ADRENALECTOMY FOR BREAST CANCER*

BY

SIR STANFORD CADE, K.B.E., C.B., F.R.C.S., F.R.C.O.G., M.R.C.P.

Senior Surgeon, Westminster Hospital

It is now recognized that cancer of the breast and prostate are hormone-dependent tumours—that is, cancers which can be controlled by the administration of sex hormones. That removal of the ovaries influences advanced breast cancer has been known since 1896, when George Beatson published the first reports on this method of treatment. By 1905 Hugh Lett had reported 99 cases of oophorectomy for the late stages of mammary carcinoma. The popularity of this operation waxed and waned during the following half-century owing to the development of radiation-induced menopause. To-day it is thought by many that radiation menopause is not equivalent to surgical castration and that it does not abolish oestrogen formation. Huggins and Bergenstal (1951, 1952) demonstrated that the adrenal cortical hormones sustain mammary cancer and that their withdrawal is followed in a number of cases by marked regression of the tumour. Prolonged survival of adrenalectomized patients on cortisone maintenance has given a great impetus to this method of treatment (West *et al.*, 1952; Taylor *et al.*, 1953; Pyrah and Smiddy, 1954).

Huggins has drawn attention to the following important observations: (1) Gonadectomy is followed by a compensatory hypertrophy of the adrenals and by increased cortical function. (2) In men, removal of the testis is followed by an increase of 17-ketosteroids in the urine, and these high values are eliminated by bilateral adrenalectomy. (3) Following oophorectomy, women continue to excrete oestrogens in the urine, but these compounds disappear from the urine after adrenalectomy. Further, Huggins and Dao (1953) formed the opinion that in a number of post-menopausal women the ovaries continue to have an active endocrine function, which indicates oophorectomy even after the menopause.

The rationale of bilateral oophorectomy and adrenalectomy is therefore the elimination of all known sources of hormones which can influence the growth of mammary cancer and the creation of a physiological environment poor in steroids.

The Natural Course of Breast Cancer

Mammary cancer varies in its rate of growth and power of dissemination from the slow and apparently harmless course of the "atrophic scirrhus" on the one hand to the rapidly fatal course of the "acute inflamma-

tory" type on the other. The variation noted in different histological types, in different age groups, in different hormonal states (pre- and post-menopausal and in pregnancy and lactation) indicates that the hormonal influence is variable and that some tumours are hormone-dependent to a greater degree than others and that some are independent of hormones. But in nearly all cases after a variable period of quiescence and localization the disease spreads locally, to the regional lymph nodes, to the skeleton, and to the viscera.

The early and localized stage of the disease can be controlled by surgical treatment; moderate extension can be alleviated by radiotherapy; in the early stages of dissemination the use of androgens or oestrogens may arrest the spread of the disease for variable periods. Bilateral adrenalectomy is indicated when the disease is disseminated and no longer amenable to treatment by surgical, radiological, and hormonal means. It is therefore a most important advance in the treatment of cancer of the breast and should be considered in patients in whom the disease is no longer amenable to the established methods of treatment.

This report is based on the experience of 69 bilateral adrenalectomies, 56 of these in advanced and disseminated breast cancer. The study of these patients has shown that about one-third are no longer under hormonal influence, and in these no benefit is obtained; that in the remaining two-thirds there is an improvement varying from complete control of the disease to an amelioration which varies in degree and in the length of time which the improvement lasts. The longest period of improvement in this series is 24 months. No other method of treatment has as yet achieved control of disseminated, widespread, and often terminal stages of breast cancer comparable to that following bilateral adrenalectomy.

Selection of Cases

In all the 56 adrenalectomized patients cancer of one or both breasts had been present for various periods of time and had been treated previously according to its stage and extent by appropriate methods. In every patient skeletal, visceral, or soft-tissue metastases were widespread and the expectation of life was very limited. The selection of patients was, in fact, simple: only those to whom nothing further could be offered were submitted to adrenalectomy. The operation was therefore put to a severe test and was deemed a justifiable experiment. It was soon found that patients with disseminated disease in the pulmonary lymphatics, with involvement of the pericardium and the heart, were not likely to benefit from adrenalectomy and that the

*Based on a Hunterian Lecture given at the Royal College of Surgeons of England on June 17, 1954.

operative risk in such cases was high. In fact, involvement of the lungs and heart to an extent which impaired vital function is regarded at present as the main contraindication for the operation.

Management

Pre-operative.—All the patients are carefully assessed, as regards the extent of the disease and the general state of health, by clinical, radