an altitude of 10,000 ft. (3,050 metres) and kept them there three hours with results that were disappointing. There may have been a counteracting effect here of cold and other factors. A trial of low-pressure chamber treatment, however, in 65 cases taken to the equivalent of 14,000 ft. (4,270 metres) yielded "rapid cure" in 31%, "undoubted

improvement" in 50%, no improvement in 16%, and 3% were made worse. Clantour (1946), in Paris, treated 127 cases by high flying with somewhat similar results. Bergquist (1948) treated 45 children in Stockholm—20 by high flying for 45 minutes and 25 in the low-pressure chamber for 45 minutes. On the basis of this very small experience and the very short period of low-pressure treatment he condemned both methods.

Harpoth (1949), in Denmark, compared 101 cases treated by high flying with 59 cases treated by decompression to the equivalent of 3,500 metres (11,500 ft.) for 90 minutes. Other smaller groups were put in the decompression chamber without adequate decompression. The difference in results obtained in the various subgroups of decompression cases was said to be negligible and on this basis he concluded that decompression *per se* had no effect. High flying, however, was thought to be effective. Lalli (1949), of the Italian Air Force, treated 476 cases with three to six flights of 20 to 30 minutes' duration every three or four days for about 15 days. This is quite a different technique from that of most other observers and the very favourable results reported are difficult to assess considering the length of time that must have elapsed from the start of treatment to the date of assessment of the results.

Discussion

The results which I report here conform reasonably well with those of Matter (1946), Baldy and Richou (1946), and Lauener and Maeder (1942), but the number of cases and the duration of the experiment have considerably exceeded those of any other observer. The method of selection of the cases, the chest radiography, the careful recording of paroxysms and vomits just before and a week after treatment, and the conservative assessment of results by two independent observers may be considered favourable points in this investigation. Nevertheless the results reported are largely derived from subjective assessment. The subjective element in the assessment of results of whooping-cough cannot be wholly avoided but it should be limited, if possible, by the use of controls. I have failed, however, to find a way of conducting a controlled investigation and I see no present prospect of achieving this aim.

It would be quite possible to make controls of each alternate batch of patients by running the motor without producing decompression of any significant amount. The patients might thus be deceived into thinking that they had had the treatment. But such deception would be unlikely to remain long undiscovered. The entire absence of ear symptoms in whole batches of patients would almost certainly arouse suspicion. The net effect would probably be to spoil the existing good relationship with patients and doctors and to stop the flow of patients to the clinic. It might also be possible to conduct a controlled experiment in the same way but with the knowledge and consent of doctors and patients. However, the local practitioners when consulted did not favour this suggestion. All hope of a controlled experiment with the present set-up had therefore to be reluctantly abandoned; and this applied also to in-patients, relatively few of whom are suitable for decompression.

The mechanism of action of the treatment has been the subject of much speculation, but is still unexplained. The low pressure of the air breathed seems to be the essential factor, since results seem to be practically similar whether high flying or the decompression chamber is used. The deeper breathing induced may help to clear mucus from the bronchi and perhaps to aerate small collapsed areas in some yet undetermined way. It is conceivable that molecular release of blood gases may be favoured, both because of the lowered pressure of the alveolar air and because of the trend to alkalosis produced by the increased pulmonary ventilation. Blood CO₂ might thus diffuse more freely through alveolar walls and help to expand collapsed alveoli and to loosen exudate in the bronchioles; this in turn could

render cough more productive. A study of the composition of the alveolar air combined with estimations of the blood gases, alkali reserve, blood pH, blood pressure, and urinary chlorides of patients while in the chamber might throw some light on the mechanism involved. But these matters are still undetermined largely because of the practical difficulties of obtaining the data in out-patients who are nearly all young children.

Leucocyte counts shed no light on the problem. A transfer of oxidase from neutrophils to red cells was observed by Seabra (1947) in men accustomed to flying at high altitudes. Rats which were decompressed for six days exhibited this transfer and resisted infection better than non-decompressed controls. These facts, however, seem to have little bearing on the effect of a single decompression.

Credit for the apparent good results has been attributed to psychological factors. Many parents certainly come with high expectations and there is a certain amount of emotion aroused in the patients by the novelty of the treatment. But after the start any excitement present soon evaporates. The children tend to become bored and the younger ones usually drop off to sleep. The mothers were warned against extravagant expectations and told categorically that the treatment had a good effect in some cases but in others had no effect at all. This warning was indeed reflected in the statement of their impressions of the result, some asserting roundly that they could see no difference after the treatment. Psychological factors in this series can, I think, be discounted.

Which cases are likely to be successful and which to be failures? It is clear that the treatment is nearly always useless at a stage of the disease earlier than two and a half weeks, that after the sixth week the percentage of apparent successes is apt to drop, and that the "acutely ill" patient is almost certain to be made worse by decompression. But when the cases are properly selected, I can answer this question no better now than I could five and a half years ago. I look upon decompression as a physical treatment which may exert a favourable influence in some unknown way on the course of the disease in a proportion of carefully selected cases. Such a favourable influence may be partially or completely counteracted by other unfavourable influences, such as "catching a cold" or poor environmental domestic circumstances. Whooping-cough not infrequently pursues an erratic course, exacerbation occurring after periods of improvement. In these circumstances the relative uniformity of the results of decompression treatment reported in the more important papers published on the subject is rather remarkable and may be thought to constitute a *prima facie* case in its favour.

A decompression clinic for whooping-cough has outstanding advantages beyond the mere question of decompression treatment. When conducted by an experienced physician it acts as a valuable centre of advice for practitioners in their difficult cases, especially those in which pulmonary collapse is found. The running costs are not high when the staff of the hospital is used, but ambulance transport may be a costly item. This has usually to be provided as a routine on grounds of the infectivity of the patient, at least in the first five weeks of the disease.

Summary

A decompression clinic for the treatment of whooping-cough by means of low air-pressures is described and incidental advantages of such a clinic are suggested.

Of 782 carefully selected and assessed cases, 28.2% were reported to show marked rapid improvement in some four to seven days following decompression, and 34.1% to show more gradual but probably significant improvement. The remainder showed no more than the expected change at that stage of the disease, or no improvement at all.

Of the children who were vomiting food more than once daily 57.7% stopped vomiting within a few days after the treatment, and in another 20% vomiting was relieved.

Decompression treatment is usually unsuccessful at a stage of the disease earlier than two and a half weeks and is harmful to the acutely ill case with pyrexia, cyanosis, or appreciable atelectasis.

The results reported are based on careful selection of cases and combined assessment by parents and doctors. An adequate controlled experiment has not yet been done but should be attempted when opportunity offers.

The mechanism of the action of decompression in whooping-cough has not been elucidated. Further trials should preferably include biochemical studies.

I thank my colleague Dr. L. J. M. Laurent for his valuable co-operation throughout, for reporting on a visit to Dr. Richou and others in Paris in 1948, for his part in the conduct of the clinic, and particularly in the assessment of the results.

CEREBRAL CYSTICERCOSIS

COMMON BUT UNFAMILIAR MANIFESTATIONS

BY

EDWIN R. BICKERSTAFF, M.D., M.R.C.P.
Consultant Neurologist

(From the Midland Centre for Neurosurgery)

Though cerebral infestation with the larval stage of the *Taenia solium* has been recognized since the middle of the last century, it was after the extensive work of MacArthur (1934), Dixon and Smithers (1934), Brailsford (1941), and Dixon and Hargreaves (1944) that cysticercosis was given an important place among the conditions causing epilepsy. So well known is this that the diagnosis is unlikely to escape consideration in a patient suffering convulsions who has lived or served in India or the Far East.

It is the purpose of this paper to emphasize the clinical manifestations of this disease, other than epileptic convulsions, which, though both important and common, have received scant attention in this country. At the same time it will be seen that India and the Far East are not the only, nor even the main, areas where the condition may easily be acquired. Brief illustrative case histories are given, grouped under appropriate sub-headings, but, as will be evident, the same patient may show several different features.

Periods of Disordered Behaviour

This group includes a wide variety of abnormal manifestations, unassociated with any true convulsion, but occurring during periods of disturbed consciousness, accompanied sometimes by involuntary micturition, and often consisting of bizarre or violent behaviour.

Case 1.—A Polish male aged 41 was examined on May 28, 1954. Since 1945 he had been subject to frequent attacks of

violent behaviour, lasting three to five minutes, accompanied occasionally by involuntary micturition, stopping suddenly, and followed by several hours' deep sleep. The day before examination he had, without warning or provocation, attacked a friend with a chair, resisted the restraint of five men, and then suddenly passed into a deep sleep, having no memory of the incident on waking. Physical examination was negative, but a white blood count showed an eosinophilia of 800 to 950 per c.mm. Skull x-ray films were normal, but x-ray films of the thigh muscles showed typical calcified cysticerci. The attacks were greatly improved by the use of primidone.

Case 2.—This patient, a Polish boy aged 11, was born in Austria and had lived five years in the Ukraine. Since early 1954 he had been subject to attacks, usually during breakfast, in which he would make grimacing movements of the face for one minute, then sit quite still staring into space for two or three minutes, then repeat several numbers, and suddenly return to normal, though sometimes a little drowsy afterwards and with slight headache. Physical examination on September 17, 1954, was negative, but a white blood count showed a constant eosinophilia of about 1,000 per c.mm. Stools were normal. X-ray films of the thighs showed calcified cysticerci.

These probably represent attacks of psychomotor epilepsy, and it is remarkable how infrequently the standard leads of the electroencephalogram are of help in cysticercosis. It is possible that the lesions are situated in areas of the temporal lobes which would require more elaborate techniques to demonstrate.

Transient Loss of Function

The sudden loss of use of, or of sensation in, a limb, or the sudden loss of speech, with subsequent rapid recovery, is not uncommon in the early stages of a cerebral neoplasm and in cerebrovascular disease. Episodes of this type are often seen in cerebral cysticercosis, and have on occasion, in apparently healthy young soldiers, been regarded as hysterical.

Case 3.—A British man aged 20 was admitted to the Queen Elizabeth Hospital, Birmingham, on November 10, 1953, complaining of three episodes, in the previous five years, of sudden loss of use of the left hand, with numbness of the hand, rapidly recovering. One attack lasted several hours. He had in addition, and at separate times, had several episodes of unexplained loss of consciousness. He lived the first ten years of his life in India. Physical examination was negative and a full blood count normal. The cerebrospinal fluid contained two mononuclear and one polymorphonuclear cells per c.mm., with 132 mg of protein per 100 ml., and a paretic Lange curve. The electroencephalogram showed only very occasional 5-6 c/sec. waves occurring synchronously in all leads. X-ray examination of the skull showed a number of small foci of intracerebral calcification, and x-ray films of the thigh muscles showed numerous calcified cysticerci.

Case 4.—A British ex-Regular-Army soldier aged 32 who had spent two periods of service in India and China was admitted to the Queen Elizabeth Hospital, Birmingham, on October 23, 1941, complaining of periods of sudden onset of loss of speech during the previous six years, usually lasting several hours, but on one occasion lasting three days. The most recent attack was accompanied by paralysis of the right arm and leg for several hours, recovery being very rapid. In addition, and at separate times, he had had periods of unexplained loss of consciousness, during one of which he had passed urine, and during another had fought off those who had come to his assistance. Physical examination was negative apart from two small subcutaneous nodules in the left arm and the left thigh. A full blood count and x-ray examination of the skull were normal, but x-ray films of the thigh muscles showed numerous calcified cysticerci. Biopsy showed the subcutaneous nodule from the arm to be a lipoma, but that from the thigh proved to be a cysticercus.

Acute Intermittent Obstructive Hydrocephalus

This, though one of the longest-known non-epileptic manifestations of intracranial cysticercosis, is one of the least well recognized in England. Bruns's symptom-complex (Bruns, 1906) consisted of the sudden onset of violent headache, vomiting, tinnitus, and vertigo, passing on in the more severe attacks to deep coma and even death, and often precipitated by sudden movements of the head. It was considered to be diagnostic of a solitary cysticercus in the fourth ventricle.

Case 5.*—A Polish woman aged 54 was admitted to the Midland Centre for Neurosurgery on October 1, 1954, having suffered for two years from episodes of sudden onset of severe headache, vomiting, and ataxia, passing on to a stupor lasting 24–48 hours, and recovering spontaneously. She was normal between attacks, but a C.S.F. pleocytosis had been demonstrated elsewhere. Shortly after admission she became rapidly comatose and despite surgical decompression died in a few hours, with signs suggestive of a medullary pressure cone. Necropsy confirmed this, and revealed a solitary cysticercus impacted in the fourth ventricle and numerous cysticerci in the substance of the hemispheres.

The solitary intraventricular cysticercus is, however, not the only cause of acute obstructive hydrocephalus. Some years ago my colleagues and I drew attention in this country to the racemose form of cysticercosis which is particularly apt to form at the base of the brain, and, being a mobile structure, sometimes with a long pedicle, is capable of intermittent blocking of the roof foramina of the fourth ventricle (Bickerstaff *et al.*, 1952).

Case 6.—We described the case of the wife, aged 50, of an ex-Indian Army soldier who for ten years had suffered attacks of headache, each of which increased in severity over several hours, accompanied by vomiting, and culminating in drowsiness and finally coma, but recovering spontaneously within 24 hours. She had had an intermittent blood eosinophilia over many years. Exploration of the posterior fossa revealed a delicate irregular elongated cystic structure, resembling a bunch of grapes, lying over and around the lower brain stem and fourth ventricle and hanging into the upper cervical region. The patient died some weeks after the operation, and necropsy revealed numerous encysted cysticerci in the hemispheres and basal ganglia. Histological examination of the wall of the racemose structure showed it to consist of three distinct cellular layers identical with the lining of the walls of the intracerebral cysts.

Since then I have investigated in the Midland Centre for Neurosurgery two further cases of this type, both Polish and both having attacks of intermittent hydrocephalus. One showed Bruns's symptom-complex, and had a solitary cysticercus in the aqueduct and a racemose structure in the left cerebello-pontine angle; the other had a racemose cysticercus extending from the third ventricle, through the aqueduct and into the fourth ventricle. This contained one large degenerating larva. These cases will be published in full clinical and pathological detail later.

Disturbance of Equilibrium

Though spasmodic ataxia may accompany the attacks of obstructive hydrocephalus, a more progressive disturbance of equilibrium, without marked ataxia of the limbs when supine, frequently accompanies the posterior fossa racemose cysticercosis, the clinical picture simulating that of a tumour of the vermis of the cerebellum.

In Case 6 the patient had in the last four years of her life become increasingly, and finally completely, incapacitated by a gross ataxia of gait, but only in the last few weeks had she demonstrable ataxia on the usual bedside tests.

Of the important series of 13 cases of racemose cysticercosis described by Arana and Asenjo (1945), 7 presented first in this manner.

Meningo-encephalitis

Attacks of meningo-encephalitis, usually self-limiting, the cerebrospinal fluid containing both lymphocytes and polymorphonuclear cells, occur not infrequently throughout the course of the disease (Schmite and Lemoyne, 1932; Dolgopol and Neustaedter, 1935; Felici, 1938; Obrador, 1948).

Our Case 6 had three episodes of headache, with meningism, vomiting, confusion, and drowsiness, lasting several days and clearing up through a period of noisy and aggressive behaviour. Her cerebrospinal fluid was grossly abnormal on each occasion—for example, 270 cells (90% mononuclear), with a protein of 150 mg. per 100 ml. and a Lange curve of 5433221000.

*This case will be published in full clinical and pathological detail elsewhere.

It is during episodes of this nature that the diagnosis, if suspected, will receive great support from the demonstration by special stains of eosinophils in the cerebrospinal fluid.

One further patient, following surgical intervention with a racemose cysticercus, developed the clinical signs of an intense meningo-encephalitis, the cerebrospinal fluid containing over 1,000 eosinophils per c.mm.

Failing Vision

Cysticerci may lodge in the eye, the orbit, or at the chiasma. Such direct local effects are, however, not always the cause of visual failure, for it may be due to the consecutive optic atrophy which follows long-standing and perhaps unsuspected papilloedema, the site of the lesion being either in the ventricular system or in the posterior fossa.

Case 7.—A 35-year-old ex-Indian Army soldier complained in 1945 of failing vision over the previous two years. He had a past history of fits, and examination revealed a chronic papilloedema which had progressed to a consecutive atrophy. His cerebrospinal fluid contained 33 mononuclear cells, 92 mg. of protein per 100 ml., and a paretic Lange curve. X-ray films of the muscles showed numerous calcified cysticerci, and an air encephalogram showed dilatation of the third ventricle, and forward displacement of the fourth ventricle. It is probable that there was a racemose cysticercus in the posterior fossa, but proof was not obtained.

Case 6 also had severe consecutive atrophy of the optic disks, with gross loss of vision, following long-standing raised intracranial pressure. Necropsy confirmed that there were no cysts in relation to the eyes or chiasma.

Involuntary Movements

Very rarely, cysts in the basal nuclei, or secondary degenerative changes in this region, may be associated with involuntary movements. Meyer (1906) described tremor of the right side; Felici (1938) described Parkinsonism, and Broughton-Alcock *et al.* (1928) and others refer to involuntary movements.

Our Case 6, for the last four years of her life, showed at first a constant restlessness which, as it increased, developed into frank bilateral choreic movements of considerable amplitude, affecting all four limbs and the face, and with the associated mental impairment the clinical picture resembled Huntington's chorea. At necropsy a large cysticercus was found in the left caudate nucleus, and seven smaller cysts in both the caudate and the lentiform nuclei.

Mental Disturbances

Personal experience of this aspect has been limited to the development of mental deterioration in patients predominantly displaying other manifestations of the disease. Stepien and Chorobski (1949) and Pinto Pupo *et al.* (1945–6) stress mental disturbance as a presenting symptom, as did MacArthur (1934).

In the present series, Case 1 was showing increasing aggressiveness, irritability, and unreliability of behaviour quite apart from his psychomotor attacks, and Case 6 for several years had had memory impairment, irritability, and mood swings, and her hospital investigations were hampered by a series of self-discharges.

One further Polish patient has recently been seen, presenting a purely psychotic state, but having scattered flecks of intracranial calcification, and a high blood eosinophilia. Cysticercosis was suspected, but so far has not been proved.

Discussion

The incidence of human cysticercosis is of course related to the amount and mode of pork consumption in a given area rather than to any local variant of the *Taenia solium*. Inhabitants of a country in which pork is often consumed in a raw or partially cooked state are constantly exposed to the danger of contracting a tapeworm, and any carrier of

an intestinal tapeworm is a potential danger to himself and others. Any fault in personal cleanliness may cause contamination of food with ova, and subsequent development of cysticercosis in the consumer's muscles or brain. It must be remembered that it is not eating measly pork which results in human cysticercosis, but the ingestion of tapeworm ova as a result of contamination of food by human faeces—a danger over which any given individual has much less control.

The number of cases found in Army personnel returning from India has fostered the view in this country that India is the most likely area where infestation may occur. Cases have, however, been reported from a great number of countries, and a good review of the geographical incidence is given by Trelles and Lazarte (1941). The ease with which now attends world travel, and the great movements of populations during the war and the post-war period, have resulted, and will continue to result, in the natives of many countries making their homes in Great Britain. There are thought to be about 600,000 natives of Poland, the Ukraine, and neighbouring countries living in this country at the present time and coming under our medical care. When one considers that in Warsaw, at the Neurological Institute, between 1926 and 1936, cerebral cysticercosis formed 1.25% of all admissions—1 in 80 patients (Stepien and Chorobski, 1949)—it would be surprising if among such a community one did not encounter many examples.

Southern Italy and Portugal provide a number of cases, and it was at one time very much more common in Germany than it is now. Surprisingly few have come from the north of Africa and Egypt, but Dixon and Smithers (1934) recorded several from South Africa. It is very uncommon in the United States, but in South America, on the other hand, some of the most extensive work on the subject has been carried out—notably the detailed review and description of 26 new cases from Brazil by Pinto Pupo *et al.* (1945–6) and the monograph by Trelles and Lazarte (1941) of Peru. It is common in Colombia; and in Chile cerebral cysticercosis formed 12½% of all suspected cases of cerebral tumour during a two-and-a-half year period (Arana and Asenjo, 1945).

The pathology of the intracerebral encysted cysticercus is well known, but in this country insufficient attention has been paid to the effects of the infestation of the cerebrovascular system. Post-mortem examinations have shown a constant periarthritis and endarteritis in both the meningeal and the smaller cerebral vessels, particularly in the vicinity of the cysts. These vascular changes may be most important in the production of transient or permanent ischaemic lesions in the brain. The sudden attacks of loss of function of a limb or of speech lasting several hours and then recovering seem more likely to be due to transient ischaemia than to be epileptic manifestations. Again, the cerebral atrophy which may develop is probably secondary to long-standing vascular insufficiency, and the mental changes and some of the degenerative basal ganglia lesions may well be of similar origin. The late clinical picture in some patients is that of a crippling hemiplegia, and it is more probable that this is due to occlusion of a major vessel than to the mere presence of cortical or subcortical cysts.

It is in South America that the major work of recent years has been carried out in connexion with cysticercosis of the posterior fossa—the solitary intraventricular cyst, the racemose variety, and the basal meningo-encephalitis. A given patient may have one of these types, or any combination of the three, and each is capable of giving a clinical picture resembling a posterior fossa tumour with increased intracranial pressure—the first by blocking cerebrospinal fluid flow through the ventricular system, the second and third by obstructing the roof foramina of the fourth ventricle.

It is important to recognize the solitary intraventricular cyst, because its successful removal will relieve the patient of his symptoms referable to C.S.F. obstruction. This has

often been done—for example, Arana and Asenjo (1945)—and, even if removal is impossible, Forkildsen's procedure may give considerable relief.

Basal meningo-encephalitis is a more serious condition, as the consequence of recurrent attacks is a chronic arachnoiditis around the base of the brain, which can cause permanent interference with C.S.F. circulation and also with blood flow within the basilar system. Relief of this surgically is rarely possible, and, though short-circuiting operations may give temporary relief, the prognosis is bad. It is interesting that during this stage eosinophils may be found in the C.S.F. if special stains are used, and it is possible that it represents an allergic response to some allergen liberated from the parasite rather than a direct result of irritation. Some support was gained for this view by a recent experience of treating such a case with antihistamines, with rapid improvement in pyrexia, the general condition of the patient, and the C.S.F. reaction.

The so-called racemose cysticercus is an elongated sac-like structure, varying greatly in size, having a central cavity from which grow many cystic projections, each having a delicate translucent wall, and the whole, though occasionally lying free in the ventricles, usually being lightly attached to the basal meninges by a long pedicle. The structure so formed resembles a bunch of grapes, and by virtue of its mobility is capable of causing intermittent C.S.F. obstruction and interference with vascular supply to the brain stem and cerebellum. The wall is histologically the same as the lining membrane of the intracerebral cysts, but the structure usually contains no hooklets or scolices.

We suggested previously (Bickerstaff *et al.*, 1952) that this structure was a reaction of the meninges to the presence of a parasite, and that its particular type of development was due to the constant flow of C.S.F. and the space allowed by the cisterns for expansion; we also thought that this received support from the fact that the other site of development was in the cavity of the lateral ventricles. As stated earlier, however, a larva was discovered in one of these racemose structures, and I now feel that they represent an actual cysticercus about which there has failed to form the host tissue reaction which completes the encirclement of the better-known intracerebral cysts, thus limiting their growth.

A similar racemose structure is formed by the larval stage of the dog tapeworm *Multiceps multiceps*, but in this case it is a coenurus and not a cysticercus which is formed—that is, a cyst containing numerous invaginated scolices, as opposed to the single scolex of a cysticercus. When a racemose body is formed in cerebral coenuriasis, several hundred scolices may be discovered (Johnstone and Jones, 1950; Becker and Jacobson, 1951). This difference in the number of scolices is important, for while several score of scolices may die in a coenurus and still many remain, the death of the single scolex in a cysticercus will result in a sterile cyst. Trelles *et al.* (1952) believe that death of the parasite disturbs a balance existing between it and the cyst wall, and disorderly proliferation follows, forming this remarkable racemose structure.

The diagnosis of these posterior fossa forms of cysticercosis is of more than just academic interest, for here there is offered a practical chance of alleviating symptoms by surgical means, which in the other forms of cerebral cysticercosis have been disappointing. Diagnosis will be made only if the possibility is always at the back of one's mind when faced by intermittent obstructive hydrocephalus, and in the differential diagnosis of posterior fossa lesions—for the confirmatory signs of cysticercosis (calcification in muscles or brain and eosinophilia in blood or C.S.F.) may all be absent. The possibility must assume greater prominence when the patient comes from, or has been in, one of the areas where the condition is frequently acquired, and attempts should then be made to obtain confirmatory evidence.

It should be remembered (a) that calcification in the brain is much less common than in the muscles of thighs

or pelvis; (b) that blood eosinophilia is often intermittent, and may be absent on any particular examination; and (c) that a pleocytosis in the cerebrospinal fluid may not only show eosinophils, if a suitable stain is used, but is often associated with a paretic Lange curve.

Finally recourse must be made to ventriculography, using air or opaque contrast media, which may not only define the site of the obstruction but also outline the shape and size of the cysts responsible, and give valuable information about the possibility of surgical removal.

Summary

Attention is drawn to clinical manifestations other than epileptic convulsions which frequently occur in cerebral cysticercosis, and to the countries other than India where infestation is often acquired.

Cases are described illustrating periods of disordered behaviour, transient pareses, intermittent obstructive hydrocephalus, dysequilibrium, meningo-encephalitis, involuntary movements, failing vision, and mental disturbances.

Stress is laid on the cerebrovascular lesions, and on the importance of the posterior fossa forms of the disease.

I wish to thank the medical staff of the Polish General Hospital, Penley, for referring to me Cases 1, 2, and 5; to Professor P. C. Cloake for permitting me to investigate Case 3; to Professor W. H. Wynn for allowing me to include Case 4; and to Sir Russell Brain for permission to use brief extracts from *Brain* (Case 6).

"The whole emphasis to-day is on drawing as little difference as possible between the handicapped child and the normal child," said Mr. DENNIS VOSPER, Parliamentary Secretary to the Ministry of Education, at a conference of the College of Teachers of the Blind at Matlock on April 22. Between 1945 and the end of 1954, he said, 256 new special schools, with 18,000 new places, had been established, but there were still considerable waiting-lists, and careful selection was essential. Only when ordinary day-school education had proved impossible was special training considered. Teaching handicapped children was onerous, and it reflected credit on the profession that there had been sufficient teachers coming forward to fill the posts in the new schools. A few handicapped children would never become self-supporting, continued Mr. Vosper, "but education will help to make them all better members of the family circle, and to make the majority more likely to take their place as worthy and self-supporting citizens in the world."

SPONTANEOUS HAEMOPNEUMOTHORAX

A SURGICAL EMERGENCY

BY

A. J. CLYNE, C.B.E., M.B., F.R.C.S.

Colonel, Royal Army Medical Corps

AND

F. H. D. HUTTER, M.B., F.R.C.S.

Wing Commander, Royal Air Force

Spontaneous haemopneumothorax is a comparatively rare condition. A review by Borrie (1953) showed the recorded total to be 93 cases with 19 deaths. Subsequently McGown (1954) has reported another case. The source of bleeding and air escape is usually a ruptured bulla with or without a torn adhesion. Sometimes a torn adhesion alone is found; sometimes there is no demonstrable lesion, which means that the breach in the lung surface, from which so much blood and air escapes, is either so small as to be missed or has already healed so far as naked-eye examination can detect. Although the precipitating factor is apparently traumatic, a history of trauma, beyond ordinary everyday activity, is usually absent, the causal episode being so mild in type as to be overlooked. The important features, for both prognosis and management, are not so much the cause and source of the bleeding as its extent, the tendency to clot earlier than in ordinary traumatic haemothorax, and the fate and subsequent effects of this clot if it remains in the pleural cavity.

The traditional method of management in medical wards, on the principle of minimum interference, has carried in the past a high mortality. In 18 fatal cases death followed conservative treatment. In the remaining case (Hansen, 1949) the patient died after delayed thoracotomy. Conservative treatment, the difficulties of which are well put in Hartzell's (1942) paper, has been challenged by several writers. Myers *et al.* (1951) recommended emergency thoracotomy if bleeding could not be controlled, and reported a successful case. Ross (1952) regards the condition as a surgical emergency, requiring urgent blood replacement and early evacuation of the intrapleural blood before it clots. This he did by underwater intercostal drainage, recommending thoracotomy if there were evidence that bleeding was continuing. He reported six cases, one of which required emergency thoracotomy, the remainder being treated by aspiration or drainage, but of these only two gained full re-expansion this way, the remainder requiring decortication. Borrie (1953) recommends immediate thoracotomy, after resuscitation, as the treatment of choice for all cases of spontaneous haemopneumothorax in which bleeding has been considerable, and he regards the condition as an acute thoracic emergency. He reports three cases—two treated by emergency thoracotomy for uncontrolled bleeding with complete success and early full expansion, and the third requiring decortication after failure to obtain re-expansion by repeated aspiration.

The object of treatment is to resuscitate the patient and replace blood loss, to arrest the bleeding and to prevent its recurrence, to remove all air, blood, and clot from the pleural cavity, and to obtain and maintain full lung expansion, so that there is a return to full normal function in a minimum of time.

Case 1

An aircraftman of the Royal Australian Air Force, aged 28, was admitted to the British Military Hospital, Singapore, in the evening of May 3, 1954, with an eight-hour history of severe epigastric pain of fairly sudden onset. There was no history of trauma, although he had played golf some hours before. He complained of severe pain radiating from a point just below the xiphisternum, up behind the sternum, and in both directions across the epigastrium. It was worse during inspiration. He was collapsed and shocked, with a pulse of 110 and a blood pressure of 115/85. The provisional diagnosis had been perforated peptic ulcer, and he was admitted to the acute surgical ward, where examination revealed an extensive left pleural effusion with an overlying pneumothorax. Exploratory needling showed the fluid to be blood. Blood transfusion was started and thoracentesis performed. Approximately two pints (1,140 ml.) of blood was aspirated from the pleural cavity, at the end of which there was clinical evidence, confirmed by x-ray examination, that at least a pint (570 ml.) of blood remained, but this would not come out through the cannula and had presumably clotted. Two pints of blood was given intravenously, by which time he had recovered from his acute respiratory distress and shock.

The patient was first seen by one of us (A. J. C.) on the morning of May 4. It was obvious that blood loss had been considerable and was possibly still occurring. It was equally obvious that there was an extensive intrapleural clot which, unless removed, would prevent lung re-expansion and require pulmonary decortication at a later date. Emergency thoracotomy was performed 22 hours after the onset of symptoms. A further three pints (1,700 ml.) of blood was given during and after operation. A careful search of the lung and of the parietal and mediastinal pleura failed to reveal any source of bleeding. There was no evidence of lung disease, nor were there any adhesions. The only departure from normal seen was a small haemorrhagic patch, about $\frac{1}{2}$ in. (1.3 cm.) in diameter, immediately beneath the pleura on the upper part of the lower lobe. The pleura here was intact. Adherent fibrin clot had already covered most of the collapsed lung, and approximately two pints (1,140 ml.) of blood, mostly clotted, occupied the pleural cavity. After removing all clot the lung was fully re-expanded and the chest closed without drainage. Convalescence was uneventful, full lung expansion being maintained. He was returned to his unit after four weeks.

Case 2

An officer of the Royal Air Force, aged 32, was admitted to the R.A.F. Hospital, Changi, on May 13, 1954, with a history of pain in the left lower chest of six hours' duration, starting as a slight pain, but becoming increasingly severe during the night. It was intensified by inspiration and by movement. There was no history of any traumatic incident. He was admitted to a medical ward and found on examination to have a left pneumothorax.

X-ray examination confirmed a large left pneumothorax and showed a small amount of fluid. By the next day his condition had deteriorated, with pallor, sweating, and dyspnoea, and severe left-sided chest pain. X-ray films showed an increase in the pneumothorax and a rise in the fluid level. Thoracentesis was performed and the fluid found to be blood, of which 100 ml. was withdrawn. Then 600 ml. of air was also aspirated, after which his general condition improved. He was kept well sedated and put on penicillin.

On May 15 his general condition was unchanged, but there was a considerable rise in the fluid level. 15 oz. (425 ml.) of blood was aspirated and more air withdrawn. Blood haemoglobin was 11.5 g. per 100 ml. On the next two days 6 oz. (170 ml.) and 12 oz. (340 ml.) of blood was aspirated, but x-ray examination showed, from a maintained high fluid level, that bleeding was continuing.

On May 18 there was no improvement, and the patient was seen in consultation by Lieutenant-Colonel W. G. Macfie, senior physician at the British Military Hospital, Singapore, who, following the recent experience with Case 1, recommended immediate blood replacement, followed by thoracotomy. The blood haemoglobin had fallen by now to 8 g. per 100 ml. Three pints (1,700 ml.) of blood was given overnight, and a thoracotomy was performed (F. H. D. H.), on May 19. Four pints (2,300 ml.) of blood and clot was removed from the pleural cavity, extensive clotting having occurred, although fibrin deposition on the lung was not a feature in this case. No actual bleeding point was found, but there were several torn adhesions, one of which, at the apex, appeared to have been bleeding recently. After removal of all clot the chest was closed with an intercostal underwater drain. Three more pints (1,700 ml.) of blood was given during and after operation.

Post-operative progress was uneventful, with progressive lung re-expansion. By June 1 full re-expansion had occurred, the drainage-tube was removed, and the patient, now allowed up most of the day, was returned to a medical ward. Repeated attempts to find any focus of tuberculosis were negative.

Case 3

A British lance-corporal aged 19 was admitted to No. 33 General Hospital, Hong Kong, on July 2, 1954, with a history of the sudden onset of a stabbing pain in the left lower chest on the previous day. This was worse on inspiration, was intensified by any form of movement, and had been gradually increasing in severity. There was a past history of occasional attacks of pain of pleuritic type, one such attack having lasted as long as two weeks. He was admitted to a medical ward.

Examination showed a pale shocked young man, with panting shallow respirations and obviously in severe pain. The blood pressure was 100/60 and the pulse rate 120. Chest examination revealed the trachea deviated to the right, with the left upper zone tympanitic and the lower zone flat dull. No breath sounds were heard on the left side. The right lung appeared to be normal. Exploratory aspiration showed that the fluid was blood and that the overlying pneumothorax was under some tension. A diagnosis of spontaneous haemopneumothorax was made.

The patient was given 100 mg. of pethidine, which was repeated at six-hourly intervals, blood and air were aspirated from the left pleural cavity, and he was started on penicillin. He was blood-grouped and cross-matched, but not transfused. We are indebted to Lieutenant D. Benazon, medical officer in charge of the patient, for the following progress report.

"He rapidly improved with pethidine and further improved when one pint (570 ml.) of blood was removed at once, and again later in the day. The pulse returned to normal and the blood pressure was 125/70. The haemoglobin next day was 58%. His pulse was taken half-hourly, and then one-hourly, and frequent blood-pressure recordings were made. Aspiration of blood was continued; at no time did it clot, and thus practically every drop could be removed over the next 14 days. It became increasingly serous, though at the start it was pure blood. The lung is now (August 13) almost completely re-expanded, and in about another week should be fully out to the chest wall. There is minimal thickening at the left costophrenic angle. Movement is good on the affected side, and breath sounds, except at the apex posteriorly where there is still a tiny pneumothorax, are as good as on the other side. The patient is feeling very well. The haemoglobin, which fell to 58%, is now back to normal with ferrous sulphate therapy. He was given plenty of breathing exercise after about 10 days, by which time it was hoped the ruptured vessels would have healed. He was covered during the first 10 days with penicillin while chest manipulations were going on and infection of the atelectatic lung was a risk.

Air continued to be troublesome, and I think has taken longer to remove than it should have done, because of the inefficient artificial-pneumothorax apparatus. We were fortunate that there was no recurrence, or perhaps at most only a slight recurrence, of bleeding. If this had occurred again I think transfusion and surgical treatment would have been needed."

Full re-expansion occurred during the following 10 days, and he returned to his unit for duty.

Comment

Although at the time unaware of Borrie's (1953) paper, we had already, from experience with traumatic haemothorax and penetrating chest wounds, appreciated the need for early exploration of the chest if there is evidence of continuing intrathoracic bleeding or if clotting has occurred. It is a life-saving procedure, and is essential if the lung is ever fully to expand again without later decortication.

In this respect the three cases reported make an interesting comparison. Case 1 was admitted initially to a surgical ward, where, on general surgical principles, the need for early exploration was appreciated. He was operated on within 24 hours, had full lung re-expansion from the time of operation, and was up fully convalescent within two weeks. Case 2 was admitted to a medical ward and treated expectantly on conventional lines for six days, during which he continued to bleed and to deteriorate progressively. Although after operation he never looked back, the delay lengthened the time required for full lung re-expansion and convalescence generally. Case 3 was treated by the traditional medical methods, surgery at no time being even considered. This case can be regarded as a successful result of conservative treatment, giving no cause for anxiety after the first few days. Nevertheless, full lung re-expansion took seven weeks. We feel that it was the layer of fibrin coating his pulmonary pleura rather than the defective aspirating syringe which was the real cause of difficulty in removing air from the pleural cavity.

We are in full agreement with Borrie that spontaneous haemopneumothorax is a surgical emergency demanding thoracotomy whenever bleeding is serious. We would go further and recommend emergency thoracotomy, after resuscitation, as the treatment of choice for all cases. At this stage it is a straightforward surgical procedure which, provided anaesthetic and surgical facilities are adequate, carries very little risk and permits direct access to the bleeding point, evacuation of all clot and air, and immediate lung re-expansion. Reluctance to operate has led to a high mortality, with a chest disability in survivors which at best results in slow convalescence with probably some permanent pleural thickening, while less fortunate cases will require the major procedure of pulmonary decortication to correct a crippling chest condition. In at least one case in five, spontaneous arrest of bleeding does not seem to occur, and these cases have contributed most of the fatalities in the past. In the remainder the chances of evacuating all blood and exudate before the occurrence of clotting or fibrin deposition sufficient to prevent ultimate full expansion appear to be less than even. It is important to remember that after initial resuscitation the patient, a healthy young adult, is fitter for surgery than he is likely to be for a long time if operation is delayed, and that the real risk in these cases lies not in operating but in not operating.

Summary

Three cases of spontaneous haemopneumothorax are reported, two of which were treated by emergency thoracotomy.

The condition should be regarded as an acute thoracic surgical emergency for which immediate thoracotomy is indicated.

We are indebted to Brigadier Douglas Bluet, Director of Medical Services, Far East Land Forces, for permission to report

Cases 1 and 3 and to Air Commodore G. P. O'Connell, Principal Medical Officer, Far East Air Force, for permission to report Case 2.

ULCERATIVE COLITIS TREATED BY TOTAL COLECTOMY AND ILEO-RECTAL ANASTOMOSIS

BY

STANLEY AYLETT, F.R.C.S.

Surgeon to the Westminster Hospital Teaching Group
(Gordon Hospital) and to the Metropolitan Hospital

In a preliminary communication (Aylett, 1953) I described an operation of ileo-rectal anastomosis with colectomy as a possible treatment of cases suffering from diffuse ulcerative colitis. The reasons for suggesting that it was possible to retain the rectum, thus avoiding a permanent ileostomy with its aesthetic and practical disadvantages, were detailed. In a further communication (Aylett, 1954) the types of cases in which the operation was indicated and in which ileo-rectal anastomosis could be achieved were described. Briefly, the operation can be carried out in all cases of ulcerative colitis in which surgery is indicated, with the exception of those in which the rectum has already been irretrievably damaged by gross fibrosis or by perirectal suppurative and fistula formation. The presence of pseudopolypi is not a contraindication for its performance.

The purpose of this short paper is to indicate certain modifications of surgical technique that experience has indicated to be desirable and to record the progress of the patients upon whom the operation has been carried out.

Modifications of Technique

Although in the first few cases the ileum was anastomosed to the rectum in its upper third the establishment of a safety-valve opening in the left iliac fossa necessitated the retention of the lowermost portion of the pelvic colon. This severely diseased portion of the large intestine may be included in the excision if the rectum is mobilized as an initial stage in the operation by division of the upper part of its lateral ligaments and of its posterior attachments. After the ileo-rectal anastomosis has been carried out the colectomy is completed by transecting the rectum through its upper part about 2 cm. above this anastomosis. It is then possible, as a result of the mobilization of the rectum, to exteriorize its open upper end through the lowermost part of the paramedian incision to act as a safety valve. The reasons for considering that such a safety valve minimizes the danger of a breakdown of the line of anastomosis, made as it is through a diseased rectal wall, have also been described previously. Moreover, this proctostomy tends to undergo spontaneous closure more readily than a colostomy in the left iliac fossa, so that the necessity for its closure by operation is required less often.

The large majority of patients are now operated upon in one stage, and in only one of the last 10 has an anastomosis and total colectomy not been effected in one operation. In this very gravely ill acute case the colon was excised and an ileostomy established as an initial stage of treatment, the upper end of the rectum being exteriorized

and restoration of continuity being delayed until the patient had been restored to good health. It is essential in the fulminating case, the case with uncontrollable haemorrhage, or the desperately ill patient to remove the colon as the first stage in operative procedure, leaving the patient with a temporary ileostomy. Subsequently the anastomosis between ileum and rectum is undertaken.

Results of Operation

The results are summarized in the accompanying table. There was no mortality in the series.

In a further two cases not included in the table the caecum seemed at operation to be so little diseased that in each it was retained and the anastomosis was effected

between it and the rectum. One of these patients has remained perfectly well over a period of 18 months, and her bowels are opened only twice in each 24 hours. The other case remained well for four months and then suffered a severe and uncontrollable haemorrhage. Operation was undertaken for this and the caecum was found to be acutely inflamed. It was resected, continuity of the bowel being re-established by an anastomosis between the terminal ileum and the rectum. On opening the caecum subsequently the whole of its mucosal lining was seen to be ulcerated and the site of multiple points of haemorrhage. The patient ultimately died. It would appear, therefore, that unless the caecum is absolutely normal no attempt should be made to retain it.

Summary of Results

Case No.	Age and Sex	Duration of Disease	Reason for Operation	Weight Before Operation	Date of Operation	Weight Dec., 1954	No. of Bowel Actions Dec., 1954		General Remarks	Result
							Day	Night		
1	30 F	12 years	Uncontrollable haemorrhage	st. lb. kg. 6 5 40.4	14/3/52	st. lb. kg. 7 11 49.4	6-7	1-2	Working normally as housewife. Developed intestinal obstruction, July, 1954. Post-operative recovery satisfactory. Prior to this episode bowels open 4-5 times in 24 hours	Good
2	44 M	7 "	Chronic ill-health. Diarrhoea, with blood and mucus	10 10 68	6/6/52	10 9 67.6	8-9	2-3	Majority of bowel actions occur after breakfast and supper. Patient works in heavy steel industry	Satisfactory (not classed as good on account of number of bowel actions)
3	10 F	2 "	Acute exacerbation with gross toxæmia	3 6 21.8	3/10/52	4 2 26.3	6	Slight faecal incontinence 1-2	Frail and physique poor	Fair
4	37 F	10 "	Chronic ill-health. Anaemia; diarrhoea with blood and mucus	8 50.8	10/10/52	9 11 62.1	6-7		Back to normal work as Civil Servant	Good
5	30 M	3 weeks	Fulminating type with perforation of colon	9 5 59.4	20/11/52	12 76.2	6	0	In excellent health. Previously professional footballer, is now on administrative side	"
6	29 F	1½ years	Severe toxæmia and subacute obstruction due to pericolic abscess	7 13 50.3	1/12/52	9 12 62.6	5-6	0-1	Working normally as housewife with one child	"
7	29 M	9 "	Patient treated by ileostomy in 1949 elsewhere	13 82.6	30/1/53	13 82.6	5-6	0	Working normally as electrician	"
8	40 F	11 "	Chronic ill-health. Severe diarrhoea, 14 times each 24 hours, with blood and mucus	9 3 58.5	5/12/53	11 69.9	5-6	1	Working normally as housewife with two children	"
9	31 M	5 "	Chronic ill-health. Severe diarrhoea, 16 times each 24 hours, with blood and mucus	9 7 60.3	11/1/54	11 69.9	5	3	Back to full work as motor mechanic	"
10	45 F	14 "	Chronic ill-health. Severe diarrhoea, 20 times each 24 hours, with blood and mucus	7 44.5	1/2/54	7 8 48.1	4-5	1	Patient back to work as clerk	"
11	20 F	6 months	Severe toxæmia—acute case	8 2 51.7	22/2/54	9 57.2	5-6	2	Back to normal work in city. Travels 50 miles by train each day	"
12	38 F	2 years	Chronic ill-health. Severe diarrhoea, 20 times each 24 hours, with blood and mucus	6 6 40.8	1/3/54	7 8 48.1	4-5	4	Back to work as shop assistant. Feels "wonderful"	Satisfactory (not classified as good on account of number of bowel actions)
13	30 F	10 "	Chronic ill-health. Anaemia; diarrhoea with blood and mucus	7 7 47.6	26/7/54	8 10 55.3	6-7	3	In excellent health. Bowels have not yet completely settled down	" "
14	49 M	9 "	Chronic ill-health and diarrhoea	10 2 64.4	17/9/54	10 5 65.8	5-6	0-1	Back to work as driver's mate	Good
15	43 M	2 "	Chronic ill-health. Diarrhoea, with blood and mucus	9 8 60.8	11/10/54	10 7 66.7	5	3	Now convalescing	"
16	51 M	2 "	Chronic ill-health and development of carcinoma in transverse colon	10 10 68	25/10/54	10 7 66.7	3	1	" "	"
17	26 F	3 months	Acute case progressing to fulminating state with peritonitis	5 12 37.2	19/7/54 (total colectomy, ileostomy, and proctostomy). 22/11/54 (ileo-rectal anastomosis)	7 44.5	6	4	Almost in extremis before operation. Bowels have not yet settled down after the anastomosis. Feels fit and well	"

Comment

The satisfactory progress of all but one of these severely and sometimes desperately ill patients, and their return to good health and to full work, seem to indicate that the method of treatment described is a satisfactory one. The follow-up is admittedly a short one and the series is not large. Nevertheless in no case has the disease flared up in the remaining rectum, and regular proctoscopic examination has shown that resolution of the inflammatory changes existing before the operation has taken place.

Addendum.—Since this article was compiled six other cases have been operated upon. Of these, two have returned to good health and three are convalescing. The sixth patient died during the fourth post-operative week following a burst abdomen. Of the patients reported on in the table, Nos. 11, 13, and 17 now have only one to two bowel actions at night.

ANXIETY NEUROSIS: TREATMENT BY THE GENERAL PRACTITIONER*

BY

RONALD A. B. RORIE, M.D., D.P.M.

Foundation Member of the College of General Practitioners; Assistant Psychiatrist, Eastern Regional Hospital Board (Scotland)

Between the world wars attention was drawn to the fact that a large proportion of chronic sickness was due to the neuroses. Gillespie (1933), while on the subject of psychotherapy in general practice, mentions the fact that, of 600 cases referred to a special clinic, 436 were diagnosed as neuroses. Halliday (1935) found that psychoneuroses accounted for as much as 30% of the sickness of insured persons in Glasgow, and there is no reason to think that this proportion has since diminished. These figures are borne out by the report of the British Medical Association (1941).

The family doctor, while he has unique opportunities for studying the factors that bear on a case, through lack of training has not the knowledge, and too often not the inclination, to attempt to deal with the obviously neurotic patient. At out-patient clinics one often hears the story that "my doctor says it is just nerves, and gives me phenobarbitone."

The palpitations, choking sensations, and innumerable phobias of the anxiety neurotic are all too real to the sufferer, and can incapacitate him totally for work. The man cannot face the bus journey to work, and, once there, has to leave the crowded workshop because of intense feelings of apprehension. The woman is unable to leave home to shop unaccompanied, and cannot attend church or go to the cinema. In face of the exhortations of the family and friends to "pull themselves together," these patients rapidly lose heart; fears of insanity follow, with suicidal impulses which may have fatal consequences.

During the last decade the general practitioner has become aware that a large part of his time is taken up by patients suffering from psychoneuroses. The coming of the National Health Service Act, leading as it has to

*From a thesis submitted to the University of St. Andrews for the degree of Doctor of Medicine.

a reduction in the time available per patient, has tended to make it difficult for the practitioner to do more than pass the case on to the specialist, with the result that only a small minority, and only the most patent cases, get treatment at all. The majority, of lesser degree, struggle along unhappily, treated by sedative. A recent analysis of prescriptions issued by practitioners under the National Health Service Act shows that the commonest by far is for sedative (Dunlop *et al.*, 1952).

Before the second world war the neurotic could expect to be treated in one of two ways. By the older school, in whom there persisted a moral disapproval of anyone suffering from a neurosis, he would be dismissed as lacking in moral fibre or as malingering. By the inter-war generations, who, while admitting the existence of an illness in such cases, could do little through lack of training, he would be given sedatives and allowed to drift.

I qualified in 1938 and do not remember ever being shown an anxiety neurosis as such during my training in mental diseases. From contact with colleagues during the war, I found that this did not simply reflect on my medical school as compared with others.

The tendency persists to diagnose neurosis in a negative manner, by exclusion of organic disorder, rather than in a positive recognition of the various neurotic syndromes. This leads to much waste of time and effort on the part of other specialists. It is as though one was afraid to admit that the complaint was functional. In practice even to-day, if a diagnosis of neurosis is made, it is necessary to explain that it implies no derogation or criticism of the patient. Even so, many patients feel insulted by such a diagnosis.

In spite of the community's increasing interest in mental illness, as shown by Press, popular fiction, theatre, and cinema, there still persists the Victorian disapproval of a subject which lays such emphasis on the emotional aspect of man's life. It is partly this disapproval which discourages general practitioners from facing and attempting to treat the vast number of minor neuroses they meet every day.

In this paper an attempt is made to describe the treatment of the commonest of the neuroses—the anxiety neurosis—from the general practitioner's point of view.

The Physician's Reaction

It is obvious that if the general practitioner refuses, consciously or otherwise, to face and treat the neurotic, and depends on the specialist, the vast majority of cases will go untreated.

When he is confronted with the anxiety neurotic, what is the physician's reaction? The complaints are indefinite but insistent; a physical examination is negative; a placebo, usually in the form of phenobarbitone, is prescribed, the only psychotherapy being a word of encouragement. If a diagnosis is requested, too often a hint of an organic condition is given—"a nervous stomach," "a tired heart," "overwork," etc. The patient is unrelieved, and on persistence is referred to one specialty after another, with negative findings. The psychiatrist is often the last consultant called in.

Two factors contribute to this maltreatment of the neurotic. The first is lack of time for proper history-taking and evaluation of the symptoms. Ross (1937), discussing the treatment of such cases, states that at least an hour should be set aside for the initial examination. It is a reflection on the conditions of service under the National Health Service Act that few general practitioners could find this easy to-day. The second factor is the blind spot

that so many practitioners retain for neurotic symptoms. One hears of the busy family doctor who proudly states that he never sees a neurosis.

Choice of Case

Before attempting treatment of an established anxiety neurosis it is necessary to decide whether the case is one that can be dealt with by the general practitioner or one for immediate referral to the specialist. Several factors bear on this decision.

The age of the patient is one such factor. With increasing age the personality becomes more rigid, and is less open to suggestion and persuasion than in the younger years. Rarely is a neurosis of recent onset encountered at this time, and the symptoms are usually complicated by involutional changes.

A certain degree of intelligence is necessary in the patient for any psychotherapy beyond suggestion and persuasion. As one proceeds to explanation of symptoms and discussion of possible causation a higher intelligence is required, and if anything of a psycho-analytical nature is attempted a higher than average intellect is essential. In an average working-class practice few patients are encountered who could benefit from such advanced treatment.

The nature of the illness itself may decide whether it should be handled by the general practitioner or by the specialist. The illnesses of long duration call for expert handling if more than temporary relief is aimed at. Patients with an apparently stable previous personality may be handled by the non-specialist, while personalities showing any marked degree of deviation from the normal should be avoided.

Probable aetiological factors should be considered before deciding to treat an anxiety neurotic. Deep-seated constitutional abnormalities such as homosexuality, if they are the basis of anxiety reactions, should be referred for specialist treatment. The general practitioner can handle with ease the anxieties resulting from sexual malpractice, domestic stress of all kinds, and marital difficulties. The illnesses resulting from war stress are probably within the specialist's sphere, as they are now of more than five years' duration, and the majority have received some form of treatment in the past and are likely to prove chronic.

A further point to be decided in the treatment of the neurotic is the ultimate aim of the treatment. This has been described as "to cure sometimes, relieve often, and comfort always." Some personalities have been anxious for a lifetime, and it is over-optimistic to promise them more than relief. The obsessional personality cannot be changed to a happy carefree nature. Similarly with the constitutional deviations, relief of the disabling anxiety symptoms should be the aim; whether or not the invert can be re-adjusted to a normal pattern of sexual behaviour is debatable; some authorities are optimistic (Allen, 1940), but Curran (1938, 1947) is of the opinion that few are desirous of cure. The latter states that the aim of treatment should be to make the congenital homosexual a better-adjusted homosexual.

Prophylaxis

The treatment of the anxiety neuroses is both prophylactic and curative, and the general practitioner's role is important in both. In aetiology, the main factors are found to be emotional stress of various kinds in the sexual, social, domestic, and other spheres, and also the stress of war service. While the stresses themselves can rarely be modified or avoided, with the exception of the last, which can be avoided by psychiatric examination on enlistment, the personal reaction to them can be modified by education and instruction.

Any general practitioner of experience knows the immense amount of ignorance that exists among patients of all classes, not only of sexual matters but of all matters affecting their general health. The effects of this ignorance are often aggravated by false enlightenment from parents, Press,

and well-meaning religious instructors. This is often the starting-point of needless anxiety and doubts about health. The family physician has unique opportunities of preventing this ignorance. In childhood he can modify the over-emphasis on health impressed by anxiety-ridden parents. He should do his utmost to prevent the unnecessary branding of a child as "delicate." Many a child is forbidden to take part in games and recreation because of some doubtful illness in earlier years. As time passes it becomes more and more difficult to remove this belief that he is not as strong as his playmates.

Careless talk by the practitioner in front of the young patient is very easy. It should be remembered that many an intelligent child in the early teens has just as much interest in its illness as the parents have, and is quick to pick up vague suggestions of "a scarred heart valve" or "a spot on the lung." Reassurance should be given in a simple manner by the doctor and not be left to the anxious parent. The handling of proved organic disorders requires fine judgment of the restrictions necessary: Menninger (1945) describes the way in which overemphasis on rest can lay the foundations of neurotic reaction, and states: "The treatment by rest originated with Weir Mitchell, but, according to modern psychiatry, is entirely false in theory and unsound in practice. It aggravates fears of disease and does not cure neuroses."

In adolescence and early adult life every opportunity should be taken to dispel ignorance and resulting worry about normal sexual manifestations such as masturbation and nocturnal emissions in males and menstruation in females. One still encounters surprising superstitions on these subjects, passed on from parent to child.

Similarly when it comes to marriage, the young couple, even of the educated classes, embark on this phase of life in a discouraging state of ignorance. Few ask spontaneously for advice, and the family physician could prevent an immense amount of unhappiness and anxiety by asking the engaged couple what they know, and correcting any misapprehensions. Marriage guidance clinics are still very few, and until these are developed the role of adviser must fall on the general practitioner.

In a discussion of the treatment of the neuroses in general practice, Guirham (1947) points out the common errors of approach, the danger of excessive physical investigation, and states his belief that "80% of married couples below the level of the petit bourgeoisie use coitus interruptus as a means of contraception." He states that "there is more to be gained in correcting patients' views on these matters than there is in studies of Freudian symbolism." From experience in general practice I am in complete agreement with both these statements.

In practice it is very easy to follow inquiries about the family with a question on what the couple are doing to prevent further additions. When these matters are brought up patients are usually very willing to discuss them, but hesitate to do so spontaneously. As Culpin (1935), however, points out, some doctors are temperamentally unable to talk about details of sex life, and simply turn a blind eye to it.

Mace (1947) discusses the problem of marriage guidance, emphasizing the importance of the general practitioner in the treatment of sexual disorders and his lack of training in such matters.

In these fields the general practitioner has great scope for the prevention of anxiety reactions. Little can be done to prevent interpersonality tension, which is the result of modern social conditions, but he can do much to prevent its development into an established anxiety neurosis.

Treatment

Psychotherapy alone can produce lasting benefit in an established neurosis. In the first place this need be only of a superficial nature, and is quite within the scope of the general practitioner. The best approach is a simple

explanation of the bodily symptoms. The familiar elements of the emotion of fear should be pointed out, with its dryness of the mouth, palpitations, nausea, tremors, weakness of the knees, headache, etc. The effects of over-attention to bodily functions should be illustrated by the difficulties in swallowing pills consciously, and breathing consciously, as compared with the ease with which these functions are carried out when the attention is diverted. The reality of emotional "lumps in the throat," "heartaches," "headaches," "butterflies in the stomach," etc., should be pointed out.

When this is accepted the next step is to explain how this emotional dysfunction has come about. Occasionally a patient will volunteer immediately where the emotional stress lies, but it is perhaps easier to give instances of the common factors in interpersonality stresses within the family, sexual stresses in adolescence, courtship, marriage, etc. Stress of work is often proffered as a cause, but it is usually found that the stress lies not in work itself but in emotional relationship between the sufferer and his fellow workers. One does not work with one's emotions.

Admission of such factors need not be insisted on, but if the patient is allowed to go home and think things over he often returns and admits them spontaneously. I used this type of discussion on one patient, but failed to get any response. Finally homosexuality was mentioned—one naturally does not begin with this suggestion—and, although strongly denied at the time, the patient returned several weeks later to admit that this was the prime cause of his anxiety.

As psychotherapy proceeds the technique varies according to the individual case. The lower intelligence group require more persuasion and suggestion to help them regain their confidence. The higher intelligence group may be allowed to talk themselves out of their troubles: any subject with a strong emotional tone should be encouraged, and the patient should be urged to face the reality of his feelings towards his environment.

Every patient wants reassurance that his symptoms are not those of insanity. Many are afraid to ask this question. The differentiation must be quite clear and definite. Confirmation that efforts of will alone are ineffectual in cure is essential. It is often necessary also to point out that in neurotic illness there is nothing to justify shame. Many sufferers are pathetically relieved to find someone who does not describe his complaints as imaginary.

After such simple discussion and reassurance many patients admit spontaneously that they feel better for days afterwards.

In the general handling of the anxiety neurosis the environmental stresses must not be neglected. These may be modified to some degree. The relatives of the patient must be interviewed and instructed concerning their correct attitude to the sufferer. It should be explained to them that the symptoms are real, and that well-meaning advice on their part may only serve to increase the patient's tension. Holidays are often suggested, but these help only if they lead to a removal of aggravating factors. A claustrophobic will feel better after a holiday in the country, but his symptoms will reappear when he returns to his previous environment. When anxiety symptoms are the result of an unsatisfactory sexual relationship, intramarital or extramarital, there will be temporary improvement during separation. In unsatisfactory marriage relationships, either physical or temperamental, both parties must be interviewed and the difficulties discussed.

While the somatic symptoms of anxiety can be expected to abate with such reassurance and discussion, the mental symptoms need special attention. The degree of depression requires careful assessment, as in any depression there is always some risk of suicide. The practitioner need not fear asking the patient if any such ideas are present. They are commonly admitted. What is the best course here? It should be realized that the only effective safeguard against such attempts is certification, but very few neurotics are

certifiable. The relatives should be informed that a certain risk is present, even though small; they would be advised to maintain a certain supervision over the patient, and so far as possible he should not be left for long periods alone. This usually leads to difficulties in the working-class home, as it is not easy to find a relative who can spare the time to supervise the invalid. When sedatives are prescribed they should not be given in excessive quantities. It must be remembered, of course, that any patient can hoard small quantities. In cases of doubt sedatives should be given only to relatives who can be responsible for their administration.

An attempt at suicide, however half-hearted, should be an indication for admission to hospital. Many of these potential suicides would be willing to enter a general hospital, but such hospitals are loath to accept mental cases, and the suggestion of admission to a mental hospital, though theoretically correct, leads to a grave exacerbation of anxiety. Suitable neurosis centres with in-patient facilities are still few and far between. Unfortunately on recovery the uncertifiable patient is returned home and if the neurosis is untreated the danger of further attempts remains.

Of the other mental symptoms the handling of the phobia presents some difficulty. The patient realizes that his fears are unjustified and fights continually against them. This fight should not be encouraged. The fears will diminish gradually with psychotherapy, and until they do the best course is to advise the patient to avoid, so far as possible, circumstances that induce them. As discussed below, sedatives can be used during this stage. Sometimes during treatment the phobia becomes attached to some comparatively non-disabling object, which can be avoided with ease.

Medical Treatment

There is no doubt that the temptation to dispose of a neurosis by prescribing sedatives is great, but in reality they play a very small part in treatment from a curative point of view.

Insomnia must be treated initially by hypnotics. Of these, phenobarbitone, though by far the most popular amongst general practitioners, is not the most useful. Neurotic insomnia usually takes the form of difficulty in falling asleep, and phenobarbitone is a slowly acting sedative. Barbitone sodium in doses of 5-10 gr. (325-650 mg.) is more useful; butobarbitone and cyclobarbitone are also useful quick-acting hypnotics. Phenobarbitone has its place in easing general tension by day in doses of 4-2 gr. (32-130 mg.).

In the treatment of anxiety symptoms amylobarbitone sodium deserves special mention. In general practice it can be given by mouth both in diagnosis and as treatment. The use of small doses of amylobarbitone sodium in diagnosis is worthy of note: 1 gr. (65 mg.) is not enough to relieve anything but emotional stress. It is the most efficacious drug for relieving anxiety, both generalized and phobic. The patient can go to church or the cinema, or undertake journeys that would otherwise be impossible or extremely uncomfortable. The student can attend classes in comparative ease.

Sedatives play an essential part in the treatment of panic states. Here the patient is quite inaccessible to psychotherapy, and the only course open is prolonged sedation with amylobarbitone sodium, intramuscularly or intravenously, combined if necessary with paraldehyde. Sargent and Slater (1944) describe the various uses of these drugs in detail.

Relaxation

In all cases both mental and physical tension may be greatly relieved by instruction in methods of relaxation. A suitable form of relaxation exercise is one devised by Dick Read (1943). Many of the more intelligent patients benefit from this: muscular tension is reduced and a calm

state of mind induced which often leads to sleep. A summary of instructions to be given to the patient is reproduced below. That this falls within the general practitioner's realm is emphasized by the fact that these exercises are taken from a work on the management of pregnancy, being used to reduce muscular and mental tension in childbirth.

Position.—The patient should lie on the back on a wide couch or fairly hard bed with a small bolster under the head and shoulders, and a smaller pillow or cushion under the knees; arms by the side, elbows half bent, hands half closed, knees slightly separated—that is, all joints so far as possible in semiflexion. Relaxation is obtained as follows: (1) shoulders, by thinking of them "opening outwards"; (2) arms, by imagining them falling out of the shoulder-girdle "as though they did not belong to you"; (3) back—sinking through couch on to the floor; (4) legs, knees, and feet—falling outwards by their own weight; (5) head—making a dent in the pillow; (6) eyelids—half closing by their own weight; (7) face—as though hanging from the cheek-bones; (8) jaw—hanging loose. Give about two minutes to each group, and take them in the same order each time.

Breathing.—Let the chest wall collapse with its own weight on expiration, and pause for two seconds (or until the need for a new breath) at the end of expiration. Get a feeling of general relaxation, letting all the joints give a little more with each outgoing breath. This should be done six times. Note the train of sensation in the limbs—usually heaviness followed by lightness or "floating"; faint, transient pins-and-needles in the hands; feeling of warmth passing up from the extremities. A pleasant, torpid, day-dreaming state generally ensues (as in sunbathing), and any tendency to direct thinking should be deliberately diverted into a day-dream.

Duration.—Half to one hour (the sense of the passage of time is often lost or blunted).

Exercises for the Neurasthenic

Exercises of a different nature are to be recommended for the "neurasthenic" type of anxiety neurosis. Many of these patients believe themselves so incapacitated that they take to bed. Graduated physical exercise is required in such cases. It should be clearly explained to the patient that he must not expect to leave bed and feel absolutely fit. Hill and Dewar (1945), in a survey of effort syndrome, mention that graduated exercise is easily arranged in the armed Services, but in civilian practice such procedures are not possible. However, it is sufficient to get the patient to take gradually increasing daily walks, starting with a few hundred yards, and increasing slowly until he finds himself walking several miles without any discomfort.

It is customary to advise special diets and other measures to improve the general health in all neuroses. In domiciliary practice under present-day conditions this is extremely difficult, but it is important to keep in mind the possibility of avitaminosis. In case of doubt it is advisable to administer vitamins, especially those of the B complex, as psychotherapy proceeds.

It might be objected that the practitioner to-day does not have time to carry out the above treatment. Watts and Watts (1952) give a very good reply to this, showing that the time involved is no more than that necessary for the conduction of midwifery practice. As a result of experience in general practice and in out-patient psychotherapeutic clinics I find that, in suitable cases, six interviews of half an hour each suffice to relieve the sufferer of disabling symptoms.

Hospital Treatment

The treatment so far described is that within the scope of the general practitioner. What symptoms raise the question of admission to hospital?

In the first place, depression of suicidal degree makes it necessary for this to be considered. If home supervision is adequate it is possible to treat the case there, but in the average middle- and working-class home it is difficult to find a responsible relative who can spare the time for constant watch on the patient. The depressed anxiety neurotic living alone can cause more concern to the practitioner than

the flagrant psychotic. The latter can be certified with little difficulty, whereas it is often impossible in the case of the former.

A second group that often require admission to hospital are the cases of extreme agitation. The patient is restless, tearful, and wears out herself, her relatives, and her medical adviser with her demands.

Thirdly, admission to hospital may be necessary in the treatment of the anxiety neurosis with symptoms of anorexia, with or without vomiting. Such symptoms can eventually endanger the life of even a young and physically healthy girl.

Lastly, the phobias can restrict the patient's activities to such an extent that he is unable to undertake out-patient treatment even if he were willing. Cases can be recalled in which the sufferer was completely confined to his house by panics which overwhelmed him at every endeavour to leave.

In all these cases the choice lies between admission to a psychiatric unit of a general hospital or to a mental hospital. In either case admission should be on a voluntary basis; but it rarely happens, in cases which cannot be supervised at home, that the sufferer can endanger his or her life and, being uncooperative, make certification unavoidable.

Out-patient psychiatric clinics have been developing rapidly during the past five years, commonly associated with a general hospital. These help in the diagnosis and treatment of early psychiatric illness. In chronic deep-seated anxiety neuroses, prolonged specialist psychotherapy is often required, lasting several months or even years.

Of the various methods of psychotherapy there is no end. From a continuation of superficial explanation, reassurance, and discussion, methods vary through free association, modified analysis, to full analytical methods. As stated previously, the scope for the latter is very small indeed. The growing numbers of cases referred for treatment have now led to a development of group methods of therapy, in which the patients are instructed as a group in the nature of their troubles, and are encouraged to work their way out of them in the group, by various means.

Various abreactive techniques can be carried out on an out-patient basis, using hypnosis, intravenous barbiturates, ether, carbon dioxide, and other aids. These methods were of particular use in the treatment of traumatic war neuroses; the patient is encouraged to work off his previously repressed emotions.

Out-patient electric convulsion therapy, although primarily of use in the treatment of psychotic depressions, has a place in the treatment of anxiety neuroses. It is almost essential in the case of the depressed suicidal neurotic. Although it may increase agitation while it is being applied, the effect is to lessen the depression and to relieve insomnia, and often an increase in appetite and physical well-being is achieved.

In-patient treatment for neuroses still presents great difficulty. The fear of the neurotic that he might be sent to a mental hospital is quite understandable: in practice a relatively small proportion enter such a hospital on a voluntary basis, and they rarely stay long enough to benefit. While a large percentage of neurotic cases are admitted to general wards, they are discharged as soon as such a diagnosis is made. Few hospitals for purely neurotic patients exist. In hospital, further treatment is available for the anxiety neuroses. Modified insulin therapy can be applied to selected cases. It is specially indicated in the agitated and physically debilitated case. Anxiety can lead to profound loss of weight, and this can be replaced rapidly by the use of insulin in dosage sufficient to induce varying degrees of hypoglycaemia. It also acts as a sedative, and psychotherapy can be carried out concurrently.

Continuous narcosis is of use in the case of the acute anxiety state, and is possible only in hospital. The patient is kept continuously under the influence of hypnotics for a period of a week or more, being roused only for nourishment,

which is given in the form of fluids. This method is of little use in the case of the chronic anxiety state, the patient usually returning to his previous broodings on his health when sedation is stopped.

Conclusion

When the above methods have failed, one is tempted to consider the problem of leucotomy for the sufferer from chronic anxiety. The place of this treatment in the case of the neurotic is still a matter of argument. Although spectacular successes have been reported (Sargant and Stewart, 1947), the result must always be unpredictable. While anxiety is usually relieved and intelligence is rarely impaired, the effects of treatment cannot be undone. The result of the operation might be a bigger social problem than the original illness.

There is a very strong case for a small psychiatric unit in all general hospitals, to provide the above out-patient and in-patient treatments, without the "stigma" of visiting a mental hospital, which deters so many sufferers from seeking help.

My thanks are due to Dr. J. D. Uytman, consultant psychiatrist, Dundee Royal Infirmary, for his suggestions on "relaxation exercises," and to William Heinemann, Ltd., for permission to reproduce the extract from *Revelation of Childbirth*, by G. Dick Read.

THE NEURASTHENIC PSYCHOPATH

BY

W. L. TONGE, M.D., D.P.M.

Deputy Medical Superintendent, Cheadle Royal Hospital for Mental Diseases, Cheshire

Full social participation is now commonly regarded not only as a sign of health but as an essential for its achievement. Interest is therefore aroused by those who do not participate in the activity, basic to our society, of work. The findings of a survey and follow-up of a group of psychiatrically disabled men, both employed and unemployed, have previously been reported (Markowe *et al.*, 1955). In the course of the investigation some of the subjects with long-term unemployment asked for psychiatric help, and 28 of these attended a special clinic for twelve months. The present paper offers a discussion of the clinical patterns of these patients.

Clinical Report

In every diagnostic clinic it is often difficult to draw a formal distinction between the illness and the personality from which it springs. The syndromes presented by these patients can be seen in any psychiatric clinic; in the earlier report also it was noted that employed and unemployed subjects had similar symptoms. Twenty patients complained of neurotic symptoms, of which excessive tiredness, back-

ache and headache, hypochondriasis, and a varying mood of anxiousness or mild depression were predominant. Plainly hysterical symptoms and signs were observed in only three patients, but physical symptoms of anxiety were found rather more often. Three patients had major epileptic fits, three were defective, two suffered from involutional depression complicated by organic disease, one developed a mixed depressive psychosis, one was a chronic schizophrenic, and one developed a reactive paranoid state.

These summary diagnostic labels fail to explain the interest provoked by these patients, for they provided a clinical experience of disorders and anomalies of personality not easily gained in out-patient departments, and they afforded a more precise description of the term "inadequate psychopath." The following case history is illustrative.

A man aged 39 when first seen had had neurotic symptoms in his childhood, but did not admit to a family history of psychiatric illness. He served as a regular soldier before the war, but was invalided in 1941. He had several unskilled jobs on leaving the Army, but for the past four or five years had been almost consistently out of work, holding one job for about a month every year or so. He married in 1939 and had one son, but his wife refused to leave her mother to live with him. He was contemplating divorce proceedings when his wife sued him for desertion. He denied any other sexual activity. He lived on his own in lodgings, cooking his own meals, and had no friends. His weekly income from all sources was 69s., of which he paid 25s. for his room and 10s. maintenance for his son. He complained of attacks of anxiety, palpitations, depressions, and dizzy spells since his marriage. He was apathetic and resigned in mood. There were no physical abnormalities. In spite of his poverty he could not get work, although opportunities for employment were excellent in that area. He attempted to get in touch again with his parents: an aunt told him they had removed, but apparently he could not discover their new address.

The ineffectiveness these patients displayed in all aspects of life was also apparent on interview. They waited upon the words of their interlocutor, and rarely ventured to put forward what they wanted in life or what they would like to do. Although some might fairly be described as retarded in speech, they varied in their verbal facility; but when the interview touched on topics which, it might be supposed, would awaken their self-interest, their talk became vague. Their complaints and dissatisfactions, their present difficulties or previous happiness, their hopes and fears for the future, whatever was in question, would arouse no definite affect or point of view which could be seized upon and discussed. A striking feature was their tolerance of the worst conditions and their seeming inability not only to obtain satisfactions but even to desire them. In the case just cited the patient had given up his family and son and had no friends; with the money at his disposal he lived virtually in penury, and must at times have gone hungry. His symptoms were by no means severe, yet he was unable to earn even that little money which he would have found so helpful. With all these troubles he was only vaguely distressed. The lack of a serious disturbance of mood and the long-standing nature of his condition made it unlikely that he was suffering from a chronic depression. None of the basic signs of schizophrenia were present, nor was he cold and unfeeling; on the contrary, he maintained quite a strong affective rapport with the doctor in a dependent and pathetic way.

This lack of drive was well shown by another patient who later developed a reactive paranoid state. He managed to hold a job for a few weeks, and when asked on what he spent his money he replied that he was "putting it by." On being pressed further, he said it was to buy clothes. He neither smoked, drank, nor went to any entertainments, and had no friends of either sex. On giving up his job he forfeited the help of the National Assistance Board and went to live with an uncle, who kept him in the bare essentials of life only.

Apart from defectives, who might be expected to show some degree of inadequacy, this type of personality anomaly was observed in 18 of the remaining 25 patients in varying degrees of severity.

Other types of psychopathy were also observed. Two patients could be classed as contentious and emotionally unstable. One, a qualified laboratory technician, became aggressive and abusive whenever attempts were made to find work for him. He complained that the clinic misrepresented him to prospective employers and prevented their engaging him. He claimed to have many influential friends, but nevertheless he was living in the poorest circumstances. He alleged that a high-level inquiry had been made by the Ministry of Labour into the handling of his employment problems, which had disclosed "inefficiency and muddle all around." The other patient, no less aggressive and paranoid, attempted to borrow £50 at the first interview. At times he showed a hypomanic pressure of talk. While these patients resembled the inadequate personalities in their poor work record and history of failure, yet they were by no means ineffectual in the part they had chosen of acting out a pathological sense of grievance against official bodies.

Another patient, neither inadequate nor querulous, was yet emotionally immature, while the patients with involutional illnesses and schizophrenia had the personalities characteristic of those conditions.

Treatment and Outcome

It is hardly surprising that in face of such difficulties these patients failed to improve their adaptation as judged by their work record during the time they attended the clinic (Markowe *et al.*, 1955). The progress of some individual cases is, however, worth discussing.

One patient with an involutional depression complicated by pernicious anaemia was admitted to hospital. Adequate treatment of the anaemia and rest in hospital, without further physical treatment, restored a normal mental state, and this patient is now working. Supportive psychotherapy, while available to all patients, was in particular successful in the case of the patient who was emotionally immature. He had found work for himself, but was crippled by heavy debts. With the encouragement of the clinic he succeeded in satisfying a court order and made good progress in straightening out his affairs. A patient who had reached retiring age was settled happily in an old people's home, and a place was found for one of the defectives in an occupation centre. Although this could not be counted as rehabilitation, it represented a much more satisfactory disposal than their previous way of life.

When patients were successfully placed in jobs, this was almost always done by the local disablement resettlement officers, but there were some problems which could not be solved through the good offices of the employment exchanges. One patient, an undischarged bankrupt, was by temperament more fitted to work on his own account. He had trained himself as a french-polisher, and by borrowing money from various sources it was found possible to set him up in business again.

For many patients, however, with the gross deficits of personality already described, treatment was unrewarding. Attempts to place them in suitable employment failed, as their ineffectiveness could not long be hidden from their employers. Vacancies in Remploy were too scarce to be of practical value, but one patient was accepted by an industrial rehabilitation unit. Physical treatments were inappropriate and supportive psychotherapy was without effect. In three instances, where patients presented particularly difficult problems of adjustment, arrangements were made for their admission to the Social Rehabilitation Unit at Belmont Hospital under the care of Dr. Maxwell Jones, in the hope that vigorous social therapy would be more effective than out-patient treatment. The remainder, on the other hand, provided ample opportunities for welfare work. Those without friends were encouraged to join a social club for out-patients. In spite of National Assistance, there were some who lacked clothing and other necessities, and these patients were grateful for being put in touch with charitable organizations which could relieve their needs.

At the end of twelve months four patients had either recovered or were much improved and were back at work. Four others showed symptomatic improvement. In three cases the improvement in health preceded the return to work, in four it followed a return to work or the taking up of an occupation. Relief of financial anxiety, the feeling of again being useful, and occupation in itself were reasons given by these patients for their later improvement. One patient received symptomatic relief from sedatives without any improvement in his work record.

Two patients deteriorated while attending the clinic. One, having developed a mixed depressive psychosis with marked hysterical features soon after his first attendance, was admitted to a mental hospital. The other was an extremely inadequate man who was advised to attend out-patient occupational therapy. After some weeks his behaviour at the occupational therapy centre became disturbed, and he felt that the staff were against him. Later he believed he heard the voice of a neighbour talking about him: she knew all the details of his life and was in touch with the occupational therapy centre. He ceased attending the centre and resumed his solitary existence with his uncle. His delusions still remain, but he does not act upon them, and remains an isolated and eccentric figure.

Comment

In spite of the serious unemployment two decades ago, there are surprisingly few clinical reports of the psychiatric disturbances of the unemployed. Lewis (1935) reported on 52 such patients and found a uniform clinical picture in which hysteria was predominant. In the present series the predominant symptomatology may fairly be described as "neurasthenia." This change in the form of neurotic illness is now a commonplace observation; Mayer-Gross *et al.* (1954) attribute it in part to changing fashions in diagnosis, but Lewis noted gross hysterical phenomena in 23 of his 52 patients, which is to be compared with only 3 out of 28 patients in the present follow-up study. It is possible that the increasing sophistication and self-respect which has accompanied a rising standing of living tends to inhibit the cruder forms of hysterical response: it is of interest that Kalinowski (1950), in his review of psychiatry in the last war, comments that gross hysterical conditions, so common in the first world war, were reported as frequent only in the Yugoslav partisans.

Although the symptoms were plainly neurotic, the gross anomalies of personality suggested the possibility of more serious psychotic disorders, in particular mild chronic endogenous depression or simple schizophrenia. In almost all cases this could be discounted. Except for the one case of declared schizophrenia, thought disorder was entirely lacking and good rapport was obtained. Secondary symptoms were absent, except for the patient who developed paranoid delusions, but this could more accurately be described as a reactive paranoid state, the basic signs of schizophrenia being lacking. Similarly, the cardinal features of depressive psychosis were absent in all except the patient admitted to a mental hospital; one other patient who had lost weight and was slightly retarded was also suspected of suffering from a mild depression. Signs of an organic dementia were not found in any patient. In almost all cases, therefore, a supporting diagnosis of constitutional personality disorder had to be made.

The term "inadequate personality" has come to be widely used, and is now included in the *International Classification of Diseases*. Published descriptions of this condition are not, however, entirely applicable to the cases here described. Henderson (1939) notes that such patients "may show a condition approaching apathy, but it is not so much an apathy as a self-centredness which takes no thought of others, and has for its aim the individual's self-gratification and glorification." Mayer-Gross *et al.* (1954) describe the "unstable drifter" (*Haltlosigkeit*) in similar terms: "His immediate wishes, affections, or disgruntlements rule him completely, and he is indifferent about the future and never

considers the past." These are descriptions of the typical psychopath, unable to steer a steady course, seduced by each passing temptation, and certainly apply to two patients in the present series. No doubt this type of behaviour also occurs in the remaining patients to some extent, but the heart of the matter lies elsewhere. Their characteristic and common feature is lack of drive; the pattern of repeated failure is to be seen as due, not to lack of control, but to a profound enfeeblement.

Janet's (1903) words are more apt: "Presque toutes ces personnes présentent quelquefois depuis leur première enfance un caractère bien reconnaissable: ce sont des mous, des indolents, des paresseux." Janet distinguished his concept of psychasthenia, with obsession and rumination, from neurasthenia: "Certains malades sont très abouliques, ne peuvent plus faire attention et présentent de l'amnésie continue... chez ceux-là les troubles de l'obsession sont peu à redouter." He writes of mental sickness in a context where the term personality disorder is now preferred, but the point to be made is that the ineffectiveness of the patients here described is closer to the older concept of neurasthenia than to that of psychopathy, as now generally understood. Schneider, too, included asthenia in his list of psychopathies.

It is hardly surprising that this type of personality disorder has not caught the attention of writers to the same extent as the more troublesome unstable psychopath: it is of their nature to pass unnoticed. When, however, there is a strong social pressure to work, as in the present period of full employment or in times of war, their disability becomes apparent. The clinical impression of these patients upon me could be compared only with my experience of Army psychiatry, and in both instances patients were often referred for administrative reasons. In discussing the effort syndrome Lewis and Jones (1941) pointed out that symptoms were of little consequence in a man's decision to soldier on; more important was his attitude to military service. This is patently the same problem of adjustment as is presented by the present unemployed.

If, as I am inclined to believe, it is this type of personality disorder which forms the core of the disabled unemployed and not the "unstable drifter," the question of treatment remains. In the Army, group techniques tended to be developed (Foulkes, 1948; Maxwell Jones, 1952), which have since been continued by the Social Rehabilitation Unit at Belmont Hospital. Promising results are claimed—44% satisfactory adjustment on follow-up (Maxwell Jones, 1952)—in patients for whom the criterion for admission was social failure; but it is uncertain whether this outcome applies equally to the type of patient here discussed. By the showing of the present clinic, out-patient attendance alone is not sufficient to improve their level of adjustment. Rehabilitation may even be ill-advised for some patients at particular stages of their illness. Attempts to break down the defensive social isolation were found intolerable by the patient quoted above, who developed a reactive paranoid state when he was exposed to the stimulation of an occupational therapy centre.

The discussion of the differential diagnosis should perhaps have included the lay interpretation of laziness, as a description not of behaviour (as with Janet) but of motive. Nothing could be farther from the truth. The economic sanction of withdrawal of National Assistance benefit did not change the adjustment of the patient concerned, and, even if by these harsh means some were induced to re-enter employment, there is some evidence that they do not become productive workers (Markowe *et al.*, 1955).

When such conditions occur in wealthy men they are regarded as amusing eccentrics, like Goncharov's Oblomov; in poorer men, however, our society takes a sterner view. The possibility remains that, like Oblomov, these unhappy people can be neither treated nor coerced into becoming more productive citizens, but remain a charge on the kindly employer or the welfare services, even requiring the more

able to search them out, for they are as ineffectual in seeking help as in all other things.

Summary

Attention is drawn to a type of personality disorder which was observed in patients attending a clinic for unemployed psychiatrically disabled men. This disorder is characterized by absence of drive and irresolution rather than by emotional instability as in other forms of psychopathy.

The response to out-patient treatment both in occupational adjustment and in mental health was unrewarding.

It is considered that, although these patients may not often be suitable for rehabilitation, they are almost always in great need of social welfare services.

I wish to thank Professor A. J. Lewis, honorary director of the unit, for his advice and stimulating criticisms, and Dr. M. Markowe and Dr. G. M. Carstairs for making available to me observations on patients under their care.

THE FOOT AS A HALF-DOME

BY

J. MCKENZIE, M.B., Ch.B.

Department of Anatomy, University of Aberdeen

Although the foot is usually described as having medial and lateral longitudinal arches and a transverse arch, a few writers—for example, Ellis (1889) and Wood Jones (1949)—have compared the foot to a half-dome, the weight being transmitted from the talus to the periphery of the foot, which forms more or less a half-circle as seen in the footprint.

There are three sound reasons why this latter method of regarding the foot should be more widely taught.

(1) The trabeculae within the bones indicate the direction of weight transmission, and in radiographs of the individual bones of the tarsus the fan-like arrangement of the trabeculae in the navicular and their downwards and lateral direction in the cuboid are particularly noticeable. Sections through the bones show the pattern even better; in a longitudinal section through the calcaneum the trabeculae radiate forwards, backwards, and downwards, while in a cross-section of the calcaneum through the sustentaculum tali they splay downwards and laterally. If these trabeculae are projected on to the surface of the bones and the bones then articulated (Fig. 1), a picture is formed of a series of "half-arches" or "quarter-meridians" radiating from the talus to all the peripheral weight-bearing part of the foot (Fig. 2). Naturally there are still longitudinal and transverse arches, depending on how the foot is sectioned, but these arches are of no significance in the function of the foot unless the sections coincide with bony trabeculae.

(2) Most students have obviously, and unfortunately, obtained the ridiculous impression that a person uses only the longitudinal arches when walking, whereas between coming down on the heel and pushing off with the toes a

FIG. 1.—The trabeculae projected on to the surfaces of the articulated foot-bones.

FIG. 2.—Diagrams to illustrate the relations of the half-arches to the bones of the foot.

walker bears weight, in turn from behind forwards, on all the half-arches. In fact, in the case of an in-toeing walker, who does not push off with his big toe (he uses the lateral toes), most of the strain is put on arches running neither longitudinally nor transversely, but obliquely. To describe the foot as having longitudinal and transverse arches only, simply does not cover this type of case.

(3) By comparing the foot to a half-dome, we get a better understanding of the deformities seen in flat-foot (or weak-foot). When a normal foot takes the weight of the body there is the well-known but variable elongation of the foot, because the half-arches, reaching anteriorly and posteriorly, have flattened or yielded under the strain. But what happens to the transverse and oblique half-arches? When they yield under the body weight they throw the summit of the half-dome—namely, the talus—medially. Fig. 3 shows a person sitting with his feet just a little apart; when he stands up without shifting his feet (Fig. 4), notice how the medial malleoli come together. In a case of flat-foot which is the result of faulty posture or weakness of muscles and ligaments, one obvious feature is the low medial border of the foot; but it is well known that in the normal foot the arching or doming may be very high or very low, so this feature is no criterion. If, however (Fig. 5), the talus and medial malleolus have been pushed medially and downwards to a marked degree (or, as it is sometimes expressed, have "rolled-in"), thereby giving pronation of the fore-foot and valgus deformity of the heel (Fig. 6), then there is no doubt that we are dealing with a foot whose doming or arching has collapsed.

Look again at the diagrams (Fig. 2) and the positions of the bony trabeculae in the foot (Fig. 1) and it becomes obvious that this is the only way in which a foot can possibly flatten out—that is, for the summit of the dome to be pushed medially as well as downwards. The alternative, were it possible, would be the summit sinking straight downwards, requiring a splaying out of the transverse and oblique half-

arches at their peripheral weight-bearing ends, thereby producing a longer lateral border to the foot: but these half-arches, with a few exceptions, are contained within the calcaneum and therefore cannot separate from one another. Even if the calcaneo-cuboid and cubo-metatarsal joints were to open out (and there is no attempt at this in flat-foot), it would not be sufficient, because most of the transverse and oblique half-arches are behind these joints.

FIG. 3.—Feet bearing no weight: medial malleoli just a little apart. FIG. 4.—Same feet as in Fig. 3, and in same position but bearing body weight: medial malleoli now in contact.

FIG. 5.—Flat-foot, showing pronation of forefoot.

FIG. 6.—Flat-foot, showing valgus deformity of heel.

Summary

Comparing the foot to a half-dome has these three advantages over the older description: (1) It gives a true picture of how the weight is transmitted through the foot. (2) It forbids false impressions of how the foot is used in walking. (3) It allows of a better understanding of the deformities seen in flat-foot.

I am indebted to Professor R. D. Lockhart for his helpful criticism in the preparation of the paper; to Mr. A. Cain, A.R.P.S., for the photographs; and to Mr. W. Cruickshank for the diagrams.

Medical Memoranda

Anorectal Ulcer in Chicken-pox

Chicken-pox lesions situated on uncommon sites such as the conjunctiva, prepuce, vulva, larynx, and trachea often give rise to symptoms. This report presents a case of chicken-pox, with constipation and a severe bearing-down pain, in which proctoscopy showed an ulcer of the anorectal region.

CASE REPORT

A boy of 12 was referred to the casualty department on April 7, 1953, as a possible abdominal emergency. He had previously been well, and his family and detailed past history was not significant. Six days before admission a skin lesion appeared on the left hip, and crops of lesions erupted each day during the next three days, the general order of spread of the rash being from hip to abdomen and back, to lower limbs, and to head and scalp. This chicken-pox eruption was heavy and generalized. The temperature rose to 38.5° C. on the second day of illness.

On the fourth day of the eruption, two days before admission, the boy complained of pressure in the lower abdomen and a desire to defaecate. This increased on the following day, but he was unable to pass a motion because of the onset of a severe sharp pain in his rectum on attempting this. Periodic attacks of the pain even woke him at night. As these pains increased in severity and frequency, he was referred to hospital. Micturition also became painful.

On admission he was rolling about and complaining of severe pain in the lower abdomen; physical examination was therefore difficult. He was an intelligent and well-nourished boy. The temperature was 37.7° C. The scalp, face, trunk, and lower limbs showed numerous scabbing chicken-pox lesions. The tongue was coated with a yellow fur, but the edges were moist. On palpation a fullness of the lower abdomen and the possible presence of a mass on the left side were noted. Rectal examination was not successful, since the boy resisted the procedure and the sphincter was in marked spasm. During a barium enema x-ray examination shortly after admission, the medium was seen to enter the descending colon, and soon afterwards a large soft faecal stool was passed, free from blood and scybala. Analgesics were given during the day, in the course of which three more bulky motions were passed. The next day he was still in pain, and sigmoidoscopy was performed under thiopentone anaesthesia. The presence of faeces prevented adequate inspection of the mucosa. Following this

examination, apparently because of the dilatation of the anal sphincter, the patient experienced much relief, and it was possible to give cleansing enemata. On the third day of hospitalization proctoscopy showed a yellowish-grey ulcer about 8 mm. in diameter situated 2.5 cm. from the anal margin at about 2 o'clock, the surrounding mucosa being redder than elsewhere. The anal sphincter was then well stretched.

Much relief followed this second endoscopic examination, although he still complained of some pain during defaecation, and the sphincter remained in spasm. He was discharged on a regime of liquid paraffin by mouth and suppositories. Follow-up proctoscopy on April 13 showed the ulcer to be shallower with a clean base, and sigmoidoscopy to a depth of 10 cm. revealed no abnormality. On April 23 proctoscopy showed complete disappearance of the ulcer and a normal mucosa. The patient had no complaints. Full examinations of faeces and urine had been repeatedly negative.

COMMENT

The symptoms referable to the anorectal region appeared during the eruption of successive crops of chicken-pox lesions, and there was no other known cause for the ulcer, such as scybala, a generalized proctitis, or any trauma. It is almost certain, therefore, that this ulcer developed from a chicken-pox lesion. It was not possible to locate the site of the lesion in relation to the pectinate line, but the symptoms, the severe spasm of the sphincter, and the relief following stretching of the anus suggest that the ulcer was within the upper limits of the anal canal. This point is relevant because of the difference in histology between the rectum and the anal canal, the lining of the latter being transitional epithelium.

Although vesicles of the buccal mucosa are quite common in chicken-pox, there are few records of lesions in other parts of the alimentary tract. The usual clinical examination naturally does not reveal such lesions, and so benign a disease rarely yields necropsy material. Mitchell and Fletcher (1927) note two patients with "ileo-colitis" among 775 cases of chicken-pox. Bullowa and Wishik (1935) list appendicitis in five patients and intestinal intoxication in three among the complications in 2,534 cases of chicken-pox. It is probable that the above were unrelated to the initial illness. Dr. H. Stanley Banks (personal communication, 1953) has not encountered intestinal ulceration in chicken-pox.

Post-mortem reports on patients dying with chicken-pox occasionally refer to gastro-intestinal findings. Johnson (1940) described five small shallow ulcerations of the oesophagus in an infant of 7 months, the lesions showing areas of focal degeneration similar to those in the skin. Oppenheimer (1944) reported a premature infant dying at 11 days who showed disseminated necroses and intranuclear inclusions in the oesophagus, stomach, and intestines. Lucchesi *et al.* (1947) noted that the stomach of an infant of 12 days showed hyperplasia and hypertrophy of the surface epithelium and a few tiny scattered areas of necrosis associated with intranuclear inclusions. In a woman aged 32, whose case is described by Claudy (1947), the sole abnormality in the digestive tract was a few small haemorrhages in the crests of the intestinal folds. Numerous shallow ulcers of the oesophageal mucosa with chronic inflammation of the submucosa were noted by Frank (1950) in a woman of 34. Eisenbud (1952), in a necropsy on a woman aged 71, found a few small haemorrhages in the wall of the small intestine extending through the entire thickness of the gut. Hackel (1953) studied the necropsy findings in 11 patients who died with active chicken-pox and (personal communication, 1953) found no lesion of the gastro-intestinal tract.

The reports of visceral involvement in chicken-pox support the view of Scott (1951) that the virus is carried via the blood stream. There seems no reason, therefore, why

any part of the body should not occasionally show localization of the virus, which, furthermore, has a predilection for epithelial structures.

I wish to thank Dr. W. Falk for permission to report this case and Mr. T. J. Shields, B.M.A. Librarian, for help with one of the references.

Asphyxia Pallida Responding to Endotracheal Insufflation after 140 Minutes

Much interest has been aroused by recent publications on the treatment of asphyxia neonatorum by endotracheal insufflation and intragastric oxygen. Little mention is made, however, of how long these measures should be continued when there is no response. This case is of interest because the infant made a dramatic recovery after complete absence of spontaneous respiration for two hours and twenty minutes.

CASE REPORT

The mother was a primigravida aged 32. She was booked for hospital confinement and attended the antenatal clinic regularly. Her general condition was excellent throughout. Her blood was Group O, Rh positive; haemoglobin 84%. The W.R. and Kahn test were negative. Breech presentation was diagnosed at 36 weeks and external cephalic version was attempted but was not successful. X-ray pelvimetry showed the pelvis to be of good shape and ample dimensions.

Labour was induced at 39 weeks, this being the customary treatment of breech presentation in a primigravida at this hospital. Medicinal induction consisting of castor oil, 2 oz. (60 ml.) by mouth, followed by an enema and a hot bath, was first given. This was followed by surgical induction with a solid rubber bougie. Labour pains began two hours after the latter procedure. The first stage of labour was uneventful and lasted 24 hours. The membranes ruptured after 16 hours. Sedatives given were syrup of chloral, 30 gr. (2 g.), at 12 hours, and pethidine, 100 mg., at 20 hours. The second stage lasted 30 minutes. Spontaneous breech delivery followed under pudendal block anaesthesia. A liberal episiotomy was performed and the head was delivered easily with Wrigley's forceps. The foetal heart was regular throughout. There was no cord anomaly.

The infant gave one gasp after delivery but made no further attempt at respiration. The nostrils, mouth, and pharynx were sucked clear of mucus and liquor, and the infant was placed in a warm cot in an inverted position. After five minutes there was still no attempt at respiration, and the infant had the classical appearance of asphyxia pallida. The heart was beating regularly at 110 a minute. After 10 minutes intragastric oxygen was begun with Akerrén's method. This treatment was continued for a further 10 minutes, but the infant remained pale and was flaccid and inert. The heart rate dropped to 100. In view of this, endotracheal intubation was carried out with a Magill infant laryngoscope and a Magill No. 3 endotracheal catheter. Laryngoscopy showed that the larynx and pharynx were patent and clear of mucus. Insufflation was started with a Gibberd insufflator. Pure oxygen was delivered from the bag 30 times a minute at a pressure of 20 mm. Hg. After

five minutes the infant became pink but remained atonic. The heart rate rose to 120. The only evidence of spontaneous respiration was isolated gasps occurring at half-minute intervals.

For the next 90 minutes insufflation was continued. The state of the baby remained unaltered and shallow gasps continued to occur at the rate of two a minute. Resuscitating measures had now been in progress for 110 minutes. After two hours signs of improvement appeared. There was a deepening in the respiratory gasps and the infant gave a feeble cry. During the next 20 minutes there was a rapid recovery of muscle tone, with deepening and quickening of respirations, culminating in normal spontaneous respiration after 140 minutes. The endotracheal tube was then removed. One hour later the infant was breathing normally and crying lustily.

The birth weight was 6 lb. 6 oz. (2,890 g.). The infant was vigorous and normal in every way. The grasp and Moro reflexes were present and the muscle tone was good. Its cry was quite normal. It was breast-fed without difficulty and weighed 6 lb. 7 oz. (2,920 g.) when discharged after 14 days.

Stimulant drugs given during the period of asphyxia were as follows: lobeline into the umbilical vein, 3 mg., at 10 and at 60 minutes; nikethamide, 0.5 ml. intramuscularly, at 15 and at 40 minutes.

COMMENT

Recovery, as judged by spontaneous respiration, is recorded by Lord *et al.* (1953) as having occurred two hours after delivery in a child treated by endotracheal insufflation of oxygen. This is the longest interval that we have been able to find recorded between delivery of an asphyxiated child and the initiation of respiration. The asphyxia in this case was severe, and was due to the inhalation of large quantities of blood and liquor. Gibberd and Blaikley (1935) state that recovery occurs a few minutes after beginning insufflation. Akerrén and Fürstenberg (1950), describing the treatment of asphyxia by intestinal oxygen, record no cases in which recovery did not occur within ten minutes.

The change in colour which followed immediately after starting endotracheal insufflation is evidence of the superiority, in our case, of this method over that of the relatively more simple one of gastric oxygen. The cause of the asphyxia in our case is not clear. Although a breech delivery, no undue difficulty was encountered. We can assume that the usual doses of sedation employed did not depress the respiratory centre to a dangerous degree, and that, in view of ultimate recovery, cerebral haemorrhage was unlikely.

It will be necessary to observe this child over a period of years to be certain that no lasting damage has been sustained. We have taken the normal appearance of the child and its capacity for suckling as evidence of an intact nervous system. In view of the importance attached at present to birth asphyxia as a cause of neurological and psychiatric disturbance later in childhood, the follow-up in this case should prove of some interest.

Finally, in view of the successful outcome it is worth stressing that the resuscitating team must be prepared to persevere as long as the heart beat is maintained.

We wish to thank Mr. Rufus C. Thomas and Mr. K. G. Seager for permission to publish this case and for their help and encouragement in preparing the case report.

Reviews

ARTHRITIS AND RHEUMATISM

Arthritis and Rheumatism: The Diseases and Their Treatment. By Charles LeRoy Steinberg, M.D., with five contributors. (Pp. 326+ix; illustrated. 70s.) New York: Springer Publishing Company Inc. London: Lange, Maxwell and Springer Ltd. 1954.

During recent years there have been considerable advances in our understanding of the rheumatic diseases, and many arthritic conditions have been more accurately described and more precisely defined. This has led to considerable improvements in the diagnosis and management of patients suffering from polyarthritis and rheumatic disorders. At the same time there have been great advances in our understanding of the nature and behaviour of the connective tissues. It would be most valuable to the general practitioner and the medical student if this new information could be clearly and concisely summarized in book form.

At first sight Dr. Steinberg's book would appear to fulfil this need. It is about the right size, is well illustrated and produced in an attractive, readable form, and contains a useful bibliography after most chapters. But the text is disappointing. For example, the chapter on rheumatoid arthritis does not give a clearer picture of this important disease than can be obtained from any textbook of general medicine. Some statements are definitely misleading. Thus, in describing the treatment of spondylitis the authors state that "rest is important for these patients," whereas most British rheumatologists would agree that exercise was all-important and rest deleterious for patients with this condition. The section on Reiter's disease gives a very full account of Reiter's original paper, which was both a misleading and unimportant contribution to this subject, whereas it fails to mention the important accounts of the epidemics of this condition which have occurred in Eastern Europe and does not even consider the possibility of venereal transmission of the disease. Under the heading "Hypertrophic Pulmonary Osteoarthropathy" the authors state: "These changes are limited to the soft-tissue structures and are associated with curved or parrot-beaked nails," no mention at all being made of the important bone and joint changes. And a little later they reproduce a radiograph of a hand in which the only abnormality that can be seen is minimal osteoarthritis of the terminal interphalangeal joints, though the figure carries the caption of "Acromegaly showing tufting of the phalanges. This may easily be confused with osteoarthritis of the hands." In the bibliography, however, the authors quote papers in which the joint changes in hypertrophic pulmonary osteoarthropathy and acromegaly joint disease are described in great detail.

These may be minor points, but they do not suggest that this book provides either a useful or an accurate account of recent work.

J. H. KELLGREN.

PAEDIATRIC DIAGNOSIS

Pediatric Diagnosis. By Morris Green, M.D., and Julius B. Richmond, M.D. (Pp. 436+xvii; 50s.) Philadelphia and London: W. B. Saunders Company. 1954.

The authors of this book feel that the significant decrease in morbidity in childhood, coupled with a growing parental regard for the maintenance of their children's health, has changed and broadened the scope of the work of paediatricians to-day.

The book is divided into four sections, with an appendix of percentiles. The first section deals with history-taking, and this is full of good practical advice. The second deals with the physical examination, arranged anatomically, from above downwards, and this part, too, is well set out. The third section is concerned with common signs and symptoms and their significance, and this is perhaps the least valuable part of the book, for it consists to a large extent in lists

of causes—as, for example, of constipation, diarrhoea, pleurisy, and cyanosis—and short paragraphs in the nature of synopses on various subjects. However, many references are given, both interspersed in the text and at the end of sections. These are well chosen, up-to-date, and generally accessible.

The fourth section is on health supervision, considered under the headings prenatal, infancy, pre-school, school years, and adolescence—in each group the physical and psychological development being considered separately. The authors stress that the evaluation of a healthy child requires the same considered diagnostic approach as that applied to the evaluation of symptoms related to disease. Certain self-evident statements in diagnosis might have been omitted—for example, that testicular function may be impaired after surgical castration, and that pruritus may be marked in patients with infantile eczema and scabies; and certain other statements are doubtful—for example, that kernicterus may be a complication of severe diarrhoea, that anal fissure is the commonest cause of melaena in young infants, and that bow-legs are a cause of leg pains.

The book follows the modern trend of stressing the importance of the psyche in child health; indeed, there seems to be an undue stress on this aspect—as, for example, the parents' psychological instability in their anxiety about premature and malformed infants and their worry about the irregularities of respiration in early life, the authors saying that referral for psychiatric help may be considered in such cases.

The book is well produced; the printing is good and the text singularly free from typographical errors. Much of it may be read with interest and profit by child psychiatrists: paediatricians too may be interested in this method of presentation of paediatric diagnostic methods.

WILFRID GAISFORD.

PHYSICAL TREATMENT IN PSYCHIATRY

An Introduction to Physical Methods of Treatment in Psychiatry. By William Sargent, Eliot Slater, and Denis Hill. Third edition. (Pp. 352. 20s.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

This book has already earned general acceptance in this country as a practical and readable guide to physical methods of treatment, and in the third edition the authors have succeeded in bringing each section up to date while preserving the character of the book as a whole. The radical changes made in the selective bibliography bear witness to the volume of recent literature from which they have had to pick out reliable improvements in method. The book has now reached an ideal length for the psychiatrist in training or in hospital practice, and its arrangement is such that it can be used for reference by the undergraduate medical student and the harassed nurse who is trying to keep up with an ambitious syllabus.

The present edition follows the previous plan by which, after a short but penetrating account of the general principles of treatment, the rationale of each method is discussed before a detailed account is given of its practical application. The authors are able from their own personal experience to illustrate and comment on the methods described, and are, in fact, rather loath to present methods with which they have not full practical acquaintance. Their coverage of the subject does not include hydrotherapy, physiotherapy, methods of physical rehabilitation, or occupational therapy.

The attitude to physical treatment is throughout that of the well-informed optimism with which any method of treatment must be approached once it has been decided to carry it out. In discussing the choice of treatment, time, even in small doses, is not perhaps given the credit it deserves as a healer.

There is a new chapter on the treatment of alcoholic addiction, and the section on the effects of leucotomy operations has been entirely revised in the light of the longer follow-up studies and the results of accurately localized

operations that have become available since the last edition. A reasonable and restrained attitude to the numerous new drugs has been maintained, and, while all are mentioned, the tendency is to recommend the tried remedy until there is adequate experience of the new preparation under controlled conditions.

This is likely to be the accepted text in this country for some time to come.

CORONARY DISEASE IN YOUNG ADULTS

Coronary Heart Disease in Young Adults: A Multidisciplinary Study. By Menard M. Gertler, M.D., and Paul D. White, M.D., with the aid and advice of seven editorial assistants. (Pp. 218; illustrated. 40s.) Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1954.

By its increasing frequency and as a leading cause of death, obliterative coronary disease has become in the last ten or twenty years the outstanding malady of our time. The problem not only concerns the individual and his treatment, it also has widespread economic repercussions on the family, on industrial efficiency, and ultimately on the welfare of the State itself. Yet what is known of the aetiology of coronary atherosclerosis, and what can be done to prevent its development, check its progress, or arrest its ravages, now so prevalent in middle life at the peak of a man's powers?

This monograph, which emanates from the Harvard Medical School, presents a summary of an intensive search for significant aetiological clues. The work has been conducted by a team whose contributions are summarized by Gertler and White. The topics considered range widely from the clinical to the genetic, morphological, hormonal, psychological, and biochemical aspects—truly an ambitious undertaking. With the intention of investigating the uncomplicated disease the authors have wisely restricted their inquiries to 100 patients surviving a myocardial infarct sustained before 40 years of age. For each aspect of the investigation a "matched-pair" control composed of healthy individuals was made available for comparison. Had a third group consisting of some other form of vascular disease with a predilection for the male been available—say thromboangiitis obliterans—it would have enhanced the value of the authors' findings.

Among many aetiological clues it is certainly an outstanding fact that below the age of 40 acute myocardial infarction—the hall-mark of coronary disease—is 20 to 30 times more frequent in males than in females. With successive decades the ratio declines until in the age group 60 to 69 years there are two males for every female. After age 70 the sexes are equally affected. The relative immunity of premenopausal women, which has its counterpart in the experimental work of Katz on the protective influence of oestrogens on the cholesterol-fed cockerel, opens a line of inquiry which calls for further study.

One virtue of this book, which deals with so many aetiological considerations, is that it points the way for further clinical and biochemical investigations. It makes a distinct contribution to a perplexing subject, provides a rich store of information, confirms and extends our knowledge of the problem, and will long prove a source of reference for workers in this field. Unfortunately, the English at times is disjointed and jarring, lacking that free flowing style which holds the reader's attention and facilitates ready assimilation of the facts.

A. RAE GILCHRIST.

MEASUREMENT OF UTERINE ACTION

Clinical Measurement of Uterine Forces in Pregnancy and Labor. By S. R. M. Reynolds, Ph.D., D.Sc., Jerome S. Harris, M.D., and Irwin H. Kaiser, M.D., Ph.D. (Pp. 328+xiv; illustrated. 69s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954.

The important work of Reynolds, the physiologist, is well known to those clinicians who take an active interest in uterine physiology. In recent years he has collaborated

with several practising obstetricians in developing an apparatus for recording uterine action in late pregnancy and labour. This instrument, the multichannel strain-gauge tokodynamometer, is a mechano-electrical device based on the familiar principle of a "button and ring," measuring and recording movements of the abdominal wall caused by the anterior displacement of the uterus which occurs during contractions. Unlike some of its forerunners, Reynolds's tokodynamometer is simple to use. It thus has found wide application in extensive clinical surveys and has been the basis of a long series of publications on uterine action.

This new book now brings together in one convenient volume the results of the authors' earlier work, hitherto only accessible in the many original papers. Early chapters include a comprehensive review of the history of the subject, including the recent developments with internal methods by Alvarez and Caldeyro of South America and by Karlson of Sweden. As to the authors' own work, the theory of the normal "gradient of activity" from fundus to lower segment is described in detail together with methods of mathematical analysis of the tokodynamometric records. The action of commonly used drugs is discussed, and studies of the emotional control of uterine activity indicate the necessity for having adequate controls in any clinical trial of new drugs when the measure of effect is a subjective one.

This book will be welcomed by obstetricians and physiologists alike as providing a useful summary of the studies of human uterine action to date—studies which, in the future, may yet provide the key to the unsolved problems of aetiology and ideal treatment of inefficient uterine action in labour.

W. J. GARRETT.

ARTIFICIAL RESPIRATION

Artificial Respiration: With Special Emphasis on the Holger-Nielsen Method. By T. O. Garland, M.A., M.D., D.P.H. (Pp. 60; illustrated. 6s. 6d.) London: Faber and Faber, Ltd. 1955.

This is a book which should be read by every doctor, whether or not he is engaged in teaching first-aid methods. The production is excellent and the text is illustrated with eminently practical photographs and diagrams. Using simple language, the author combines clarity of expression and explanation of technical data, which makes the subject easily understood by doctors and laymen alike. After a concise account of the mechanics of breathing there is a brief review of artificial respiration from earliest times up to the Pask experiment in 1943. This is rightly described as being of great historical importance, leading as it did to the American experiments in 1950 and 1951, in which the effectiveness of the various procedures was evaluated. This integrated research at certain American medical schools proved conclusively that the tidal air flow and blood-oxygen saturation in the Holger-Nielsen method were immensely greater than in the Schäfer, and furthermore that this arm lift-back pressure procedure was easy to learn and only slightly more fatiguing. Stress is rightly laid on the vital importance of a prompt start of artificial respiration and on methods which can be applied in difficult circumstances—for example, in a small boat, or at the top of a pole when a man is hanging in his safety-belt after electrocution. The latter certainly requires very special training and practice. Eve's rocking method is fully described and illustrated, mention being made of one possible serious drawback to this procedure—the regurgitation of stomach contents into the mouth, whence they may be inhaled into the lung. The author advises that artificial respiration should be maintained for two hours while the patient is kept warm and oxygen administered, though he adds a note of caution on the possibility of over-ventilation.

This admirable book makes it clear that as soon as the Holger-Nielsen method has become widely known the Schäfer method should be dropped altogether.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 30 1955

U.S.A. TRIALS OF POLIOMYELITIS VACCINE

A report of the field trial of poliomyelitis vaccine whose outcome was announced and discussed in these columns last week has now become available and a summary appears at page 1083 of this issue of the *Journal*. In any piece of research the validity of the results depends on the method of investigation, which in this study was of necessity complex. A vaccine evaluation centre established under the directorship of Dr. Thomas Francis, jun., at the University of Michigan, and sponsored by the National Foundation for Infantile Paralysis, co-ordinated the work of about 150,000 people. Study areas were chosen in counties where high incidence of poliomyelitis had been experienced in recent years and where local conditions were suitable.

Two distinct plans were adopted, called the "observed control study" and the "placebo control study." In the first, children in the second grade of school, mainly 7 years old, were to be vaccinated and their subsequent experience of poliomyelitis compared with that of children in the first and third grades of the same schools. This plan was adopted in 127 areas of 33 States. The parents of just under 70% of children in the second grade agreed to let their children take part, and subsequently 221,998 children, 62.4% of the total in the grade, received the complete course of three injections. These were completed between late April and mid-June, 1954. In the report the results are given of the incidence of poliomyelitis in this vaccinated group between two weeks after vaccination and December 31, 1954, compared with the incidence in the 725,173 unvaccinated children in the first and third grades. Unfortunately this procedure is open to criticism. It may not be a fair assumption, for instance, that the experience of second-grade children would be the average of that for first and third grades in the absence of vaccination. A more serious bias lies in the selection of the children in the second grade whose parents agreed to have them vaccinated. Confirmation of this comes from an ancillary study conducted by the survey research centre of the University of Michigan in areas in which the alternative, placebo control study, was adopted.

¹ *Amer. J. Hyg.*, 1954, 60, 371.

Here, in a sample of 1,300 families, they found that the second-grade children whose parents agreed to their taking part had been more frequently vaccinated against smallpox, diphtheria, and whooping-cough, that their mothers were as a group better educated, and that the families were better housed and came from higher income groups than the second-grade children whose parents did not agree to their taking part in the trial. Therefore, if the vaccinated children were not representative of all second-grade children, it is not a fair comparison to use all first- and third-grade children as controls. A better control group would have been those first- and third-grade children who would have participated if vaccination had been offered to them, but these could not be determined from the records. Alternatively, the experience of all second-grade children, vaccinated and unvaccinated, should be taken against that of all in the first and third grades, and the watering down of any protective effect accepted. This is to be done in a subsequent report, and until this alternative analysis is available it would be unwise to draw conclusions from the observed control study.

In the placebo control study half the participating children in first, second, and third grades of public schools were to be given the three injections of vaccine, while the other half were to be given three injections of a material similar in appearance but containing no vaccine. The identity of the vaccine and of the placebo was concealed by the use of code numbers. This plan was adopted in 84 areas of 11 States. Just over 60% of this group agreed to take part in the trial, and subsequently 57.7% of the total in the three grades received the complete course of three injections; the numbers of children completing the course of vaccine and placebo were 200,745 and 201,229 respectively. In these groups, virtually identical in size, there were 57 cases of all types of poliomyelitis among the vaccinated and 142 among the controls. Of these, paralytic cases were 33 and 115 respectively, giving rates of 16 and 57 per 100,000. The vaccinated group therefore experienced only 28% of the poliomyelitis of this type seen in controls, a difference which was highly significant. Spinal paralytic cases numbered 28 in the vaccinated and 70 in the controls, bulbar cases 3 and 5, and bulbo-spinal 2 and 36; the 4 fatal cases (undefined) were all in controls. The greatest difference lies therefore in the bulbo-spinal type, but this is difficult to interpret in view of the small difference in pure bulbar cases. Within the spinal group the records revealed little difference in the severity of paralysis between vaccinated and control children who developed this type of disease. Non-paralytic cases numbered 24 in

the vaccinated and 27 in the controls, so that here no difference was observed.

The report puts emphasis on the laboratory-confirmed cases and on virus-positive cases, the incidence of these categories in the vaccinated group being a fifth or less of that in the controls. The criterion for a serologically positive result was a fourfold rise in titre to one type of virus only—or to the homologous type if virus was isolated in the stools—observed between the first and second specimens. The report includes evidence that the frequency of a fourfold rise in titre is dependent on the level of antibody in the serum before vaccination. As the prime effect of vaccination is to raise the level of antibody above that in the controls, it would seem that the criterion of serological positive would operate unequally between the two groups. The comparison by means of serologically positive cases only may not be so good, therefore, as reliance on paralytic cases, which were in any case fully investigated and reported. A similar argument applies to virus isolation as a standard for comparing vaccinated and controls. H. A. Howe¹ has shown that alimentary infection in chimpanzees given Type I virus orally is of shorter duration in vaccinated animals than in similar controls. If this result is applicable to man, it might account for the relative difficulty of virus isolation in a vaccinated group, and once again insistence on such a criterion would give a biased comparison. In practical terms a vaccine is wanted which will prevent paralytic poliomyelitis, and this effect is ably demonstrated in this study without reference to laboratory confirmation of diagnosis.

Several batches of vaccine had to be used in the study, and in some areas several lots were used in combination. Their antigenic potency was found to vary widely. Lots, or combinations of lots, were graded, "good," "moderate," "low moderate," and "poor" in antigenic potency. The difference in incidence of paralytic poliomyelitis between vaccines graded "poor" and their corresponding controls was as great as that between vaccines graded "good" and their controls. This may be partly because the grading depended largely on the response to Type I virus, and one lot producing little antibody to Type I was antigenic for Type III, the strain which, by chance, predominated in the epidemic seen in the area in which it was distributed. Even so, the lack of correlation between serological and field trial results is interesting. Special attention was paid to reactions to vaccination. No difference was observed in the frequency, nature, and severity of reactions between vaccine and placebo groups, and in particular kidney disease was equally rare in both. No localization of

paralysis to the limb of inoculation was seen in children who developed poliomyelitis within one month of vaccination.

The report seems to establish clearly from the placebo control study that the vaccine prepared by Dr. Jonas E. Salk is safe and protects against paralytic poliomyelitis. Such a report, produced with admirable promptness, is bound to raise problems and leave questions unanswered. The antibody titres have been observed for a relatively short time in vaccinated children, and it is too early to say whether the fall in the levels seen in samples taken in November, 1954 (about six months after vaccination), is significant and indicates that the duration of protection without reinforcement will be short. The relation between antigenic potency and field response requires detailed study, particularly in other epidemiological environments. The extent of the protection is far from absolute, but again it is too soon to say whether it might not be adequate if most of the community at risk were vaccinated. The authors of the report and their many collaborators are to be congratulated on this enormous and important undertaking, and in Britain this preliminary publication will be received as a challenge and as a stimulus to important work still to be done.

CRITICS OF THE N.H.S.

The worst that could happen to medicine in this country would be an apathetic acquiescence in the working of the National Health Service. We are all caught up in its mechanism, a mechanism of forms and administration, committees and reports of committees, ministries and Civil Servants and their endless stream of regulations—and with it all there is the temptation to believe it is all for the best, that the right formula for a health service has been found. The two opening articles in this week's *Journal*—one by a middle-aged consultant and the other by a young general practitioner—should shatter this illusion, if indeed anyone holds it. Neither author complains of poor remuneration. Neither complains of overwork. "There is no doubt," writes Dr. Grant, "that the established young general practitioner in partnership practice to-day has a much easier time of it than his predecessors. . . . Finally, he has a secure pensionable job." Comparing the present with the past position of registrars Dr. Kennedy asks: "I wonder if this security is altogether a good thing. . . . The present-day system breeds a mentality whose horizon is bounded by the hospital walls." And within the hospitals walls he observes the evil effects of the fear of litigation with its stifling of the initiative and enterprise that have prompted so much of the advance

of medical, and especially surgical, treatment. Dr. Kennedy and Dr. Grant both see apathy creeping in, with the inevitable deterioration of standards. If they are right in the observations they make and the conclusions they draw then neither public nor profession can remain indifferent.

"What a system!" says Dr. Grant: a system "designed to undermine incentive and initiative," a system in which a list of "heads" has to be built up to provide a living wage, a system in which "the G.P. can very easily degenerate into a rather apathetic kind of sorting clerk." And Dr. Grant finds himself cut off from the hospital in which he spent six of the best years of his life. He finds "a widening gap between hospital staff and general practitioners." He finds in the city in which he practises that his obstetric patients must attend an antenatal or local authority clinic if they want to be assured of a hospital bed. He finds a "very real danger that the young practitioner, excluded from the hospital and committed to his desk *by the system* [our italics], may become apathetic. . . ." The reader of Dr. Grant's article will probably conclude that it is not written by someone who feels himself miscast as a general practitioner: it is clearly in the work of a general practice that he sees the opportunity of fulfilling his sense of vocation—if it were not for "the system."

Dr. Kennedy qualified twenty-five years before Dr. Grant, and with the disillusionment of middle-age approaches his selected topics in a more prosaic fashion, stirred out of this by his indignation, shared by so many, over the merit awards: "Cloaked in such diabolical secrecy as these awards are, it is often difficult to get at the truth, and not unnaturally the wildest rumours run riot, but enough is known to say that wrongful decisions have been made." Dr. Kennedy looks back with nostalgia to the days when he and his generation had the thrill of the struggle to make headway by their own ability and initiative, a struggle not for security but for advancement. Both he and Dr. Grant see in the private practice of medicine a liberation from the trammels of "the system," and it is of interest to note that the young general practitioner sees in this a stimulus to practising better medicine, not to earning a better living. But whatever changes may yet take place it would seem safe to say that some nine-tenths of the population will always take advantage of the publicly provided service. It is perhaps for this reason that Dr. Grant appears to advocate one characteristic of private practice—fee for item of service in place of the capitation fee.

"I began to see," writes Dr. Grant, "that my job was mainly people—people as personalities, as

human beings, who had families and worries. . . ." "Let us never forget that our first aim should be to heal and cure the sick," writes Dr. Kennedy. This job and this aim are the focus of the practising doctor's work. Does the National Health Service provide "a system" which, with minor imperfections inseparable from any activity, enable the job to be done and the aim to be fulfilled in the best way possible? Dr. Kennedy and Dr. Grant have doubts which probably others share.

TUBERCULOSIS AFTER B.C.G. VACCINATION

Progressive tuberculosis can certainly occur in previously tuberculin-negative persons who have been recently vaccinated with B.C.G. with apparent success, as judged by tuberculin conversion and sizable vaccination lesions. Sporadic local complications due to the B.C.G. infection, even including regional glandular abscesses (occasionally erroneously diagnosed as due to Koch's bacillus by an observer unaware of the facts), should be excluded from consideration of how such a progressive infection develops; so should disease that follows a natural infection occurring just before vaccination or a few weeks afterwards during the "pre-allergic" phase, and also disease due to reinfection occurring some years later when protection may be expected to have waned. The following remarks are thus mainly concerned with exogenously caused tuberculosis due to inadequacy of protection, and with progressive lesions apparently due to the B.C.G. itself.

No one now believes that B.C.G. vaccine gives complete protection, and a study of tuberculosis from human or bovine sources in the vaccinated has little statistical meaning unless the number observed is related to the number vaccinated, and unless this proportion is further seen in relation to similar observations on comparable unvaccinated persons. However, even the bare description of tuberculous manifestations in those known to have been recently and successfully vaccinated can provide information on

two points—the frequency of different types of case and the time of their onset. When tuberculin sensitivity due to B.C.G. has developed (usually about two months after vaccination), clinical primary tuberculosis is much reduced in frequency, though a primary focus can still result from superinfection.¹ If Dahlström and Dif's² figures for 36,000 B.C.G.-vaccinated Swedish soldiers are broken down so as to show tuberculosis with onset between 6 and 12 months after vaccination—when protection might be expected to be maximal—the number of all cases was 39 (but there were 105 at a corresponding time among the 25,000 unvaccinated in their series). Of these 39 cases, 10 were classified as of primary tuberculosis (as against 42 of the 105) and 29 as of post-primary tuberculosis. The primary forms were composed of primary complexes, hilar tuberculosis, and erythema nodosum; while the post-primary cases—following the conceptions in Wallgren's³ "time-table" of tuberculosis—consisted of pleurisy (21), pulmonary tuberculosis (6), and other types (2). There were no cases of meningeal or miliary tuberculosis during this period among the vaccinated (but 11 in the unvaccinated). The prognosis of some forms of tuberculosis—for example, of primary disease and pleurisy, but not of post-primary pulmonary tuberculosis—was better when they occurred in vaccinated than in unvaccinated individuals in this series.⁴ Differentiation between primary and post-primary pulmonary tuberculosis, however, is often difficult and may be of doubtful value.

Simon⁵ obtained somewhat different results, for in a German children's clinic he saw 13 children who developed tuberculosis between 3 and 24 months after apparently satisfactory vaccination accompanied by proved tuberculin conversion. These 13 included 2 cases of hilar adenitis, 1 of pleurisy, 6 of pulmonary tuberculosis (4 with cavitation), 1 of miliary tuberculosis, and 2 of meningeal tuberculosis. Simon concluded that almost all forms of tuberculosis can appear after B.C.G. vaccination, even when immunity can definitely be postulated. The proportion of his cases with pulmonary tuberculosis is higher than in some series; and the occurrence of miliary and meningeal disease is of unusual interest, since, as Ustvedt¹ remarks, although indirect evidence suggests that the frequency of these forms in particular is reduced by B.C.G. vaccination, this has not yet been shown statistically in a convincing way. The clinical onset of meningitis in Simon's two cases was 16 and 24 months after vaccination, and it is therefore unlikely that the children were infected before the effect of vaccination had developed. The author attributes

the failures of protection by vaccination to various factors, including constitutional defects, coexisting other infections or metabolic disorders, and, particularly, to massive reinfection. The progress of the tuberculous disease was similar to that expected in unvaccinated children.

As anticipated by Jensen⁶—who pointed out that B.C.G. has the same order of virulence as some strains isolated from natural lupus vulgaris—B.C.G. has been reported, though very rarely, to produce lupus in and around the vaccination site. Marcussen⁷ has reviewed the three previous cases in the literature and added three more of his own; he believes these infections to have been caused by the B.C.G. and not by superinfection from man or milk. A seventh case has since been described by Ødegaard,⁸ who suggests that revaccination at the original site of vaccination may be a predisposing factor. Response to treatment is similar to that of natural lupus. Progressive systemic lesions caused by B.C.G. through haematogenous or lymphatic spread have also been reported, again rarely; these include abscess of the knee-joint,⁹ multiple bone lesions with lupus vulgaris,¹⁰ and three fatal cases of generalized B.C.G. tuberculosis.^{11 12 13 14} That most of these more recent cases come from Scandinavia must be ascribed to the large numbers vaccinated there and the thoroughness of observation and documentation. The reason for their occurrence has been speculatively attributed to poor individual resistance—for instance, from transient causes such as measles¹⁰ or from constitutional deficiency.^{11 12} As James¹⁵ points out, the old fear that the attenuated B.C.G. might regain the virulence of its ancestral bovine strain is not supported, for no ill effect was seen in other children receiving the same batch as did Meyer's^{11 12} patient, and the tubercle bacilli recovered from the latter showed the same low virulence as B.C.G. when tested in guinea-pigs. The production of progressive lesions by B.C.G. has its experimental counterpart. Thus in silicotic guinea-pigs infected with B.C.G. the organisms were rendered pathogenic and the animals died with silico-tuberculosis, but it is significant that here too the virulence of the B.C.G. when recovered was unaltered.¹⁶ More recently Dubos¹⁷ has shown that experimental B.C.G. infection could become generalized and fatal in mice whose resistance was reduced by dietetic means. The fact that B.C.G.-produced tuberculosis can occur in man is clearly of great interest, but the danger is too remote to be alarming. Nevertheless, while apparently rare, these cases are likely to be noted more frequently now that attention has been drawn to their existence.

WORLD FIGHT AGAINST DISEASE

In the world political situation, oppressed and threatening, full of antagonisms and mistrust, the Annual Report of the Director-General to the World Health Assembly and to the United Nations¹ comes as a cool refreshment. It is as though the word "international" had been taken out of its murky context and given a thorough cleaning. The report (which unfortunately has no index) contains a list of over three hundred major health projects being carried out in 1954—20 of them in Africa (the continent in which the work of W.H.O. seems to have been least developed), 58 in the Americas, 66 in south-east Asia, 62 in Europe, 72 in the eastern Mediterranean, and 51 in the western Pacific. They include surveys, seminars, the founding of institutes and schools, field missions, control measures, and much else, many of the projects lasting over several years. It is not difficult to illustrate from them the imaginative help that W.H.O. gives—a quarantine station for pilgrims at Jeddah, a five-year project in Tokyo to investigate the causes of prematurity and devise methods of preventing it, the control of bejel and syphilis in Syria, the teaching of pharmacy in the Sudan, the extension of mental health services in Jerusalem and Bethlehem, a midwifery school at Teheran, fellowships for training in cardiology in Yugoslavia, postgraduate education in public health in Athens, the establishment of a physiotherapy centre in Bombay, a school for male nurses in Afghanistan—all these together with innumerable operations to control disease, such as anti-malaria schemes, which were current in 20 countries in 1954, and assistance towards combating tuberculosis in 28.

Nevertheless, the aim of W.H.O. is not short-term campaigns, although many of its projects are in that category, but to strengthen the permanent structure of public health services in its eighty-three member-states. One encouraging feature, noted by Dr. Candau, the Director-General, is the growing acceptance of the idea of joint action between neighbouring countries. Regional efforts covering several countries are not only more effective as such but promote good relations. An instance of such co-operation is the establishment of an Inter-American centre of biostatistics at Santiago to serve the whole of Latin America, and another is a regional college of nursing in association with the University of Alexandria to raise the level of nursing in the Eastern Mediterranean area. The most outstanding co-ordination of national efforts last year was the campaign of the American countries represented at the Fourteenth Pan-American Sanitary Congress (which served also as the sixth session of the W.H.O. Regional Committee for the Americas) for a five-year plan to eradicate malaria for good and all from the Western Hemisphere.

Not only is W.H.O., with its panels of experts in thirty-three subjects, a complete organization in itself—a full-bodied one beside which the admirable Health Organization of the League of Nations appears in retrospect a mere wraith—but it works in collaboration with

many other bodies. These include the Economic and Social Council and other branches of the United Nations, and non-governmental agencies, twenty-five in all. Among them is the World Medical Association, which is co-operating with W.H.O. in questions concerning the preparation of the *Pharmacopoea Internationalis*. Another is the Council for International Organizations of Medical Sciences; this has been making a critical assessment of the usefulness and potentialities of large international congresses and other types of scientific meetings.

W.H.O. looks back on six years' experience during which public health has covered the world map in a way it has never done before. This raises some wider problems of ecology. Much has been said about the possibility of contamination of air, soil, and water owing to the increased use of atomic energy. But that, if it is occurring, is only one of the obscure changes which may be working themselves out. To what extent may the balance of nature be subject to interference by the wholesale destruction of insects? Dozens of the projects which W.H.O. is sponsoring in various parts of the world have to do with insect control. Again, what will be the long-term results of the extensive use of antibiotics? How will the trends of disease in whole populations be influenced by the intense efforts to raise the standards of environmental sanitation? These are new questions, and only an organization of the compass and equipment of W.H.O. can in due course answer them and meet the challenge which some of them may make.

GIANT CELLS IN MEASLES

The presence of giant cells in measles cases was first reported by C. Ciaccio¹ in 1910 and by G. Alagna² in 1911. Little interest was aroused until A. S. Warthin³ in 1931 and W. Finkeldey⁴ in the same year reported independently on a peculiar type of giant cell which they had found in the tissues of patients in the prodromal stage of the disease. Warthin, having noted these cells in tonsils removed at operation in one case, was able successfully to predict the onset of measles in three later cases in which he found the same type of cell. Since these reports the cells have often been described, and they are now generally known as Warthin-Finkeldey cells. They have been seen in tonsils, adenoids, lymph nodes, spleen, thymus, and appendix. They occur in the germinal centres of lymphoid tissue, and in the tonsil they have been found especially just beneath the surface of the crypts, where they can occur in very large numbers. Their appearance is so striking that Warthin suspected that his first case might be one of Hodgkin's disease or lymphoblastoma. The cells are round or irregularly lobed, and they have a variable number of nuclei, sometimes as many as 100. The nuclei never show a peripheral distribution and they

COUGH SYNCOPE

In 1876 J. M. Charcot first drew attention to the transient loss of consciousness which sometimes follows severe bouts of coughing in patients afflicted with paroxysmal cough.¹ He thought they were induced by irritation of the laryngeal nerves during cough, and, from analogy with Ménière's syndrome, called the attacks "laryngeal vertigo." Subsequently the condition has been described under a variety of different titles, and it has been a popular diagnosis on the Continent for many years. It has not been so widely recognized in Britain, but, as C. Baker affirmed in describing nine cases, it is as common here.² The attacks usually afflict middle-aged men suffering from chronic bronchitis; thick-set people addicted to tobacco and alcohol are particularly prone. After a bout of severe unproductive coughing the patient momentarily loses consciousness; he may fall to the ground and perhaps twitch. Full consciousness quickly returns and the patient carries on as though nothing untoward had happened. In less severe attacks the patient experiences dizziness or temporary mental clouding but does not become unconscious. The mechanism of syncope after coughing was studied by E. P. Sharpey-Schafer.³ He found that unconsciousness occurred at the end of the coughing attacks just when the arterial blood pressure was at its lowest and the intrathoracic (and therefore the venous) pressure at its highest. Thus he concluded that syncope resulted from cerebral anoxia due to diminished blood flow through the brain. In some patients, however, syncope is preceded by only a single short cough, and it seems likely that these are cases of primary epilepsy having cough as an epileptic aura.⁴

The importance of recognizing this benign disorder is to exclude more serious causes of loss of consciousness. Once the characteristic clinical history is known, diagnosis is a simple matter, but the patients are not always aware of the association between coughing and syncope until closely questioned. Although cough syncope is almost confined to middle-aged men, it may sometimes present a difficult diagnostic problem in childhood, and J. M. Sutherland⁵ has recently described the disorder in a child of 9 years.

Treatment should aim at preventing the paroxysms of cough. Reduction of smoking and carrying out breathing exercises are sufficient in some cases; sometimes a clear explanation that coughing is the direct cause of the attacks will encourage patients to change their bad habits. Weight reduction and sedatives are also of some help. Nevertheless, many patients continue to have attacks in spite of treatment, and the loss of consciousness is not only distressing but may also be a source of danger both to the patients and to others.

We record with deep regret the death on April 26 of Dr. Egbert Coleby Morland, who joined the staff of the *Lancet* in 1915 and was its editor from 1937 to 1944. He was 80 years of age.

are said to be commonly found as grape-like clusters in the centre of the cell. Often the cells are found in a degenerate stage, when they show strongly eosinophilic cytoplasm and pyknotic nuclei. The time of their appearance and disappearance is not known with certainty; they have been reported as early as four days after exposure to infection, and it seems certain that they will be present five days before the onset of the rash and that they persist for one or more days after the rash appears. Many views have been expressed about their origin—that they are formed by fusion of lymphocytes, that they originate by amitotic division of cells of the lymphocyte series, that they come from the reticulo-endothelial system, and that they are macrophages which have phagocytosed lymphocytes attacked by the measles virus. There is, however, general agreement about their specificity, and their appearance in lymphoid tissue has been used as a criterion of a successful experiment in the inoculation of monkeys with measles material.

Another type of giant cell has been described in measles, this time in respiratory epithelium, but the specificity of this cell is still under discussion. J. Denton⁵ in 1925, in a report of a series of necropsies on fatal cases of measles, drew attention to a giant cell which he found in the bronchial epithelium; it had 5 to 20 nuclei, and cytoplasm which might be well preserved or might be degenerate. Other observers have confirmed his findings. In appearance these cells are usually stated to resemble fused epithelial masses in the earlier stages, and sometimes the normal cilia are retained. The presence of inclusion bodies in the cells has been reported, but not by all observers. At a later stage they become eosinophilic and the nuclei shrunken and pyknotic. Sometimes in these cases epithelial cells become fused into large sheets rather than into small syncytial masses, and such sheets have often been found lying free in the bronchi. A similar fusion of epithelial cells has also been noted in the intestinal mucosa. The specificity of this type of cell has often been questioned, and its relationship to the giant cells which may occur in other virus infections is not clear. Possibly these cells are identical with the giant cells found in so-called giant cell pneumonia, which itself can be associated with measles. C. H. Bunting⁶ in 1950 found such cells lying free in the bronchi, and interest in them has been revived recently by M. D. Tompkins and J. C. Macaulay.⁷ They have confirmed the finding of these cells in the bronchi in a fatal case and have also demonstrated them in smears made by the Papanicolaou technique from sputum obtained from children in the prodromal stage. Having found sputum difficult to obtain from children, they examined nasal secretion by the same technique, and found that the cells were regularly present in ten cases ranging from five days prodromal to the day of the appearance of the rash. If their findings are confirmed they will constitute an interesting application of diagnostic cytological methods, and the possibility of diagnosis in the prodromal stage might be of some importance in children's institutions and hospitals. It is probable, however, that as with other cytological methods only the positive results will be significant.

EMERGENCIES IN GENERAL PRACTICE

"THE BLEEDER"

BY

R. G. MACFARLANE, M.A., M.D.

Clinical Pathologist and Radcliffe Lecturer in Haematology, Radcliffe Infirmary, Oxford

The first experience of bleeding which cannot be controlled by conventional treatment is alarming for both patient and doctor. This alarm, which is seldom justified by any immediate danger of exsanguination, is largely due to what seems an unnatural occurrence. We are so used to the fact that minor injuries stop bleeding spontaneously that automatic haemostasis is taken for granted. Yet, since the circulating blood is subject to the ordinary laws of hydrostatics, it is actually one of the many biological mysteries.

The mechanism responsible is only partly understood and is of great complexity. Its components are the coagulation of the blood, the contraction of injured vessels, and the adhesion of the platelets, these events being probably closely integrated and to some extent interdependent. The important fact is that any serious defect in their operation will result in prolonged bleeding from even trivial injuries, and only when attempts are made to arrest this is it realized how dependent we are upon the normal mechanism. Dressings, tight bandages, plugging, and sutures are all useless; the blood seeps through them as if it were water, or, worse, if its free escape is prevented it infiltrates the tissues. Bleeding can be arrested by the application of pressure to cut off the blood supply to the injured area, but this cannot be maintained for long without causing necrosis and an extension of the area of bleeding. The usual methods for arresting haemorrhage act only by assisting the physiological mechanism; they cannot replace it.

Temporary pressure is normally useful, as it allows time for vessels to contract and for a firm clot to form. Dressings accelerate normal clotting by providing a large surface and also reinforce the clot; sutures close a wound cavity, so that the clot has the greatest occlusive effect. But if the clot fails to form, or the vessels to contract, these measures are ineffective and may be positively dangerous. It is therefore important for the doctor to recognize when he is dealing with haemorrhage due to these failures, and it must be emphasized that, unless the bleeding can be readily controlled by the methods described in this article, the patient should be transferred to hospital without delay. The recent establishment of regional "haemophilia centres" for the diagnosis and treatment of the haemorrhagic states is likely to assist greatly in the efficient hospital treatment of these conditions.*

Diagnosis

Fortunately, bleeders, or those of them who bleed dangerously on slight provocation, are rare. Haemophilic subjects, who, because of the severity of their disability, form the most important group, occur in the proportion of only 1 or 2 per 100,000 of the population of this country. But there are other conditions which cause abnormal bleeding, and, since their appropriate treatment differs, the doctor should know what sort of case he has to deal with.

*See *British Medical Journal*, 1954, 2, 1287.

Briefly, the haemorrhagic states can be divided into those due to defective coagulation and those due to abnormalities involving the vessels or platelets; these two groups can each be subdivided into constitutional conditions, often hereditary, and acquired conditions, often secondary to some underlying disease.

It must be first decided whether excessive bleeding is merely due to a locally overtaxed but otherwise normal haemostatic system or to one of these haemorrhagic states. Persistent bleeding may occasionally occur in normal people; after tooth extraction, for example, it may go on for perhaps 24 hours; epistaxis due to local vascular erosion may be prolonged or frequently repeated; secondary haemorrhage from infected wounds is due to proteolytic digestion of blood clot and tissues; and in uterine bleeding the bounds of normal are notoriously hard to define. But these episodes can usually be distinguished from the bleeding of the haemorrhagic states by the patient's history, and from certain features of the bleeding itself. If the patient has experienced previous injuries or operations such as tonsillectomy without serious haemorrhage, he is unlikely to have a constitutional haemorrhagic state.

The genuine bleeder almost always has a long history, often going back to infancy, of prolonged bleeding not limited to one particular part of the body, but from any minor injury or operation site, and in the form of epistaxis, gastro-intestinal bleeding, easy bruising, purpura, or the formation of haematomas and swellings of the deep tissues and joints, and so on. A point of diagnostic value is the occurrence of similar troubles in other members of the family. Symptoms which might be equivocal by themselves become significant if they also occur in blood relations.

The bleeding itself may give information on the type of defect which has caused it. In cases of defective clotting the vessels are usually normal, and bleeding does not occur unless they have been damaged. In such cases, following an injury which might have been thought trivial by ordinary standards, there is often only slight bleeding at first which may even cease for some hours; it then begins again and becomes uncontrollable, sometimes continuing for days and even weeks. Haemorrhage into the tissues occurs usually after a blow or strain, producing massive haematomata involving any part of the body, particularly the muscles and joint cavities.

Bleeding due to vascular or platelet abnormalities, on the other hand, is often spontaneous and is mainly limited to the skin and mucous membranes. Petechiae and ecchymoses appear without obvious cause; bleeding from the nose and gums is common, being a diffuse oozing without any definite bleeding point; gastro-intestinal bleeding and menorrhagia may be dangerously profuse. It is characteristic of these purpuric conditions that even small needle punctures bleed persistently.

Further differentiation may be obtained by considering the characteristics of some of the different members of the two groups of haemorrhagic conditions, but only the commoner conditions are described here.

All types of clotting disorders tend to produce a similar symptomatology. In the constitutional group both haemophilia and Christmas disease (also called haemophilia A and haemophilia B respectively) are inherited as sex-linked

recessive conditions, affecting only males and being transmitted through apparently normal females. They cannot be distinguished by clinical findings alone.

In the group of acquired clotting defects there is a haemophilia-like state occurring in females which is due to an anticoagulant in the blood, developed during or after pregnancy, perhaps as an immune reaction. An acute fibrinogen deficiency may also occur with disastrous rapidity in some cases of premature detachment of the placenta, with uncontrollable uterine and sometimes generalized bleeding. It is due to the intravascular entry of placental fragments which cause the removal of fibrinogen from the circulating blood. Lastly, the widespread use of the coumarin drugs in the treatment of thrombosis produces a few cases of overdosage, with external and internal haemorrhage due to factor 7 and prothrombin deficiency.

Of the purpuric conditions the commonest is secondary thrombocytopenic purpura, which is often due to drug sensitivity, leukaemia, aplastic anaemia, or carcinomatosis. In a smaller group of cases the thrombocytopenia is apparently essential.

Principles of Local Treatment of External Bleeding

When the bleeding point is accessible local attempts can be made to produce a firm clot. However, even the most rapid clotting cannot extend against a flow of blood, since the fibrin will be washed away from the bleeding point. It is therefore essential to arrest the blood flow by pressure or by stimulating vascular contraction. If clotting is defective it will also be necessary to apply a coagulant, of which the best is thrombin. If used in sufficient concentration, solutions of thrombin will clot in a few seconds any blood that contains fibrinogen. Another useful coagulant is Russell's viper venom. It is more active than thrombin in low concentrations, except in cases of prothrombin deficiency, but like thrombin will not clot blood lacking fibrinogen.

The best way of applying these coagulants is by means of a dressing saturated with the solution. But as ordinary gauze or cotton-wool packs have eventually to be removed and this often restarts the bleeding, an absorbable dressing such as "oxycel" or "calgitex" should be used. These become pliable and adhesive when moistened, and can be accurately moulded to the bleeding point and left in position until digested.

Treatment of Specific Haemorrhages

Epistaxis

Since epistaxis often stops spontaneously drastic measures should not be undertaken unless the blood loss is serious. In cases of defective clotting the bleeding point is likely to be on the anterior part of the septum, where it may be seen and dealt with directly. A pad of oxycel or calgitex gauze, a few millimetres square, should be soaked with thrombin or viper venom, applied to the bleeding area, and held there by the gentle pressure of the flat handle of a scalpel or some similar instrument. After four to five minutes the instrument is removed, leaving the dressing adhering to the bleeding site. If this is effective the dressing should be left alone until it comes away naturally. If it fails, the process should be repeated, but great care should be taken not to damage the membranes of the nose and start new areas of bleeding. Thermal or chemical cauterization should never be used in these cases. If the bleeding point cannot be seen, a mixture of thrombin solution and 1/1,000 adrenaline in equal parts can be sprayed into the nose with an ordinary atomizer; the anterior nares are then plugged with gauze and the patient holds his head forward, so that a firm clot forms in the nasal cavity. He should refrain from swallowing during this proceeding, or the clot may be dislodged. No attempt should be made to plug the posterior nares. If bleeding is not stopped further local treatment should be abandoned, since it is likely to do more harm than good. The patient should lie so that the blood does not run back into his throat and cause vomiting, and often bleed-

ing will cease before a dangerous amount of blood has been lost. If it still continues, arrangements should be made for transfer to hospital.

Epistaxis in the purpuric conditions is usually a diffuse oozing which is difficult to control but seldom profuse enough to be dangerous. Plugging is often useless, and fresh bleeding points may be started at the slightest touch. A thrombin-adrenaline spray may be effective, and an ice pack applied to the nose may also be tried.

Bleeding Tooth Sockets

Dental extraction occasionally reveals for the first time that the patient is a bleeder. It need hardly be emphasized that good conservative dentistry is particularly important for such patients: unfortunately their teeth are often grossly and needlessly neglected.

In dealing with tooth sockets the object is not merely to stop the bleeding but to avoid delaying healing, since haemorrhage is likely to recur until this is complete. Tight plugging should not be used, therefore, as it causes eversion of the socket, nor clamping of the jaw with tight bandages, which may cause necrosis of the gum, nor caustics and styptics, as they destroy the tissues. In cases of defective clotting the gum margins should never be sewn together, since the blood, unable to escape, may infiltrate the tissues of the tongue and throat and cause fatal asphyxia.

A method which is applicable to almost all haemorrhagic states is as follows. A pledget of oxycel or calgitex, about the size of a marble, is soaked with thrombin or venom solution, and moulded into the shape of a mushroom. Any loose blood clots are washed away from the socket and the stalk of the "mushroom" is lightly pressed down into the cavity, the head fitting over the edges of the socket. A cotton-gauze swab or pack of the size required to fill the gap between the socket and the opposing teeth is then applied over the dressing and firmly pressed into position by the thumb and forefinger, which should also squeeze the edges of the socket together. This pressure must be maintained for at least five minutes and relaxed without dislodging the cotton pack. The patient can then close his jaws and if the pack is properly placed the bite should hold it in position without excessive pressure. In almost every case this procedure will stop the bleeding for several hours at least, though it is then apt to restart owing to digestion of the clot. It is a great advantage to have a small dental splint made which, better than the cotton pack, will hold the coagulant dressing firmly in place. Dressing with new applications of coagulant can be repeated once or twice in the 24 hours as required, but no attempts more drastic than these should be undertaken to control the bleeding. If it becomes dangerous the patient will require admission to hospital and transfusion.

Open Wounds

In cases of defective clotting, an open wound should be treated in much the same way as a tooth socket. It should be cleaned carefully and, if the edges fall together naturally, irrigated with thrombin or venom solution, and a pad of oxycel or calgitex, soaked with coagulant, laid over it. This is then covered with cotton gauze bandaged firmly in place, and manual pressure applied for five minutes. If bleeding recurs a repetition of the process should be carried out. If the edges of the wound tend to gape they can be partly drawn together by strapping, after lightly packing and covering with absorbable dressing and coagulant. The strapping should not be so tight as to prevent the escape of blood to the surface. When healing is complete the strapping can be removed without damaging the skin, by soaking it in a mixture of equal parts of liquid paraffin and petroleum ether. Wounds should not be stitched in cases of haemophilia or Christmas disease, though it may be necessary to ligate large bleeding vessels. Prolonged pressure, cauterization, or diathermy should never be employed, as subsequent sloughing inevitably causes bleeding from a larger area than before. If injections of tetanus antitoxin or antibiotics are

considered essential they should not be given intramuscularly since they may cause serious local haemorrhage. Intravenous injections can be made with less risk of bleeding, but the danger of anaphylaxis must always be remembered.

In the purpuric conditions bleeding from skin wounds can usually be controlled by temporary pressure and a firm dressing. There is not the same danger of haematoma formation in these states, so that suturing is not contraindicated.

Internal Bleeding: Deep-Tissue Haemorrhages

Extensive bleeding into the tissues is common in haemophilia and its related conditions, and may involve a whole limb or half the trunk. Serious pressure effects and dangerous loss of blood may therefore occur. Unfortunately little can be done to limit these haemorrhages. As soon as it becomes obvious that bleeding is taking place the part should be put at rest and elevated if possible; local application of ice packs has been recommended. Pressure dressings are not of much use unless the haematoma is small and is overlying bone; a haematoma of the scalp can be restricted, for instance, by a pad of "sorbo" rubber and a firm bandage. Haematomata should never be incised; the blood is almost always interstitial and cannot be evacuated by surgical means, and the incision itself becomes a new source of bleeding.

The most dangerous site for tissue bleeding is into the tongue and throat, because any swelling here interferes with the airway, sometimes with devastating rapidity. As soon as it is diagnosed arrangements should be made for the immediate transfer of the patient to hospital, where facilities are available to pass an endotracheal tube. The doctor must travel with him and be ready to pass an oral airway (as used by anaesthetists) to separate the tongue from the posterior pharyngeal wall, or failing this to pass a shortened rubber endotracheal tube through the nose, so that the tip passes beyond the obstruction and lodges at the level of the entrance to the larynx. If respiratory obstruction threatens it is a misplaced kindness to give morphine to relieve the patient's distress. His survival for the time being depends on vigorous respiratory efforts on his part, and the administration of any respiratory depressant can have fatal results.

Bleeding into the spinal cord, with signs of increasing compression, may occur, and demands immediate admission of the patient to hospital. Diagnostic difficulties are produced by retroperitoneal haemorrhages which may cause abdominal pain, tenderness, rigidity, vomiting, and fever. Such cases have been frequently misdiagnosed as appendicitis or a perforated ulcer, and the significance of abdominal symptoms in a patient known to be suffering from a haemorrhagic state has therefore to be considered with great care. Operation is justified only if it is certain the patient will die without it.

Haematemesis should be treated in the normal way. Haematuria, which may sometimes be prolonged for many days in patients with haemophilia and Christmas disease, can be treated only by rest and transfusions.

Haemarthroses are frequent in haemophilia and its related conditions, and the joint destruction which follows is the cause of much disability. In the acute phase the joint is extremely painful and morphine may have to be given, although non-habit-forming analgesics are preferable. The affected joint should be elevated and immobilized in a slightly flexed position. Ice packs are sometimes comforting.

General Treatment

Haemophilia and Related Conditions

Correction of the specific clotting defects cannot easily be carried out in the patient's own home. In haemophilia the blood defect can be temporarily corrected by transfusions of several pints of normal blood or plasma, which must be given within a few hours of its collection from the donor, as the active factor is very labile. Concentrated preparations derived from human and, quite recently, from bovine blood are being tested clinically, and it may be that in the near

future they may be made generally available. If this hope is fulfilled then many of the local measures described here for the treatment of haemophilia will happily become obsolete.

In other clotting defects it is probable that amounts of fresh blood similar to those now necessary in haemophilia are required for efficient treatment; a possible exception is Christmas disease, in which it appears that stored blood or serum may be effective and that relatively smaller amounts are needed.

Apart from its effect on clotting, the patient may need a transfusion to restore a dangerously depleted blood volume, possibly before removal to hospital. If the blood pressure is falling alarmingly, the practitioner himself may be able to give a transfusion of 1 or 2 pints (about a litre) of reconstituted dried human plasma, or 1 or 2 pints of dextran solution, neither of which involves grouping or cross-matching, but a blood sample for grouping and cross-matching must be taken before giving dextran, as this substance interferes with grouping technique. Cutting down on a vein must be avoided if humanly possible; destruction of available veins by irresponsible transfusion technique may cost the patient his life when another transfusion is needed. No general treatment of the constitutional clotting defects other than blood transfusion or the injection of the specific blood fractions has been found to be effective.

Acquired Clotting Defects

In cases of haemorrhage due to overdosage of one of the dicoumarin group of drugs, immediate contact should be made with the hospital which is undertaking laboratory control of the patient's treatment. An adequate dose of vitamin K₁ should be given as soon as possible. An oral preparation is "konakion," which acts in a few hours. If the doctor is in the habit of collecting blood samples for prothrombin determination he should take a sample before giving the vitamin K₁.

Bleeding due to fibrinogen deficiency or the acute defibrination syndrome which may rarely complicate cases of premature detachment of the placenta must be treated with massive blood transfusion and, if it can be obtained, by injecting intravenously about 2 g. of human fibrinogen in solution.

The Purpura Group

In thrombocytopenic purpura the first essential to general treatment is diagnosis, which in most cases requires laboratory investigation. Leukaemia, aplastic anaemia, sensitivity to drugs such as "sedormid," quinine, or even aspirin, or to certain chemicals, are the commonest causes, and these, when identified, must be treated by the appropriate means. In idiopathic thrombocytopenic purpura splenectomy gives the best chances of recovery. If splenectomy fails, or as a preparation for operation, a course of cortisone sometimes leads to considerable clinical improvement. Purpuric bleeding may occasionally be arrested by transfusion of fresh blood.

I have discussed the relevant parts of the treatment described in this article with Sir Robert Macintosh and Mr. G. Livingstone, of the Departments of Anaesthetics and Otolaryngology, Radcliffe Infirmary, and Dr. J. Grant, of the Oxford Regional Blood Transfusion Centre. I am most grateful for the advice they have given me.

Next article on Emergencies in General Practice.—"Antepartum Haemorrhage," by Mr. F. Stabler.

Refresher Course Book.—Copies of the second volume of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The volume contains 60 articles, all of which were revised by their authors for publication in the book. The first volume is now sold out and out of print. Copies of the second volume may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

SIGNIFICANCE OF SYMPTOMLESS HYPERTENSION

A CIBA FOUNDATION CLINICAL FORUM

[FROM A SPECIAL CORRESPONDENT]

"Symptomless Hypertension" was the subject of the Ciba Foundation's fourth Quarterly Clinical Forum last month, held under the chairmanship of Lord HORDER. In his introduction Lord Horder made a plea for the suppression of the word "malignant" as a description for certain forms of hypertension. He suggested also that the use of the term "essential," by concealing ignorance of the subject, might of itself constitute a possible bar to progress. The four main speakers were a cardiologist (Dr. PAUL WOOD), a clinical scientist (Professor G. W. PICKERING), a general practitioner (Dr. M. D. RAWKINS), and a doctor concerned with life insurance (Dr. T. W. PRESTON).

High blood pressure by itself results, as Dr. PAUL WOOD pointed out, in few or no symptoms, and it is only when neurological, retinal, cardiac, or renal complications supervene that symptoms appear. In that sense uncomplicated hypertension is always symptomless. The problem which faced the Clinical Forum was the assessment of the prognosis and need for treatment in patients found to have raised blood pressure at the time of a routine examination or when being examined for some unrelated disability. The controversial issue of what level of systolic or diastolic blood pressure merits a diagnosis of hypertension was not raised.

Prognosis

Professor PICKERING stressed that the level of blood pressure was progressively graded throughout the population in all age groups, and therefore no dividing line could be drawn between normal and pathological levels. The prognosis in patients with symptomless hypertension taken as a group is undoubtedly poorer than in the population as a whole, as has been demonstrated by Bechgaard's series in Sweden and the figures of the Actuarial Society of America. The prognosis declines progressively as the level of blood pressure rises. Although this generalization applies to the group taken as a whole, there is great individual variation in prognosis within the group. Thus, attention was drawn to the well-recognized fact that the prognosis for a given level of blood pressure is better in older than in younger people, and best of all in post-menopausal women.

Even in patients of similar age, sex, and blood-pressure level the prognosis may be widely different. In explaining the actuarial standpoint, Dr. PRESTON made it clear that no allowance in loading could be made for these individual variations in future behaviour, since at any given stage there was no known way of forecasting how the process would develop in the individual. However, actuaries were prepared to accept as "good risks" older people with a level of blood pressure in the presence of which, if occurring in younger people, they would have insisted on loading the premiums or rejecting altogether.

No conclusions were reached on the importance of transient rises in blood pressure observed particularly in younger people at the time of the first examination. The attitude of insurance doctors to these fluctuations is variable and the proposer may be accepted at normal rates. However, there is evidence that these cases taken as a group are more likely to develop sustained hypertension, although, as Dr. RAWKINS remarked, general practitioners are well aware that there are individuals within this group who show no rise in blood pressure when followed for very many years. Dr. Rawkins drew attention to the great importance of excluding underlying and possibly remediable causes for hypertension occurring in the younger age groups.

Two problems under the heading of prognosis are outstanding. Firstly, how can the course of the blood-pressure changes be predicted in the individual? No answer to this was forthcoming from the Forum. Secondly, why is

it that some people develop symptoms when others do not at the same level of blood pressure? Since the symptoms of the complications of hypertension depend, with the possible exception of heart failure, on vascular degenerative processes, Dr. H. DE WARDENER suggested in the discussion that emphasis might well be shifted away from the concept of the primacy of the level of blood pressure in hypertension towards the study of the behaviour of arteriolar wall under the stresses of hypertension. Professor K. J. FRANKLIN also advocated a further study of arteriolar smooth muscle and of the peripheral nervous system in relation to hypertension. If some way could be found of determining experimentally how arterioles would withstand raised intravascular pressure, it is possible that this might provide a clue to the liability of complications in an individual developing a raised blood pressure.

Selection of Cases for Active Treatment

The problem of the treatment of symptomless hypertension is still a vexed one. The life insurance doctors had naturally little to say about this, but it was cheering to hear that they realized how often they were the unwilling beggars of many anxiety states in patients who for the first time were made aware that their blood pressures were elevated. In the great majority of cases of symptomless hypertension the prognosis is to be measured in years or decades, and a decision whether or not to treat with active vasodepressor drugs may be extremely difficult. Such treatment has to be continued indefinitely, and in view of its inherent side-effects the patient may be handicapped for years, at the end of which time the clinician may be in doubt about whether the survival has been longer than it would have been without treatment. Both Professor J. McMICHAEL and Professor M. L. ROSENHEIM expressed the view that patients with symptomless hypertension should not be treated, for there is no evidence at present that this improves the prognosis. On the other hand, Dr. PAUL WOOD advocated treatment if the E.C.G. indicated myocardial involvement. The Forum was certainly not prepared to lay down any general rules for the selection of patients with symptomless hypertension for treatment, and for the time being it is clear that each case must be judged on its own merits after an adequate period of observation. A carefully controlled clinical trial of vasodepressor drugs in this type of case was called for by Professor PICKERING. Such a trial would be most difficult to conduct, since it would extend over many years, during which time patients would have to be under constant supervision.

POLIOMYELITIS VACCINE

AMERICAN TRIALS IN 1954

The Salk vaccine tested in the U.S.A. by means of clinical trials in 1954 was found to have been about 60-90% effective against paralytic poliomyelitis. While it is not possible to give simple numerical expression to the effectiveness of the vaccine, the report,* published in the U.S.A. on April 12, suggests these figures as an estimate of the vaccine's success.

Plans for Tests

Cases of poliomyelitis appeared with greater frequency in some areas of the U.S.A. than in others during recent years. Therefore, as a preliminary to testing the Salk vaccine, areas with a consistently high incidence of poliomyelitis were noted, and in these areas two distinct but concurrent trials were carried out. In one of them uninoculated children were used as controls; in the other the controls were children inoculated with a substance other than the vaccine and having "no influence on immunity to poliomyelitis." The "observed control study," as the first was

*Evaluation of 1954 Field Trial of Poliomyelitis Vaccine. Vaccine Evaluation Centre, University of Michigan, U.S.A., April 12, 1955.

called, covered 127 areas of 33 states, and the other, the "placebo control study," covered 84 areas of 11 states.

In the observed control study children in the first, second, and third grades of the public (state) schools were identified, and 221,998 children in the second grade received complete vaccinations. These comprised 62.4% of the second grade, and 20.5% of the children in all three grades. As controls, 725,173 children of the first and third grades were used. Certain statistically significant differences were noted between the vaccinated and the unvaccinated in the second grade. For instance, frequency of vaccination against other diseases was strongly correlated with participation in this trial, and the families of those participating were on the average better off financially than those not participating.

In the placebo control study the children in grades one, two, and three were taken together, numbering 749,236, and, of this number, 200,745 received the complete series of vaccine injections and 201,229 complete placebo injections.

Three injections of 1 ml. were given intramuscularly, the second a week after the first and the third four weeks after the second. Vaccinations took place during April 26-June 17, 1954. Elaborate arrangements were made for reporting cases and virological testing. As soon as possible after a case was diagnosed a summary of the clinical history and signs (including the state of the cerebrospinal fluid) was entered on a special form, which was sent to an evaluation centre. No case was admitted to the study unless the form was duly completed and the diagnosis acceptable at that stage. As early as possible a specimen of stool (or two) and a specimen of blood were sent promptly to the designated laboratory in the patient's area; the blood and a second specimen taken three to four weeks later were used for antibody titrations. The stools were studied for presence of poliomyelitis or other virus. Virus isolation, from stool specimens chiefly, was attempted in monkey kidney cells or HeLa cells. A negative specimen was retested at least once. Some specimens were also tested by inoculation of monkeys. Ten to twenty days after the onset of illness a physiotherapist examined the patient, and recorded in a predetermined classification any muscle disability found. The examination was repeated 50-70 days after onset. Post-mortem examination was held on patients who died.

These arrangements were not fully carried out: in the placebo control study, for instance, 13.1% of cases did not have their stools tested, while the figure was 17.3% for the observed control study. Likewise, serological tests were not done in 18.7% of patients in the placebo control study and 15.7% in the observed control study.

Incidence of Poliomyelitis in Study Areas

The number of cases of poliomyelitis reported in the U.S.A. in 1954 was about the same as the average of the previous five years. In the trial areas, which had been selected because the incidence had previously been higher there than elsewhere, the attack rates exceeded those of the rest of the country by 11% in the placebo control areas and 36% in the observed control areas, respectively, or 26% in all trial areas combined. Even so, this percentage was 18% below the previous five-years average for these areas. In the areas excluded from the study the incidence was 4% higher than the five-years average. The following table from the report (here Table I) compares the incidence of poliomyelitis in the trial and the non-trial areas.

TABLE I.—Comparative Incidence of Poliomyelitis in Trial and Non-trial Areas, 1954

Area	Reported Cases—All Ages			Case Rate per 100,000 Population	
	Average 1949-53	1954	% Change	Average 1949-53	1954
U.S. total	39,468	38,768	-1.8	25.7	24.1
All study areas	10,199	8,341	-18.2	33.2	28.9
Placebo control	4,293	3,133	-27.0	28.9	25.6
Observed	5,906	5,208	-11.8	37.3	31.3
Non-study areas	29,269	30,427	+4.0	23.9	23.0

Paralysis Closely Following Vaccination

The data were examined to see whether it was probable that vaccination itself had given rise to poliomyelitis. In all, 129 cases of presumed poliomyelitis were reported during the vaccination period or up to four weeks after vaccination. There was "no evidence of disproportionate frequency of paralytic poliomyelitis in vaccinated or inoculated children up to four weeks after the completion of vaccinations, nor was there any indication of selective localization of paralysis when present."

Effect on Kidneys

The report states that data collected during the trial failed to indicate any apparent relationship between vaccination and kidney disease, and "there are a few additional data derived from studies of other groups which tend to confirm the lack of any such association." Nor was rhesus sensitization detected in 32 Rh-negative children who were among those immunized.

Results

During the study period from two weeks after vaccination to December 31, 1954, a total of 1,013 cases were reported as poliomyelitis. Of these, 14.8% were finally classified as doubtful or not poliomyelitis, 67.6% as paralytic poliomyelitis, and 17.6% as non-paralytic poliomyelitis. Of those classified as poliomyelitis, 79% were paralytic cases. In the placebo control areas the ratio among patients with poliomyelitis of those who received placebo to those who received vaccine was about 2 to 1; for paralytic cases only the ratio was 3.5 to 1. On the other hand, there was no difference in the attack rate of non-paralytic poliomyelitis between vaccine and placebo groups. The number attacked and the attack rates in the various groups are shown in Table II (Table 2b in the report).

Examination of the data in greater detail showed that the differences between vaccination and control groups tended to increase with the severity of the disease. For example, in the placebo control trial "33% of the spinal paralytic cases in the two lowest grades of paralysis occurred in the vaccinated, but only 23% of cases in the three higher grades were vaccinated, and only 2 of the 38 bulbo-spinal cases received vaccine. The four fatal cases of poliomyelitis occurred among children in the placebo control group." In the observed control trial all 11 fatal cases of poliomyelitis were in the control population (a case fatality rate of 2.5% among the controls).

The distribution of the cases by age, sex, and vaccination status is recorded for the placebo control areas in Table III and for the observed control areas in Table IV (Tables III and IV of the appendix in the report).

The cases in which positive diagnostic tests were obtained are analysed separately. In the placebo control areas 198 cases were reported, comprising 170 in which virus was isolated, 23 in which there was no virus but a fourfold or greater rise of antibody in paired sera, and 5 cases in which the virus was recovered from a family member. The following cases were found in the various groups (with the rate per 100,000 in parentheses): vaccinated cases 18 (9), placebo cases 86 (43). The difference between the two groups is statistically significant ($P = 0.001$). Of 53 paralytic cases (excluding bulbar) the vaccinated numbered 8 (4) and the placebo cases 45 (22). This difference is also significant ($P = 0.001$). Among 17 non-paralytic cases the vaccinated numbered 6 (3) and the placebo cases 11 (5). This difference is not statistically significant. In the observed control areas 300 cases were found with positive laboratory evidence of infection. Among these cases the vaccinated numbered 25 (11) and the controls 248 (35). This difference is statistically significant ($P = 0.001$). Among 134 paralytic cases (excluding bulbar) the vaccinated numbered 7 (3) and the control cases 127 (18). This difference is statistically significant ($P = 0.001$). Among 39 non-paralytic cases the vaccinated numbered 8 (4) and the control cases 31 (4).

TABLE II.—Summary of Study Cases by Diagnostic Class and Vaccination Status (Rates per 100,000)

Study Group	Study Population	All Reported Cases		Poliomyelitis Cases						Not Poliomyelitis

* Includes four cases with incomplete injections.

Effect on 6-year-olds

The analysis shows that "the protective effect with respect to paralytic poliomyelitis is significant for each year of age except for the 6-year-olds, where, based on 16 and 23 paralytic cases, the attack rates are 37 and 53 per 100,000 of the population in vaccinated and placebo controls respectively." The protective effectiveness apparently increased with increasing age. A careful comparison of the serology and other data for the 6-year-olds and the rest of the children showed no discrepancy that could account for the difference in protection conferred by the vaccine, and "the data available are inadequate to allow further speculation on the difference."

Trials in Canada and Finland

Placebo control trials were also carried out with the same vaccine in Canada—in the province of Manitoba, the province of Alberta, and Halifax, Nova Scotia—and also in Helsinki, Finland. Although the number of cases admitted to these trials was small, the attack rate, when they are combined, was found to be significantly lower in the vaccinated children than in those who received placebo ($P = 0.035$). Only Type I virus was recovered from study cases in Canada and Finland.

Final Estimate

Among non-paralytic cases there was no significant numerical difference between vaccinated and control patients. When paralytic cases are considered, an estimate of 72% effectiveness for the vaccine was obtained in the placebo areas and 62% in the observed control areas. The effectiveness of the vaccine measured against the incidence of spinal-paralytic cases was nearly the same in the placebo control areas and the observed control areas—82 and 83% respectively—and the corresponding lower limits of estimated effectiveness were 65 and 64% respectively. Its effectiveness against bulbo-spinal cases was estimated at 91% in placebo control areas and 60% in observed control areas; these figures are unreliable because of the small numbers concerned. The effectiveness of the vaccine in placebo areas was 68% against Type I virus, 100% against Type II, and 99% against Type III. Some differences were noted between different lots of vaccine. The same trend was noted in the observed control areas, but "the calculated effectiveness was less than in the placebo areas." The report concludes: "It may be suggested that vaccination was 80–90% effective against paralytic poliomyelitis; that it was 60–70% effective against disease caused by Type I virus, and 90% or more effective against that of Type II and Type III virus. The estimate would be more secure had larger number of cases been available."

BLAND-SUTTON CENTENARY

The Middlesex Hospital and Medical School commemorated on April 22 the centenary of the birth of Sir John Bland-Sutton, who was born at Enfield in 1855. In the school in which he served and the Institute of Pathology which he created, visitors were able to see the latest scientific developments, such as the manipulation and dispensing of radioactive materials, and also some Bland-Sutton personal relics. These last included a photograph of his characteristic last message to the nurses tending him: "I feel too sad to talk, so write my thoughts in chalk on this wall. Nurses well train'd and kind, better no man can find. Farewell."

Tributes from his Friends

In the school library, under the presidency of Professor Sir CHARLES DODDS, F.R.S., who acted as dresser at Sir John Bland-Sutton's last operation at the Middlesex, three former associates of the great surgeon paid delightful personal tributes. Sir Gordon Gordon-Taylor, Sir William

Gilliatt, and Lord Webb-Johnson each approached the subject from a different angle, but all threw new light upon it.

Sir GORDON GORDON-TAYLOR recalled that Bland-Sutton's ashes in a Burmese urn still reposed in the Middlesex Hospital Medical School, where he had spent so many years teaching on the dead the better to serve the living. From the very first he had determined to be a surgeon. Perhaps fortune brushed him with her wings in the time at which he came into surgery. The abdominal surgeon at the end of the last century "graduated along the pathway of the female pelvis." The scene was set for Bland-Sutton. The abdomen was a territory of vast possibilities for the removal of the gigantic tumours to be found at that time.

As a surgeon Bland-Sutton worked at incredible speed, but without the appearance of haste. He came into the theatre with a certain air. He did not wear a mask—such would have covered his Napoleonic features. But he also came in with the assurance of a Field-Marshal Montgomery. There was no loss of self-control, no flurry. No matter what the urgency, all that was audible was, "It's all right. It's all right." He was the first surgeon in this country to excise a duodenal ulcer. As a writer he was as tireless with his pen as he was indefatigable with his dissecting knife and scalpel. Bland-Sutton's operating theatre was the Mecca to which surgeons came from all over the world. He approached more nearly to John Hunter than any other surgeon who had ever lived.

Birth of the Gynaecological Surgeon

Sir WILLIAM GILLIATT pointed out that Bland-Sutton transformed the gynaecological physician into the gynaecological surgeon. He performed some vaginal operations, but he was essentially an abdominal surgeon. In the face of his success, opposition to the operative treatment of ovarian fibroids died down. Soon every gynaecologist was adopting removal by hysterectomy. At the Chelsea Hospital for Women Bland-Sutton had his assistant surgeon to help him, instead of his house-surgeon, and Sir William Gilliatt thought this might be regarded as the beginning of surgical team-work in operations. Bland-Sutton was well aware of his rapidity in operating, and as an example of just how rapid he was the speaker instanced three subtotal hysterectomies completed within an hour. He used fewer instruments than most surgeons, and these he carried in a small case which resembled the jewel case of the Edwardian era. He disliked rubber gloves because he thought they reduced his tactile sense, although in his books he made a plea for them. A chance encounter with Victor Bonney caused the latter to be become a gynaecologist, and the making of a gynaecologist of Bonney might be regarded as the greatest of the great contributions which Bland-Sutton made to gynaecology. He added that one could not be in Bland-Sutton's presence without learning from him. Especially did one learn, when working with him, to avoid unnecessary detail.

LORD WEBB-JOHNSON mentioned that punctuality was an outstanding characteristic of Bland-Sutton. As a surgeon he was a prima donna; he was not only a master surgeon, but basically a master anatomist. Lord Webb-Johnson went on to speak of Bland-Sutton's connexions with the Royal College of Surgeons. One president remonstrated with him for not giving a full hour's lecture. At his next lecture Bland-Sutton arranged for an attendant to put the clock on a quarter of an hour at an interesting point, and the same president congratulated him on a lecture so absorbing that the time had simply flown. Bland-Sutton tried six times in ten years for a seat on the College Council. After his defeat in 1909 Lord Webb-Johnson asked someone the reason, and was told that it was because Bland-Sutton was on the staff of the Chelsea Hospital for Women. In those days there was a prejudice against specialists, particularly gynaecologists. When the remark was repeated to him, Bland-Sutton resigned his appointment. "Hang it all, he was a surgeon at heart, not a gynaecologist." In the following year—1910—he was elected.

Nova et Vetera**ONE HUNDRED YEARS OF ARMY PATHOLOGY**

One hundred years ago the British troops who had wintered in the Crimea were falling sick and dying in such numbers that public opinion at home was greatly disturbed. One of the consequences of this was that Lord Panmure, the Secretary of State for War, appointed an Irish physician, Dr. R. S. D. Lyons, and "two able assistants," Dr. William Aitken and Dr. Doyle—"both accustomed to and versed in the operations of the dead house"—to investigate, especially in the hospitals at Scutari, the nature of the diseases from which the troops were suffering. Dr. Lyons received his instructions relating to the "pathological researches" he was to make in a letter from the War Office dated April 27, 1855, and it is interesting that the following cautionary note was contained therein: "As the office to which you are appointed is new in the Medical Department of the Army, it is possible, although not probable, that some difficulties may arise in the prosecution of your researches." The three pathologists sailed for the Crimea shortly afterwards; and the report of their researches was published in a Blue Book which was presented to Parliament in 1857. Such was the firm foundation on which military pathology was established a century ago.

Inquiries into military medicine in the Crimea revealed the inadequacy of the instruction given to probationers of the Army Medical Department; and this resulted in the establishment of the Practical Army Medical School at Fort Pitt, Chatham, in October, 1860. It is to the credit of the War Office that the importance of pathology was recognized at that early date, and Dr. William Aitken was selected by Mr. Sidney Herbert, Secretary for War, to be the first to fill the chair of pathology at the new Army medical school—an apt tribute to the excellence of his work in the Crimea. The school moved to Netley three years later and remained there until it was transferred to London in 1903.

William Aitken

William Aitken had a long and distinguished career, holding the professorship of pathology for thirty-two years; he was elected F.R.S. in 1873 and knighted in 1877. His success as a teacher was linked with his skill at correlating morbid appearances with clinical findings. As the father of military pathology he was in a position to stimulate the interest of medical officers into research, and the rising generation of young Army pathologists felt his influence—men like Lewis, Bruce, Leishman, Semple, and others who were to contribute so much to unravelling the mysteries of tropical medicine. Almoth Wright succeeded Aitken in 1892 and held the chair of pathology at Netley until his resignation, in 1902, to become pathologist to St. Mary's Hospital. The work of Wright, Semple, and Leishman laid the foundations for prophylactic immunization on the scale we know it to-day. The third professor of pathology at the Army Medical School was William Leishman, who held the appointment until the outbreak of the first world war.

Research which had been previously individual, or encouraged through voluntary association of kindred minds, was now to be replaced by organized directed research—such as the Anti-typhoid Committee, the Sleeping Sickness and Malta Fever Commissions, the Medical Research Committee (later the Medical Research Council). After the war various wartime consultative committees were merged to form the Army Pathology Advisory Committee, and the Pathology Directorate was established at the War Office in 1919, with Major-General Sir William Leishman, first Director of Pathology, as chairman.

Wartime Achievements

The mobile bacteriological laboratory came into use for the first time during the war of 1914–18, and in no previous war had investigations been carried out so near the front line. Pathologists, collaborating with physiologists, also

investigated the mode of action of chemical warfare agents, and in the past forty years their responsibilities in this respect have increased rather than diminished. During the interwar years Brigadier J. S. K. Boyd's classical work did much to place our knowledge of the dysenteric group of diseases on a firm basis. Investigations carried out by him at the Royal Army Medical College led to the introduction of active immunization against tetanus in the British Army before the outbreak of the second world war, and this was undoubtedly responsible for the low incidence of tetanus among the wounded. Another outstanding medical achievement of the second world war was the development of the Army Blood Transfusion Service under the direction of Sir Lionel Whitby.

The influence of the Army Pathology Service on the course of tropical pathology and medicine, and on bacteriology and immunology, can be judged from the numerous eponyms in the nomenclature—*T. lewisi*, *T. brucei*, the Brucella group, the Flexner-Boyd group, Leishman stain, and Leishman-Donovan bodies. The names of Lewis, Bruce, Leishman, Semple, Cummins, Boyd, and many others will always remain an inspiration to those who continue the work.

A. SACHS,
Major-General, A.M.S.

Reports of Societies**UNSOLVED PROBLEMS IN THE BODY'S REACTION TO BURNS**

The extent of present-day research into problems associated with severe burns, and some of the fields needing further investigation, were indicated at a meeting of the Basingstoke Plastic Centre Medical Society at Rooksdown House on April 14.

The chairman, Mr. PATRICK CLARKSON (casualty surgeon, Guy's Hospital), explained that the programme had been arranged with special emphasis on basic questions of pathology and metabolism in burns. It was significant, he said, that there had been no dramatic improvement in the mortality of burns (within burns centres) during the last five to eight years. Nor, indeed, since the three important developments of the middle 1940s, which had been: an understanding of the early colloid and electrolyte needs of severely burnt patients; the effective use of antibiotics; and prompt, more radical surgery in the removal of sloughs and in grafting. What was now needed were new therapeutic developments based on fuller knowledge of the enzyme chemistry and electrolyte and colloid exchanges in the early stages, on better understanding of the later metabolic and endocrine factors, and on improvements in homo-graft techniques.

Skin Enzymes

Professor R. H. S. THOMPSON (Department of Chemical Pathology, Guy's Hospital) submitted evidence for the view that altered enzyme action occurred in the peripheral parts of burned areas, and discussed briefly the part enzymes might play in some of the local and general effects seen in burns. There were two possible modes of action, he said: there might be abnormal local cell metabolism as a result of the inactivation of enzymes by heat; or the release of active enzymes from damaged cells into the general circulation. That selective skin enzyme inhibition could cause local redness and blistering was clear from knowledge of the action of lewisite. By combination with certain enzymes this arsenical inhibited cell oxidation systems in varying degrees, and dimercaprol, which prevented the development of the lewisite blister, acted by reversing these changes. It could be accepted, then, that redness and blistering could result from selective enzyme inhibition by a chemical factor. Though further investigation was needed, thermal sensitivities of skin enzymes were known to vary very much, and therefore, in the peripheral zone of a burned area, conditions were present which might cause selective enzyme inhibition.

It was less certain that enzyme systems released from burned tissue played a significant part, but it had been suggested that liberated proteinase, acting outside the cell, could contribute to such serious effects as vasodilatation and loosening of the epidermis prior to blister formation.

Professor Thompson finally considered histamine and acetylcholine, two vasodilators present in skin. With Dr. I. A. Magnus, he had found the level of cholinesterase in the skin lower in sufferers from heat urticaria than in normal subjects, and there was the possibility, therefore, that this factor played a part in the wealing tendency. Cholinesterase was heat-sensitive, and if it were reduced in amount in burned skin acetylcholine might act unchecked and contribute to the production of blisters.

Abnormal Carbohydrate Metabolism

Dr. W. J. H. BUTTERFIELD (M.R.C. Clinical Research Unit, Guy's Hospital) read a paper describing his investigations of deranged carbohydrate metabolism in burned patients, made whilst working in America in the burns unit directed by the late Everett Evans. It was the practice there, as soon as the patient had been adequately resuscitated, to begin feeding with a very rich diet with the object of preventing the usual loss of weight during the period of reparative surgery. The diets contained much carbohydrate, liberal protein, and ample fat. There was a standard intake of 50-60 calories per kilogram of body-weight per day. Beginning with the observation of glycosuria in a patient so fed, Dr. Butterfield found a similar abnormality of metabolism in 14 of 140 consecutive admissions to the unit. This abnormality consisted of glycosuria without acetonuria, a high fasting blood-sugar level, and an elevated glucose tolerance curve. It began, as a rule, during the first week and lasted for periods of days, weeks, or months, but was usually briefest in children. When long-lasting, the glycosuria waxed and waned and was aggravated by plastic surgical operations. This diabetic state did not occur in controls given the same diet; they simply gained weight. It seemed that, in the group of burned patients, carbohydrate could not be used as a protein sparer, and it banked up in the blood. The aggravation of the condition by operations, the absence of acetonuria, and a negative nitrogen balance were all in accord with adrenocortical overactivity as the basis for the diabetes. This possibility was supported by the finding of high urinary corticoids and low eosinophil counts in the diabetic cases and by the production of similar metabolic patterns in volunteers following the administration of A.C.T.H. and hydrocortisone.

Dr. Butterfield then found that in its earlier phase this diabetic state showed insulin resistance. Further investigations led him to believe that the adrenocortical response disturbed carbohydrate metabolism at the pyruvate level through interference with SH metabolism. An SH donor, dimercaprol, appeared temporarily to correct this disturbance at the pyruvate level.

Research on Homografting

Dr. P. A. GORER (Department of Pathology, Guy's Hospital) spoke on the serological approach to the homograft problem. There was general agreement, he said, that the destruction of the graft was due to an antigen-antibody reaction, and he gave a brief account of current ideas concerning its nature. Damping down the antibody response by such agents as x rays and cortisone had obvious disadvantages. Improved results might be obtained if skins could be typed. Skin itself was hardly suitable for serological work, but the following methods could be applied to man: (1) tests with soluble extracts, (2) tests with small particles derived from skin, and (3) a search for antigens shared by skin and free cells such as leucocytes or erythrocytes. Shared antigens had actually been demonstrated in man. A great deal of further work was needed, and volunteers would have to be used if progress was to be accelerated. However, women below the menopausal age could not be used owing to possible dangers to the foetus, and even with men there was some risk of causing later difficulties in matching them for blood transfusion.

Fluid and Electrolyte Problems

Dr. J. P. BULL (M.R.C. Industrial Injuries and Burns Unit, Birmingham Accident Hospital) dealt with early electrolyte and fluid balances in burned patients. The total amount of plasma loss had been measured experimentally: it was approximately 1 ml. for each 1% of the body surface burned per kilogram of body-weight; but these estimates were made on untreated animals and treatment might influence the results.

Dr. Bull then described findings in 33 patients on the fate of administered sodium and water. Beginning soon after burning, there was a period of marked retention of these substances by the kidney, and it was greatest in the more extensive burns despite the replacement of sufficient colloid fluid to correct the haematocrit reading. During this time it was possible to raise the excretion of sodium and water to some extent by giving further quantities, but only a small proportion was excreted and greater positive balances occurred. Pulmonary oedema might follow the resulting increase of the extracellular fluid volume, and it was unwise in otherwise adequately treated cases to attempt to increase the urinary output by increasing the fluid intake. The plasma sodium level also was low temporarily, but he had not seen symptoms which could be attributed to it. On the other hand, in the early stages after burning, potassium excretion was increased, and unless the potassium was replaced there was a danger of abnormally low serum levels after a few days.

Whether a kidney lesion played a part in these exchanges remained an open question. There was some histological evidence of tubular damage in severe burns, but, unlike the excretion in tubular necrosis, in burned patients total anuria was rare, the urine could be moderately concentrated, and there was sodium retention. It was likely that adrenal cortical activity was a factor, but the finding that severe injuries of other types did not develop sodium and water retention if given adequate blood and colloid fluid suggested that the retention syndrome might be determined by circulatory dynamics.

Early Primary Surgery

Mr. A. J. EVANS (Plastic and Jaw Unit, Rooksdon House) described the treatment practised in the Basingstoke Burns Centre, and some of the lessons learned in treating 500 cases during the past five years. The exposure method was introduced at the beginning of this period, and they had been pleased with the results. Infection, especially with *Ps. pyocyanea*, was less common, the general condition of severely burned patients was better, and excision of the slough on or about the 14th day left a good surface for immediate skin cover. Primary excision was the ideal, but, owing to the difficulty of assessing the depth of many burns, it had only a limited application. It was their practice to use the method only when the area was restricted and the depth certain.

In cases of extensive burns it was important to remove sloughs early, and most had been excised by the 14th day. The operation was a formidable one, but had been shortened by using the Humby knife or by the electric dermatome to remove adherent sloughs and by developing better teamwork in the theatre. With at least two surgeons and two sisters scrubbed up, adequate dressings prepared beforehand, and the help of an anaesthetist experienced in this work, it was possible to complete the operation in 45 minutes.

Homografts had been used only in widespread burns as a life-saving measure, and it was their practice to use grafts, from relatives or the skin bank, placed alternately with autografts. With this technique, regrafting had often been found unnecessary.

In conclusion, Mr. Evans said that the exposure method had given satisfactory results in cases with hand burns. It allowed active movements to be commenced on the third or fourth day, and encouragement of this was important.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Exchange Transfusion in Haemolytic Disease of the Newborn

SIR.—In the interesting article by Drs. W. Walker and G. A. Neligan (*Journal*, March 19, p. 681), they point out that a biochemical investigation of the effects of exchange transfusion in the newborn infant might help to explain the deterioration in the clinical condition which sometimes occurs. In a study of the electrolyte changes involved during exchange transfusion in infants suffering from erythroblastosis foetalis, I have been able to make the following conclusions from a series of 20 cases.

Serum collected as the transfusion progressed had a marked inhibitory effect upon the amphibian heart, and since this corresponded to high serum citrate concentrations it is not unreasonable to assume the presence of a citrate-induced hypocalcaemia. Serum ionized calcium was estimated to be well below levels associated with active tetany at some stages in the transfusion, yet none of these infants showed recognized signs of tetany. Increased pulse rate and signs of irritability were observed in some of the infants, but these could have been due to discomfort, circulatory failure, or shock. The absence of tetany is not easy to explain. It may be that muscle in the newborn responds differently from that in the adult, or that serum ionized calcium under such acute conditions is not necessarily an indication of the concentration of ionized calcium in the interstitial fluid.

Calcium gluconate (1 ml. of 10%) administered for every 100 ml. of blood exchanged had little effect upon the level of serum ionized calcium, probably because the amount of ionized calcium actually injected was very small relative to the high serum citrate concentration. E.C.G. changes consistent with hypocalcaemia have been recorded in the literature. Gustafson¹ noticed irregularities in the isoelectric line which he attributed to muscle tremor, although tetany was not apparent. The E.C.G. reverted to normal after calcium gluconate, which tends to substantiate the use of calcium gluconate in contrast to the biochemical findings above. I was also able to demonstrate that hyperkalaemia can develop during the transfusion, and, since some infants have a pretransfusion hyperkalaemia, the desirability of using fresh donor blood cannot be too strongly emphasized. The one fatal case of the series showed a simultaneous hyperkalaemia and hypocalcaemia at the time of death. The existence of pretransfusion hyperkalaemia might well increase the incidence of heart failure, since the physiological effects of a high potassium and a low calcium potentiate each other. The results of this investigation will be published in due course.—I am, etc.,

Edinburgh.

E.S.R. at Low Temperature

SIR.—It was with some considerable interest that we read Dr. K. D. Gupta's article (*Journal*, March 19, p. 703) on the rise of the erythrocyte sedimentation rate at low laboratory temperature, and in which he suggested that this phenomenon might prove to be indicative of parenchymatous liver damage. While we have not estimated the E.S.R. at various temperatures, we have noted a definite correlation between the height of the E.S.R. and the extent of liver damage as indicated by three separate tests of liver function—all of these being performed at about 60° F. (15.5° C.) room temperature.

Our observations were made in a group of 15 cases of Sjögren's syndrome, in none of whom was there any obvious

clinical sign of liver dysfunction. The liver function tests were carried out as part of a general investigation of the function of the secreting glands of the body. Two empirical tests were employed—the thymol turbidity and the alkaline phosphatase, since they are considered to be the most sensitive means of detecting subclinical impairment of hepatic function.¹ The thymol turbidity test was above the normal value (1.00) in 14 cases, while the alkaline phosphatase test was above the upper limit of normal (6-10 units) in 10 cases. A third test, based on the synthetic function of the

The relationship between thymol turbidity, alkaline phosphatase, and γ globulin in serum and the erythrocyte sedimentation rate in 15 cases of Sjögren's syndrome.

liver, was carried out—that is, the estimation and fractionation of serum proteins by electrophoresis² and by chemical estimation.³ In all cases the serum albumin was low, and the globulin fraction, in particular the gamma globulin, was raised. In contradiction to the generally accepted view that a high E.S.R. is accompanied by a raised blood fibrinogen, the latter was found to be low in each of the six cases in which it was estimated.

The accompanying graph shows that in 13 out of the 15 cases quite a close correlation exists between these tests of liver function and the height of the E.S.R.—We are, etc.,

Immunological Concept of Cancer

SIR.—Professor H. N. Green, in a footnote to his admirable article (*Journal*, December 11, 1954, p. 1374), says that "recent findings indicate that serum antibodies disappear when the skin carcinomata appear." Does this apply to human cancer? Apparently the homologous antibody to human cancer is still hypothetical. In support of his concept, there is evidence of cancer influencing non-specific immunity mechanisms. Cancer interferes with the hyper-sensitive skin reaction to the mumps virus.¹ In the malignant lymphomas, anergy develops to tuberculin, mumps virus, and other antigens which produce delayed reactions.²

The defect in the skin reactions is presumably due to interference with the cellular mechanism of the reticulum cell and its derivatives, rather than to pure antibody deficiency. In my experience patients with chronic lymphatic leukaemia react normally to the mumps virus and also to tuberculin,³ possibly due to the free circulation of lymphocytes. Human carcinomas, but not sarcomas, progressively inhibit the mumps virus skin test as neoplasia advances, a finding which does not apply to the tuberculin reaction. In these skin tests, human cancer depresses tissue reactions not directly concerned with homologous tumour immunity. Is the immune reaction to cancer also depressed as cancer develops?—I am, etc.,

Malignant Melanoma and Pregnancy

SIR.—Perhaps I may add another case of malignant melanoma complicating pregnancy to the list which is growing in your columns. In 1941 I saw such a case in a patient aged 27 who was eight weeks pregnant. There was a firm pedunculated swelling on the right labium majus which had been present for many years without alteration. It was about 4 cm. in diameter, and without evident pigmentation. It was thought to be a fibroma, but on section some of the cells were found to contain melanin. Section of the pedicle suggested that removal had been complete; in view of this fact, and because of the pregnancy, no more was done and she had an uneventful delivery. Two years later an enlarged inguinal gland was observed in another hospital. Bilateral dissection of the inguinal glands was performed, and two glands were found to contain growth. The patient died in 1945 with widespread deposits. An almost identical case was reported by Curtis.¹—I am, etc.,

London, W.1.

Meningo-encephalitis in Mumps

SIR.—Mumps is said to be increasing in severity, but three cases of definite meningo-encephalitis in an outbreak of 29 cases of mumps in a school is, happily, unusual. The boys affected were aged 9, 9, and 10 years respectively and had nothing of importance in their previous histories, except that the most severe case had had migraine.

The outbreak of mumps was started by one boy. The first case of meningo-encephalitis occurred in the first wave on the 22nd day, the second in the second wave on the 33rd day, and the third on the 49th day. The cerebral complications began with headache, vomiting, photophobia and drowsiness, a sharp rise in temperature—102° F. (38.9° C.) or 103° F. (39.4° C.)—and slight stiffness of neck and back. This stiffness of neck and back and Kernig's sign increased on the second day. There were never any other signs in the C.N.S. or macular signs of increased intracranial pressure. The onset of this complication occurred on the third, second, and first days respectively of the parotitis, which was less marked than usual, and it lasted for four, three, and six days respectively.

The pyrexia was higher than in the uncomplicated cases of mumps and for a longer period—that is, between 100° F. (37.8° C.) and 103° F. (39.4° C.) for five, seven, and six days respectively—and the temperature did not become normal for twelve, ten, and seven days, whereas amongst the uncomplicated cases the temperature rarely rose to 100° F. (37.8° C.) or above, and never lasted for more than three days, and the average duration of pyrexia was five days and the maximum eight. The patients with meningo-encephalitis in this outbreak of mumps were certainly more ill than the uncomplicated cases. They all made complete recoveries. Dr. J. O. Terry examined the first and third cases and confirmed the diagnosis.

Injection of the parotid duct has often been mentioned as a diagnostic sign in mumps, and most practitioners have found it quite unreliable. However, in this epidemic it was noticed that the parotid duct was injected the day before the parotid gland enlarged, but became normal as soon as the gland enlarged. It may therefore be a little help in diagnosis if this time relationship is remembered.—I am, etc.,

Colwall, Malvern.

J. RICHARDSON.

Encephalitis After Yellow Fever Vaccination

SIR.—I would like to endorse, with great conviction, the views put forward by Dr. Leonard Roodyn (*Journal*, November 20, 1954, p. 1226) on the subject of the vaccination of infants against yellow fever. In recent weeks four cases have been reported in which, in infants between the ages of 5 and 13 weeks, signs of a meningo-encephalitis have followed vaccination with 17D yellow fever vaccine in England. There is, however, no evidence of any kind that this meningo-encephalitic syndrome was necessarily due to the 17D yellow fever virus; it is certainly possible that it could have been, if only from the fact that the incubation period in three of the four cases was 9–11 days. In the fourth case, that of Dr. L. G. Scott (*Journal*, November 6, 1954, p. 1108), the incubation period was 12–16 days—that is, if the date of admission to hospital was September 29, and not September 9 as printed. But, as Dr. Roodyn points out, cases exactly similar to those reported occur frequently in infants who have received no injections.

Of the four cases reported, the first (that of Dr. J. Hewgill Smith (*Journal*, October 9, 1954, p. 852)) had a lesion in the chest, sufficient in a child of five weeks to produce a meningeal syndrome. The third case (that of Dr. Leslie G. Scott (*Journal*, November 6, 1954, p. 1108)) had virulent organisms in the throat, while the fourth case (that of Dr. E. A. Beet (*Journal*, January 22, p. 226)) was possibly a result of a double vaccination against yellow fever and smallpox. The clinical details of the second case are scanty (case of Dr. L. Haas (*Journal*, October 23, 1954, p. 992)) and the meningeal irritation disappeared after 24 hours.

It is my submission that there is little or no evidence in any of these four cases to incriminate the yellow fever vaccine. The figures given by Dr. Roodyn on the numbers both of vaccinations given and of reactions reported are sufficient to warrant a very careful assessment of the implications in incriminating the yellow fever vaccine. In Lagos, during the past fifteen years, some 35,000 vaccinations against yellow fever have been given; many of these have been given to infants; both Rockefeller Foundation and Burroughs Wellcome vaccine has been used; no case of reaction in an infant has been reported. It would be well, I think, to reserve judgment on the four reported cases in England. There can be no doubt that the expert virologists who produce yellow fever vaccines are continually on the look-out for reactions, and are competent and honest enough to state forthrightly whenever a vaccine has become dangerous. The important point, so well put by Dr. Roodyn, is that such meningo-encephalitic reactions in infants are so rare that it would be quite wrong to withhold vaccination from an infant who is proceeding to an area where endemic yellow fever exists. The risk of an infection with yellow fever in such an area is very much greater than the risk of a reaction to the vaccine.—I am, etc.,

Yaba, Nigeria.

D. A. CANNON.

Salicylates in Anticoagulant Therapy

SIR.—Dr. M. H. Singer's suggestions (*Journal*, April 2, p. 851) regarding the use of salicylates as anticoagulants do not seem practicable from the pharmacological point of view. Salicylates have one-twentieth the prothrombinopenic effect of dicoumarol, and this effect, which is more marked with fever and a high metabolic rate as in acute rheumatism, tends not to persist with continued exhibition.

To produce an effect anywhere near the "therapeutic" about 6 g. a day would have to be given and this would be

quite likely to produce salicylism in a high proportion of cases.¹ Although a patient who has recovered from the initial shock of a myocardial infarction might justifiably be exposed to this high dose of salicylate, it is not for just this type of patient that he suggests this line of treatment. Further, such prothrombinopenic effect as would be obtained would not appear for 36–48 hours, and by this time the patient would be fit for transfer to hospital.—I am, etc.,

Natural Childbirth

SIR.—As a general practitioner doing midwifery, and trying to carry out the principles of natural childbirth, I have followed this correspondence with great interest. I have never quite understood the opposition to Dr. Grantly Dick Read's methods, which, it seems to me, can at the worst do no harm and at the best promote truly painless labour. The letter from Mrs. Constance Lynn (*Journal*, April 2, p. 851) does give an apparently reasonable argument, though I do not feel her one experience gives her the right to condemn natural childbirth methods in quite such a wholesale fashion. She says, in the light of her experience, "is it worth having one's morale high in pregnancy, only to be battered in labour, and very low post-natally?", and goes on to say that all other recent mothers she talked to felt the same. I have the greatest sympathy with Mrs. Lynn, for I have had cases of my own who appeared to derive little or no benefit, but I think she is wrong to condemn a technique that did not work for her. I honestly believe that the majority of mothers are helped by their antenatal training to a greater or lesser extent. Why then does it sometimes fail?

Although we do not know the medical details of Mrs. Lynn's case, I think a study of her experience is revealing. She says, "... a great deal of what I was taught to do was physically impossible in labour." I find it hard to believe that something a woman has done easily in late pregnancy is "physically impossible," though I realize it may be very hard. I believe the clue to what happened may lie in her next words, "much of what was possible one hadn't the inclination to do at the time." This admission makes me wonder whether the medical and nursing staff who helped her in her labour were fully conversant with and used to relaxation methods, for even the best and most enthusiastic patient needs considerable help and encouragement from the beginning of labour (a point Dr. Dick Read has made again and again in his writing). If she did not get this help, and her confidence waned as labour progressed, then I can well believe that she was worse off than the unprepared patient. As she says, "... so becalmed and relaxed and optimistic had I become that I was totally unprepared for the really serious and hard business involved." Here again, if she was totally unprepared for it, then her antenatal teaching was at fault. I have found it necessary on occasion to caution the over-enthusiastic patient not to expect complete painlessness, and to point out that, pain apart, the physical stress and effort attendant on labour are considerable. If a woman understands this, and is properly helped throughout labour, then she will surely, I believe, be helped by her training. I would add that she will be helped the more if the staff assisting her in her labour are people she has seen throughout the antenatal routine, for I am sure this is an important factor in the promotion of natural childbirth, and that if she sees no one she knows in the labour-room, as is the case in most hospital practice, she will be less likely to succeed in her efforts. To sum up, I say, with Dr. Anthony Ryle (*Journal*, March 19, p. 725), that I feel justified in promising mothers treated this way that their pain will be diminished considerably in nearly all cases, and entirely abolished in some.—I am, etc.,

Bristol, 3.

MICHAEL B. LENNARD.

SIR.—One salient point arises from this interesting correspondence: the mother must produce her own baby. Doctors, nurses, midwives, physiotherapists, analgesics, and anaesthetics may help or hinder her, may make labour more pleasant or more fearful, but the mother is the key figure.

If a mother is to obtain maximum help from the galaxy anxious to assist her, she must (1) be in harmony with her surroundings and (2) have complete faith in her attendant. Many mothers are forced into hospital who would rather be delivered at home, and vice versa. The domestic cat has more choice of place and arrangement of her confinement basket than the modern mother. In our organized maternity service how can a mother acquire faith in her attendant? During the course of her pregnancy, delivery, and post-natal care she may see four or five doctors, eight or ten nurses, one or two physiotherapists. It is very difficult to attract the attention of any individual in this throng. If the mother does have faith in someone at the fourth month, there is no guarantee that that person will conduct her confinement.

I witnessed my first delivery in an isolated Red Cross hospital in French Canada when I was a student. An elderly primipara, with a flat pelvis, lay quietly on the bed. Beside her sat a doctor she knew well and trusted. Only his eyes were visible behind the "Ku-Klux-Klan" garb worn for deliveries. His gloved hands were folded loosely in his sterilized lap. There was an anaesthetic machine and a trolley laden with drugs and instruments, but nothing seemed to be needed. At each contraction the doctor's voice, soft but firm, reiterated, "*Fermez la bouche, madame, et poussez, longtemps, longtemps.*" Presently a 9 lb. (4 kg.) baby was eased over the perineum. The mother was weary but triumphant. In the efficient tension of the modern well-equipped labour ward I have often longed for the absolute peace of that truly natural childbirth.—I am, etc.,

London, W.8.

ROSAMOND BISCHOFF.

SIR.—I was interested to read the letter of Mrs. Constance Lynn on natural childbirth (*Journal*, April 2, p. 851). Before the birth of my first baby two years ago, I also attended weekly relaxation classes, but found to my dismay (being naturally of an athletic and energetic disposition, and having been taught the benefits of Dr. Grantly Dick Read's theories) that it seemed a tremendous effort to have to do any exercises whatsoever (albeit for relaxation), and my natural inclinations at the time were to be completely lazy. During the latter months of this pregnancy I stopped attending the classes and instead substituted for the daily exercises a daily rest and sleep. My labour was short and uncomplicated, and certainly far less painful than I had ever imagined. Before the birth of my second baby, born six months ago, I did no exercises whatsoever. I was in the labour ward for only ten minutes during this second birth.

This might illustrate that to have completely natural childbirth one should follow the natural demands of one's own body. I have known so many mothers whose labours have been long and difficult, and yet who have most faithfully attended these relaxation classes. Most of them were women who in the normal state of affairs took no exercise nor played any games, and yet whilst pregnant flung themselves into these exercises.—I am, etc.,

Gibraltar.

DIANA CAMPBELL.

Diabetic and Insulin Coma

SIR.—In his most interesting and instructive article on the above subject, Dr. J. D. N. Nabarro (*Journal*, April 9, p. 902) omits to mention a very swift but effective treatment for hypoglycaemic coma—that is, the subcutaneous injection of 0.5 to 1.0 ml. of liquor adrenalin. 1:1,000. I have proved the efficacy of this procedure in a recent case, the patient rousing sufficiently after about five minutes to take sweetened drinks by mouth; moreover, it is much easier than giving large quantities of intravenous glucose solution.

Incidentally, I feel that many consultants are too ready to advise intravenous medication, which may possibly be the ideal treatment in the hospital ward, but which may be difficult and even dangerous when one is working single-handed in the patient's bedroom, often with inadequate lighting. I shall quote only two examples from personal experience. The drug aminophylline I have found to be quite effective and reasonably speedy when given by deep intramuscular injection rather than intravenously. For some years now I have carried in my bag ampoules of digoxin for intravenous injection, but I have never used one, as I have yet to meet a case requiring such urgent digitalization that oral digoxin with suitable sedation is not sufficient.

I shall be most interested to hear the views of other general practitioners and consultants on the points I have raised.—I am, etc.,

Birmingham.

H. JOSEPHS.

Eclampsia

SIR,—Dr. A. W. Bauer (*Journal*, April 2, p. 848) in his reply to my letter (*Journal*, March 12, p. 666) has incorrectly assumed that I attributed the authorship of the thesis under review to him. I stated that he had invoked it.

In his original communication (*Journal*, February 19, p. 481) he adduced certain data which presumably were offered for corroboration, and certain hypotheses for integration into the aetiology. It was this latter that appeared impossible to effect. For, even admitting that abnormal reactions can continue after the "focus" (presumably the placenta in this case) had ceased to act, and accepting this in explanation of the occurrence of post-partum eclampsia, it would be impossible to reconcile such a process with the regression of the signs in certain cases of intragestational eclampsia—coincident with the death of the foetus—followed by their eventual recrudescence in labour a week or more thereafter.

The determinate role of sodium in the aetiology of toxæmia is supported by much evidence from animal experiment,^{1,2} from the effects of sodium on the toxæmic³ and the anuric,^{4,5} and from the beneficial action of cation exchange resins.⁶ Consonant with this evidence it is salt restriction that must be accorded paramount importance in the diet advocated by Dr. Bauer. Thus resolved the thesis invoked is not a conflict with the concept that renal ischaemia is responsible for the syndrome. Elsewhere I have shown⁷ that myometrial resistance to stretch can effect this change in the kidney and afford the aetiological explanation.—I am, etc.,

London, W.1.

Hypodermic Injection Technique

SIR,—Dr. K. D. Salzmann (*Journal*, April 9, p. 909) describes a technique for painless hypodermic injections, supported by sound physiological reasons. May I add a footnote on a further modification of technique, based, I think, upon equally sound anatomical grounds? As a student I was taught that sensory nerve endings, responding according to their type to stimuli of pain, touch, stretch, or temperature, were scattered comparatively sparsely in any one area of skin. When as a newly qualified "locum" in general practice during a particularly busy winter I was in danger of being myself laid low, the remaining principal in the practice ensured my useful survival with penicillin injections which, as far as the actual injections were concerned, were completely painless. His technique was to grasp the upper arm with his left hand, exerting downward pressure with the thumb so that the skin was stretched and

unable to recede or roll under the pressure of the needle-point. Since that time I have always used the same technique myself, with most satisfactory results; and I have always found that the immediate pain of an injection is in direct proportion to the area of skin "displaced" by the procedure. I am sure that injections given through loose skin stimulate nerve endings sensitive to stretching which would be completely unaffected if the skin under the needle-point were prevented from dimpling. The gauge of the needle used is of less importance than the possession of a sharp point and a long bevel; a short-bevelled needle pushes rather than penetrates the skin; so, of course, does a long-bevelled needle which has been allowed to acquire a "hook." In my part-time appointment as medical officer to the local Army unit I always use my own 22 standard wire gauge needles for routine inoculations because the 26 S.W.G. Army issue needles have a 45° bevel which will not penetrate without pushing and hence causing pain.—I am, etc.,

Chieveley, Berks.

JOHN RICHARDS.

SIR,—One way to make injections less painful, as now generally used in Sweden, is the combination with a local analgesic. The diphtheria toxoid is especially difficult, the intense burning sensation several minutes after the injection making it very unpopular among the children. About a ¼ volume of lignocaine 1% is enough, either mixed with the toxoid, or better still, if there is no hurry, separately. This is done by drawing into the syringe first the toxoid and then carefully the lignocaine, giving two separate layers. Inject slowly, make a pause of a few seconds after the lignocaine, and let the toxoid follow. This procedure does not affect the immunization process.—I am, etc.,

Gothenburg, Sweden.

N. R. BLUME.

The Ban on Heroin

SIR,—Dr. A. H. Douthwaite has done a great service in drawing attention to the ban on heroin (*Journal*, April 9, p. 907). I am appalled by the way in which this valuable drug is being taken from us, for valuable it undoubtedly is. Whether or not there have been any consultations with the profession on this matter I do not know, but, if there have, such consultations have clearly not been with the right people. It is notorious that the more eminent a man is the less he is in touch with the art of day-to-day general practice. In this I do not include therapeutics by means of whatever happens to have come through the letter-box most recently, but treatment by well-tried and reliable methods. As Dr. Douthwaite says, heroin is very useful in the treatment of tracheitis. A host of other preparations are available, many of them in proprietary form. I have used most of these myself. Some of them are satisfactory, while others produce undesirable symptoms. Some patients' tracheitis seems to be resistant to them all. In such cases linctus heroin, often produces relief.

There are, of course, many other conditions besides tracheitis in which heroin is a most useful drug. Many of these have been mentioned by Dr. Douthwaite. Even had the profession been well advised of the possible withdrawal of this drug, and had they considered all the possible drawbacks inherent in such withdrawal, yet they might have agreed to its loss if they were persuaded that the sacrifice was made for a good reason. But, so far as I can see, this is certainly not the case. We are told that it is to ease the situation of drug addiction not in this country but in the United States. There is a lot to be said for nations helping each other in medical matters, but how can the ban on its manufacture here possibly help the situation in the U.S.A.? Does the World Health Organization really believe in its own name? Has it forgotten the U.S.S.R. and China? These countries will clearly continue to manufacture heroin, and undoubtedly they are at least as well versed as ourselves in the art of surreptitious export. The more one looks into the argument, the less water it appears to hold. Alcohol addiction is not uncommon in the United

States—can we expect that the World Health Organization has sufficient confidence in its reasoning to attempt the treatment of this problem the same way?

I only mention these obvious matters to show how the whole situation seems to be clouded by woolly thinking. As a result of this so-called thought, and without the general practitioners having been consulted, the general public is to be robbed of a most useful drug.—I am, etc.,

London, N.W.1.

R. HALE-WHITE.

SIR,—Dr. A. H. Douthwaite's letter (*Journal*, April 9, p. 907) is a timely reminder of a Governmental act which cannot but have adverse effects on patients with disease of the brain calling for surgical treatment. For many years now it has been the custom in neurological departments, both medical and surgical, to use for the relief of intolerable headache due to cerebral tumour ½ gr. (11 mg.) heroin given in powder form with phenacetin by mouth. This type of analgesia is not associated with the risk of the development of a marked rise in intracranial pressure which is liable to occur when morphine and pethidine are exhibited in such cases.

It is now established that satisfactory anaesthesia for neurosurgery demands immediate recovery of consciousness on withdrawing the anaesthetic, combined with the maximum possible depression of the cough reflex during operation, yet minimal accompanying respiratory depression. With this in view a large number of analgesic drugs have been tested as premedication, and as supplements to nitrous oxide and oxygen, in the course of the last few years. Pethidine, methadone, and L-methorphan have all been found wanting mainly because it proved impossible to obtain the necessary depression of the cough reflex without simultaneously reducing respiratory displacement to the point at which serious rise in intracranial pressure occurred. Heroin alone has stood the test of time in these cases, and its withdrawal from the *Pharmacopoeia* cannot but result in hardship, suffering, and, it may be, fatalities.

There seems little hope that the use of "nalorphine" to antagonize respiratory depression will make the previously rejected drugs any more acceptable; for Payne¹ has shown that the effect of this drug, although initially stimulating, is subsequently depressant. Perhaps N-allyl-nor-dromoran will be a little more satisfactory in this respect, but, even so, the lack of heroin can only be made good by months, or it may be years, of searching for another agent with the same properties. It seems a pity that some patients should suffer unless it can be conclusively demonstrated that the result is really going to benefit a vastly greater number of potential addicts. An embargo on the import and manufacture of heroin, confined to this and a few other countries, is obviously insufficient to attain this end. Indeed, unless the manufacture of the drug is discontinued everywhere there will be no gain to offset the suffering of these patients whose pain cannot otherwise be satisfactorily relieved.—We are, etc.,

A. R. HUNTER.

The Aftermath of Hysterectomy

SIR,—In support of Dr. Winifred Coppard's letter on "The Aftermath of Hysterectomy" (*Journal*, April 2, p. 852) may I make some observations? About four months ago I underwent a total hysterectomy for a large fibroid of long standing, my ovaries being left *in situ*. For several years the thought of a hysterectomy had loomed towards me, and in November last a bad uterine haemorrhage was the final thing which made me agree, at the age of 42, to get on with it. At the time of operation I was fortunate in having a married woman surgeon of great wisdom, understanding, and humour, and her remark to me in discussing my forthcoming operation, "Some

women have such a sentimental attachment to their uterus," put the whole affair into the right perspective. That, coupled with being married and having three children, helped a lot. All went well, I was up on the third day after operation, walked out of hospital on the tenth, and after a further five weeks of gradual resumption of normal activities I returned to my usual full domestic and public life. Now, after four months, I feel very fit, and able to plan my days without the tiresome worry of heavy periods every 3½ weeks. In addition, after 20 years of contraceptives, married life is now unhampered and happy.

Having seen other women in a similar position to myself during the past few months, but without the help and support of a married woman medical adviser, and making slow and anxious recoveries, might I suggest that when a hysterectomy is advised it is to the gynaecologist of her own sex that a woman can turn with advantage?—I am, etc.,

DOCTOR'S WIFE.

SIR,—I wish to congratulate Dr. Winifred Coppard on her letter (*Journal*, April 2, p. 852) drawing the attention of our profession to the aftermath of hysterectomy. Many general practitioners are aware that those who have undergone this mutilating operation are among the most regular attenders at the surgery, for not only do cyclical attacks of depression occur as mentioned by Dr. Coppard, but also attacks of headache, backache, nausea, and blackout.

Since 1952 I have collected records of 30 women who underwent hysterectomy for non-malignant conditions some 2–12 years previously. Of these, 15 women considered their general health had deteriorated since operation, 5 considered their health was about the same, and only 10 women appreciated the benefit this major operation had brought to their general health. In reply to a question on marital happiness, 3 of the 19 married women stated that they had divorced since operation, and a further 8 reported deterioration in their marital harmony, leaving only 8 women who reported no change in their marital happiness. Intercourse had not been attempted since operation by 9 women, because of lack of knowledge or lack of desire, 4 women complained of dyspareunia which made intercourse a rare event, and only 6 women reported normal intercourse. This legacy of marital problems stresses the need for trial of alternative treatment in preference to the easy policy of "If thy womb offend thee, cut it out." Too few hospitals call the husband into consultation or ask his permission before the decision to operate is made. In the past twelve months I have referred two patients to different gynaecologists for investigation into infertility, and on both occasions the consultants advised hysterectomy for small symptomless fibroids. I consider it my duty in general practice to protect the patient from an unnecessary hysterectomy, and where this is inevitable to discuss the operation with both marriage partners, advising on subsequent intercourse and the probable need for hormone therapy.

At the Royal Society of Medicine recently I remarked that "hysterectomy does not cure premenstrual syndrome, but it does transfer the patient from the gynaecologist's wing to a specialty dictated by the site of the symptoms." The same may be said of other functional disorders for which hysterectomy is to-day practised. One may well ask the gynaecologist, "Is your operation really necessary?"—I am, etc.,

London, N.18.

KATHARINA DALTON.

Neon Lighting in Hospitals

SIR,—Dr. William B. Bacon's letter (*Journal*, March 12, p. 666) contains statements which cannot go unchallenged. Presumably your correspondent is referring to fluorescent and not to neon tubes, since the latter are never used for lighting purposes. Fluorescent tubes operate on the mercury discharge principle and are fundamentally different from neon tubes, which are used in advertising signs.

While it is true that some types of fluorescent tubes have, in the past, over-emphasized the blues and greens, and so could give rise to danger to which Dr. Bacon refers, during recent years there have been great improvements in colour-rendering properties, and modern installations are completely satisfactory. From the wide range available tubes may be chosen to give almost any desired colour rendering, including that of tungsten, and if the installation is designed by a competent lighting engineer there need be no fear of a patient becoming cyanosed and escaping attention due to poor lighting.

Fluorescent tubes have been used in the lighting of the surgical corridor of this hospital, which includes a thoracic surgical unit, with perfectly satisfactory results, following conversations with the consultant surgical staff, who were naturally interested in the points now raised by your correspondent.—I am, etc.,

Churchill Hospital, Oxford.

C. F. SHARE,
Assistant Administrator.

Medical Numismatics

SIR,—Your reader Dr. G. E. B. Payne (*Journal*, March 19, p. 729) might be interested to know that the full name of Dr. Eady was Samuel Phillips Eady, and (according to records preserved at the Westminster Public Library at Buckingham Palace Road) he lived at 38, Dean Street, Soho, from 1820 until 1825.

There is a reference in the *Gentleman's Magazine*¹ which might well refer to him. In describing a book intended for purchase the writer says, "The work contains 24 leaves somewhat broader and handsomer than the soft sybilline effusions in which Dr. Eady's merits are recorded." This might suggest that Dr. Eady (if, indeed, it is the same man) used other forms of advertisement than the token, and was, therefore, presumably not a professional man.—I am, etc.,

C. J. CITRON,
Chairman,
Public Libraries Committee.

Tropical Pulmonary Eosinophilia in a West African

SIR,—Contrary to Dr. James A. McFadzean's belief (*Journal*, March 26, p. 771), eosinophil counts of the order mentioned by him are by no means unusual in persons with Calabar swellings due to loiasis. In our view his patient presented the ordinary features of this common West African disease, and we regard his diagnosis of tropical pulmonary eosinophilia as mistaken.—We are, etc.,

Recognition of Dental Fluorosis

SIR,—With regard to Mr. N. J. Ainsworth's reference to his visit to an Oxfordshire village in 1939 (*Journal*, April 9, p. 911), may I refer him to the reprint, which was sent to him that year, of the first published description of dental fluorosis at Bampton,¹ in which I stated: "I noticed dental fluorosis in adults and children in different parts of the village, and Mr. Ainsworth very kindly came to Bampton and has confirmed my findings"? There was no implication in this statement or in the quotation from it (*Journal*, March 26, p. 789), which Mr. Ainsworth mentions, that dental fluorosis was present in every one of a group of villagers who were collected for his diagnosis. Later that summer a number of Bampton inhabitants with severe dental fluorosis were demonstrated at the meeting of the Physiological Society held at Oxford.—I am, etc.,

Oxford.

Dermatomyositis

SIR,—I cannot agree with Dr. Allan Bigham (*Journal*, April 9, p. 909) that there is any doubt about the diagnosis of the case of dermatomyositis described by me (*Journal*, March 26, p. 770). Dr. Bigham's chief doubts seem to arise from the fact that there was painful joint swelling, and that the orbital tissues were not involved. I agree with him that the presence of painful joints is against the diagnosis of dermatomyositis, and it was this very fact which led me to make the original erroneous diagnosis of acute rheumatism. Furthermore, as the case progressed it became clear that skin and muscle swelling and tenderness were the major features, whereas joint tenderness had been present in the initial stages. My description did not perhaps make this sufficiently clear.

While agreeing with Dr. Bigham's description of a typical case of acute dermatomyositis, which includes swelling of the infra-orbital tissues, the absence of facial swelling in my case in no way invalidates the diagnosis. Few diseases present all the features of their classic descriptions.

Finally, the histological findings of round-cell infiltration with fragmentation of muscle bundles and proliferation of their nuclei, which were present in my case, may not be regarded as specific of dermatomyositis, but these are the findings which have been present in most recorded cases.—I am, etc.,

Richmond, Yorks.

HILLAS G. SMITH.

Chlorpromazine in Mental Disease

SIR,—Miskolczy¹ in 1938 suggested that only those parts of the brain which reached their fullest development in man were affected in schizophrenia, and I believe much evidence has accumulated since then to support the view that schizophrenia is a phylogenetically and otogenetically determined encephalopathy with disordered action of brain cells in the frontal lobes and hypothalamus particularly, and, to a lesser extent, in the parietal and temporal lobes. Further, that the affected cells may recover or become inactive, so that the process may be arrested at any level, but that fully developed cases go on to functional loss of much of the frontal lobes and of the lateral and posterior hypothalamus. I hope you will allow me to comment on the possible incidental light thrown on this hypothesis by the article on the use of chlorpromazine in mental hospital patients by Dr. J. Lomas (*Journal*, April 9, p. 879).

The information supplied by Dr. Lomas confirms what has been stated several times before, that the chief effect of chlorpromazine is on the diencephalon and not on the cortex; in fact, that it is a partial chemical hypothalamectomy which is achieved and not a chemical leucotomy, as suggested by Delay and Deniker.² Bearing this in mind, and the hypothesis which has been briefly stated, one should not be surprised if (1) chronic, emotionless schizophrenics are little affected and can tolerate large doses, (2) schizophrenics with emotional disturbances are helped most, and this applies whether leucotomy has been performed or not, (3) some patients—those, I suggest, with either an intact hypothalamus or in whom the hypothalamic disease process is inactive—may fail to improve with chlorpromazine and yet benefit by leucotomy.—I am, etc.,

Benzene Hexachloride Nomenclature

SIR,—There would appear to be a widespread misunderstanding which has even appeared in government publications such as *Memorandum on Measures for the Control of Mosquito Nuisances in Great Britain, 1954*, as to the correct description of the insecticidal material known as benzene hexachloride, or, as it is commonly termed, B.H.C.

(gamma isomer). Your leading article (*Journal*, April 2, p. 836) and the refresher course article by Dr. E. F. Edson (p. 841) emphasize the necessity of describing the active constituent by its proper term.

Benzene hexachloride is in strict chemical terminology 1:2:3:4:5:6-hexachlorocyclohexane, and this correct chemical description is commonly used on the Continent. B.H.C. as primarily produced is a mixture of numerous isomers of which the gamma isomer is outstandingly the most active, and it is on the content of this isomer that standardization is carried out. The term "gammexane" is the registered trade mark of one producing company of B.H.C. and for products manufactured by them containing it, and therefore the name gammexane applies only to those products produced by the owners of that trade mark and is not standardized. B.H.C. is now produced almost all over the world in various concentrations of the gamma isomer, and manufactured products containing the insecticide are also widely produced. The pure gamma isomer is now known fairly generally by the term lindane, although this term is not included yet in the British Standard Recommendation for common names for insecticides. None of the names recommended by the British Standards Institution have any proprietary implication, neither has lindane. It is therefore only necessary to indicate the content of gamma isomer B.H.C. in recommendations unless one is anxious to describe the material in the strict chemical form. While there are notable differences in effectiveness between compounded preparations, the use in literature of a proprietary trade mark to describe an insecticidal substance in world-wide manufacture and use is liable to cause confusion and lead to misapprehension, and should be avoided.—I am, etc.,

London, W.C.1.

KARL B. EDWARDS.

Night Cramps

SIR,—Your annotation (*Journal*, March 12, p. 653) and Dr. H. R. Odum's letter (*Journal*, April 2, p. 848) on the above subject encourage me to add some further observations on a condition which may cause much distress. The circumstances under which the cramps show themselves are not at all what might have been expected, for they usually occur after a period of repose, and when the feet are comfortably warm; the early morning hours, after the night's rest, are usually the worst time.

Cold feet in bed are in themselves an affliction, but they have one advantage in that they do not occur simultaneously with cramps. Cold may also be employed to alleviate the cramps when they occur. For this purpose, the bed-clothes should be turned back at the foot of the bed, thus forming a kind of potential tunnel or passageway. When cramps occur, the feet should be pushed through this tunnel and the bare soles pressed against the cold varnished surface of the foot-board of the bedstead or of some improvised substitute. The feet should be moved about from one cold surface to another, and movements should be performed stretching the affected muscles. A few moments usually elapse before the cramps disappear, suggesting the effects of a neurovascular reflex, whereby the excitability of the diverse muscle groups is reduced, thus restoring their balance. To obviate recurrence, bedsocks should be removed after an attack and the feet kept cool. Patients sometimes obtain relief by walking about barefoot on a cold surface, but the methods described may be equally effective while causing less disturbance.—I am, etc.,

Sheffield, 10.

R. G. ABERCROMBIE.

Manipulation and Low Back Pain

SIR,—In your correspondence column Mr. W. D. Coltart and Mr. H. Osmond-Clarke (*Journal*, March 26, p. 790) and Professor J. H. Kellgren (*Journal*, April 9, p. 910) have not unnaturally inquired as to the progress and ultimate fate of the "missing" 16 patients in our recently published series of patients with low back pain (*Journal*, March 19, p. 705).

These 16 patients consisted of 10 males and 6 females. Ten of this group, dissatisfied and unhappy at our apparent policy of *laissez aller*, sought advice and treatment elsewhere. This consisted of manipulations (usually by private osteopaths), various heat treatments, and occasionally traction of the lumbar spine, so that, although seen for examination, they obviously could not be included in the final figures. Three patients developed signs and symptoms of sciatica with severe pain at rest within three weeks, and were placed in plaster lumbar corsets. The final three, of itinerant habits, have returned to Ireland, and we cannot determine how they fared over the vital six weeks. With regard to patients who were using sagging beds, part of our postural instructions ensured that they used a better mattress or employed plaster boards beneath the faulty mattress whilst under treatment during the period in question.

Drs. P. J. R. Nichols and D. J. E. Cheshire (*Journal*, April 23, p. 1032) write about "historical controls" and the fact that we recorded no accurate diagnosis. For the type of case considered (see "Method"), and the as yet unknown pathology of many such cases (see introduction), we consider that our series was controlled as well as possible. After all, what better end-point than full painless lumbar range of movement and full straight-leg raising? We have simply sought to establish whether or not manipulation has a place in the treatment of recent low backache, and, as our results have shown, we are perfectly aware that treatment by rest and analgesics alone is a very good one indeed. We realize that there is yet a tremendous amount of work to be done on the accurate elucidation of the pathology in all cases of low lumbar pain, with or without sciatica, and sincerely trust that our paper will stimulate interested workers to try and gain further insight into this very controversial subject.—We are, etc.,

London, W.C.2.

A. B. COYER.

I. H. M. CURWEN.

Alcohol and Road Accidents

SIR,—As the new *Highway Code* has just been issued with its warning, "Alcohol, even in quite small amounts, makes you less safe on the roads," it seems an appropriate time to call the attention of the profession to a grave defect in all official statistics of road accidents, whether published by the Ministry of Transport, the Registrar-General, or by one of the various accident prevention societies. They all minimize (or omit) the role of alcohol in the causation of such accidents. For instance, in the latest Ministry figures¹ of personal injury accidents (in 1952) out of a total of 114,000 "drivers" accidents only 870 were attributed to motorists and cyclists who were "under the influence." In many reports of local accident prevention societies alcohol is not mentioned, nor does it appear in the Registrar-General's statistics of deaths by violence, and yet, in the opinion of all who have studied the subject, thousands of accidents (and probably hundreds of deaths) are caused annually by intoxicated drivers, pedestrians, and cyclists. The B.M.A. Committee on the recognition of intoxication says "several thousands."²

The police reports of all the fatal road accidents in Leicestershire and Rutland for 1953 make a sad catalogue of carelessness and needless deaths: There were 77 fatalities, about one-third of them being old people or children carelessly on the road. In only one case was the condition of the road the main cause of the accident; in one sudden illness; and in two cases a burst tyre. All the rest were due to the personal element—carelessness in drivers, cyclists, or pedestrians, in some cases attributable to alcohol. Between 8 and 10 p.m. there were four fatalities, none due to alcohol, whereas between 10 and 12 p.m. there were thirteen, three of them being drunken pedestrians on the road. The other ten were due to drivers, of whom two as I think were certainly intoxicated, one probably so, and three possibly. Between 12 p.m. and 2 a.m. there was only one accident, early on Christmas morning, and due to drink; but it resulted in the death of three youths. My opinion, from

the above small survey, which I hope to supplement, is that at least half the fatal accidents occurring after 10 p.m. in this area in 1953 were due to intoxication in motorists, cyclists, or pedestrians.

None of the above fatalities will be recorded in the official statistics as having any connexion with alcohol, the verdicts being "accidental death" (with a note of the chief injury), even in those cases where the driver was almost certainly drunk. Unless a driver is examined at once and is very obviously drunk, no conviction of intoxication can usually be obtained. In night accidents he seldom is seen at once. The certificate which is sent by the coroner to the registrar of deaths is based on anatomy and according to the chief injury—for example, fracture of skull—and there is no place for "conditions contributing to the death" such as is provided in the ordinary G.P.'s death certificate. The Ministry of Transport's Report also does not get to the root of the matter. It lists over 30 "contributory factors" to "drivers" accidents, but these so-called factors really are the manoeuvres or mistakes which lead to the accident, such as "cutting in" or "speeding," the real "contributory factor" at the back of many of them being slight intoxication. In fact, official statistics support the pretence that a drinking driver is only a small danger.

No test for carelessness has ever been devised, other than by numbering the mistakes or accidents resulting, and by this test there is conclusive evidence that slight intoxication makes a man "accident-prone," and that the accident rate rises proportionately to the alcohol in his tissues. For this reason I think that chemical tests as well as clinical tests should be authorized as a routine in the examination of intoxicated persons.—I am, etc.,

N. I. SPRIGGS.

Difficulties of Child Adoption

SIR,—I know two patients, a childless married couple aged 49 and 48, who have for the last four years been trying to adopt a girl of about 5 years old from anywhere. After strenuous efforts by myself and their solicitor, they have just been bitterly disappointed for the last time. They have given up in despair because the societies say they have no children available. This I cannot believe, judging from the agonizing letters which we receive from these societies through the post.

I can only attribute the shortage of children to the ridiculously jealous restrictions hedged around the children by the societies, and to an unfounded suspicion of those kindly disposed couples who wish to adopt, and of the medical profession, who often try to bring a child into a home in order to preserve the happiness of that home. The societies will reply "Aha! a child must be required for its own sake, and not in order to bolster up an unhappy home." But why? I should have thought that an otherwise unwanted child which could make an unhappy couple happy would more than justify its existence, and be far better off doing this than merely being an inmate of a home.

My object in asking you to print this letter is to find out if other general practitioners have had similar experiences, or if my problem is an isolated one.—I am, etc.,

North Walsham.

P. M. FEA.

Cricket

SIR,—The B.M.A. v. Law Society Cricket Match takes place on Sunday, May 29, at Hurlingham Club, London, at 11.30 a.m. I have been asked by Council to make the necessary arrangements on behalf of the Association, so will any members who are active cricketers and who wish to have their names considered please get in touch with me as soon as possible, stating their "potentialities"?—I am, etc.,

The Little House,
Broadwater Down,
Tanbridge Wells.

R. PROSPER LISTON.

POINTS FROM LETTERS

Postcards for In-patients

Dr. R. DOUGLAS HOWAT (London, S.E.24) writes: One of my friends, who has been an invalid, has made out a scheme which, in my opinion, will save money and also undue anxiety, besides easing the calls made upon the overworked members of hospital staffs. The suggestion is that all hospitals should offer their in-patients printed prepaid postcards which they can send to their next of kin. Briefly, such cards would have a list of questions requiring only a "yes" or "no," or, where it is not possible for the patient to do this, a plus or minus sign can be substituted for "yes" and "no." The following questions are suggested: (1) Do you feel better? (2) Are you sleeping better? (3) Do you require any cash? (4) Do you require any cigarettes? Fruit? Chocolates? (5) Do you require any underclothes? (here specify type required); etc. A space would be left at the foot of the card for any additional wants by the patient, also a space for comments by the doctor, sister, or staff nurse. . . . Consider also the enormous saving of unnecessary telephone calls such a system would ensure, also the saving of unnecessary anxiety both on the part of the patient and the relative. Such cards would, of course, require to be of three types—namely, for men, women, and children.

"Topical"

Surgeon-Commander C. J. ROBERTS (B.F.P.O. 51) writes: Is the use of this word in relation to analgesia of the urethra really necessary? Most laymen and at least one doctor understand "topical" to mean "in the news." If your correspondent Dr. B. G. Forrest (*Journal*, March 12, p. 665) used the word "surface," his meaning would be almost as clear to the learned and far clearer to the unlettered.

Night Cramps

Dr. H. ANGELL LANE (Battle, Sussex) writes: Dr. H. R. Odum's letter (*Journal*, April 2, p. 848) suggests one unusual cause of night cramps, which I observed in my own case. I suffered practically every night for four years from severe cramps, chiefly in the calf muscles. This was during the war. No treatment suggested was of any value. I was 75 years of age and to keep going in my job I took daily amphetamine. I discontinued this in 1946. I also discontinued the cramps. They return only after I take amphetamine again for two or more consecutive days.

Infected Clothing

Dr. G. C. PETHER (Hitchin) writes: When I have a cold my germ-laden handkerchiefs go into one pocket and then another. It is true that the tailors do provide what is known as a handkerchief pocket, but this receptacle, in an inconvenient position and badly designed, cannot hold many handkerchiefs when I have a streaming cold. They wander uneasily from place to place and, presumably, infect my clothes in the process. Would it not be sound to have at least two of our larger pockets lined with a washable material and designed to hold our handkerchiefs and nothing else? They could be wiped out with disinfectants, and presumably our germs would not wander along our waistcoats, braces, and other fittings. Has any work been done to discover what pathogens, if any, are put away with our winter clothes in the spring, to emerge, after a good rest, eager for the fray in the autumn? It would be reassuring to know that this cannot happen. If it can, then some sterilization of the clothes before storage would seem wise.

Tetanus Immunization

Dr. D. N. EVERINGHAM (Guildford, N.S.W., Australia) writes: Your annotation (*Journal*, January 29, p. 278) suggests that active immunization may be preferable in combined vaccines or in armed forces, in view of the risks of horse serum. The main risk of giving serum routinely is that there is less protection, in the event of delayed sporulation, than from toxoid. In any case most patients will have several gravel grazes, punctures by thorns, and contaminated cuts for every major injury which takes them to a doctor, and often they will be more at risk from these than from the "major" injury. This is confirmed by two simple facts: (1) most patients who ask for an anti-tetanus injection have clean or well-opened wounds, or slightly contaminated wounds well flushed by bleeding, or (in this country) dog bites, cuts of a thumb web or other interdigital cleft, or open laceration by a rusty nail (all of which are thought to be tetanus risks); (2) most people to whom anti-tetanus injection is given do not come for that purpose. Therefore I consider I am giving longer, more comprehensive protection by giving toxoid routinely, and recommending a return for a booster on each occasion of a soil-contaminated injury until three injections are given, then a booster for such injuries at three- to five-year intervals.

Obituary

R. DAVIES-COLLEY, C.M.G., M.Ch., F.R.C.S.

We record with regret the death on April 16 of Mr. R. Davies-Colley, which took place at Guy's Hospital, the hospital with which he had been associated as a student and as a member of the staff throughout his professional life. He was 73 years of age.

Robert Davies-Colley was born at Petworth, in Sussex, on August 8, 1881. His father, the late Mr. J. N. C. Davies-Colley, was also on the senior surgical staff at Guy's Hospital. Surgery ran in the family, for Robert's elder brother, Hugh, who died in 1938, was chief surgeon to the Cambridge Military Hospital, Aldershot; and his sister, Eleanor, who died in 1934, was the first woman to obtain the F.R.C.S. of England. From Westminster School Robert Davies-Colley went on to Emmanuel College, Cambridge, taking his B.A. (Natural Sciences Tripos) in 1902. He then continued his medical education at Guy's, qualifying in 1906, taking his F.R.C.S. in 1908 and the M.Chir. the following year. After junior house posts he became obstetric registrar at Guy's, and then demonstrator in anatomy. In 1912 he was appointed to the surgical staff. Among other posts he held at Guy's during the early part of his career were the lectureship in surgical pathology and the curatorship of the museum of the medical school. In due course he became senior surgeon at the hospital, and, on his retirement, consulting surgeon. He was also on the staff of the Florence Nightingale Hospital and the Kent County Hospital, Farnborough, and he acted as consulting surgeon to the London County Council.

During the first world war Mr. Davies-Colley served in France and afterwards as consulting surgeon to the Mesopotamian Expeditionary Force, when he was mentioned in dispatches, and was made Commander of the Order of St. Michael and St. George. After demobilization he was granted the rank of honorary colonel of the Army Medical Services. In the following years he became as well known a London surgeon as his father had been before him, and was appointed examiner in surgery to the University of London and to the Society of Apothecaries. He was also a member of the court of examiners of the Royal College of Surgeons, and Erasmus Wilson lecturer from 1939 to 1946. His contributions to the literature were on general subjects as well as on the subject of surgical pathology, in which he was always keenly interested.

He married in 1908 Emily Crosby Jones, who was a nurse at Guy's and had previously worked at Great Ormond Street Hospital. After her marriage she continued for many years her active voluntary work on behalf of Guy's. Mrs. Davies-Colley died in 1953. They are survived by two daughters.

T. B. L. writes: Everybody called Robert Davies-Colley "Bobby" or "D.C." rather than by his full name, which came to him from his grandfather, a doctor in Shropshire who inherited some mountain land in Montgomeryshire. His family was a good example of the hereditary principle in medicine, for I think it went back at least one generation further. In his own time there were three Fellows of the Royal College of Surgeons in the family at once. His father had faced a carcinoma of the gall-bladder with stern heroism in 1900, going on with his work as a surgeon at Guy's until his jaundice began to distress his patients. Bobby came up to us from Cambridge three years later,

his first task being to work for the Primary Fellowship, which we took together when Arthur Keith was examining for it. He got on the junior staff as obstetric registrar a year before I did; and then we started together the St. Thomas's and Guy's section of the O.T.C., and got up early to learn horsemanship at the riding school in Regency Street. I think his disappointment at not getting on to the staff as an obstetrician lasted, to some extent, all his life, but at that time it looked as though there would be no vacancy for many years. So Bobby slipped over from obstetric registrar to the dissecting-room, as the routine pathway to the surgical staff, and we taught anatomy together till we both were elected to the staff when Charters Symonds went off—the rise of specialism making two vacancies, and these almost at once.

With the war we both found our ways to different parts of the Middle East, and five years later assumed the positions of friendly colleagues with work that no longer brought us together. His great friends were A. S. Blundell Bankart and G. W. Nicholson, and together they formed a trio of intellectual attainment outstanding in the junior staff of the time. D.C.'s work under Targett and his friendship with Nicholson enabled him to step into the former's place as the leading opinion in the surgical work on the microscopical appearance of a slide, while he was the only man at Guy's who could discuss with Nicholson microscopical pathological anatomy once there had arisen the new cytology which was developing at the end of the first decade of this century. Bankart left us early to become a great orthopaedic surgeon; but D.C.'s friendship with Nicholson was close and devoted and passed on to the next generation. All three of them came from Cambridge at a time when it was the thing there to suppress all evidence of emotion, including enthusiasm (not that they did not have this). But there were always some who saw through this seeming pose and recognized that in him were high-minded principles upon which there was no weakening; and these men were always in the higher ranks of thinking persons. In this I think he was like his father, for there are still some Guy's men of the 'nineties who have the same high opinion of Mr. J. N. C. Davies-Colley as men of the late 'twenties and 'thirties have of his son Robert. Bobby Colley was capable of great generousities and of small kindnesses, both of which he kept to himself, and of which, as a recipient, I have grateful memories.

W. ARTHUR YOUNG, M.B., D.T.M.&H.

Dr. W. Arthur Young, for many years Rockefeller professor of bacteriology at the King Edward VII College of Medicine, Singapore, died at his home at Westcott, near Dorking, on April 3, a little more than a fortnight before his 65th birthday.

William Arthur Young was born at Blackheath, London, on April 18, 1890, the second son of Mr. H. R. Young. From University College, London—where he graduated B.Sc., with honours, in 1911—he gained an entrance scholarship to Guy's Hospital Medical School, qualifying M.R.C.S., L.R.C.P. in 1914 and winning the Golding-Bird gold medal in bacteriology. He then entered the R.A.M.C. to serve in the first world war as medical officer in charge of a mobile laboratory with the British Expeditionary Force in France and later as director of the pathological department at the Royal Herbert Hospital, Woolwich. After the war he took the London degrees of M.B., B.S., and became pathologist to the Royal Chest Hospital, St. John's Hospital for Diseases of the Skin, and the Grosvenor Hospital for Women.

In 1927—the year in which he obtained the D.T.M.&H.—he was appointed Rockefeller professor of bacteriology at Singapore, becoming also curator of the Keith museum in the King Edward VII College of Medicine.

While at Singapore he devoted all his energies towards creating an efficient department of bacteriology, by training laboratory technicians and by raising the teaching of the students to a much higher standard in both practical and theoretical work. He also took immense pains to help his students solve their difficulties. His laboratory was excellently equipped and always in perfect order, and he was most scrupulous about the way the work of the laboratory was done. Although he carried out many investigations, he published very little; it seemed sometimes that the possibility that some unrecognized error might have influenced his results discouraged him from describing his work in print. He completely reorganized the Keith museum on modern lines and spent much time and hard work investigating the best methods of mounting specimens in the Tropics and in cataloguing exhibits for the benefit of students and visitors. During the second world war he served first in the Royal West Africa Frontier Force and later as lecturer and examiner in pathology at the Royal Army Medical College, Millbank, with the rank of major in the R.A.M.C. After the war he returned to Singapore and in 1946 gave great help in restoring the medical college after the Japanese occupation had virtually destroyed everything except the building. In 1948 he took up the appointment of director of medical laboratories, Western Australia, and retired to this country only last year. He is survived by his widow, formerly Miss Ina Heslop, and a son, who is lecturer in Slavonic studies at Cambridge, and a daughter, a teacher of physiology at St. Thomas's Hospital Medical School.—R. B. H.

R. H. SANKEY, B.M., F.F.R.

Dr. R. H. Sankey, honorary consulting radiologist to the Radcliffe Infirmary, died at his home at Oxford on April 6. He was in his 81st year.

Richard Harvey Sankey was born at Littlemore, Oxford, on June 11, 1874, the son of Dr. R. H. H. Sankey. From Radley College he entered Christ Church, Oxford, in 1893, and received his clinical training at St. Bartholomew's Hospital. He qualified M.R.C.S., L.R.C.P. in 1902 and two years later obtained the degrees of B.M., B.Ch. From 1903-4 he held house appointments at the Radcliffe Infirmary and then settled in general practice at Oxford, where his services were soon much in demand, for he achieved early in his career a reputation both as an obstetrician and as an anaesthetist. In 1908 he became public vaccinator for the city, holding the appointment until 1923, and from 1905 to 1909 he was clinical assistant at the Oxford Eye Hospital, becoming anaesthetist to the hospital in 1909.

Sankey will always be remembered as the pioneer of x-ray work in Oxford. In 1907 he was appointed the first radiologist to the Radcliffe Infirmary, where the x-ray department began in a very small hut. Later it extended to two small rooms. In the first world war he was radiologist, with the rank of captain in the R.A.M.C., to the military hospital established in the examination schools. After the war the work of the x-ray department increased, but not the allotted space, until, in 1933, he planned a new building which forms the present department. He intended to retire in 1939, but on the outbreak of the second world war he agreed to carry on his work, which he did until 1945. In addition to his appointment at the Radcliffe Infirmary, he was also consultant radiologist to Horton Infirmary, Banbury, and to the Oxford County and City Mental Hospital.

A very careful and conscientious worker, Sankey was much interested and particularly skillful in skin therapy, as well as in x-ray diagnosis. A very likable man, with a shy and retiring disposition, he was popular with his patients and very considerate to them. He was a long-standing member of the British Institute of Radiology, and in 1936 was awarded the Fellowship of the British Association of Radiologists, now merged in the Faculty of Radiologists. A past-president of the Oxford Medical Society, he served as president of the Section of Radiology when the British Medical Association held its Annual Meeting at Oxford in 1936.

For relaxation Sankey enjoyed shooting: he was also an expert designer and carpenter, and in the summer term he always liked to have a look at the cricket in the University Parks. His well-earned retirement was marred by severe arthritis, which in time prevented him from getting about. He had a host of friends who will treasure his memory, and their sympathy goes to his widow and two sons, one of whom is a doctor.—D. T. B.

Dr. P. S. MARTIN died at Weston-super-Mare on February 20 after a long illness. He was 69 years of age. Philip Stanley Martin was born on January 7, 1886, the son of Dr. E. F. Martin, who died in 1936, and the grandson of Dr. Edward Martin. He studied medicine at University College, London, and at University College Hospital Medical School, qualifying M.R.C.S., L.R.C.P. in 1909. After holding a number of appointments at University College Hospital and a clinical assistantship at The Hospital for Sick Children, he joined his father in practice at Weston-super-Mare in 1912. As a Territorial officer in the R.A.M.C. he was mobilized on the outbreak of the first world war and served in France and in Egypt, in the Dardanelles landings, and in Palestine, where he won the Military Cross at Beersheba in 1918. After the war he took over the practice at Weston-super-Mare, becoming the third generation of his family to practise in the town. He was appointed to the surgical staff of Weston General Hospital in 1919 and worked there until his retirement in 1952, being chiefly interested in orthopaedics. He was a keen supporter of the work of the St. John Ambulance Brigade, being an exceptionally good lecturer himself, and for some years held the post of county surgeon. For his services he was appointed a serving brother of the Venerable Order of St. John of Jerusalem. He was a great family man, and his hobbies included sailing and carpentry. A member of the British Medical Association for 44 years, he was chairman of the East Somerset Division in 1946-7. He will be remembered as an able and kindly doctor, and as one who was always ready to help a younger man. His son, Dr. L. T. Martin, succeeds him in general practice.

The death occurred on April 4 of Dr. A. T. WOOLWARD at his home at Bishopsteignton, South Devon, at the age of 64. Arthur Trevor Woolward was born at Totterhoe vicarage, near Dunstaple, on February 13, 1891, and was educated at Haileybury and at Caius College, Cambridge. His medical studies at the London Hospital were interrupted by combatant service in France during the first world war, when he was a lieutenant in the Royal Field Artillery from 1914-16. Returning to the London to finish his medical training, he qualified M.R.C.S., L.R.C.P. in 1917. He then entered the R.A.M.C. and was sent to Mesopotamia, returning home at the end of the war with the rank of captain. Dr. Woolward was resident medical officer at the old Baschurch Home for a time and moved with it to Gobowen, when it became known as the Shropshire Orthopaedic Hospital. In 1923 he returned to practise at Baschurch and afterwards moved to Colston Basset, Nottinghamshire. Ten years later he went back to Shropshire and

practised at Grinshill until 1946, when he retired owing to ill-health. In 1937-8 he was president of the Shropshire and Mid-Wales Branch of the British Medical Association. After the last war he lived at All Stretton, where he was chairman of the local Conservative Association for two years. In 1953 he moved to Devonshire, where it was hoped the milder climate would restore his health. He is survived by his widow, formerly Miss Hilda W. Hunt, of Baschurch, whom he married in 1915.

Dr. R. D. MOORE died on April 8 at Platt, Borough Green, Kent, where he had been living with his married daughter for the past two or three years. He was 88 years of age. Reginald Devereux Moore was born on June 5, 1866, and was educated at King Edward's School, Birmingham, and at St. Mary's Hospital, London, qualifying L.S.A. in 1894. After qualification he served as a ship surgeon on the South African run and then held the appointment of house-surgeon at the North Lonsdale Hospital, Barrow-in-Furness, before entering general practice at Stoney Stanton, near Hinckley, Leicestershire, in 1897. Three years later he moved to Churchdown, Gloucestershire, and there he remained for just over fifty years, some thirty-five of them in general practice. During the first world war he served in the R.A.M.C. and was in his 52nd year when, in 1918, he was awarded the Military Cross for "working continuously for eight days attending to the wounded at an advanced dressing station, often under shell fire. His organization of the work was excellent, and by his courage and cheerfulness he inspired all ranks with confidence, which assisted them materially in the performance of their duties." He was demobilized in 1919, by which time he had attained the rank of major, and returned to his beloved Churchdown, near Gloucester, and not far from his native Tewkesbury, to rejoin his partner, Dr. J. J. Foster. Later, they were joined by Dr. H. S. K. Lowry. The end of the first world war saw the establishment of a number of ex-Servicemen's organizations, and Dr. Moore was chiefly responsible for the foundation of the Churchdown and District United Services Club and was its joint honorary secretary for more than a quarter of a century. Similarly, he encouraged the formation of a local branch of the British Legion, being its president for many years, and for a time he was vice-president of the Legion's East Gloucestershire district. He was also an honorary life member of the British Red Cross Society and the first honorary treasurer of the Churchdown Nursing Association. He held the appointment, rare among rural practitioners, of honorary governor of St. Mary's, his old teaching hospital. He always followed the fortunes of the Gloucestershire Cricket Club with keen interest, particularly the performances of his nephew, Mr. D. N. Moore, the former Oxford captain, who also played for the county. A widower since 1930, Dr. Moore is survived by his younger son and a daughter, his elder son having been killed in action in Flanders in 1917.

Medico-Legal

DEATH FROM MERSALYL INJECTION

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In October, 1951, Albert William Howse, a warehouse manager, aged 43, was in the Maida Vale Hospital for Nervous Diseases for myelographic x-ray investigation for unexplained attacks of sciatica. While there he was given an intrathecal injection of mersalyl in error for "myodil," a lipoid iodine compound. At that time such injections were given in the wards, but subsequently they have been given in the theatre. Both drugs were made up in small capsules.

Mr. Howse was unconscious for five days after the injection, was completely paralysed for some time, and remained in hospital until March, 1954, when he was discharged

paralysed below the waist, but able to get about on two sticks. His bowel control was not good, and he was always left with residual urine causing recurrent infection.

In October, 1954, he was readmitted and a left nephrectomy was performed for stones. Efforts to preserve his right kidney were successful until March, 1955. On March 29 he was readmitted with an acute uraemia and pyelonephritis, which did not respond to antibiotics, and of which he died.

At the inquest held at the St. Pancras Coroners' Court on April 6 Dr. Arnold Levene, pathologist of University College Hospital, who carried out the necropsy, gave evidence that death was due to the urinary infection following the paraplegia caused by the intrathecal mersalyl injection nearly three and a half years before.

A verdict of accidental death was returned accordingly.

Medical Notes in Parliament

THE SALK VACCINE IN BRITAIN

THE MINISTER OF HEALTH made a statement to Parliament on April 25 about British intentions for the manufacture, testing, and use of the Salk vaccine for poliomyelitis. He said the whole House would wish to congratulate Dr. Salk on what was clearly a momentous and historic advance in the protection of human well-being. The Health Department and the Medical Research Council had been in close touch with these developments in the United States.

For our part, he continued, we shall go ahead with the increased production of the new vaccine in this country. Two important firms were already arranging to do this as fast as possible, and it was the Government's intention to ask these firms to sell to the Government their whole output, and in due course a Supplementary Estimate will have to be submitted to the House for that purpose. No supplies, in any material quantity, were at present obtainable from the United States. Home production should assume really useful dimensions by the late autumn, and he was advised that in any case it would be medically unwise—even if it were possible—to embark on any large-scale vaccination during the peak season of the disease, which began to end about then.

This new vaccine involved inoculating our children at repeated intervals with a preparation derived from the kidneys of dead monkeys. The House and the country will surely agree that they must carry out intensive tests as to the exact effects so that they could eliminate any possible dangers from it. They were already doing this. They must also make sure that it was effective against the particular strains of the virus most commonly found in this country; indeed, it was not sure yet that it was fully effective in the case of children of about 4 or under, where the incidence of the disease was highest in Britain, and it seemed it might be less than normally effective against Type I of the virus, the commonest type over here. But these reservations did not affect their determination that the people of this country shall benefit from it to the fullest possible extent.

Mr. WALTER ELLIOT (Glasgow, Kelvingrove, Con.) said the whole House would support the decision to have this tested before embarking on large-scale treatment of children. Mr. MACLEOD said that the question of research was one for the Lord President of the Council. He understood that the Medical Research Council was carrying out trials in Southend, Manchester, Sheffield, Belfast, and Glasgow.

Mr. G. DARLING (Sheffield, Hillsborough, Lab.) asked if it was the Minister's view that research should be encouraged in this country to find a more suitable vaccine for our circumstances. Mr. MACLEOD said: "Certainly. This is an important and exciting discovery. It is not necessarily the end of the story. Many people think a killed virus will not prove the most effective. Research on that and other matters is going on."

Mr. H. MARQUAND (Middlesbrough, East, Lab.) said the Opposition would be ready to support a Supplementary Estimate in view of the fact that this was being kept under Government control. He asked if by late autumn the tests would have reached such a stage that inoculation could begin. Mr. MACLEOD said that pilot batches of the vaccine were already available. One would hope that testing would have been finished by autumn, and that substantial quantities of the vaccine—it was difficult to estimate, but perhaps between 500 and 1,000 l.—would be available by the end of the year.

Lady TWEEDSMUIR (Aberdeen, South, Con.) asked if British vaccine would be available for the Commonwealth. Mr. MACLEOD told her that even though supplies were small the House would wish that some of our resources should be sent to other parts of the Commonwealth if required, even if only pilot batches in the first instance.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked why the Minister had decided that manufacture should be undertaken by two private firms instead of in national laboratories. Mr. MACLEOD said that he had not decided that. These two firms were going ahead, and it might be that other firms might take it up in due course. He could not think that the Ministry was centrally equipped to undertake the work.

Mr. R. FORT (Clitheroe, Con.) asked for an assurance that the programme would not be held up by a shortage of monkeys. Mr. MACLEOD replied that the major limiting factor for some time, unless a new medium could be discovered, might be a shortage of monkeys. They had taken action to make contact with the Government of India, and the M.R.C. had already sent representatives to Africa to study the possibility of further supplies from there.

Blood Tests for Motorists

Sir HUGH LUCAS-TOOTH, Under Secretary, Home Office, informed Mr. SOMERVILLE HASTINGS (Barking, Lab.) on April 21 that on no occasion last year did a motorist charged by the Metropolitan Police with being under the influence of drink while in charge of a car ask for a blood test. In one case samples of blood and urine were taken by a doctor called on behalf of a person who had been arrested for such an offence. Mr. HASTINGS suggested that this test, which had been largely used in other countries, might usefully be tried out here so that some idea could be obtained of its real value. At present its value seemed to be somewhat uncertain. Would the Minister make this test possible for those who applied for it? Sir HUGH LUCAS-TOOTH said that opinion about the value of blood tests was sharply divided.

Malaria Control in Hong Kong

Mr. LENNOX-BOYD, Secretary of State for the Colonies, replying to Mr. J. RANKIN (Glasgow, Tradeston, Lab.) on April 20, stated that there had been no reduction this year in the medical and health department estimates in Hong Kong. The total medical department estimates for 1955-6 showed an increase of 2m. dollars over 1954-5, and the malaria control vote showed an increase of 12,000 dollars. Mr. RANKIN asked that careful thought should be given to malaria control.

Lead Glazes in Pottery Making

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Education on April 21 whether he was aware that although raw lead glazes had been forbidden in the manufacture of pottery made in factories, and that specific restrictions applied to low-solubility glazes, there was no such control when pottery was made in schools or adult education classes. In view of the danger of lead-poisoning to teachers and children, he asked the Minister to ensure that all glazes should be of the leadless type. After 100 years of constant effort the pottery industry had

succeeded in getting rid of lead-poisoning. It seemed incredible that raw lead glazes and metallic poisons so dangerous to human beings should be creeping into schools and adult classes. Mr. D. VOSPER, the Parliamentary Secretary, said the Minister was grateful to Dr. Stross for bringing the question to his notice. He was looking into it.

Medical Attention in the Army

Mr. SOMERVILLE HASTINGS (Barking, Lab.) on April 19 asked the Secretary of State for War whether he was aware that on occasions non-commissioned officers refused to allow men in their charge to apply to a medical officer for examination or treatment; and what right of appeal the men had against such refusals. Mr. F. MACLEAN, the Under Secretary, replied that he was satisfied that, in general, no obstacle was put in the way of men wishing to report sick. Every soldier had a statutory right by s. 43 of the Army Act to make a complaint to his platoon or company commander in such a case.

Dentists' Remuneration

The MINISTER OF HEALTH stated on April 21 that he and the Secretary of State for Scotland, after a full investigation into earnings and practice expenses of dentists, had agreed with the British Dental Association on an increase in the present remuneration. The new scale would be designed to give dentists a net income comparable, having regard to the volume of work done, with what they would have received in the period covered by the investigation had the 10% reduction not then been in force. They had also agreed, as an interim measure while the new scale was being worked out, to cancel the 10% reduction in the present scale. It was estimated that the cost of these changes would be about £4.1m. in a full year.

Principals and Assistants

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, informed Mr. SOMERVILLE HASTINGS (Barking, Lab.) on April 25 that on July 1 last year 19,300 general practitioners were practising in the Health Service. Altogether 837 doctors practised single-handed, and 614 partnerships employed assistants other than trainees.

Mr. HASTINGS asked whether, in view of the exploitation of assistants by general practitioners under the Health Service Act which had occurred in certain cases, the Minister would limit the increased number on a list to a maximum of 1,500 when an assistant was employed. Miss HORNSBY-SMITH replied "No." The relationship of principals and their assistants could not readily be regulated by statute. In any event the Minister did not think that reducing by 500 the number of additional patients a principal with an assistant might accept on his list would have the effect Mr. Hastings seemed to anticipate.

Mr. HASTINGS said that many doctors had great difficulty in getting the necessary capital to start in practice, and were therefore liable to be exploited by those who employed them as assistants. The figures that had been given showed there was some evidence of that. What was the Minister going to do about it? Miss HORNSBY-SMITH replied that the number had been decreasing, and was not now unduly high. The matter had been considered by the British Medical Association and the Medical Practitioners' Union, but the Ministry had had no decision from them.

Mr. H. A. MARQUAND (Middlesbrough, East, Lab.) said there had been a definite promise by the profession that they would seek to reduce the number of assistants and increase the number of principals. Was the Parliamentary Secretary satisfied that the profession was giving real co-operation? Miss HORNSBY-SMITH said she thought they were co-operating where they felt there was hardship. There had been an increase in partnerships, and a reduction in the number of those who had spent a long period as assistants. Mr. HASTINGS said the B.M.A. were by no means happy about the situation.

Miss HORNSBY-SMITH also told Mr. Hastings that information was not available about the number of doctors or partnerships who had employed the same assistant for five or more years; but on July 1 last year 131 assistants were still in posts which they had taken up before July 1, 1949. Mr. HASTINGS described this as a very serious matter. The figures showed that doctors might derive a good deal of benefit from paying assistants to go on year after year. Miss HORNSBY-SMITH replied that the matter must be kept in proportion. There were 1,504 assistants in July, 1954, and of that number 131 had been in their posts since 1949. On the other side 320 assistants were taken into partnership during last year, and there was a steady increase in the trend towards partnerships.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following degrees were conferred in Congregation on March 5:

M.CHIR.—G. R. C. Peatfield.
M.B., B.CHIR.—G. Verbury, A. M. Freeman.
M.B.—Inez R. Aldous, R. J. C. Pearson, J. A. Dryden.

Professor O. L. Zangwill has been elected into a Professorial Fellowship of King's College.

In Congregation on March 19 the following degrees were conferred:

M.D.—J. R. Smythies, G. P. Blanshard, and R. Hodgkinson.
M.CHIR.—P. F. Boreham.

*By proxy.

UNIVERSITY OF LONDON

The degree of M.S. was awarded to D. J. Robertson on March 23. The degree of Ph.D. in the Faculty of Medicine was awarded to K. C. Basu Mallik on March 16 and to T. W. A. Glenister, M.B., B.S., and M. C. Lancaster on March 25.

UNIVERSITY OF BIRMINGHAM

Professor Solly Zuckerman, F.R.S., will represent the University at the sixth International Congress of Anatomy to be held in Paris in July, 1955.

The title of University Research Fellow in Anatomy has been given to Dr. A. B. Kar, of the Central Research Institute, Lucknow, and in Pathology to Dr. J. S. Howell, who is working for the Birmingham branch of the British Empire Cancer Campaign Committee, the title to be held during the tenure of their present posts.

Mr. A. J. H. Rains, Mr. P. G. Bevan, and Mr. G. Slaney have been appointed Lecturers in Surgery.

UNIVERSITY OF LIVERPOOL

Mr. C. H. de Boer has been appointed a part-time Assistant Lecturer in Clinical Obstetrics and Gynaecology.

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M.D.—R. Burwell (with distinction).
PH.D. IN MEDICINE.—R. S. Edmundson.
M.B., CH.B.—B. Dawson and M. S. Losowsky (both with second-class honours and distinction in surgery). J. D. Atwell, P. M. Binns, J. M. Challinor, Aileen A. R. Collinson, Patricia J. Corley, R. C. Cotton, A. D. Crew, D. W. Daly, D. De Souza, Jean McG. Exley, R. F. Folkes, Margaret E. Hall, B. McKibbin, Dorothy Mainwaring, D. B. Marshall, G. Mitchell, M. J. Oldroyd, J. F. Poppleton, Ethel A. Richardson, J. B. Richmond, June M. Roberts, Heather Sanderson, D. R. M. Stuart, P. H. Tattersall, C. M. Tonks, P. J. Truesdale, Evelyn Walker, Jean L. Ward, G. Warnes, D. A. Youdale.
DIPLOMA IN PUBLIC HEALTH.—R. Barnes, Mrs. Ruth M. Bowker, E. P. Griffiths, Diana J. Haiste, I. H. Lewis, J. P. Neylon, A. R. Robertson.
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—H. Ellett-Brown, D. McC. MacGregor, A. H. Moyes, N. C. Surya, R. W. Whiteley.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

On April 1 the following candidates were admitted to the Licence of Medicine and Midwifery of the College: C. M. Bahemia, M. J. Doyle, J. B. Fanibunda, M. H. Heller, J. S. P. MacGill, Cecilia M. McMorrow, B. M. Rosovske, Muriel M. Tynan.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 9 (No. 14) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

England and Wales in First Quarter

Deaths of children under 1 year of age numbered 4,824, giving a record low infant mortality rate for a March quarter of 29.0 per 1,000 related live births, compared with 31.0 in the first quarter of 1954 (the previous record). In 1938 the corresponding rate was 69.3. Live births numbered 169,361, giving a rate of 15.5 per 1,000 population. Comparable rates for the first quarters of 1954 and 1953 were 15.9 and 15.8. Deaths numbered 168,637, giving a rate of 15.4 per 1,000 population, compared with 14.0 in the first quarter of 1954 and 15.8 in the first quarter of 1953. 3,997 stillbirths were registered, giving a rate of 23.1 per 1,000 live and stillbirths, compared with 23.7 in the corresponding quarter of 1954. The rate for the first quarter of 1938 was 38.3.

Neonatal Mortality in 1954.—Deaths of infants aged under 4 weeks during 1954 numbered 11,944, giving a rate of 17.7 per 1,000 related live births. This is the same as in 1953 and is the lowest annual rate recorded.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ———, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

A large decline was recorded in the incidence of infectious diseases in England and Wales during the week ending April 9. The falls in the number of notifications included 5,491 for measles, from 32,324 to 26,833, 539 for whooping-cough, from 1,849 to 1,310, 415 for dysentery, from 1,869 to 1,454, 178 for acute pneumonia, from 1,050 to 872, and 157 for scarlet fever, from 822 to 665.

The largest falls in the incidence of measles were 1,014 in London, from 4,103 to 3,089, 551 in Lancashire, from 1,849 to 1,298, 468 in Essex, from 2,157 to 1,689, 375 in Kent, from 1,223 to 848, 339 in Surrey, from 1,291 to 952, 322 in Derbyshire, from 1,070 to 748, 308 in Yorkshire West Riding, from 4,115 to 3,807, 293 in Middlesex, from 1,998 to 1,705, 258 in Durham, from 998 to 740, 238 in Cheshire, from 812 to 574, 207 in Warwickshire, from 3,406 to 3,199, 201 in Northumberland, from 846 to 645. The only fall of any size in the trends of scarlet fever was 26 in Lancashire, from 119 to 93. The largest declines in the number of notifications of whooping-cough were 94 in Warwickshire, from 130 to 36, and 81 in London, from 156 to 75. 5 cases of diphtheria were notified, being 4 fewer than in the preceding week; 3 of these cases were notified in Liverpool C.B.

9 of the 13 cases of paratyphoid fever were notified in Lincolnshire (Sleaford U.D. 7, Bourne U.D. 2).

7 cases of acute poliomyelitis were notified, and these were 2 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. No area had more than one case.

The largest returns of dysentery were Lancashire 479 (Oldham C.B. 117, Manchester C.B. 62, Blackpool C.B. 55, Blackburn C.B. 37, St. Helens C.B. 29, Liverpool C.B. 28, Royton U.D. 22, Chadderton U.D. 21, Salford C.B. 18, Middleton M.B. 16, Lytham St. Anne's M.B. 10), Durham 224 (Easington R.D. 71, Seaham U.D. 54, Felling U.D. 25, Gateshead C.B. 23, South Shields C.B. 22), London 97 (Hackney 23, Shoreditch 23, Islington 17, Camberwell 11), Yorkshire West Riding 92 (Leeds C.B. 44, Huddersfield C.B. 14), Northumberland 90 (Bedlingtonshire U.D. 22, Newcastle-upon-Tyne C.B. 14, Blyth M.B. 13, Ashington U.D. 12,

Newburn U.D. 10), Leicestershire 60 (Leicester C.B. 49), Norfolk 52 (Norwich C.B. 27), Surrey 43 (Banstead U.D. 15, Woking U.D. 15), Yorkshire North Riding 39 (Middlesbrough C.B. 35), Cheshire 36 (Stockport C.B. 25), Warwickshire 34 (Nuneaton M.B. 30), Glamorganshire 23 (Cardiff C.B. 14, Swansea C.B. 9), and Middlesex 20.

Venereal Diseases

In England and Wales during the quarter ending December 31, 1954, 1,360 new cases of syphilis were reported as attending the clinics. Of these 187 were classified as primary, secondary, or latent in the first year of infection. 16 cases of congenital syphilis in children aged under 1 year were reported, and 141 cases in persons over that age. New cases of gonorrhoea numbered 4,419, of chancroid 75, and of non-gonococcal urethritis (males only), 3,374.—*Monthly Bulletin of the Ministry of Health*, April, 1955.

Week Ending April 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 597, whooping-cough 1,474, diphtheria 7, measles 32,969, acute pneumonia 804, acute poliomyelitis 20, dysentery 1,191, paratyphoid fever 2, and typhoid fever 2.

Medical News

British Trial of Poliomyelitis Vaccine.—As announced by the Minister of Health in Parliament this week (see p. 1099), there are now sufficient supplies of home-produced poliomyelitis vaccine for a small clinical trial of the vaccine to start in Britain. The centres will be London (St. George's Hospital Group and Southend), Manchester, Sheffield, Glasgow, and Belfast. The arrangements for the trial, due to begin next month, are local, but an M.R.C. committee is co-ordinating the work of the various centres. At each centre, it is understood, two batches of vaccine will be tested, each on 100 to 200 children between the ages of 1 and 12 years. The size of the trial is too small to allow a useful appraisal of the clinical protection afforded by the vaccines: the object is simply to study the antibody response to the three inoculations the children will receive. It is therefore important that those included in the trial should have little or no previous natural immunity to any of the three types of poliomyelitis virus. To check this, antibody titres will be estimated before any child is accepted for the trials; then, if little or no immunity is found, three injections of vaccine will be given, probably the second injection one week after the first, and the third four weeks after that. At the time of the second inoculation the antibody status will again be checked, and the final blood sample taken two weeks after the last inoculation. This will give the immediate antibody response to inoculation. It is possible that later studies of the antibody levels will also be made. Each centre is based on a virus laboratory. The speed and scope of the trials are likely to be governed partly by the availability of non-immune children, partly by vaccine supplies, and partly by the numbers of monkeys available to the laboratories. All parents will be fully informed about the trial beforehand, and only volunteers taken. In view of the nature of the trial no dummy vaccine will be needed for control purposes.

Association of British Pharmaceutical Industry.—The annual dinner was held at the Dorchester Hotel on April 20, and Sir RUSSELL BRAIN, President of the Royal College of Physicians, proposed the toast to the pharmaceutical industry. He spoke of the debt owed by the medical profession to the industry—for the magnificent research which all hoped would increase and prosper; for the day-to-day services provided for the medical profession; and for the kindnesses received by individual doctors and never-failing help to the profession as a whole. The pharma-

ceutical industry, he emphasized, had the full backing of the medical profession. Mr. J. F. BOUCHER, President of the Association of British Pharmaceutical Industry, proposing the health of the guests, paid a tribute to the research done in university departments and research institutes—work which helped to lay the foundations for new drugs. Referring to pharmaceutical exports, Mr. Boucher said the efforts of the industry were phenomenal considering its size: out of a total annual production worth £120m., no less than £33m. worth of drugs was exported. Replying to the toast, Professor A. ROBERTSON, President of the British Veterinary Association, spoke in lighter vein with overwhelming success.

British Association of Physical Medicine.—The annual dinner was held on April 22 at the Royal College of Surgeons, with Lord HORDER presiding. In proposing the main toast of the evening, Sir JOHN CHARLES, Chief Medical Officer to the Ministry of Health, spoke of the importance of physical medicine in helping to reduce the costs of medical care: it encouraged the patient's recovery and early return to work—for which there was reduced incentive these days. Rehabilitation should be an integral part of all medical practice. "The march of science has varied your armamentarium," Sir John concluded. "Every man is a potential claimant for your skill." Lord HORDER, in reply, emphasized that physical medicine should infiltrate the general practice of medicine much earlier and more deeply than hitherto—long before the point at which rehabilitation began. Physical medicine was not concerned only with certain residues in the population. The British Association of Physical Medicine should have the onus of determining the criteria on which consultant status in physical medicine should be based. Lord Horder added, "I think one of the criteria should be the diploma in physical medicine." Sir WILLIAM GILLIATT responded to Dr. HUGH BURT's genial speech of welcome to the guests, and made the point that specialists in different branches of medicine often knew all too little about the work of their colleagues in different fields. He recommended, particularly for the older man, a visit to a modern department of physical medicine so as to see the work in progress.

New Antibiotic.—A letter to *Nature* (April 23, p. 722) from Dr. A. T. FULLER of the National Institute for Medical Research, Mill Hill, reports the successful trial of a new antibiotic against haemolytic streptococcal infections in mice. The report says that larger quantities are now being prepared for therapeutic and chemical investigation. The antibiotic is derived from a spore-bearing bacillus isolated from soil from East Africa. It is non-toxic and inhibits *in vitro* the growth of *Staph. aureus*, *Pasteurella muriseptica*, and *Str. haemolyticus* (Group A) in dilutions, respectively, of 1 in 20, 1 in 50, and 1 in 18 millions.

Opening of Rheumatism Research Unit in Edinburgh.—On April 23 Commander T. D. GALBRAITH, Minister of State for Scotland, opened new buildings to extend the Rheumatic Diseases Research Unit, directed by Dr. J. J. R. DUTHIE, at the Northern General Hospital, Edinburgh. The cost of the buildings (£27,000) has been provided by the Nuffield Foundation from the Oliver Bird Fund, a fund of some £450,000 established by the gift of Captain Oliver Bird for research on the prevention and treatment of rheumatism. In addition, since 1949 the Nuffield Foundation has given £12,000 in grants from the Oliver Bird Fund to support the Unit, and has promised a further £38,000 to meet its running costs during the next five years. The new buildings, which are close to the existing rheumatism beds in the main hospital block, consist of two single-storied units linked by an all-glass entrance hall. They provide accommodation for six consulting-rooms, treatment rooms, laboratories, an animal house, offices, and a conference room. Captain OLIVER BIRD, who is himself severely crippled, was present at the opening ceremony, which was presided over by the chairman of the Managing Trustees of the Nuffield Foundation, the hon. GEOFFREY C. GIBBS.

U.K. Delegation to World Health Assembly.—The United Kingdom delegates and advisers to the eighth World Health Assembly, which opens in Mexico City on May 10, will be: Sir JOHN CHARLES, Chief Medical Officer, Ministry of Health; Sir ERIC PRIDIE, Chief Medical Officer, Colonial Office; Mr. W. H. BOUCHER, Ministry of Health; Mr. J. F. HUNT, Ministry of Health; Dr. M. T. MORGAN, Ministry of Transport and Civil Aviation; Mr. A. E. JOLL, General Register Office; Mr. H. T. MORGAN, H.M. Embassy, Mexico City; Dr. A. A. PEAT, Director of Medical Services, Trinidad; and Dr. J. W. P. HARKNESS, Medical Adviser to the Development and Welfare Organization, West Indies.

Central Midwives Board.—On April 1 a new Board took office for the three-year period until March 31, 1958. At the first meeting, on April 14, Mr. ARNOLD WALKER was elected chairman and Professor A. A. MONCRIEFF deputy chairman. The members of the new Board are: Miss G. M. GODDEN, Dr. I. G. INNES, Mr. G. T. MILNE, Dr. J. A. SCOTT, Miss V. R. SHAND, and Mr. ARNOLD WALKER (appointed by the Ministry of Health); Professor A. A. MONCRIEFF (appointed by the Royal College of Physicians); Professor A. M. CLAYE (appointed by the Royal College of Surgeons); Mr. VICTOR LACK (appointed by the Royal College of Obstetricians and Gynaecologists); Dr. JEAN MACKINTOSH (appointed by the Society of Medical Officers of Health); Miss E. K. BALLY, Miss M. I. FARRER, Miss E. J. MERRY, and Miss M. WILLIAMS (appointed by the Royal College of Midwives); Dr. A. ELLIOTT (appointed by the County Councils Association); and Professor F. E. TYLECOTE (appointed by the Association of Municipal Corporations).

Conference on Psychosomatic Research.—The first European Conference on Psychosomatic Research was held at the Maudsley Hospital on April 22 and 23. Workers from Belgium, Denmark, Finland, France, the Netherlands, Portugal, Spain, Germany, and the United Kingdom attended. It was decided to hold a further meeting in 1956 in Amsterdam. Details of the programme will be announced later.

Honorary Degrees at Glasgow.—At the Commemoration Day celebration on June 21 the honorary degree of LL.D. will be conferred on Dr. R. A. LENNIE, formerly Regius Professor of Midwifery at Glasgow University, and on Professor R. T. LEIPER, F.R.S., Professor Emeritus of Helminthology, London University.

Consultant Pathologist to the Army.—Professor R. J. V. PULVERTAFT, professor of clinical pathology at Westminster Hospital Medical School, has succeeded Professor GEOFFREY HADFIELD as honorary consultant in pathology to the Army at Home.

"Family Doctor."—The May issue, which includes an article by Dr. F. H. K. GREEN on the work of the Medical Research Council, is now available. Among the medical subjects discussed are "Anxiety" (Dr. F. R. C. CASSON) and "Caesarean Births" (Professor J. C. McCLEURE BROWNE).

COMING EVENTS

Institute of Dermatology.—Exhibition on "Cutaneous Reactions Associated with Visceral Malignancy," May 5–25.

Royal Society of Medicine.—150th anniversary dinner at the Dorchester Hotel, London, on June 7. Single ticket 45s. (excluding wines).

Royal Free Hospital Ball.—On June 10 at the Park Lane Hotel, London. Double tickets (including refreshments) £2 15s.

Croonian Lecture.—Professor C. H. BEST, F.R.S., of Toronto University, will deliver this year's Croonian Lecture to the Royal Society, London, on June 16. His subject is "Dietary Factors in the Protection of the Liver, Kidneys, Heart, and Other Organs in Experimental Animals—the Lipotropic Agents."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, April 30

ASSOCIATION OF CLINICAL BIOCHEMISTS (SOUTHERN REGION).—At Radcliffe Infirmary, Oxford, 2 p.m., meeting. Scientific papers.

Monday, May 2

EDINBURGH UNIVERSITY.—At West Lecture Theatre, University New Buildings, 5 p.m., Dr. D. J. Guthrie: Magic, Witchcraft, and Medicine.

Tuesday, May 3

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. Bronson Crothers (Boston, Mass.): Methods of Neurological Appraisal in Childhood.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. F. R. Bettley: Eczema-Asthma Syndrome.

OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, Oxford, 8.15 p.m., Dr. J. Tarsh: The Negligent Doctor.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Croonian Lecture by Sir Horace Evans: Significance of Certain Symptoms and Signs in Disease of the Kidneys.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Dr. M. Grace Eggleston: Tubular Reabsorption and Secretion.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. I. R. McCaul: Intracranial Aneurysm.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Altmouth Wright Lecture by Sir Zachary Cope: Some Peculiarities of the Clinical Pathology of Actinomyces.

Wednesday, May 4

EUGENICS SOCIETY.—At 26, Portland Place, W., 5 p.m., Galfon Lecture by Sir Cyril Burt, D.Sc.: Meaning and Assessment of Intelligence.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Disinfection and Sterilization.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor B. G. Macgregor: On the Importance of Having a Circulation.

ST. MARKLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. Colman Kenton: Management of the Psychiatric Emergency.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., lecture-demonstration in psychiatry by Dr. J. A. Hobson.

Thursday, May 5

● FACULTY OF HOMOEOPATHY.—At the Barnes Hall, Royal Society of Medicine, 3 p.m., Hahnemann's 200th Birthday Celebration. Oration by Dr. F. H. Bodman: Hahnemann and His Patients; Dr. T. D. Ross: Homoeopathy's Heritage and Outlook To-day.

HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Mr. E. L. Farquharson: Early Ambulation and its Contribution to Surgery.

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. Bronson Crothers (U.S.A.): Adaptation of the Patient and the Family in Cases with Severe Extrapyramidal Disturbance in Cerebral Palsy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Croonian Lecture by Sir Horace Evans: Significance of Certain Symptoms and Signs in Disease of the Kidneys.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Sir Clement Price Thomas: Some Aspects of Suppurative Disease of the Lungs.

ST. ANDREW'S UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. A. H. T. Robb-Smith: Extracellular Tissue in Health and Disease.

Friday, May 6

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. T. Brain: Skin Diseases in Children.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.

NEWCASTLE REGIONAL CHEST SURGERY CENTRE.—At New Lecture Theatre, Royal Victoria Infirmary, Newcastle-upon-Tyne, 5.30 p.m., 15th Rutherford Morison Lecture by Professor C. Crafoord (Stockholm): Diagnosis and Surgical Treatment of Inter-Atrial Septal Defects. (Illustrated by a film.)

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. Reginald Lightwood: Care of the Premature Baby.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Professor F. R. Winton: Physical Factors Affecting Renal Function.

Saturday, May 7

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—12 noon, special lecture by Professor Fritz Zöllner: Diagnosis and Treatment of Tympano-sclerosis.

WEST MIDLANDS PHYSICIANS ASSOCIATION.—At Warneford General Hospital, Leamington Spa, 11 a.m., spring meeting.

Sunday, May 8

SIGERIST SOCIETY.—At 45, Russell Square, W.C., 3 p.m., debate between Dr. Stephen Taylor and Dr. Hugh Faulkner: Health Centres and the Future of General Practice.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crawford.—On April 8, 1955, to Jeanne, wife of Dr. I. B. Crawford, a brother for Belinda Jane—Steven Andrew.

Dunn.—On April 18, 1955, at Birmingham Maternity Hospital, to Sylvia (formerly Matheson), M.B., B.S., wife of Andrew Dunn, L.D.S., Flight Lieutenant, R.A.F., a daughter—Ailsa Margaret.

Hetherington.—On April 17, 1955, at St. Mary's Hospital, Manchester, to Pamela Marjorie (formerly Baird) and Dr. Harold Dudley Grindley Hetherington, a son—Hugh Vincent Grindley.

McEwen.—On April 18, 1955, at Redlands Hospital, Glasgow, to Dr. Jean (formerly Mann), wife of Dr. Malcolm McEwen, twin sisters for Alasdair—Fiona and Morna.

Tasker.—On April 14, 1955, at Northampton, to Anita, wife of Dr. J. R. Tasker, a daughter.

DEATHS

Moore.—On April 8, 1955, at Pigeons Green, Platt, Borough Green, Kent, Reginald Devereux Moore, M.C., L.S.A., L.M.S.S.A., formerly of Churchdown, Cheltenham, Glos, aged 88.

Any Questions ?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Appendicitis at Sea

Q.—How should a single-handed ship surgeon deal with acute appendicitis?

A.—The management of appendicitis by a single-handed ship surgeon would depend very much upon circumstances—for example, if the ship is in port, or if there is a surgeon among the ship's passengers, it would be easy for him to arrange an immediate consultation or operation. A decision to treat appendicitis conservatively in the first 48 hours of the disease must always involve some risk that the peritonitis will spread. This risk is commonly, and I think correctly, regarded as greater in children, undernourished adults, and old people than it is in healthy adults. An age limit below which the risk is prohibitive cannot be stated. In every case the risk of operation performed by an unskilled single-handed practitioner.

The question suggests that the ship is some distance from port, and that professional help is not available. Under such circumstances the patient should be kept propped up in bed, without food or fluid by the mouth, and should be given repeated small doses of morphine—1/6 gr. (10 mg.) four hourly for a previously healthy adult. Morphine may be used in the conservative method of treatment at any age provided the dose is carefully regulated, the most important evidence of over-dosage being slowing of the respiratory rate. Between the ages of 1 and 3 years the dose of morphine sulphate is from 1/48–1/24 gr. (1–2.5 mg.); between 3 and 6 years 1/24–1/12 gr. (2.5–5 mg.); between 6 and 12 years 1/12–1/6 gr. (5–10 mg.). Water should be administered by rectal drip, a small quantity of salt (to make a solution of 0.18% NaCl) being added if the patient is sweating; by this method he may be kept sufficiently hydrated until signs and symptoms indicate that feeding may be commenced by the mouth. Though I do not regard antibiotics as an essential element in the conservative regime, intramuscular injections of penicillin and streptomycin are generally regarded as being of value in combating such an intestinal infection, and could be given during the period when nothing is allowed by the mouth.

Under this treatment the attack is likely to subside completely; or an abscess may form in the neighbourhood of the appendix which may rupture into the bowel, or may require simple drainage. On most voyages this operation can be delayed till port is reached, but if it became a matter of necessity it could be undertaken with very little skilled assistance.

Toxic Dose of Methylpentynol

Q.—A patient is to my knowledge obtaining seventy-five 250-mg. capsules of methylpentynol a week. What are the immediate and long-term dangers of excessive dosage? Does addiction occur? What control is there over the dispensing of the drug?

A.—The patient is obtaining a total of 18.75 g. of methylpentynol a week, and therefore takes from 2.5 to 3 g. each day. Doses up to 2 g. a day have been taken for long periods without harm, but doses above 4 g. daily may be toxic, and 10 g. a day has caused severe poisoning. In one case death may have been caused by an amount between 4 and 6 g.

Toxic symptoms disappear completely within 48 hours after discontinuing the drug. May and Ebaugh¹ say that the total dose in 24 hours should be kept below 5 g., and

that toxic effects are likely to develop if doses between 5 and 6 g. are given for more than two or three days.

The Council of the Pharmaceutical Society has advised pharmacists not to supply methylpentynol without a doctor's prescription (July 31, 1954), but a recent letter to the medical press² states that the drug is still widely used without a prescription. Neurotic patients and alcoholics often take excessive amounts which produce a confused and highly emotional state with slurring of speech and ataxic gait, but there is no evidence of true addiction. In a case described by Schaffarzick and Brown³ methylpentynol was given as an anticonvulsant in epilepsy for six weeks; this resulted in impaired liver function as shown by a positive cephalin flocculation test.

Mumps in Early Pregnancy

Q.—What increased risk is there of a deformed or blind baby following mumps in the early months of pregnancy? What is the generally accepted attitude to-day towards termination of pregnancy in such a case?

A.—Foetal malformation, abortion, intrauterine death, and premature labour are ascribed to mumps as well as to other virus diseases, provided they occur within the first 12 weeks of pregnancy. The situation in regard to rubella is fairly well established and is not considered here. In regard to other virus infections the number of cases in individual reports is small and the evidence is not of statistical significance. A review of the literature on this subject was published by B. M. Kaye, D. C. Rösner, and I. F. Stein,¹ and they concluded that there is a 20% risk of foetal malformation among mothers contracting virus diseases other than rubella in the first trimester of pregnancy. When they considered mumps alone the risk was similar. So far as this country is concerned there is as yet no evidence which permits a firm conclusion that mumps is a cause of foetal malformation.

Even if it is believed that mumps can impair foetal development it still remains doubtful whether it constitutes an indication for therapeutic abortion. As the law stands in this country abortion is not justified in the interests of the foetus, but only in the interests of the mother. There might be an indication if the expectation of foetal malformation were so high as to cause the mother such anxiety as to threaten her health, but each case would have to be judged separately.

Myoclonus on Falling Asleep

Q.—What is the likely cause, significance, and treatment in a woman of 55 of kicking and twitching movements of the legs on falling asleep? They go on for half an hour to an hour. There have been no painful cramps in the legs. Treatment with sodium phenobarbitone 1 gr. (65 mg.) at night has not been very successful in controlling them.

A.—The condition of myoclonus occurring as a person is falling asleep is one of the hypnagogic experiences that are common in normal people. These may also take the form of visual or auditory hallucinations, and the experience may sometimes be multisensorial, so that a loud bang is both heard and felt. These phenomena usually occur only once and then the person falls asleep. At times, and particularly during stress or as an accompaniment of a neurosis, they may be repetitive and totally prevent sleep.

These disturbances of the central nervous system are not epileptic in nature but fall into the group of disorders of which narcolepsy, cataplexy, and sleep paralysis are components. They are most difficult to treat apart from the relief of the overlying nervous state, and I usually give a large dose of a short-acting barbiturate half an hour before the patient intends to retire so that sleep rapidly supervenes. Once the patient is asleep, he is safe from the myoclonus.

Sulphone Poisoning

Q.—What are the symptoms of poisoning by swallowing an overdose of one of the sulphone group of drugs? Is there any specific antidote? Apart from the usual emergency measures of giving emetics and gastric lavage, what should be the general treatment of such a case?

A.—The symptoms of sulphone toxæmia are varied. The chief toxic effects are anaemia, dermatitis, hepatitis, and psychosis.

Anaemia is detected in the usual way, but it must be remembered that the anaemia which is produced by sulphone therapy, particularly by the oral administration of the tablets, may be very sudden, and therefore if the weekly dose is above 800 mg. a week regular haemoglobin estimations should be done at least every fortnight. With lower doses this is not so necessary. In any case it is wise to combine oral sulphone with iron in some form or other and also with a preparation of vitamin B complex. If anaemia is severe, sulphone therapy must be stopped at once. If it is not severe and there is only a comparatively small drop in the haemoglobin index, the sulphone doses should be reduced and iron and vitamin B complex should be supplemented.

Dermatitis starts as a general itchiness of the skin, followed by a slight scaling. Sometimes there are rashes which are usually papular. If this is not noticed the condition may go on to an exfoliative dermatitis and the patient becomes seriously ill and his life endangered. On any symptom of itchiness or irritation of the skin, particularly if there is any observable lesion noticed, sulphone should be stopped at once and antihistamines given. In very severe dermatitis, where the patient's life is in balance, cortisone has been a life-saving measure, but this must be used very cautiously and with due consideration to all the other factors.

The first symptom of hepatitis is usually that the patient feels unwell and is unable to take his food. There is also nausea. If the hepatitis goes on to the more severe forms, urobilin appears in the urine and there may be liver tenderness and actual jaundice. The remedy is to stop sulphones at once and treat as for any acute hepatitis due to a toxin.

Psychosis is not common, but it starts with sleeplessness, and if a patient who is taking sulphone is complaining of sleeplessness then sulphones should be stopped and sedatives given.

Once there have been any manifestations of a severe toxæmia due to sulphone therapy D.D.S. orally should be stopped, and personally I prefer the patient to receive a 50% solution of solapson ("sulphetron") parenterally, starting at 0.25 ml. once a fortnight and increasing by 0.25 ml. each fortnight until 1 ml. a fortnight is reached. Then increase by 1 ml. at monthly intervals until 3 ml. twice a week is given. Solapson should not be given by mouth, as it is expensive and is only broken down to the parent substance. Solapson when injected as the 50% solution is broken down to a mono-substituted sulphone, and therefore is not so toxic as the mother substance.

There is no antidote for sulphone poisoning so far as I know. It should be treated on general lines with eliminative treatment and stoppage of the drug. The golden rule in sulphone therapy is to remember to start at a very low dose and increase very gradually. The optimum dose is about 400 mg. twice a week, and ordinarily should not be exceeded.

Effects of Prolonged Thyroid Administration

Q.—I often find that depressed elderly women are helped by small regular doses of thyroid. How rapidly is thyroid metabolized in the body? Is there any danger of depressing pituitary thyrotrophic activity after prolonged dosage, with consequent rebound phenomena on withdrawing treatment?

A.—The duration of action of a single dose of thyroid hormone occupies a period of 50 to 70 days, this being the

time taken for the metabolism and complete elimination of the hormone. Since the patients in question are benefited by small doses of thyroid, it may be concluded that they are slightly hypothyroid. The small doses given will therefore replace the amount in which they are deficient, bringing the blood thyroxine up to the normal level. This will cause depression of pituitary thyrotrophic activity to normal limits, for prior to the administration of thyroid the secretion of thyrotrophin would have been somewhat increased as a result of the lowered blood level of thyroxine. If too large a dose of thyroid is given abnormal depression of thyrotrophic secretion will take place and the patient's thyroid gland will produce correspondingly less thyroid hormone. In these circumstances sudden withdrawal of thyroid after a prolonged period of administration will result in a temporary increase in the hypothyroidism.

Risk of Fire During Oxygen Therapy

Q.—Is there any danger of explosion or fire when oxygen is administered by means of the usual sort of equipment to a patient at his home or in a hospital ward?

A.—Oxygen itself does not burn, but in its presence any inflammable object burns more readily and with more vigour. Oxygen therapy should therefore not be conducted in the presence of any source of ignition. Smoking, open fires, gas rings, and so forth should all be prohibited in a room where oxygen therapy is being administered. A spark from a cigarette or fire, in the presence of oxygen, might easily set fire to bedclothes or to the material of an oxygen tent. It is a wise precaution to exhibit a notice, such as "Danger—Fire. Smoking Forbidden," in the vicinity of a patient receiving oxygen therapy.

NOTES AND COMMENTS

Prognosis and Treatment of Asthma in Children.—Mr. T. S. ALLEN (Hove) writes: In answering this question ("Any Questions?" March 26, p. 801) your expert did not comment upon one very important point in the history: this child had whooping-cough at the age of 2. He should certainly be seen by an otolaryngologist, since chronic tonsil sepsis is an almost invariable legacy of whooping-cough in early life.

OUR EXPERT writes: Although it is not my experience that there is an invariable relationship between whooping-cough and tonsil sepsis in early life, the answer included the suggestion (to a doctor regarding his son) that "the advice of an ear, nose, and throat specialist might be obtained." The role of whooping-cough as a causative factor in asthma has long been the subject of conjecture and controversy. In a study of 250 asthmatics and 250 controls the writer (with colleagues) found a previous history of whooping-cough in 80 (32%) of the asthmatics and 73 (29%) of the controls. The controls were matched for age and sex and were questioned regarding illnesses they had experienced before the date of onset of asthma for the patient with whom each was matched. There appears to be no significant difference.

Correction.—Dr. Jonas E. Salk and his staff developed the poliomyelitis vaccine at the University of Pittsburgh, not Michigan (*Journal*, April 23, p. 1016).

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Ailology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. SOME PROBLEMS IN THE STUDY OF CANCER IN MAN

BY

Sir ERNEST KENNAWAY, D.M., D.Sc., F.R.C.P., F.R.S.

From the Department of Pathology, St. Bartholomew's Hospital, London

Cancer research is now unavoidably divided into two sections: (a) *fundamental*, which looks for an answer to the question "Why, and how, does a cell divide?"; and (b) *empirical*, which seeks to identify carcinogenic factors which we can avoid. The first of these has passed wholly into the field of physics and chemistry and requires the most refined methods, both technical and theoretical, of those subjects. To many persons, distressed by the mortality from cancer, progress may seem very slow, but they should remember that the full application of biophysics to the problem is of very recent growth, and that whole areas of knowledge which we do not yet possess may be required for success. No doubt Wellington could have saved a great number of British lives at Waterloo by the discreet use of an atomic bomb of very modest dimensions before the armies engaged, but the requisite technique simply did not exist.

The present paper brings together some of those questions in purely empirical cancer research which seem to be ready for further inquiry. However anxious we may be to simplify the problem of cancer, we must recognize that it is inherently complex because the animal body itself is complex. Even when a reasonably satisfactory answer can be given to the fundamental question "Why, and how, does a cell divide?" the application of this knowledge to the very peculiar distribution of cancer by sex and organ must present many problems.

Cancer of the Cervix and Circumcision

The view is now advocated that the association between cancer of the cervix and non-circumcision of the male (Wynder *et al.*, 1954; Wynder, 1955) is due to transference of carcinogenic smegma in the act of intercourse, a process which would be identical in nature with a mouse-painting experiment. Whatever one may think of the likelihood of this explanation, it certainly offers a remarkable instance of the specificity of carcinogens for different tissues. In England and Wales in 1945 there were 4,039 deaths attributed to cancer of the uterus other than of the corpus; if any large fraction of these was due to application of smegma it is remarkable that in the males, where the contact of this material with the epithelium is intimate and continuous, there were only 132 deaths from cancer of the penis, though some other cases may have been cured by surgery.

A causal connexion between cancer of the cervix and non-circumcision was suggested first by W. Sampson Handley (1936), who wrote of "marital infection with the sub-preputial flora" and seemed to think of this factor as sufficient in itself and as already proved. Such certainty is quite unwarranted, because we do not know (1) that the

vaginal flora is in fact altered, although this question is quite accessible to investigation; or (2) whether any such alteration is pro- or anti-carcinogenic.

The use of a condom protects the cervix from any transfer of carcinogenic material from the male more effectually than does any other method, and in theory provides the ideal experiment for settling this question, but actually it is difficult to ascertain the constancy of the practice over a number of years.

Cancer of the Cervix in Jewish Women

The low incidence of cancer of the cervix in Jewish women is established by a number of investigations. The literature up to 1947 was summarized (Kennaway, 1948) and much confirmatory material has been published since then (Wynder *et al.*, 1954).

Various possible explanations have been suggested, of which one is the Jewish law relating to menstruation. A section (Niddah) of the Talmud, consisting of 10 chapters, forbids coitus during the flow, and for not less than five days, and for seven days afterwards, hence the whole period of abstention is $n+7$ days and n is never less than 5. Under normal conditions, abstention for 12 days would allow resumption near the time of ovulation, of which process those who laid down this rule of course knew nothing (for further details see Kennaway, 1948).

To assume that the law of Niddah is, for all practical purposes, obsolete, is easy, and this solution of the question is often put forward and sometimes seems to be welcome. But such matters of purely private conduct need very careful inquiry. The lack of any adequate investigation from Jewish sources is perhaps not very surprising. To the orthodox believer all such laws are the direct expression of God's wisdom, and human approval or disapproval of them is wholly irrelevant, while to one of the modern school they are elements of a primitive religion with which he may not wish to be associated. But any attempt to gain from this source more knowledge is surely in no way inconsistent with the belief that the practice is of Divine institution. All recent work upon cancer of the cervix (the literature is reviewed by Wynder *et al.*, 1954) indicates that marriage, apart from child-bearing, and especially early marriage, increases the liability, while the celibate life of nuns (Gagnon, 1950) gives protection. By "marriage" in this sense one means, not any civil or religious state, but coitus. Between these two extreme conditions of early marriage and virginity there is surely the bare possibility that the partial abstention enjoined by the law of Niddah gives partial immunity. At any rate, the question is worth investigation; and why can it not be settled one way or the other in the next year or two?

Any idea that the law of Niddah is now an almost forgotten matter, of merely antiquarian interest, is simply

untrue. In London, at any rate, a Jewish girl whose engagement is announced in the Press receives from one or other of certain Jewish societies a simple, practical, and forcible statement of the law, and often this is her first acquaintance with it. How far these instructions are obeyed is of course another matter altogether, but those to whom they are of most concern cannot be ignorant of them even here at the present day.

There are at least two methods of investigating this question—namely, to ascertain (1) the proportion of women who obey any part of the relevant law in a Jewish community in which the incidence of cancer of the cervix can be ascertained, but the inquiry about obedience to the law must be a genuine one, not mixed up with any assumptions or general impressions; (2) the personal history of any Jewish woman who develops cancer of the cervix. This would appear to be the simplest and quickest method of approach, because the results in, say, a dozen cases might show whether this line was worth following, although such a number would be considered quite inadequate statistically. This method has been applied by Wynder *et al.* (1954), who obtained the following result (Table I).

TABLE I.—Observance of Talmudic Law in 20 Cases of Cancer of the Cervix in Jewish Women (Wynder *et al.*)

	Days' Abstinence after Menses
Class A: In 10 women	0
" B: " 5 "	5, 4, 3, 3, 2
" C: " 5 "	7

One may suggest that the value of these 20 cases as evidence is not uniform. Of the 10 women who practised no abstinence, 7 had intercourse with more than one partner, and hence one can believe that they were not scrupulous in obeying any part of the Talmudic law; whether the statements of the 5 women of Class C, that they observed the seven-days rule, are equally convincing, may be a matter of opinion. All the women in C and 3 of the 5 in Class B had one partner only. Wynder *et al.* (1954) ignore this aspect of the matter altogether and discuss only the data relating to age and circumcision, while Wynder (1955), in his most recent paper, says, without quoting any tabulated data, "Twenty Jewish cervical cancer cases do not suffice for statistical comparison, but they seem to be in line with the controls. Five of the 20 patients in this group did not abstain after menses." He does not explain the reduction from 10 to 5 of the non-abstaining cases. The relevant passage in his summary, "The abstinence period practised by orthodox Jewish women after the end of menses is not believed to be the basic factor accounting for the low incidence of cervical cancer among Jewish women," does not encourage further investigation.

Table I certainly indicates that further inquiry is very desirable. After all, one may not get a quite clear-cut result because all cases of cancer of the cervix may not have the same cause, just as all cases of cancer of the lung are not due to smoking. In any case, this one series of 20 cases cannot be held to settle the matter, and material for further inquiry must be available in Jewish practice in London. In both inquiries, (1) and (2) above, the truthfulness of the replies is, of course, vital, and it is therefore all-important that the women should not regard the questions as a moral inquisition. Probably the best interviewer would be a Jewish woman doctor.

Cancer of the Lung in Non-smokers

This process is of great importance as the background upon which the effects of smoking are superimposed. The number of deaths in both sexes attributed to cancer of the lung in England and Wales annually is now about 15,000. Doll (1953) considers that about one-fifth of these deaths—that is, about 3,000—are not due to tobacco. The consumption of tobacco, especially in the form of cigarettes, has increased considerably in the last 30 years, and hence any form of cancer due to smoking would be expected to

increase also at some later period. We do not know the cause, or causes, of the 3,000 cases independent of tobacco, and therefore we have no reason to think that this factor has increased. Even if it has increased, it is extremely unlikely that it has done so in close parallelism to the increase in the consumption of tobacco. As we know nothing to the contrary, we may assume for the moment that this factor has not altered in, say, the last 30 years.

If this were so, the unknown factor would have produced about 3,000 cases every year during this period. But as recently as 1935, when the number of deaths was 3,195, this source would have supplied the whole number which occurred, and, proceeding backwards, the total falls to 612 in 1922 at the beginning of the 30-year period (Fig. 1). It is

FIG. 1.—Deaths from cancer of lung. Males and females. England and Wales.

of course quite easy to invoke "defective diagnosis" as the sole explanation of any such process, whatever its magnitude or time-relations may be, and to attempt no further investigation, but any assumption that such errors are exactly adequate numerically for this purpose is purely arbitrary. The unknown factor may be (a) extrinsic or (b) intrinsic. (a) It is unlikely to be one of the known occupational factors which are carcinogenic to the lung (chromates, arsenic, nickel, asbestos, radioactivity), because these affect only small numbers of persons, chiefly of the male sex. (b) The absence of any sexual difference and the lack of any correlation with density of population suggest an intrinsic factor. The identification of this factor would be of very great interest.

No doubt the crude data shown in Fig. 1 require careful analysis in view of the considerable changes in the age structure of the population which have taken place in the last 30 years, but that is a matter for statisticians.

The proportion of non-smokers is important when the consumption of tobacco in different classes or countries—for example, Britain and Finland—is being compared. Thus in the latter country women appear to smoke very little, and hence the consumption "per head" falls very largely upon only one-half of the population.

In the long run it may appear that this sorting out of the cases not due to tobacco is the most valuable part of the immensely important contribution of Doll and Bradford Hill, and others, to cancer research; this same unknown factor may be the cause of malignant growth in other organs also. We can avoid the one factor, tobacco, if we wish, because we know what it is; we cannot avoid the other.

Deaths Attributed to Cancer of the Lung in Women

In England and Wales the increase in 1953 amounted to only 11 cases (Registrar-General, 1954), whereas the deaths of males showed an increase of the usual amount (891 cases). Of course, this halt may not persist, but, if it does so, the problem of the factors, perhaps first active many years ago,

which are concerned in this change will be very attractive, or, if one is then still expected to think that a very large part of the increase in deaths attributed to cancer of the lung is due to improved diagnosis, an explanation of this sexual difference must be found.

Histological Characters of Cancer of the Lung

These cancers show about five different types, which may differ in aetiology. Hence when one compares the total incidence of cancer of the lung upon different populations and countries one may be concealing important differences in the proportions of these types. Recently Kreyberg (1954) has emphasized the importance of this question. The practical difficulty is to obtain data from large numbers of unselected cases in which the diagnosis has been made by competent histologists, and some experienced observers are doubtful about the value of such classifications on the ground that more than one type may occur in the same lung.

Systemic Effects of Tobacco

The obvious method by which tobacco smoke can have a carcinogenic effect is by the arrest of the droplets of which it is composed upon the bronchial mucous membrane. But the inspiration of this smoke has such powerful systemic effects that one wonders whether these may possibly play a part also. The discharge from the posterior pituitary has so strong an antidiuretic effect (Walker, 1949) that the comment has often been made that one wonders how some cigarette smokers pass any urine at all (Fig. 2).

FIG. 2.—Systemic effect of tobacco. The subject drank 900 ml. of water at zero. He emptied his bladder at 15-minute intervals. The continuous line shows the volume of urine excreted. After 45 minutes he smoked one cigarette, which produced the inhibition shown in the graph. The broken line shows the total chloride excretion. Note the rise in total chloride coincident with the inhibition (Walker, 1949). Reproduced by permission of Dr. Walker and the *Quarterly Journal of Medicine*.

This secretion of the posterior pituitary is also bronchoconstrictor, and this action might slow down the inspiratory current and thus favour the deposition of particles, but so far no such effect of smoking has been demonstrated. Dr. H. G. J. Herxheimer, of University College Hospital, London, very kindly subjected two smokers to a test with his apparatus which measures resistance to expiration, and could find no effect. But possibly other systemic effects might be worth consideration.

Amount of Cancer

When the occurrence of cancer in different populations is compared, the incidence may be found to fall more or less upon one or another organ, while the total number of individuals remains about the same whatever the organ or organs chiefly affected. There seems in these cases to be something that may be regarded provisionally as an "amount" of cancer, and the anatomical distribution of this "amount" is variable (E. L. and N. M. Kennaway, 1937).

"There appears to be a general law that when in a given population the incidence of cancer in one particular organ

is markedly increased as compared with another population, there is then a compensating decrease in the incidence of cancer in a number of other organs. As a result, the incidence of cancer in different populations, whether of the same sex or not, may represent a very different distribution over the various organs or tissues, but the sum total—the total incidence of cancer—remains on an even level. This phenomenon shows that the development of malignancy in a given site, although in itself a strictly localized process, is conditioned by factors lying outside the site, which may therefore be called 'general' or 'systemic' factors" (Cramer, 1931).

This phenomenon was described first by Snijders and Straub (1924) in Sumatra; a small selection from their results is given in Table II.

TABLE II.—Incidence of Primary Cancer of the Liver in Sumatra, and in England and Wales (Snijders and Straub)

	Javanese Men	Corresponding Group from Dutch Statistics	Javanese Women	Corresponding Group from Dutch Statistics
Mortality from cancer per 100,000 per year	26.6	24.3	25.4	24.5
Primary cancer of liver % of all cancers	84	4.8	22.2	4.7

Perhaps the simplest instance of the "amount" of cancer is afforded by a comparison of cancers in the two sexes in the same country (Table III).

TABLE III.—Deaths from Carcinoma, 1940-2, England and Wales (General Register Office)

Males		Females	
Cancers of male reproductive organs	7,172	Cancers of female reproductive organs	38,916
Scrotum, prostate, testis, penis, etc. 7,009		Uterus, ovary, tubes, vulva, vagina, etc. 18,867	
Breast	163	Breast	20,049
Other organs	82,730	Other organs	58,090
Total	89,902	Total	97,006
Excess of cancers in females			7,104

For instance (Table III), the total deaths from carcinoma in males (89,902) and females (97,006) show a difference of only about 7%, yet the latter total includes 38,916 deaths, or 40% of the whole, from carcinoma of organs peculiar to the female, among which organs the female breast, being capable of lactation, must for the present purpose be reckoned.

One wishes that statisticians would some day examine this matter and tell us to what extent the figures merely illustrate the fact that a person who dies of a disease A does not die of a disease B. But it is difficult to believe that that is all that can be said about it.

Localization of Malignant Growth

This extremely important subject seems to attract very few investigators, probably because it does not promise to yield quickly that "something to publish" which assures renewal of annual grants and is the bane of cancer research.

Cancer of the breast causes the death of about 7,300 women in England and Wales per annum. If one omits the other cases cured by surgery and divides this number by 365, one finds that every day only about 20 of the 13½ million women aged 30 and over begin to develop this form of cancer. Moreover, in the great majority of these, the disease begins in one of the two breasts, and at one small area in this glandular organ of considerable size. Hence the importance of localizing factors is obvious, but we know hardly anything about them. In recent years much has been learned about hormonal factors in relation

to the breast, but these are distributed in the blood stream and there is no apparent reason why their action should be localized. Such considerations apply also to some forms of cancer of the lung where substances introduced and dispersed with the inspired air represent the hormonal factors in the case of the breast.

Possibly every case of cancer arises from the conjunction of a number of factors, as yet unknown to us, at one spot. Those who think that the carcinogenic action of, for instance, cholesterol (Hieger and Orr, 1954) can be ignored because this compound is "a normal constituent of the body" show little comprehension of biochemical matters. The highly dangerous properties of another normal constituent—namely, potassium—are kept under control only by the balance of other factors.

Incidence of Cancer in Town and Country

A number of investigations have shown, with varying degrees of distinctness, a higher incidence of various forms of cancer among town dwellers. In seeking for a reason, the fact that better methods of diagnosis are more accessible in towns is always easy to invoke and difficult to assess. Where the respiratory tract is concerned one must of course consider atmospheric pollution and exposure to soot containing at least one carcinogen—namely, 3:4-benzpyrene (Stocks, 1936, 1953; E. L. and N. M. Kennaway, 1951; Curwen *et al.*, 1954). But does this latter factor affect any other parts of the body? Cancer of the scrotum is rare in agricultural workers and is almost unknown in those social classes who wash most (E. L. and N. M. Kennaway, 1946). Thirty years ago the suggestion was made that "it would seem possible that cancer of the scrotum is influenced by exposure to coal-smoke—in other words, possibly all town dwellers are in some very slight degree liable to "chimney-sweep's cancer" (Kennaway, 1925). A complete survey is required of the incidence of every form of cancer upon dwellers in rural districts, and in the various grades of urban areas, in which every effort is made to discriminate between the effects of better diagnosis, and of town smoke; the latter factor is remediable by methods already in existence. Probably various carcinogens, with the exception of sunlight, are more abundant in towns and their actions may summate, a process about which we know very little; the latest contribution on this question is that of Cloudman *et al.* (1955).

Cancer and the Consumption of Milk

Cow's milk contains a carcinogenic factor in the non-saponifiable fraction, as do various human organs (Hieger, 1949), and, as a constituent of diet, has a protective action against some forms of cancer (Hoch-Ligeti, 1952). The consumption of milk by man shows great differences in different countries, dependent upon a variety of factors such as the character of pasture, the tsetse fly, sexual and social taboos and conventions, and so on. In some parts of Africa the numerous cattle are not regarded as sources of milk, nor of meat, but as currency, especially for the purchase of wives. In some areas milk is taboo for men, as it was in effect in this country not very long ago (Kennaway, 1951). The numerous travellers in Tibet who write books always emphasize the abundance of Yak butter, while Australasia had no source of milk until the nineteenth century. Even countries in Europe show considerable differences in this respect; thus the daily consumption of milk is high in Finland (Kennaway, 1954), being about 1.34 pints per head as against 0.72 pint in the United Kingdom.

Anyone wishing to make a literary investigation of this matter would find a great quantity of data scattered through official and other publications; the results might or might not show any correlation with any forms of cancer, and could of course be used in the study of any other diseases also. Two valuable publications are those of the Food and Agriculture Organization of the United Nations (1952, 1953).

A Suggestion

Cancer research, like other branches of science, is tending to be buried under its own literature. Those whose business it is to attempt to keep a watch upon this literature know that many investigations are reported which appear to promise further results, and yet, in say ten years' time, if they are remembered at all, they are found to have had no progeny. This may be because they are inherently infertile, or because the investigator has been diverted to other matters which appear more productive of results and annual grants: these forgotten researches are hidden, like coelacanths, beneath an ocean filled by other developments. Surely some persons should be appointed to pick over the literature of, say, the last 25 years in the light of later knowledge and to seek for anything worthy of resuscitation; they should hold a quite definite appointment with good remuneration, should be under no obligation to produce anything, and should be trusted to carry on their work efficiently without any compulsion to write endless reports about it. They will reject many researches because the technique was inadequate at the time or is shown by our later knowledge to have been so; but now and then something useful may be disinterred.

In 1945 J. C. Mottram described a greater yield of tumours of the skin of mice from 3:4-benzpyrene when applied at midnight than when applied at midday; he attributed this difference to greater mitotic activity at night, and did not consider any other possible diurnal differences in metabolism. This result indicates that the conditions during the first few hours after application determine the yield of tumours during the second and later months. At the present time research on cancer is much concerned with such periods of incubation. Thus, Nielsen and Clemmesen (1954), in a very short paper of great interest, have plotted figures for the mortality from cancer of the lung in 1950 against those for the consumption of cigarettes in 1930. Mottram's result is of such importance that one wonders whether the experiment has ever been repeated. He used only 6, and 24, mice in his two experiments, and made the day, and night, paintings on opposite sides of the same mouse, which is not the only possible, and perhaps not the best, procedure. A very experienced worker with whom I have discussed the result is very dubious about it. Those who knew Mottram, who died in 1945, will agree that, though he was far from infallible, his numerous ideas were always interesting; at heart he was much more a zoologist than a pathologist.

SMOKING AND CHEWING OF TOBACCO IN RELATION TO CANCER OF THE UPPER ALIMENTARY TRACT

BY.

L. D. SANGHVI, Ph.D.

K. C. M. RAO, M.Sc.

AND

V. R. KHANOLKAR, M.D.

Indian Cancer Research Centre, Parel, Bombay, 12

There is accumulating reliable and well-sifted evidence to suggest that the tendency for cancer generally to grow in man is about the same in most parts of the world. On the other hand, the "organ distribution" of cancer is often strikingly dissimilar in different groups of population, varies greatly from one country to another, and differs in different communities in the same geographical region. Thus, for instance, an earlier study (Khanolkar, 1950) showed that intraoral cancer was relatively more prevalent in Bombay than in New York or London. It accounted for 35.9% of all cancer cases at the Tata Memorial Hospital, Bombay, as against 16% of cancer cases in the New York and 6.7% in London hospitals. Further, even as regards the commonest site for the occurrence of oral cancer there is a noticeable difference in various localities in India. Cancer of the lip is the commonest type of oral cancer in Bihar, of the buccal mucosa and alveolar margin in Travancore and some parts of Madras, of the base of the tongue in

During recent years a large number of studies have demonstrated that there is an association between lung cancer and the amount of tobacco smoked (Doll and Hill, 1950, 1952, 1954; Levin *et al.*, 1950; Mills and Porter, 1950; Schrek *et al.*, 1950; Wynder and Graham, 1950; McConnell *et al.*, 1952; Koulumies, 1953; Sadowsky *et al.*, 1953; Wynder and Cornfield, 1953; Breslow *et al.*, 1954; Watson and Conte, 1954). So far as mouth cancer was concerned, it became evident that the habit of smoking and chewing tobacco, with or without other ingredients, called for a special investigation.

The Investigation

In Western India the chewing of betel nut, betel leaf, and tobacco, and the smoking of locally prepared cigarettes ("bidis") are common habits.* It was therefore decided to collect and analyse the information available in this respect in the records of the Tata Memorial Hospital. The routine form to be filled up for every patient who is registered in the hospital contains under the head "Personal History" an item "Habits (alcohol, tobacco, etc.)." In 1952 an analysis was carried out of the information collected in this column of the cases registered during the period 1941-9. The information was scanty in the case sheets of patients with cancer other than intraoral, and those suffering from non-neoplastic conditions. This circumstance did not permit a comparison of oral cancer cases with a control group. Even in intraoral cancer, information concerning these habits was not available in as many as 19.1% of cases. Nevertheless, an analysis of the available information on the habits of patients with

TABLE 1.—Data on the Habits of Smoking and Chewing of Tobacco in Relation to Cancer of the Upper Alimentary Tract

I-VI: Total	284 (38.9%)	340 (46.6%)	84 (11.5%)	22 (3.0%)	730	5 (4.5%)	9 (8.2%)	61 (55.5%)	35 (31.8%)	110
Misc.: Other cancer	28 (26.2%)	49 (45.8%)	14 (13.1%)	16 (14.9%)	107	3 (2.7%)	4 (3.5%)	24 (21.2%)	82 (72.6%)	113

Bombay, of the oral surface of the palate in Andhra, and of the hypopharynx in Assam. In Bombay, cancer of the inner lining of the cheek was four times more common among Deccani (Marathi-speaking) Hindus than among Gujarati Hindus, though their total attendance at the hospital was in the ratio of 3:2. Cancer of the base of the tongue and tonsils was more than twice as common among Gujaratis than among Deccanis, and more than 9 out of 10 cases occurred in men, although the male to female ratio of attendance of Gujaratis was roughly 3:1.

A study of these relative differences revealed several facts of considerable interest, particularly as the communities under investigation showed notable differences in habits, customs, occupations, and nutritional status. It was therefore felt that a detailed analysis of such data may yield valuable information. It may also help in assessing the contributory role of hereditary and environmental factors in the production of cancer in man.

intraoral cancer at three different sites—namely, (1) buccal mucosa, (2) anterior third of the tongue, and (3) base of the tongue—seemed to indicate that the habit of chewing tobacco was more common in persons with cancer of the buccal mucosa and that the habit of smoking was more common among cases of cancer of the base of the tongue.

These tentative inferences obviously suggested that a systematic investigation of the chewing and smoking habits of patients with cancer of the upper alimentary tract, if it was carried out along with a corresponding control series of "no cancer" and "other cancer," was worth while. A detailed questionnaire was therefore drawn up and filled in for 1,460 new patients who attended the clinic during the years 1952-4. The present paper deals with an analysis of the data collected for the purpose of this investigation.

*A short note on the substances used for chewing and smoking in Western India is given in the Appendix.

Data

Table I contains the data on smoking and chewing of tobacco. Patients who were referred to the cancer clinic for a "check-up" and who showed no evidence of neoplastic disease were taken as the "control group." Cases of cancer of the upper alimentary canal in men were numerous enough for further analysis. There was a sufficient number of cases of cancer of the buccal mucosa to treat these as a single group (Group I). The rest of the cases of oral cancer (Group II) included: cancer of anterior tongue, 56; cancer of alveolus, 39; cancer of palate, 37; cancer of lip, 6; and cancer of floor of mouth, 4. Group VI (cancer of oropharynx) included 54 cases of cancer of the tonsil. Further analysis was not possible for women, owing to the small number of cases. The "other cancer" group consisted of cancer at sites other than the upper alimentary canal, and cancer of the breast and cervix uteri predominated in women.

The data in Table I are graphically presented in Fig. 1, which shows the percentages of smoking and chewing of tobacco in cancer cases. In Fig. 2 the percentages of men

addicted to smoking and chewing are added to those accustomed to smoking only, so as to obtain the total percentages of "all smokers." Similarly, those smoking and chewing are added to persons accustomed to chewing tobacco to give the percentage of "all chewers."

The figures show that for both men and women the "non-cancer" group is similar to the "other cancer" group in smoking and chewing habits. Women with cancer of the upper alimentary tract show a higher incidence of smoking and about two and a half times the incidence of chewing compared with the control group. In men the results are more striking. It is possible to see several gradients in the incidence of habits among the different types of cancer. The proportion of men with "smoking and chewing" habits is higher in all the six groups compared with the control group, showing a diminishing proportion from group I to group VI. Similar gradients are also seen with "no habit" and the habit of "chewing only"; whereas a reverse gradient is seen with the habit of "smoking only." Fig. 2 shows the gradients of smoking and chewing separately for groups I to VI and for the control group.

FIG. 1.—Analysis of cases of cancer of upper alimentary tract in relation to tobacco habit.

FIG. 2.—Percentage of "all smokers" ("smoking and chewing" plus "smoking only"), "all chewers" ("smoking and chewing" plus "chewing only"), and of those with no habits.

Statistical Analysis

It was necessary to take into account four variables—community, age, occupation, and sex—for purposes of evaluating the statistical significance of the smoking and chewing of tobacco in relation to cancer of the upper alimentary tract. As the two sexes presented very different patterns in habits, they were treated separately. No further analysis was carried out on the data on women owing to the small number of cases. For men, the data concerning community and age could be broken down into well-defined classes. Table II shows the differences in the smoking and chewing habits in the "non-cancer" group with respect to these two variables.

TABLE II.—Percentage of Smokers and Chewers Among Non-cancer Men Classified According to Community and Age

	Smoking and Chewing	Smoking Only	Chewing Only	No Habit	No. of Persons
Community:					
Hindu Deccani	31.9	39.8	12.4	15.9	113
— Gujarati	9.2	70.4	—	20.4	54
Muslim	27.3	43.6	10.9	18.2	55
Other	19.7	56.0	7.6	16.7	66
Age:					
Less than 50	21.7	50.2	10.2	17.9	207
50 to 60	30.9	45.5	5.4	18.2	55
More than 60	26.9	57.7	3.9	11.5	26

An attempt to subdivide data dealing with occupation in different classes turned out to be unprofitable. It was necessary to introduce so many groupings that finally it was difficult to justify them. Moreover, an analysis carried out on such groupings did not change the significance pattern of the types under consideration.

Dr. C. A. B. Smith, of the Galton Laboratory, London, suggested a method of analysis suitable for the present purpose. The method in essence consisted in breaking down the cancer and control cases into a number of cells for which it could reasonably be assumed that the internal variability had been substantially reduced and studying the difference and its variance for each cell. Such differences and variances could then be weighted and added to give the significance for the whole group.

Consider the following cell:

	With Habit	Without Habit	Total
Cancer cases	a_r	b_r	$a_r + b_r$
Control "	c_r	d_r	$c_r + d_r$
Total	$a_r + c_r$	$b_r + d_r$	$a_r + b_r + c_r + d_r = n_r$

$$\text{Difference } D_r = \frac{a_r}{a_r + b_r} - \frac{c_r}{c_r + d_r}$$

$$\text{Variance of difference } D_r = \frac{(a_r + c_r)(b_r + d_r)}{(a_r + b_r)(c_r + d_r)(n_r - 1)}$$

This variance is calculated on the basis of the exact distribution, keeping the marginal totals fixed.

The weighted combination of differences $D = \sum W_r D_r$, summed over all the cells, accordingly has the variance $V = \sum W_r^2 \text{var } D_r$.

The weights W_r can be chosen arbitrarily, provided that, of course, they are decided upon previously and not in-

TABLE III.—Statistical Significance of the Differences in Smoking and Chewing Habits in Patients (Men) with Different Types of Cancer Compared with the "Non-cancer" Group

Group	Smoking and Chewing	Smoking Only	Chewing Only	No Habit	Total Smokers	Total Chewers
I: Buccal mucosa	$0.133 \pm 0.057^*$	$-0.233 \pm 0.071^+$	$0.175 \pm 0.040^+$	-0.075 ± 0.058	-0.100 ± 0.066	$0.308 \pm 0.061^+$
II: Oral cavity (excl. group I)	$0.200 \pm 0.048^+$	$-0.157 \pm 0.051^+$	$0.100 \pm 0.034^+$	$-0.143 \pm 0.036^+$	0.043 ± 0.046	$0.300 \pm 0.050^+$
III: Oesophagus	$0.137 \pm 0.066^*$	0.017 ± 0.076	-0.014 ± 0.041	$-0.140 \pm 0.055^*$	$0.154 \pm 0.065^*$	0.123 ± 0.070
IV: Hypopharynx	$0.160 \pm 0.046^+$	-0.021 ± 0.052	0.000 ± 0.030	$-0.139 \pm 0.036^+$	$0.139 \pm 0.044^+$	$0.160 \pm 0.049^+$
V: Base of tongue	$0.200 \pm 0.046^+$	-0.040 ± 0.049	-0.005 ± 0.027	$-0.155 \pm 0.032^+$	$0.160 \pm 0.040^+$	$0.195 \pm 0.048^+$
VI: Oropharynx	0.109 ± 0.062	0.083 ± 0.070	-0.030 ± 0.041	$-0.162 \pm 0.050^+$	$0.192 \pm 0.061^+$	0.079 ± 0.067
Misc.: Other cancer	-0.023 ± 0.051	-0.006 ± 0.059	0.051 ± 0.036	-0.022 ± 0.046	-0.029 ± 0.054	0.028 ± 0.055

* Shows significance at 5% level. † Shows significance at 1% level.

fluenced by the observed experimental results. Since the larger cells will give more reliable information than the smaller ones, it seems reasonable to take the weight W_r to be proportional to the total number n_r of observations in the cell. That is, we can take $W_r = \frac{n_r}{N}$, where $N = \sum n_r$.

It is obvious that the method will fail if there are no cases, either cancer or control, in any particular cell. This limitation made it necessary to restrict the analysis to three age groups—namely, under 50, 50 to 60, and over 60. Table III gives the weighted differences, and their standard errors.

This analysis shows that the habit of chewing is associated with cancer of the oral cavity (groups I and II). It shows that the combined habit of smoking and chewing is associated with cancer of the hypopharynx (group IV) and of the base of the tongue (group V). Finally, only smoking is associated with cancer of the oropharynx (group VI) and of the oesophagus (group III). There is no significant difference in smoking and chewing habits in patients with other cancers compared with the "non-cancer" group.

It was possible to make a further analysis of the smoking habit. Of the persons who smoked, 88.7% smoked bidis. During the course of the investigation, information was collected about the number of cigarettes (bidis) smoked by the patients. This information must admittedly be approximate because, even if the exact number smoked could be ascertained, there is bound to be a variability in the length of the bidis smoked by different persons. Table IV gives the average number of bidis smoked by the men in the various groups.

TABLE IV.—Number of Bidis Smoked Daily by Patients (Men) With Different Types of Cancer of the Upper Alimentary Tract

Control group.	Non-cancer	14.1 ± 0.6
Group I.	Buccal mucosa	12.5 ± 1.1
„ II.	Oral cavity (excluding group I)	14.6 ± 0.8
„ III.	Oesophagus	15.3 ± 1.2
„ IV.	Hypopharynx	16.9 ± 0.8
„ V.	Base of tongue	17.4 ± 0.7
„ VI.	Oropharynx	18.5 ± 1.0

It is interesting to note that the percentage of smokers and the average number of bidis smoked show a similar trend in groups I to VI. It was not possible to carry out a further analysis of the chewing habit, as the quantities reported were often unreliable. Information regarding the duration of smoking and chewing was also unreliable.

Discussion

Experimental work on cancer has made it clear that to resort to a single or a simple explanation for the aetiology of cancer, however tempting it may be, is likely to result in failure. The contributory factors may be broadly grouped as hereditary and environmental. Such a classification is probably arbitrary, but it satisfies the needs of the present discussion.

The present study indicates that tobacco may be one of the environmental factors responsible for a large number of cases of cancer of the upper alimentary tract seen at the Tata Memorial Hospital. These populations differ sharply from other populations in their habits of tobacco chewing. The habit of chewing tobacco and the associated types of cancer lead to an assumption of the existence of a sub-

stance or substances in tobacco which may initiate or promote the production of cancer at the sites of prolonged contact.

The marked differences in the chewing and smoking habits among the Deccanis and the Gujaratis partly explain the differences in the incidence of cancer of the buccal mucosa and of the base of the tongue in these two communities. They also presumably explain the striking difference in the incidence of base of tongue cancer in the two sexes.

It is, however, not possible to explain all the differences on the basis of the habit of smoking and chewing of tobacco, as in all the types of cancer of the upper alimentary tract there were some persons who did not smoke or chew tobacco at all. Therefore it is necessary to explore other environmental and hereditary factors.

Sanghvi and Khanolkar (1949) encountered striking differences in the distribution of seven genetical characters among the six endogamous groups in Bombay. Data were obtained on the ABO, A₁A₂, MN, P, and Rh blood groups, taste reactions to phenylthiocarbamide, and colour vision. One endogamous group belonged to the Gujarati Hindu community, and the rest to the Deccani Hindu community. No information is available about the association of susceptibility to cancer of the upper alimentary tract with genes responsible for the above characters. It may, however, be suggested that similar differences exist for many of those genes responsible for susceptibility to cancer among different communities in India as well as in the rest of the world.

Strong and Sanghvi (1951), as a result of their study on the effects of selection on chemically induced tumours in mice, suggested tentatively that the control of tissue susceptibility to cancer might be at a different level in the mechanism of heredity than total susceptibility to cancer. They found that in mice, by selecting breeders with a longer and longer latent period (time between the injection of carcinogen and development of tumour), large variations could be brought about in the sites at which the two sexes of mice developed tumours during the course of 16 generations, without affecting to any appreciable extent the total incidence of cancer. The net result of the experiment was to increase considerably the latent period and hence the life-span of the mice which developed tumours. The mice therefore developed tumours at the sites which took an increasingly longer time interval to develop them. Such differences in the tissue susceptibility may offer one of the reasons for the habit of smoking affecting the mucosa of the upper alimentary tract in one population and the lung in another. There exists a possibility that the physical state and internal dispersal of smoke particles from bidis might differ from those of ordinary cigarettes.

Summary

The 1,460 patients who attended the cancer clinic during 1952-4 were questioned regarding the habit of smoking and chewing of tobacco in relation to cancers of the upper alimentary tract. Results of the statistical analysis showed that the habit of chewing was associated with cancer of the oral cavity; that the combined habit of smoking and chewing was associated with cancer of the hypopharynx and base of the tongue; and that only smoking was associated with cancer of the oropharynx and oesophagus. These findings are discussed.

APPENDIX

The Indian form of cigarette is known as bidi, a smoke for the common man in the country. It is made by rolling with the fingers 0.25 to 0.5 g. of tobacco flakes in a rectangular piece of dried leaf of temburni (*Diospyros melanoxylon*). Leaves of other genera and species such as *Bauhinia racemosa*, *Bauhinia vahlii*, *Butea frondosa*, and *Castanopsis indica* are also used for wrapping the tobacco. Out of about 50 known species of tobacco, only two are

grown in India—namely, *Nicotiana tabacum* and *Nicotiana rustica*. Both types are used for making bidi, as well as for chewing. The tobacco is usually sun dried and cured. Bidis vary in length from 5 to 8 cm. (Fig. 3). They are conical in shape, with the tucked end (the end which is lighted) broader than the end which is held between the incisor teeth. This end is tied with a thread and flattened by pressing.

In Western India the common ingredients used for chewing are betel nut, betel leaf, and tobacco. The betel nut is the fruit of the areca or betel palm (*Areca catechu*). The betel leaf is the leaf of the betel vine (*Piper betle*). Cracked or powdered dried betel nut, or slices, may be chewed alone along with a preparation of betel leaf, known as pān. Pān is prepared by applying slaked stone or shell lime and catechu to a betel leaf, and wrapping it around pieces of betel nut, with spices like the cardamom, cloves, aniseed, and several others. Catechu is an extract obtained from the wood of two species of acacia (*Acacia catechu* and *A. suma*). In Gujarat, plain tobacco is sometimes added in the preparation of a pān, whereas in the Deccan the dried and cured tobacco is commonly chewed along with betel nut and lime.

The active co-operation of our clinical colleagues at the Tata Memorial Hospital, particularly Drs. J. C. Paymaster and P. D. Schroff, made it possible for us to collect the data which have been analysed above. We should like to record our gratitude to our colleagues and to Dr. C. A. B. Smith, of the Galton Laboratory, London, for his suggestion of an appropriate statistical method.

Mr. KENNETH PICKTHORN speaking on April 26 in a Parliamentary debate on education: "Everyone goes on repeating the stuff about science getting more and more specialized, technicalized, departmentalized, compartmentalized, and my impression, not as a scientist but as a man who has spent his life partly in intimate conversations with many of the greatest and best-informed scientists, is that the opposite has been the fact for some considerable time: the sciences have all tended more and more, during the last 20 years especially, to approximate to mathematics, and to need mathematics for any understanding of them. In that sense they have come together again."

CIGARETTE SMOKING AND BRONCHIAL CARCINOMA

EFFECT OF THE ASSOCIATION UPON SMOKING HABITS OF A GROUP OF DOCTORS

BY

D. A. PYKE, M.B., M.R.C.P.

Senior Medical Registrar, Radcliffe Infirmary, Oxford

Doll and Bradford Hill (1950) demonstrated a significantly higher incidence of carcinoma of the bronchus among those who smoked cigarettes than among those who did not. This finding has been confirmed and amplified here and in America, and public endorsement has been given by the Minister of Health and the Secretary of the Medical Research Council.

What effects have these statements had? Do people now smoke less?

In an attempt to answer these questions a small inquiry has been made of 217 doctors. It was thought that doctors would be sensitive to scientific argument and might be among the first to reduce their smoking in the face of evidence of its danger; they are more likely to be familiar with the facts making up this evidence and with the character of the disease.

Material and Methods

All the 217 doctors working in the hospitals in Oxford were sent a short questionnaire. Nine-tenths of them were men; their ages ranged from about 24 to 65, about two-thirds were under 40.

DO YOU SMOKE CIGARETTES?

If "Yes," for how many years have you smoked?

Do any of these statements represent your views?

(i) I am not satisfied with the evidence linking cigarette smoking with carcinoma of the bronchus.

(ii) I am satisfied with the evidence and hope to give up smoking, but have not yet been able to bring myself to do so.

(iii) I am satisfied with the evidence but do not intend to give up smoking.

(iv) Other.

If "No," have you ever smoked (by which is meant at least one cigarette a day for a year or more)?

If you have once smoked but have given it up, can you give the date (as precise as possible) of stopping?

What was your reason for stopping?

Non-smokers were also asked to say whether they were satisfied or not with the evidence linking smoking with carcinoma of the bronchus.

Pipe and cigar smoking was not considered, nor was the number of cigarettes smoked. Figures of the national consumption of cigarette tobacco and of the number of smokers in the country were also obtained.

Results

Replies were received from 211 (97%) doctors. Less than half of them smoked cigarettes. About a quarter had discontinued the practice, and another quarter had never smoked (Table I).

TABLE I

	211 Doctors	General Population (U.K.)*
Smoke now	47.4% (100)	57% (men 72%, women 42%)
Once smoked	25.1% (53)	43% (men 28%, women 58%)
Never	27.5% (58)	

* Figures calculated from the Hulton Readership Survey and the 1% sample of the 1951 census.

Changes in the Number of Smokers

Smoking Begun.—In the last eight years 11 of the 211 doctors have started to smoke cigarettes. Five began to do so eight years ago, one seven years ago, two six years ago, one five years ago, one four years ago, one two years ago.

Smoking Stopped.—In the last eight years 40 of the doctors have stopped smoking. The dates of stopping were: Before September, 1946, 13; September–December, 1946, 1; 1947, 6; 1948, 6; 1949, 2; January–September, 1950, 3; October–December, 1950, 2; 1951, 3; 1952, 3; 1953, 5; 1954, 9. In the four years immediately before the publication of Doll and Bradford Hill's first paper (September, 1946, to September, 1950), 18 persons stopped smoking. In the next four years, ending at the time of the survey (October, 1954), the number was 22.

Reasons for Stopping Smoking.—The 53 members of this group gave 63 reasons for having stopped smoking (Table II).

TABLE II

Minor ill-health (e.g., cough, sore throat)	15
Expense	13
Lack of desire	8
Risk of carcinoma	8
After or during an illness	6
Unclassified	13

The 13 doctors giving expense as a main reason had stopped smoking in 1947 (2), 1948 (1), 1950 (2), 1951 (1), 1952 (2), 1953 (1), 1954 (4).

National Figures.—The decline in the number of smokers among this group of doctors is not reflected in the national figures (Table III).

TABLE III.—Number of Cigarette Smokers and Their Weekly Consumption per Head (United Kingdom)*

	No. of Cigarette Smokers (Millions)			Average No. of Cigarettes Consumed Weekly per Cigarette Smoker		
	Males	Females	Total	Males	Females	Total
1947	11.7	8.4	20.1	113	49	97.9
1948	11.8	7.8	19.6	105	42	79.9
1949	11.8	7.6	19.4	99.4	45.5	78.3
1950	11.9	7.3	19.2	100.1	45.5	79.3
1951	11.8	7.3	19.1			
1952	11.4	7.5	18.9	105	46.9	81.9
1953	11.2	7.5	18.7	100.8	49.7	80.3
1954	11.4	7.9	19.3	102.9	51.1	81.7

* Based on the Hulton Readership Survey. Figures are not available for the years before 1947 and only abbreviated ones for the year 1951.

The fall in the number of cigarettes smoked, but only slightly in the number of smokers, between 1947 and 1948 may have been due to the large tax increase in the budget of 1947. Since then, and during the time when an association between smoking and carcinoma has been known, there has been very little change. Figures of the total cigarette tobacco consumption (in lb. per annum per head of the population of the United Kingdom)† show the same steadiness in recent years (Table IV).

TABLE IV

1946	1947	1948	1949	1950	1951	1952	1953	1954
4.6	4.0	3.7	3.6	3.6	3.8	3.8	3.9	4.0

Opinion of the Evidence Linking Smoking and Bronchial Carcinoma

Opinions of the validity of this evidence were given by 193 doctors. Rather more than half were satisfied with the evidence of an association between smoking and carcinoma of the bronchus, but the figures differ considerably among the smokers, non-smokers, and former smokers (Table V).

If the 193 are divided into (1) present and past smokers and (2) non-smokers, and their opinions examined separately it is seen that in group (1) 76 were satisfied and 57

† Based on estimates provided by the Board of Trade.

TABLE V

Opinion of the Evidence	Smokers	Former Smokers	Non-smokers	Total
Satisfied	46	30	34	110 (56.5%)
Not satisfied	45	12	5	62 (32.5%)
Undecided	9	3	9	21 (11.0%)

unsatisfied with the evidence, a ratio of 1.3 to 1. In group (2) the figures are 34 and 5, a ratio of 6.8 to 1 in favour of accepting the evidence. Thus, excluding those who were undecided, over five times as many non-smokers as present and former smokers accepted the evidence.

Of the 46 smokers who do accept the evidence 14 hope to discontinue smoking and 32 do not intend doing so.

Discussion and Conclusions

Less than half of this small group of doctors smoke cigarettes, a lower proportion than among the general population. The proportion of those who have never smoked (27.6%) corresponds closely to Doll and Bradford Hill's (1954) finding of 28.5% of non-cigarette smokers among male doctors aged 35-44.

In the present group of 211 doctors the number who smoke cigarettes is gradually declining. Eight years ago it was 129, now it is 100.

To judge from the reasons which those who have discontinued smoking give for doing so and from figures of national tobacco consumption it appears that increased cost is a considerable factor in reducing cigarette smoking, but that the risk of cancer is not (although it may be a deterrent to starting the habit). This is supported by the fact that the number of doctors giving up smoking since an association with bronchial carcinoma was discovered has not increased. It seems, therefore, that further demonstration of this association will not lead to many more doctors stopping smoking.

The proportion of those who accept the evidence of an association between smoking and carcinoma of the bronchus is so much higher among the non-smokers than among the smokers, present and past, that personal prejudice may have played some part in shaping these opinions. Possibly the pleasures of tobacco addiction persuaded some of the smokers to discount the evidence of its dangers.

Summary

The 217 doctors working in the hospitals of Oxford were questioned about their cigarette-smoking habits, and 211 (97%) replied: 47.4% smoke cigarettes, 25.1% once smoked, and 27.5% have never done so. The proportion who smoke is gradually declining, but the number of doctors giving up smoking has not increased since the discovery of an association between smoking and carcinoma of the bronchus. Figures for national tobacco consumption and number of smokers have shown no decline since 1950, when Doll and Bradford Hill's first paper appeared.

Only a little over half (56.5%) of the doctors were satisfied with the evidence linking carcinoma of the bronchus and smoking; but the proportion was more than five times higher among the non-smokers than among the smokers. Perhaps the smokers were persuaded by their fondness for tobacco to discount unpalatable evidence.

I am most grateful to the 211 doctors for their co-operation and to Dr. A. M. Cooke for his criticisms.

PHYSIOLOGICAL PRINCIPLES IN THE TREATMENT OF THE UNCONSCIOUS PATIENT*

BY

WILLIAM W. MUSHIN, M.A., M.B.
F.F.A.R.C.S., D.A.

Professor of Anaesthetics, Welsh National School of Medicine, Cardiff

The title of this paper crystallizes the main concern of the anaesthetist so far as the administration of general anaesthesia is concerned. He deliberately administers combinations of powerful drugs to produce unconsciousness of varying depth. His skill lies not only in the administration of these drugs, but in the treatment of the resulting unconscious state. The essential problems attendant on unconsciousness *per se* are the same whatever the cause, be it anaesthesia or head injury or barbiturate overdose. There therefore seems to be some justification for extending the discussion beyond the confines of anaesthesia to include unconsciousness in general. As for the physiological principles which underlie the treatment of the unconscious state, the need for them here is no less than in the treatment of other pathological states—indeed more, since a disregard of such principles so easily leads to permanent damage or death.

What is Unconsciousness?

"Unconsciousness" is a term applied to three separate states which have much in common with each other and yet differ fundamentally in their aetiology and prognosis. They are natural sleep, anaesthesia, and coma. In each of these the patient loses his power of perception of the world in which he lives, and on recovery has no memory of events which took place during that time. Though he may respond in a reflex manner to stimuli, such reflex activity leaves no trace in his conscious memory. Natural sleep is distinguished by the fact that it occurs in the absence of disease or the administration of drugs. It terminates spontaneously after a varying interval, but in any case is easily interrupted by the application of external stimuli of very moderate intensity. Anaesthesia differs from coma only in the fact that it is to a great extent reversible and controllable by the anaesthetist. It is the result of the deliberate administration of drugs or of physical agencies such as cold or electrical currents. The term "coma" is best reserved for states of unconsciousness associated with disease, injury, or overdose with certain drugs. It may on occasion be reversible, but it is generally not controllable. The two differ little so far as the physical state of the patient is concerned, and it would be generally impossible on clinical examination alone, and without knowing the circumstances, to say whether the state is one of anaesthesia or of coma.

The depth of unconsciousness may vary widely from patient to patient, and is determined by the individual ability to respond to stimuli of varying intensity. When a patient responds reflexly to mild painful stimuli his unconsciousness is said to be light, but in profound unconsciousness it may be that no stimulus of any kind produces a response and only a beating heart and active respiration show that the patient is still alive.

*Based on a lecture given before the Royal Faculty of Physicians and Surgeons of Glasgow on January 19, 1955.

Why Treatment is Needed

It might appear that the unconscious patient needs no treatment apart from the removal of the causes of his unconsciousness, whereupon he would return to consciousness and recover. This is certainly true in a number of instances, but there is a great risk that in the absence of positive treatment certain complications may arise which may be fatal or leave permanent effects.

Respiratory Depression

The very state of unconsciousness is outward evidence of a depressed activity of the cerebral cortex. Concomitant with this there is always depression of the rest of the brain, including the medullary centres. Respiration is therefore also depressed. Even more important than the reduction in the total minute volume of respiration is the reduction in tidal volume. When the size of the latter approaches that of the physiological dead space, hypoxia is present in some degree and the patient becomes cyanosed. This is because, in these circumstances, at each breath exchange of air takes place only between the dead space and the outer air. A good example of this is the patient who has tachypnoea due to an overdose of trichlorethylene. The respiratory rate may be 40-50 per minute, but, since at each breath no more than perhaps 200 ml. of air is inhaled, cyanosis is present, even though the minute volume of respiration is high—10 litres or more per minute. Another example is the depression that occurs after overdosage with morphine or a barbiturate drug. Not only is the respiratory rate slowed, but the breathing is very shallow. When the volume of each inspiration is reduced to 150-200 ml. the patient usually becomes cyanosed. This explains why there is a limit to the slowing of respiration before death supervenes. Even were the patient taking good-sized breaths of 500 ml., at least three or four of them every minute would be required to give him enough oxygen. It is therefore impossible for such a patient to breathe at less than, say, four times a minute and live. Periodic breathing is common in unconscious patients, and is further evidence, if such were needed, of suboxygenation of the medulla.

Respiratory Obstruction

The respiratory depression of the unconscious patient may be, and often is, complicated by obstruction of the airway, either by a relaxed tongue and pharynx or by secretions or vomit. Secretion in the respiratory tract appears very quickly in the presence of respiratory obstruction, and such fluid is not salivary in origin. In these circumstances the secretion is generally the result of some degree of what is known, for want of a better term, as pulmonary oedema. The high intrapulmonary negative pressure consequent on respiratory obstruction upsets the delicate equilibrium at the alveolar membrane which keeps fluid from entering the alveoli from the blood stream. Liquid then easily passes from the blood stream into the alveoli and thence into the respiratory tract. (See under "Complications.")

Circulatory Depression

Treatment is also needed because of the disturbances of circulation. Particularly in anaesthesia, but also in many other states, the heart muscle itself is depressed, and in any case will soon become so when hypoxia develops. The action of the heart is further hindered by the depressed breathing. The "thoracic pump" effect of breathing on the venous return of blood is lessened, the output of the heart is reduced, and the blood pressure tends to fall. At the other end of the circulatory system the capillaries are affected by hypoxia and by the accumulation of metabolic products, which quickly follow in the train of depressed breathing. Peripheral resistance is lowered and the blood pressure tends to fall still further. A vicious circle is started: poor cardiac output and low blood pressure mean poor pulmonary circulation and poorer oxygenation; the lower blood pressure ultimately means less coronary flow and still further depression of the heart muscle.

Other Effects

Metabolism is generally lowered during unconsciousness. Water loss, too, occurs continuously, and ultimately with the passage of time the problem of water balance and nutrition arises. There are certain other problems, minor if guarded against, but major in their possible ill-effects. Two examples are the possibility of the inhalation of vomit and the possible development of nerve palsies through malposture.

If untreated, therefore, the unconscious patient develops increasing hypoxia, with tissue and pulmonary oedema and circulatory failure. His metabolism is lowered and his fluid balance disturbed; secretions and vomit may be inhaled and postural palsies develop.

Treatment of the Unconscious State

The first principle of treatment of the unconscious patient, and one on which all else depends, is the maintenance of an adequate supply of oxygen to the tissues. Air or oxygen must first reach the alveoli in sufficient amount, and then enter the blood stream. I am sometimes shocked that this elementary fact is not appreciated outside the field of anaesthesia. My last experience of this was in connexion with a case labelled "cerebral malaria," to which I had been called because an oxygen regulator was out of action. The toothless patient, with a hanging lower jaw, was propped up in bed, unconscious, cyanosed, and clearly dying. Each breath was made with effort, and the sucking-in of his chest was striking. I immediately held up the patient's jaw, and to the amazement of those present the stertor disappeared, the patient became pink, and within a few hours was fully conscious. He ultimately left hospital a fit man.

If the jaw cannot be held in such a way that breathing is free for long periods of time, or if the unconsciousness is profound, an endotracheal tube should be inserted without hesitation. The insertion of a tube into the trachea should no longer be regarded as requiring unusual skill or as carrying great hazard. The manoeuvre is performed daily by anaesthetists, and is a life-saving measure when the patency of the airway cannot be maintained by other means. The introduction of the practice of intubating seriously ill patients with respiratory insufficiency in spinobulbar poliomyelitis, and more recently in tetanus, has had a dramatic effect on the prognosis of these diseases. I believe that a more widespread appreciation of the importance of a perfect airway will lead to a greater use of tracheal intubation with good results. If the unconsciousness is likely to persist for more than one or two days a tracheostomy is preferable to an endotracheal tube, since trauma to the cords is avoided and the respiratory tract is more easily kept free of secretions.

Suction

An important accessory aid to a clear airway is the use of mechanical suction. There can be few hospitals without a suction apparatus, and one of these instruments must also be regarded as essential for domiciliary use. Without going too deeply into mechanical matters, I would like to point out that the "power" or "strength" of the apparatus refers to the rate at which it removes fluid. The negative pressure indicated on a manometer is by itself of little interest. A good hypodermic syringe can produce almost a vacuum, but is useless as a "sucker" because its liquid removal rate is maintained for only a brief moment. The accompanying chart gives the results of some experiments with a piped suction installation, and illustrates some further points. For the removal of vomit or secretion a mechanical sucker is unequalled. Even with an efficient sucker, and certainly in its absence, gravity can still save life. A head-down position allows vomit to fall to the floor and prevents its accumulation in the pharynx, whence it may be inhaled.

Carbon Dioxide

Even when the airway is perfectly clear hypoxia may still be present owing to shallow breathing. The administration

of oxygen helps in these cases, but until ventilation has increased and tidal exchange become larger inadequacy of oxygenation may persist. Shallow breathing is a temptation to use carbon dioxide. But poor ventilation itself results in an accumulation of carbon dioxide, and the depressant effects of this gas on the central nervous system and the myocardium are now being appreciated to a much greater degree than formerly. The carbon-dioxide content of the blood of a depressed unconscious patient is generally high,

Chart showing the results of experiments with a piped suction installation. In the case of small-bore tubing, increasing the diameter of the metal sucker end has little effect in improving the fluid-removal rate. Improvement is effected by shortening the connecting tubing. The best results are obtained with large-bore connecting tubing and large-bore metal sucker end.

and more than enough to stimulate the respiratory centre if only the sensitivity of the centre is restored by an adequate supply of oxygen. Carbon dioxide from a cylinder plays little or no part in the treatment of respiratory depression. There is, indeed, a grave danger attached to its use, since a concentration above 7% has a powerful depressant effect on the central nervous system; in fact a high concentration was at one time deliberately used as an anaesthetic.

Oxygen

The average patient produces between 200 and 300 ml. of carbon dioxide per minute, and this must be expelled through the respiratory tract. At least 5 to 6 litres of other gases is required if this amount of carbon dioxide is to be diluted to 5%, the normal concentration in the alveoli. If oxygen therapy is instituted, at least 6 litres of oxygen must flow into the bag or tent. A smaller amount than this cannot possibly produce a sufficient partial-pressure differential of carbon dioxide across the alveolar membrane for the expulsion of the full amount of the gas.

Analeptics

An old-fashioned way of treating narcotic poisoning was to slap the patient's face and drag him round the room; another was to dilate the anal sphincter. The aim of these and similar methods, including the injection of analeptics, is to stimulate breathing reflexly. I cannot, however, support or encourage such methods. When a patient is deeply depressed, only oxygenation of his vital organs, particularly the brain, could keep him alive. Analeptics and physical stimuli are generally useless in such cases. Their continued administration when they fail to produce response is usually evidence of lack of appreciation of the depth of depression of the patient's central nervous system. It should be borne in mind, however, that spontaneous respiration in the presence of anoxia may be largely the result of stimulation of the carotid body by anoxia. Oxygen overcomes this, but if the respiratory centre is too depressed for carbon-dioxide

stimulation to be continued apnoea may result. Such a patient may need assisted respiration until his respiratory centre recovers sufficiently from its depression.

Artificial Respiration

An excellent method of maintaining artificial ventilation of a depressed patient for long periods of time is the box or cabinet respirator. The fact that a sub-atmospheric pressure is produced round the body with this type of apparatus should not obscure the similarity between it and rhythmic positive-pressure ventilation. In both the essential feature is the creation of a differential between the pressure at the lips and that in the chest. It makes little gross difference to the respiratory or circulatory mechanics whether that differential is produced by raising the air pressure round the head or by lowering it round the body.

Of the numerous methods of artificial respiration that are still in common use, the only one suitable for emergency clinical use is inflation of the lungs. There was at one time among physicians a general suspicion of inflation of the lungs with air or oxygen at a pressure above that of the atmosphere, on the ground that such a pressure may injure the alveoli. It should be remembered in this connexion that when the procedure is carried out with a thin rubber bag the maximum pressure attainable is of the order of 30-40 cm. of water. This is far below the intrapulmonary pressure of over 100 cm. of water which can be voluntarily generated by closing the larynx and forcefully expiring. It is likely that a pressure much in excess of 150 cm. of water is required before alveolar damage occurs. None of the foregoing would, of course, exclude the risk of rupturing an unsuspected subpleural bulla, but this risk is present in everyday life quite apart from artificial respiration. There are, however, certain disadvantages of positive-pressure inflation of the lungs which should be known, though they are generally insignificant as compared to the advantages. There is, first, a possibility of occluding the alveolar vessels at the peak of each inflation. To avoid this the mean inflation pressure should be as low as possible, with peaks not in excess of 15-20 cm. of water, and even this pressure should not be maintained for more than a fraction of the cycle. A sharp peak to the pressure curve rather than a plateau is the objective. The other risk is that too vigorous, and particularly too frequent, a rhythm of positive pressure may so tamponade the heart and impede the normal return of venous blood by the thoracic pump that the cardiac output is impaired. Prophylaxis here consists in applying a slow rhythm and allowing a rapid return of the intrapulmonary pressure to that of the atmosphere at the end of each inflation. These measures ensure that the mean intrapulmonary pressure is low and the circulatory impedance as low as possible.

Posture

The common practice of placing an unconscious patient flat on his back exposes him to the hazards of respiratory obstruction and of inhaling vomit and secretions. A better posture, and one which to a large extent overcomes these risks, is to place him on his side. Vomit and secretions collect in the cheek and, if there is a slight head-down tilt, will run out, while the flaccid tongue falls to one side and the airway does not become obstructed. At regular intervals, say once an hour, the patient should be turned to the other side to encourage good circulation on the two sides of the body to improve venous return.

Maintenance of Fluid Balance

In an unconscious patient it is essential that the fluid and electrolyte balance be maintained. Only losses should be replaced. The accurate and careful charting of fluid balance should be started at the earliest moment, regard being paid to the importance of vomit and sweating as sources of fluid loss. Nutrition becomes a problem only in unconsciousness lasting more than a couple of days; owing to the low metabolism in such cases a daily intake of about 1,500 calories is generally adequate.

Complications

Resistance to Breathing

In discussing the treatment of unconsciousness attention should be drawn to the importance of minimizing the resistance to breathing imposed by the use of such devices as endotracheal tubes and oxygen-therapy apparatus. It is essential that a patient, particularly one whose respiration is depressed, should not be required to make more effort to breathe than is necessary. If such effort is called for the patient becomes physically exhausted, and if the effort required is too great he may be incapable of making it. As a result the lungs are not filled quickly enough and oxygen intake is lowered. In addition, the intrapulmonary negative pressure at the height of inspiration may be greatly increased and the path prepared for pulmonary oedema. With an endotracheal tube, or any other gas pathway through which the patient is made to breathe, the factors which influence resistance are the diameter and length of the instrument and the presence of sharp corners—all being equally important. In any case, the use of endotracheal tubes, invaluable though it is in preventing respiratory obstruction, does not mean that further obstruction cannot occur. Kinking at the back of the pharynx and the passage of a tube into one bronchus are not infrequent and must be watched for.

Pulmonary Oedema

A common complication of the altered mechanics of respiration in the unconscious patient is pulmonary oedema. Most physicians and anaesthetists have had experience of the speed with which moist sounds, and even frothy sputum, appear in the respiratory tract of such a patient. To understand why pulmonary oedema readily appears in these circumstances it is necessary to indicate briefly the normal equilibrium across the alveolar membrane which keeps liquid within the circulatory system. This consists of a balance of forces. On the one hand there is the pressure within the alveoli, falling a little at each inspiration and returning to atmospheric pressure during expiration; on the other side of the membrane is the vascular system. A filtration force of 10 mm. Hg, the systolic pressure, tries to force fluid out into the alveoli, while the osmotic pressure of the blood proteins, of about 20-25 mm. Hg, acts in the reverse direction. When respiratory obstruction is present the intra-alveolar pressure falls unduly at each inspiration, tending to expel fluid. This is further enhanced if the patient has a right heart failure of any degree, leading to a high pulmonary arterial pressure, or has been injudiciously given blood transfusion or saline infusion. If in addition there is a general anoxia, the alveolar cells and the alveolar vessels also become anoxic, their permeability is increased, and a vicious circle created. Suction can clear fluid only from the trachea and main bronchi; it cannot empty the alveoli. Positive-pressure ventilation with an unobstructed airway can reverse this process. Confirmation of this view may be found in the growing practice nowadays of treating the respiratory depression of barbiturate overdose, the respiratory paralysis of poliomyelitis, and also the paralysis induced by curare in cases of tetanus, by means of tracheostomy, positive-pressure ventilation, and frequent suction. In these instances oxygenation is ensured, the respiratory tract kept clear, and pulmonary oedema prevented.

Summary

An outline is given of the main physiological problems common to unconscious patients whatever may be the underlying cause, and in particular those of interest to an anaesthetist.

Treatment resolves itself into ensuring adequate oxygenation by means of a clear airway, with some form of assisted or artificial respiration where indicated. The improved circulation, with fluid loss made good, combines with the improved oxygenation and respiratory

mechanics to prevent the altered dynamics across the alveolar membrane which leads to pulmonary oedema and may prove fatal. Many an unconscious patient who has been adequately treated for the underlying cause dies unnecessarily because these fundamental physiological requirements are not met.

TREATMENT OF LEUKAEMIA AND ALLIED DISORDERS WITH 6-MERCAPTOPURINE

BY

JAMES R. FOUNTAIN, M.B., M.R.C.P.Ed.

Medical Tutor, Department of Medicine, the General Infirmary at Leeds

Within the past ten years a number of chemical agents which produce temporary beneficial effects in leukaemia and allied diseases have been discovered. Their introduction has usually come about in one of three ways: (a) the observation that a compound being investigated for other reasons has a depressant effect on haemopoietic tissues—for example, nitrogen mustard and urethane; (b) the synthesis of compounds related chemically to substances already known to be effective, such as in the case of triethylene melamine, triethylene phosphoramide, and naphthyl-di-2-chlorethylamine (R.48); and (c) the synthesis of analogues of nucleic-acid precursors. It is on the last group that so much attention is now being focused. Undoubtedly the observation by Farber *et al.* (1948) that two folic-acid conjugates, pteroyl-diglutamic acid and pteroyl-triglutamic acid when given to children with acute leukaemia resulted in an acceleration of the leukaemic process gave considerable impetus to research in this particular field. The sequel was the synthesis of the 4-amino analogues of folic acid, aminopterin and amethopterin, which were found to suppress the growth of leukaemic tissue and produce temporary remissions in some children with acute leukaemia (*Proceedings of the Second Conference on Folic Acid Antagonists*, 1952).

With the knowledge that folic acid was essential for the synthesis of nucleic acid, antagonists of other nucleic-acid precursors have been prepared and tested for antileukaemic activity. 2:6-Diaminopurine, an analogue of adenine, has been shown (Burchenal, Bendich, *et al.*, 1949; Burchenal, Johnston, *et al.*, 1949) to prolong the survival time of mice with transplanted leukaemia. Burchenal, Karnofsky, *et al.* (1951) reported remissions in five of a series of 25 patients with acute leukaemia treated with this compound. Compounds containing the 2:4-diamino-pyrimidine moiety, including those with antimalarial activity (Falco *et al.*, 1949), were shown to be competitive antagonists of folic acid in the growth of *Lactobacillus casei* (Hitchings *et al.*, 1952), and in animals states indicative of folic-acid deficiency were observed. These findings suggested that such compounds might be effective in acute leukaemia, and it has been shown (Burchenal, 1954) that one such pyrimidine analogue, 2:4-diamino-5(3'4'-dichlorophenyl)-6-methylpyrimidine, produced occasional remissions in children with this disease. Farber, Foley, *et al.* (1953) have shown that a related series of compounds, the dihydrotriazines, have the property of temporarily inhibiting the growth of the leukaemic process in children.

Of the purine and pyrimidine derivatives discovered to date, the most effective in the treatment of leukaemia is the analogue of adenine and hypoxanthine, 6-mercaptopurine (6-MP). This substance, known by the proprietary name "purinethol," has been shown by Burchenal, Murphy, *et al.* (1953) to have produced good clinical and haematological remissions in 15 out of 45 children with acute leukaemia, and in another 10 patients partial remissions and clinical improvement. The same authors described occasional remissions in adult patients with the disease, and encouraging results in patients with chronic myeloid leukaemia.

The present study is based on experience gained in the treatment of 26 patients since June, 1953. Of these, 13 had acute leukaemia, 7 chronic myeloid leukaemia, 2 chronic lymphatic leukaemia, 2 multiple myeloma, 1 mycosis fungoides, and 1 erythroderma secondary to an underlying reticulosis of undetermined type.

PLAN OF TREATMENT

Patients were unselected and none received other forms of chemotherapy previous to, or as a supplement to, treatment with 6-MP. Blood transfusions and antibiotics were prescribed as the need arose. All patients received the initial course in hospital, and clinical and haematological examinations were performed daily or on alternate days. The bone marrow was examined at intervals, generally of two weeks, in cases of acute leukaemia. Patients who improved sufficiently were later followed up in the out-patient department and had blood examinations at weekly or fortnightly intervals.

The dosage of 6-MP was based on that suggested by Burchenal, the initial dose being approximately 2.5 mg. per kg. body weight. Thus a 5-year-old child was started on 50 mg. and an adult on 150–200 mg. per day, measured to the nearest 25 mg. The same dosage scheme was used both for patients with acute and those with chronic leukaemia, and in all instances the daily amount was divided into doses of 25 or 50 mg. given over the 24-hour period.

RESULTS OF TREATMENT

A. Acute Leukaemia

The criteria for a complete remission were strict and consisted of: (a) disappearance of all clinical evidence of disease and return of patient to full activity; (b) return of peripheral blood picture to normal; and (c) return of bone marrow to apparent normality with disappearance of blast cells or reduction to less than 10% of total cell count. A partial remission was said to be present when clinical and haematological improvement was considerable but fell short of the criteria of a complete remission.

Of 13 patients, seven responded to treatment. Five (two children and one adult with acute lymphoblastic leukaemia, and two adults with acute myeloblastic and acute monocytic leukaemia respectively) developed a complete clinical and haematological remission lasting from seven weeks to seven months. One patient, a child aged 3½ years, relapsed after remission lasting three months, but further treatment resulted in a second remission of four months' duration. Resistance to therapy has been observed following relapse, and in only one case has 6-MP been effective a second time. One adult and one child showed temporary, partial clinical and haematological improvement, while six patients (three adults and three children) failed to respond to treatment, four dying within the first week.

Illustrative Cases

CASE 1: ACUTE LYMPHOBLASTIC LEUKAEMIA.—A boy aged 3½ years was admitted to the General Infirmary at Leeds on June 20, 1953. Five weeks previously mumps had been diagnosed, and he then got rapidly worse. He lost appetite and pain in the legs prevented him from walking. Increased pallor was noticed and the temperature was at times raised.

On admission he was anaemic, and there were enlarged lymph nodes in the cervical, axillary, and inguinal regions, also numerous small scalp tumours. The skin, throat, and mouth appeared healthy; the liver and spleen were not palpable. There was no pyrexia.

Blood studies supported a diagnosis of acute lymphoblastic leukaemia. On June 26 blood findings were: Hb, 6 g. per 100 ml.; R.B.C., 1,900,000 per c.mm.; reticulocytes, 1.9%; platelets, 60,000 per c.mm.; W.B.C., 4,800 per c.mm. (blast cells 17%, lymphocytes 83%). The tibial bone marrow was highly cellular and replaced by lymphoid cells, of which 56% were primitive cells with the characteristics of lymphoblasts, while the rest were more or less mature lymphocytes. Packed red cells were immediately transfused, raising the haemoglobin level to 13.5 g. On the same day 6-MP therapy, 50 mg. by mouth daily for nine days, was started. On July 5 this was increased to 75 mg. daily for five days, and during the next two days a further 75 mg. was given. 6-MP was stopped on July 11, after a total of 0.9 g. had been given. During treatment the child's condition remained good, pain in the legs was moderate, and he was afebrile. On July 14 the lymph nodes and scalp tumours were palpable, and the white cell count had fallen to 850 per c.mm. and the haemoglobin to 9.6 g. Leucopenia persisted for three weeks and was followed by haematological remission.

On August 1 the leucocyte count was 4,000 (polymorphs 55%, lymphocytes 45%) and the platelet count 169,000 per c.mm. Blast cells in the tibial bone marrow had decreased to 6.4%; lymphocytes were 17.2%, myeloid cells 46.4%, and erythroid cells 30.0%, and the marrow was less cellular. The presence of erythroid elements was reflected in the rising haemoglobin level and red cell count, which on August 5 were 12.2 g. per 100 ml. and 4,000,000 per c.mm. respectively.

The patient was discharged on August 11. Physical examination revealed no abnormality, his appetite was good, and he regained full activity. Full clinical and haematological remission continued for three months, when relapse occurred. He was readmitted to hospital, and a second course of treatment with 6-MP for seven weeks again led to a complete remission lasting four months, during which a daily maintenance dose of 25 mg. 6-MP was prescribed. He had now become resistant to 6-MP, and A.C.T.H. was substituted. Although he has since been persistently leukaemic, his clinical condition has been fairly good. He has now survived over a year since the disease was diagnosed.

CASE 2: MONOCYTIC LEUKAEMIA (NAEGELI TYPE).—A 44-year-old baker was admitted to St. James's Hospital, Leeds, on June 9, 1953, with a four-weeks history of lumbar pain and of sweating and dyspnoea on exertion. Examination showed widespread ecchymoses, and two small skin tumours in the xiphisternal region. Sacral oedema was present; the liver was palpable 6 cm., and the spleen 5 cm., below the costal margin. The temperature was normal; no other physical abnormalities were found. A chest radiograph was normal. Biopsy showed the skin tumours to be due to leukaemic infiltration. The blood count on June 11 was: Hb, 8.5 g.; R.B.C., 2,800,000 per c.mm.; reticulocytes, 1%; platelets, 66,000 per c.mm.; W.B.C., 6,800 per c.mm. (blast cells 11%, myelocytes 11%, neutrophils 30%, eosinophils 11%, basophils 1%, lymphocytes 22%, monocytes 14%). The sternal bone marrow showed: blast cells, 59%; myeloid cells, 12%; erythroid cells, 8.5%; lymphocytes, 15%; other cell types, 5.5%. Megakaryocytes were scanty. Many of the primitive blast cells were monocytoïd, the appearance suggesting a Naegeli-type monocytic leukaemia.

Treatment with 6-MP, 100 mg. daily by mouth for seven days, was begun on June 15. On June 22 the patient had severe dyspnoea owing to a large left-sided pleural effusion, and 2 pints (1.1 litres) of haemorrhagic fluid was removed. The dose was then increased to 200 mg. daily. Whole blood was transfused on the fifth day of treatment, raising the haemoglobin level to 10.5 g. No clinical or haematological change occurred during the first three weeks of treatment. On July 8 the patient felt much better, the lumbar pain had disappeared, and his appetite improved. The size of the liver

and spleen had not changed, however, and a large pleural effusion was still present. The haemoglobin level had fallen and more whole blood was transfused. The leucocyte count was 4,200 and the platelet count 85,000 per c.mm. The leucocyte count continued to fall, and treatment was stopped on July 14, when leucocytes numbered 1,200 per c.mm.; a total dose of 5.3 g. of 6-MP had been given. He was now symptom-free; the liver was palpable, and the lower pole of the spleen could be felt only on deep inspiration. The remaining skin tumour had disappeared, but fluid was present in the left pleural cavity and a further 2 pints was removed on July 13. On July 14 the sternal bone marrow was hypocellular and blast cells had decreased to 10%.

The platelet count three days after stopping treatment rose to 192,000 per c.mm., and thereafter remained normal. Leucopenia persisted for two weeks, the leucocyte count then rising to normal. On July 29 findings on physical examination were normal and the blood picture was as follows: Hb, 11.5 g.; R.B.C., 3,800,000 per c.mm.; reticulocytes, 1%; platelets, 250,000 per c.mm.; W.B.C., 5,700 per c.mm. (neutrophils 78%, eosinophils 2%, lymphocytes 16%, monocytes 4%). The sternal bone marrow was still hypocellular, but the differential count was much improved: blast cells, 3.6%; myeloid cells, 47.6%; erythroid cells, 16.4%; lymphocytes, 13.6%; degenerate cells, 18.8%.

The patient was discharged on August 1 without maintenance therapy. For seven weeks after cessation of treatment he was symptom-free and carried out normal activities. A chest radiograph one week after discharge was normal. In early September relapse occurred and treatment with 6-MP was restarted. The disease was now, however, completely refractory to therapy and the patient died on October 8, 1953. A graphic record of the patient's progress is shown in Fig. 1.

CASE 3: ALEUKAEMIC LYMPHATIC LEUKAEMIA.—A 62-year-old housewife was admitted to the General Infirmary at Leeds on July 23, 1953, with a ten-weeks history of increasing pallor, lassitude, loss of appetite, and dyspnoea on exertion. Temperature 100.4° F. (38° C.). She was anaemic, with large lymph nodes in axillae and groins. The liver was palpable 5 cm., and the spleen 12 cm., below the costal margin. Slight sacral oedema and crepitations at both lung bases were detected. There were no other physical abnormalities. Blood findings were: Hb, 7.8 g.; R.B.C., 2,800,000 per c.mm.; platelets, 119,000 per c.mm.; W.B.C., 1,900 per c.mm. (polymorphs 36%, monocytes 2%, lymphocytes 62%). A percentage of the lymphocytes had nucleoli. Sternal bone marrow was moderately cellular; 66.4% of cells were of the lymphoid series, about half being lymphoblasts. The rest were equally divided between the myeloid and erythroid series. The picture was that of aleukaemic lymphatic leukaemia.

Packed red cells were transfused on July 26, and treatment with 6-MP, 200 mg. daily, was begun on August 7. On August 17 she felt better and her appetite improved. No change was seen on physical examination, but four days later the liver, spleen, and lymph nodes began to get smaller. Dosage was reduced to 100 mg. daily on August 24, and discontinued seven days later, a total of 4.2 g. having been given. Now the spleen was palpable and the liver edge could be felt only on deep inspiration. A few small, fleshy lymph nodes remained in the axillae. Physical examination was otherwise negative, temperature was normal, and the patient symptom-free.

Unlike in the first two cases, no significant reduction in white cell count followed treatment, and at no stage did it

fall below the initial figure. Improved distribution of leucocytes in the peripheral blood was, however, seen within ten days of the start of therapy. The haemoglobin level rose steadily, but there was little increase in platelets. At the end of treatment blood findings were: Hb, 11.2 g.; R.B.C., 3,700,000 per c.mm.; platelets, 100,000 per c.mm.; W.B.C., 3,100 per c.mm. (polymorphs 65%). The bone marrow was less cellular; few lymphoblasts (1.2%) were seen, and 33.6% of the cells were lymphocytes. Erythropoiesis was active and normoblastic, 34.0% of the cells being of this series, and the rest developing granulocytes.

The patient was discharged on September 5 feeling well. When seen ten days later improvement was maintained. The haemoglobin had risen to 12 g. and the platelet count to 275,000 per c.mm. She remained well, with a normal peripheral and bone-marrow blood picture, for seven months, being fully active and living a normal life. Maintenance therapy was not given during the remission, and since relapse in April, 1954, the disease has been refractory to further treatment with 6-MP.

CASE 4.—A man aged 41 was admitted to the General Infirmary at Leeds on April 7, 1954, with widespread purpura, epistaxis, and a large left pleural effusion. The liver and spleen were not enlarged. The blood picture was typical of acute myeloblastic leukaemia, with a total leucocyte count of 129,000 per c.mm., the majority blast cells. As he was very ill an attempt was made to induce an early response to 6-MP by a large initial dose (1 g. over the 24 hours) on April 8, followed by 200 mg. daily thereafter. The leucocyte count fell to 4,800 per c.mm. in four days with much clinical improvement. Treatment was stopped on April 14, when the leucocyte count was 2,000 per c.mm. Improvement continued, the pleural effusion cleared without paracentesis, and the enlarged lymph nodes receded. On May 1 blood findings were Hb, 12.2 g.; W.B.C., 5,400 per c.mm. (polymorphs 65%, lymphocytes 34%, monocytes 1%); platelets, 450,000 per c.mm. Sternal bone marrow: blast cells, 3.2%; myeloid cells, 43.4%; lymphocytes, 12%; erythroid cells, 39.2%; other cell types, 2.2%.

He was discharged on May 8 on a daily maintenance dose of 100 mg. of 6-MP. The remission has now lasted two months.

B. Chronic Myeloid Leukaemia

Of seven patients at different stages of the disease, including one in the acute phase, a varying response was observed in six; the other patient died of cerebral thrombosis a week after starting treatment. Improvement was

FIG. 1.

assessed on subjective, objective, and haematological changes following treatment.

Subjective improvement—increase in well-being, activity, appetite, and weight—was observed in four cases. Two others showed little subjective improvement, but there were a reduction in size of spleen and a fall in leucocyte count.

Objective improvement—diminution in size of spleen, lymph nodes, etc.—was observed in five cases. In only one case did the spleen fail to regress after prolonged treatment.

The leucocyte count fell in all six cases. In two cases erythropoiesis improved, but in another two no rise in haemoglobin level or red cell count occurred. Two patients had no significant anaemia.

Illustrative Cases

CASE 5.—A 49-year-old man had been well up to the day preceding his admission to the General Infirmary at Leeds on September 25, 1953, when he had a sudden attack of left abdominal pain with vomiting. He had a history of perforated peptic ulcer in 1945 and of partial gastrectomy in 1949. He was a pale, thin man, in obvious pain, and vomited repeatedly during examination. A large, rubbery, mobile lymph node was felt in the left axilla, and the spleen was palpable 8 cm. below the left costal margin. No other clinical abnormalities were found. Blood findings indicated chronic myeloid leukaemia and were as follows: Hb, 9.0 g.; R.B.C., 3,300,000 per c.mm.; reticulocytes, 2%; platelets, 300,000 per c.mm.; W.B.C., 128,000 per c.mm. (myelocytes 2%, metamyelocytes 17%, neutrophils 79%, eosinophils 1%, lymphocytes 1%). An occasional nucleated red cell was seen in the peripheral blood film. The sternal bone marrow was hypercellular with a marked preponderance of granular cells.

Treatment with 6-MP was begun on September 28. Within 48 hours of admission the abdominal pain and vomiting ceased, but tenderness of the left upper abdomen persisted for a week. The blood picture was unaltered until October 21, when the leucocyte count fell to 60,000 per c.mm. Two days later it was 44,000 per c.mm., and treatment was stopped, a total dose of 4.4 g. having been given. The spleen, which during the first three weeks had enlarged, became smaller. The patient was discharged on October 28, his progress being regularly followed. His condition remained satisfactory, with a rise in haemoglobin to 11.2 g., and he returned to work the following month. On November 30 the spleen was much larger and the leucocyte count had risen to 56,000 per c.mm. Treatment with 6-MP was restarted in a dose of 100 mg. daily, and after three weeks clinical and haematological improvement was again observed.

FIG. 2.

In view of previous experience and that of others a maintenance dose of 6-MP seemed necessary if a satisfactory clinical and haematological state was to continue for any length of time, therefore a dosage of 100 mg. and 50 mg. on alternate days was prescribed. On this the patient has remained well, the spleen and lymph nodes have been palpable and leucocytes and haemoglobin have been kept at normal levels for six months, during which time he has been fully active and doing a normal day's work.

CASE 6.—In a spinster aged 58 chronic myeloid leukaemia was diagnosed in March, 1952. She had no treatment during the following year, but owing to splenic enlargement and discomfort a splenectomy was performed in April, 1953. Deep x-ray therapy was then given with temporary improvement. On December 4, 1953, she was admitted to the General Infirmary at Leeds complaining of tiredness, loss of appetite, abdominal pain and distension, and swollen ankles. The liver was enlarged 12 cm. below the right costal margin, and small discrete lymph nodes were felt in the axillae and inguinal regions. Anaemia was not clinically evident. Blood examination revealed: Hb, 12.0 g.; R.B.C., 3,700,000 per c.mm.; platelets, 210,000 per c.mm.; W.B.C., 128,000 per c.mm. (myelocytes 3%, metamyelocytes 12%, neutrophils 84%, lymphocytes 1%).

Treatment with 6-MP, 200 mg. daily, was begun on December 5, but there was a delay of nine days before it took effect. After 12 days the leucocyte count had fallen to 39,600 per c.mm., the patient felt better, and the liver was smaller, being palpable 6 cm. below the right costal margin. Treatment was now stopped, a total of 2.6 g. having been given, and she was discharged with instructions to attend for follow-up. No further improvement occurred during the following week, and treatment with 6-MP was restarted in a dose of 100 mg. daily. On December 30 she felt much better and had gained 7 lb. (3.175 kg.) in weight. The liver was, however, still 6 cm. below the right costal margin, and the leucocyte count had risen to 91,200 per c.mm. Increasing the dose to 150 mg. resulted in a fall in leucocyte count to 15,400 by January 11, when the liver edge was just palpable and she was symptom-free; haemoglobin was 13.5 g. and platelets 250,000 per c.mm.

This patient has been maintained on a daily dose of 50 or 100 mg. of 6-MP for six months, during which time she has been symptom-free and fully active. No objective signs of disease have reappeared and the blood picture has remained satisfactory. The patient's progress is shown graphically in Fig. 2.

CASE 7.—A 56-year-old housewife was admitted to St. James's Hospital, Leeds, on December 18, 1953, with a seven-years history of myeloid leukaemia treated by several courses of deep x-ray therapy, the last in October, 1953. Her main complaints were repeated vomiting, a dragging sensation in the left abdomen, loss of weight, sweating, and epistaxis. The spleen was firm and tender and extended to 15 cm. below the left costal margin, and the liver was palpable 2 cm. below the right costal margin. Blood examination showed the following: Hb, 8.2 g.; R.B.C., 2,300,000 per c.mm.; platelets, 225,000 per c.mm.; W.B.C., 152,000 per c.mm. (blast cells 8.5%, myelocytes 25.5%, metamyelocytes 8.0%, polymorphs 35.8%, lymphocytes 17.5%, monocytes 2%). Sternal bone marrow was hypercellular, with blast cells 74.0%, myeloid cells 21.6%, erythroid cells 3.2%, lymphocytes 0.8%, and other cells 0.4%. The findings were characteristic of the acute terminal phase of chronic myeloid leukaemia.

Treatment with 6-MP, 200 mg. daily, was started on December 18, and on December 23 blood was transfused,

raising the haemoglobin level to 11.3 g. per 100 ml. The leucocyte count fell after three days' treatment, and by two weeks had reached 13,000 per c.mm.; the patient felt stronger, vomiting and sweating had ceased, the liver was palpable, and the spleen 9 cm. below the left costal margin. The dose of 6-MP was reduced to 100 mg. daily on January 2, and this was continued until January 14, when treatment was stopped, a total of 4.1 g. having been given in 27 days. By now the leucocyte count had fallen to 300 per c.mm., and the haemoglobin to 7.5 g., and the spleen was just palpable. More blood was transfused on January 22, and this raised the haemoglobin level to 11.7 g. The bone-marrow picture was also much improved: blast cells, 8.5%; myeloid cells, 47.5%; erythroid cells, 18.5%; lymphocytes, 24%; other cells, 1.5%. She was now well enough to get up, and although the leucopenia persisted for a month no complications resulted. The haemoglobin level was maintained without further blood transfusion, and clinical examination failed to reveal any of the usual findings of leukaemia. On February 2 she was discharged, and when next seen two weeks later she was symptom-free and doing a full day's domestic duties. Blood examination showed: Hb, 12.0 g.; R.B.C., 4,000,000 per c.mm.; platelets, 200,000 per c.mm.; W.B.C., 4,400 per c.mm. (polymorphs 80%, lymphocytes 20%). She was put on a daily maintenance dose of 50 mg. of 6-MP, and remained in good health for four and half months after completing the initial course of treatment. Relapse then occurred, and the disease was found to be resistant to further treatment with 6-MP. She died on June 26, 1954.

C. Chronic Lymphatic Leukaemia

Two patients (aged 73 and 56 years) with chronic lymphatic leukaemia showed no clinical or haematological evidence of improvement after one month's treatment with 6-MP.

D. Miscellaneous Group

Two patients with multiple myeloma, and one with erythroderma considered to be due to a reticulosis of undetermined type, failed to benefit from a month's treatment with 6-MP. One patient with mycosis fungoides appeared to be temporarily improved.

TOXICITY

An important property of 6-MP is its low toxicity. Apart from depressing bone-marrow function it has not resulted in any definite toxic side-effects in the present series. Burchenal has stated (Burchenal, Murphy, *et al.*, 1953) that gastro-intestinal symptoms may occur; but, whereas there has been vomiting in some of the cases now reported, on no occasion was it definitely attributable to the drug, nor did it necessitate interrupting treatment. Ulceration of the mouth, which is so common after treatment with aminopterin or amethopterin, was not observed. Severe thrombocytopenia attributable to 6-MP occurred in only one case—of multiple myeloma—but on no occasion was there haemorrhage. Haemorrhage due to overdosage with 6-MP has, however, been described by Burchenal and his co-workers, and must always be considered as a possible complication. Leucopenia is expected to follow treatment of acute leukaemia, and should not give rise to undue anxiety. No evidence was seen of megaloblastic erythropoiesis, which is an occasional sequel of anti-folate acid treatment.

DISCUSSION

A study of the results obtained in this limited series supports the finding of Burchenal and others that 6-MP may produce temporary remissions in a percentage of cases of acute leukaemia and modify the course of chronic myeloid leukaemia. Chronic lymphatic leukaemia, however, appears to be unaffected by it.

Until a much larger number of patients have been treated no definite information can be obtained as to age group and morphological type of acute leukaemia likely to be most responsive to treatment with 6-MP. All that can be

said is that adults as well as children have had remissions following treatment, and that remissions have been noted in the lymphoblastic, myeloblastic, and myelo-monocytic types of acute leukaemia. Thus 6-MP may be more versatile in its action than aminopterin and amethopterin, which are generally accepted as ineffective in adults and most effective in acute lymphoblastic leukaemia. As with other chemotherapeutic agents used in the management of acute leukaemia (Fountain, 1954), the remissions in patients who respond are only temporary, and, although a second response may occur, the disease gradually becomes resistant to further treatment.

A delay of 7 to 28 days was usual before the drug took effect, which suggests that four patients who died within the first week of treatment had received an inadequate therapeutic trial. In two cases a fall in leucocyte count with clinical improvement occurred, however, within a few days of starting treatment. One patient (Case 7), in the acute terminal phase of chronic myeloid leukaemia, received a routine course of treatment. The other (Case 4) had an extremely acute form of myeloblastic leukaemia with considerable haemorrhagic manifestations. In the hope that the rate of action of the drug would be increased an initial "loading" dose of 1 g. in the first 24 hours was given. Dramatic clinical and haematological improvement followed within the next four days. Although its value remains to be proved—another patient failed to respond rapidly to large doses—such a dosage scheme seems worth trying, as it is obvious that with such a disease as acute leukaemia the rapidity of action of the therapeutic agent is of prime importance. It may be of interest that both patients who responded rapidly to 6-MP had a high initial leucocyte count (over 100,000 per c.mm.), the predominant cell in each case being the primitive blast cell.

Whether patients who experience a complete remission should receive a daily maintenance dose of 6-MP remains to be answered, but from the limited data in this series it seems likely that maintenance therapy may not greatly prolong the remission. Continuous therapy seems essential in chronic myeloid leukaemia if the beneficial effect of the drug is to be maintained, for it has been my experience that in its absence clinical and haematological relapse may follow within a month of stopping treatment.

CONCLUSION

It has been shown that a new compound, 6-mercaptopurine, allied to the folic-acid analogues has been discovered with which dramatic remissions may be obtained in a percentage of cases of acute leukaemia. Unlike aminopterin and amethopterin, 6-MP has a low toxicity and can be used with little danger of added discomfort to the patient—an important consideration in the management of cases of leukaemia. That the remissions are only temporary suggests that the value of 6-MP as a research compound will at present outweigh its clinical usefulness. However, with the knowledge that aminopterin and amethopterin, A.C.T.H. and cortisone, and 6-MP may all produce clinical and haematological remissions in acute leukaemia, it seems desirable to give patients the advantage of such chemotherapy. Symptomatic relief may be obtained, and by sequential use these drugs may offer several months of useful life.

Although more patients with chronic myeloid leukaemia must be treated before the ultimate value of 6-MP is known, initial observations suggest that it will have its place in the management of this disease. The experience of Burchenal and his colleagues that 6-MP benefited two patients in the acute terminal phase of the disease has been supported by a case in this series, and it may be that one of its main uses in chronic myeloid leukaemia will be in the later acute stage of the disease.

SUMMARY

A purine antagonist, 6-mercaptopurine, has been shown to produce complete clinical and haematological

remissions in five out of thirteen patients, of various ages, with acute leukaemia, and partial remissions in two others. The remissions were only temporary, and resistance to further therapy with 6-MP eventually resulted.

Six patients with chronic myeloid leukaemia showed a varying response. One patient in the acute terminal phase had a remission lasting four and a half months.

Two patients with chronic lymphatic leukaemia, two with multiple myeloma, and one with reticulosis of the skin did not respond, while one patient with mycosis fungoides obtained some improvement.

6-MP is of low toxicity and no serious complications have followed its use.

I wish to thank the consultant physicians of the Leeds Hospitals for permission to study patients under their care, and also Dr. D. H. Collins and Dr. W. Goldie and the staff of their laboratories at the General Infirmary and St. James's Hospital, Leeds. I am indebted to Professor R. E. Tunbridge for his advice and criticism.

6-Mercaptopurine was initially supplied through the kindness of Dr. D. S. Searle, Medical Director, Burroughs Wellcome & Co. Inc., Tuckahoe, New York, U.S.A., and later by Dr. F. Prescott, Clinical Research Director, Burroughs Wellcome, London, England.

ERYTHRAEMIC MYELOSIS TERMINATING IN ERYTHROLEUKAEMIA

BY

J. R. HINDMARSH, M.D., M.R.C.P.
Consultant Physician

AND

T. A. J. WICKHAM, M.B.
Assistant Pathologist, Bournemouth and East Dorset Group
(From the Poole General Hospital, Poole, Dorset)

Malignant hyperplasia of the erythron, analogous to leucoblastic proliferation in leukaemia, was first described by Copelli (1912) and later defined as a pathological entity by Di Guglielmo (1923, 1926, 1937) when he recorded three cases as examples of true "erythraemic myelosis." These cases, with others published on the Continent, have been exhaustively reviewed by Di Guglielmo (1945, 1946) and Leitner (1949).

As with leukaemias, acute and chronic forms are recognized. Acute erythraemic myelosis (Di Guglielmo, 1945), pursuing a fatal course of one or two months, presents with severe anaemia, irregular fever, splenomegaly, slight hepatomegaly, and erythroid hyperplasia, with atypical erythroblasts in the blood, many of which

fail to mature. The chronic form (Duesberg, 1940; Heilmeyer and Schöner, 1941; Di Guglielmo and Quattrin, 1942) runs a longer course, up to two years, and the circulating erythroblasts are orthochromatic and less atypical.

In this country four examples of the chronic form appear to have been recognized, three of which have been published in Britain (Israëls, 1939; Neumark, 1948; Emery, 1951; Mackenzie and Stephenson, in *Blood*, 1952). A subacute form, terminating in acute granulocytic leukaemia, has also been recorded (Discombe and Nickol, 1954).

If in the case described below the patient had died within the first two months a diagnosis of acute erythraemic myelosis would have been accepted, but repeated blood transfusions sustained life for a further four months, during which the erythroleukaemic nature of the disease became manifest. In this respect our case closely resembles those of Verloop, Deenstra, and van der Hoeven (1952) and Discombe and Nickol (1954), lending support to the theory that erythraemic myelosis and erythroleukaemia are probably unusual variants in the onset of acute leukaemia.

Case Report

A single woman aged 30 gave up work in a soda-water factory early in August, 1953, because she felt very tired and breathless on the slightest exertion. Two weeks later she developed lumbar pain, headache, and nausea with vomiting.

On admission on August 25 she was very pale, had a temperature of 102° F. (38.9° C.) and fetid breath but no ulceration of the gums or fauces. The liver was palpable and the spleen descended five fingerbreadths in inspiration. There was no relevant personal or family history. Clinically she was considered to be a case of leukaemia, but subsequent blood and marrow pictures (see below) indicated erythraemic myelosis.

Owing to the severe anaemia she was given repeated blood transfusions, 26 pints (14.8 litres) in all, over a period of six months, the highest haemoglobin achieved being 78% (12.4 g.). Transient improvement followed each transfusion; vomiting ceased, the appetite returned, and the temperature subsided.

As her condition could not be maintained despite transfusions, liver, cyanocobalamin ("cytamen"), iron, vitamins, folic antagonists, and corticotrophin, it was decided to remove her spleen. This was done without incident on December 18. Improvement followed splenectomy, the haemoglobin remaining at 66% (10.5 g.), and in January, 1954, she was sent home on corticotrophin. She was now apyrexial, eating well, and gaining weight.

She was readmitted on February 19, 1954, with recurrent vomiting and pyrexia and the haemoglobin had now fallen to 42% (5.7 g.). Further transfusions had little effect and she continued to go downhill. Early in March a large gluteal abscess, following an injection of corticotrophin, was evacuated and 11 oz. (320 ml.) of pus obtained. The wound continued to discharge, and shortly before death on March 23 the haemoglobin had fallen to 16% (2.5 g.). Transfusions were now withheld, as she was obviously in the terminal stages of her illness.

Investigations

General.—Histamine-fast achlorhydria. Urobilinogen excess in urine but no haemosiderin in centrifuged deposit. Bile pigments scanty. Serum bilirubin, 1.2 mg. per 100 ml.

Blood.—Three representative blood counts are set out in the Table. Red cells showed marked anisocytosis, poikilocytosis, and moderate polychromasia. Platelets were scanty

Peripheral Blood

	Week of Admission	Week after Splenectomy	Week before Death
Haemoglobin	5.4 g. (34%)	10.5 g. (66%)	2.5 g. (16%)
Erythroblasts	15,370	21,000	100,600
Leucocytes	2,400	18,800	117,000
Myelocytes	1%	8%	5%
Metamyelocytes ..	4%	11%	7%
Polymorphs	29%	51%	19%
Eosinophils	1%	2%	1%
Lymphocytes	53%	20%	2%
Monocytes	12%	3%	23%
Promonocytes	—	—	34%
Stem cells	—	5%	9%

at all times. Reticulocytes 5.5% during cyanocobalamin therapy. Red-cell fragility was not significantly increased and tests for underlying haemolytic mechanisms were negative. Cold agglutinins were absent.

Sternal Marrow Punctures.—September 11, 1953 :—Easily aspirated, densely cellular, hyperplastic marrow—over 95% of the nucleated cells being erythrocyte precursors in which megaloblastic, macronormoblastic, and normoblastic erythropoiesis were evenly represented. Multipolar mitoses and nuclear-cytoplasmic "ripening" dissociation were present in minor degree. November 22 :—Same dense cellularity, but granulocytes now numbered 24.5% and red-cell precursors had fallen to 60%. As before, megakaryocytes were very scanty. Erythroid mitoses were still plentiful, but there appeared to be fewer mitotic abnormalities. An increase in megaloblasts was attributed to antifolic therapy. February 23, 1954 :—A hypocellular marrow aspirated with difficulty. Monocytes and their precursors now predominated. Some of the mature forms contained red cells.

Splenectomy.—December 18, 1953 :—The spleen weighed 41 oz. (1,120 g.). It was flabby, bright red in colour, and contained three recent infarcts. Histologically the Malpighian bodies were small and widely separated. The sinuses were filled with erythroblasts, but the reticulo-endothelial lining appeared to be normal and unproliferative. A few iron-laden macrophages and small foci of granulopoiesis were present.

Liver Biopsy.—December 18, 1953 :—Small centres of granulopoiesis, normoblasts in the portal tracts, and a sprinkling of haemosiderin in the periphery of the lobules.

Necropsy Report

Necropsy performed 16 hours after death. Several greyish macules on trunk and a few petechiae on forearms. The heart was slightly enlarged, very pale and flabby, and contained greyish-pink creamy blood. The liver (2,621 g.) was pale and yellowish grey. Two enlarged, soft, greyish lymph nodes were found at the hilum. The kidneys were enlarged and showed scattered wedges of homogeneous yellowish-grey colour with little demarcation between cortex and medulla. The marrow of sternum, ribs, vertebral bodies, and left femoral shaft was uniformly grey in colour. Several pea-sized cherry-red nodules were found in the dura over the left cerebral vertex but the brain was normal. Apart from bloodlessness the other organs appeared normal.

Histology.—The bone marrow showed a dense uniform cellularity with a few widely scattered islands of erythroblasts. The predominating cell had a round or oval vesicular nucleus with a thin rim of cytoplasm. Mitoses were scanty. Lymph-node architecture was partially disorganized, the surviving follicles at the periphery being small and devoid of germinal centres. The invading cells were a mixture of those seen in the marrow and normoblasts. The liver cells were compressed and loaded with haemosiderin in the outer and middle zones of the lobules and there were numerous monocytoïd cells and normoblasts in the portal tracts.

The dural nodules, skin, stomach, intestines, heart, kidney, adrenals, thyroid, pituitary, uterus, and ovaries all showed infiltration in varying degree by cells indistinguishable from those in the marrow.

Discussion

In the evaluation of this and other cases presented as acute erythraemic myelosis the greatest difficulty lies in excluding various forms of haemolytic anaemia. The presence of atypical erythroblasts with abnormal nuclei is among the features characteristic of the disease (Di Guglielmo, 1946), the typical failure of maturation in the erythroblasts of our cases being evidenced by the low reticulocyte counts.

Although deaths from erythraemic myelosis still occur (Emery, 1951; Schwartz and Critchlow, 1952) evidence accumulates to suggest that the longer the patient lives the more likely is acute leukaemia to develop. Gradations and transitions between erythraemic myelosis, erythroleukaemia, and myeloid leukaemia have been noted by Blackburn and Lajtha (1951) and by Martin and Bayrd (1954). Our case, in developing a monocytic element, constitutes a departure from the usual myeloblastic finale, but this may have been of Naegeli type, the so-called "monocytic phase of myeloid leukaemia." However, in describing the Schilling type, Wintrobe (1951) states that some of the cases have shown a widespread hyperplasia of monocytic cells in the connective tissue, especially about the blood vessels. It is of interest that the same perivascular reticulo-endothelial hyperplasia has been noted in several cases of erythraemic myelosis. Di Guglielmo himself describing transitional forms between reticulum cells and erythroblasts as a feature of the disease. Moreover, many cases, critically reviewed and accepted as erythraemic myelosis, have shown a frank monocytosis.

If we accept Dameshek's view that marrow reaction may be non-specific and provoke response along multiple channels, or Downey's modification of the neo-unitarian theory, ascribing toti-potentiality to the reticulo-endothelial cell, then we may conveniently regard erythraemic myelosis, erythroleukaemias, and leukaemias as manifestations of a fundamental "stem-cell" derangement and satisfactorily group them together as a reticulo-endotheliosis.

Summary

A woman aged 30 died six months after the onset of a profound resistant anaemia characterized, in the early stages, by erythroblastaemia, leucopenia, and erythroid hyperplasia in the marrow. A diagnosis of acute erythraemic myelosis (Di Guglielmo's disease) was made.

Following splenectomy the picture changed to one of erythroleukaemia, the leukaemic element being monocytic and probably of Naegeli type.

The relationship between erythraemic myelosis, erythroleukaemia, and leukaemia is briefly discussed.

We wish to thank Mr. F. P. Forrest, surgeon, Poole General Hospital, for performing the splenectomy and liver biopsy; Dr. C. H. D. Bartley, Wimborne, for tending the patient during her brief period at home after splenectomy; and Messrs. C. J. Cooper and J. Power for technical assistance.

large part or almost the whole of the stomach may be displaced into the chest, while the cardia remains in its normal position, will not affect the sphincter, and consequently oesophagitis is not produced. A combination of these two types occurs, known as a rolling hernia, in which the oesophagitis is a frequent complication (Fig. 3).

Results of Regurgitation of Gastric Juice

Superficial ulceration takes place which tends to heal and break down again. This ulceration produces spasm in the muscular coats of the oesophagus and later cicatricial contraction. Both processes lead to a gradual shortening of the oesophagus and to stricture formation.

Symptoms

Pain, dysphagia, and symptoms due to haemorrhage may all occur, together or separately, and the severity of each symptom may vary from a slight disturbance to a major illness. The pain is characteristically retrosternal and is produced by any posture or movement which encourages regurgitation. Movements such as stooping down to tie up the shoes or lying flat in bed will all tend to aggravate the pain. Besides being felt as a heartburn or retrosternal pain, radiation often occurs down one or both arms and up into the angle of the jaw. When this happens a diagnosis of cardiac pain is sometimes made, or if the distribution is very extensive the symptoms are often attributed to necrosis. The spastic contractions of the circular muscle and later the cicatricial changes will each produce dysphagia, although the spastic element will tend to improve spontaneously if the oesophagitis becomes less. The dysphagia varies from a subjective feeling of food sticking to inability to take any food whatsoever. The bleeding is usually intermittent and insidious, and in fact is suspected only when the patient is found to be grossly anaemic. Massive haemorrhage occurs occasionally in these patients, and is usually due to the fact that the stomach has been drawn up into the chest as part of the pathological process and a chronic gastric ulcer has developed in the thoracic stomach.

The diagnosis of the condition is made by x-ray and oesophagoscopy examination. It may be confused on occasion with carcinoma on the one hand and true cardio-spasm or achalasia on the other.

Treatment

The heartburn from which these patients suffer is often attributed to duodenal ulceration, and the treatment prescribed may be sufficient to relieve the symptoms. In any event, the duodenal ulcer patient who has a high gastric acidity and whose stomach possibly empties slowly owing to spasm at the pylorus will also suffer from reflux oesophagitis should his cardiac sphincter be incompetent. Where pain and anaemia are the most marked features medical management should be given in the first instance. The regime adopted should be exactly that used in treating a duodenal ulcer, with the difference that great emphasis must be placed on avoiding all postures and movements which encourage regurgitation. This regime is sufficient to improve a considerable number of patients. Even if there is some degree of stricture formation, a strict medical regime together with dilatation of the oesophagus may prove effective, but dilatation by itself must never be used in these patients because the result will be fresh stricture formation at a higher level.

If simple measures fail or severe stricture formation is present, or the presence of an ulcer in a thoracic stomach is proved or suspected, operation must be undertaken. The nature of the operation depends on the changes which have occurred in the oesophagus and whether it is possible to restore the anatomical arrangement at the hiatus to normal. If this is the case an operation aimed at replacing the stomach in the abdomen and retaining it there by suturing the phrenico-oesophageal ligament to the undersurface of the diaphragm is the basis of the procedure. This ligament,

described by Allison (1951), is not recognized by some surgeons, but there is usually no difficulty in demonstrating its presence and using it in the manner described. Decreasing the size of the actual hiatus is of little importance, because the opening in any event is an elastic one and its increase in size is brought about by the cone of stomach forcing its way upwards. If the stomach is kept down, the crus of the diaphragm will conform to the lower end of the oesophagus. As an adjunct to this form of repair I make a point of dividing both vagi to decrease the gastric secretion. To overcome the ill effects of the vagotomy the pyloric sphincter is divided. This procedure may disclose a number of cases of unsuspected duodenal ulcer.

If there is a long stricture present or a chronic ulcer has formed in the thoracic stomach, simple restoration of the anatomy is no longer effective and resection must be undertaken. The extent of the resection and the method of restoring continuity will vary according to the particular circumstances.

Hiatal Hernia and Reflux Oesophagitis in Infants

Infants present a difficult problem in that the symptoms of reflux oesophagitis may be confused with those of pyloric obstruction, and an operation for the latter condition is sometimes carried out. In some patients there seems no doubt that pyloric spasm makes the symptoms of reflux oesophagitis more apparent. The cardiac sphincter in infants is not well developed, and if too large a feed is given regurgitation will take place without any difficulty. It seems that in certain circumstances ulceration is produced either because the gastric contents are more irritating than usual or because the oesophageal epithelium is unduly sensitive. Once oesophagitis has started a vicious circle is set up and spasm and actual cicatricial contraction may occur, producing shortening of the oesophagus and stricture formation. It seems that the process can be arrested and reversed and the stomach may return to its normal abdominal position.

Treatment for these infants should again be medical in the first instance, posture being of great importance. Occasionally a gastrostomy may be called for. Anatomical repair of the hernia in the sense that the stomach is held down in its proper position, as has already been described, may be required, but it is often difficult to decide when this should be done. If the condition has been neglected or misdiagnosed, the destruction of the lining of the oesophagus and the surrounding fibrosis may be so severe that resection has to be carried out. For this reason, if a conservative or an expectant line of treatment is adopted in the early stages, a careful watch must be kept on the child and repeated x-ray examinations made so that any deterioration in the oesophageal condition can be dealt with at once. The management of these small patients sometimes presents very great difficulty.

Simple Strictures due to the Swallowing of Corrosives

The swallowing of corrosives, either accidentally or with suicidal intent, may result in the production of severe strictures, and recently there has been a tendency to treat these strictures by resection because of the supposed difficulty of carrying out dilatation effectively. The management of these strictures calls for painstaking care. After preliminary x-ray examination, oesophagoscopy is carried out, and it is sometimes found that an unsuspected foreign body lies above the stricture. Oesophagoscopy is seldom successful, because the interval between the dilations is bound to be considerable, and the presence of the rigid instrument in the gullet interrupts normal peristaltic waves which help in the swallowing of the bougie. For these reasons "auto-dilatation" is to be preferred. The method is quite safe provided no force is used, and it is successful in nearly every case. When the stricture is so severe that a preliminary gastrostomy is called for the patient is encouraged to swallow a ureteric catheter, which is then recovered through

the gastrostomy opening and utilized as a guide for introducing a rubber tube and eventually a series of bougies of increasing size. By one or other of these methods dilatation has been successfully carried out in every case.
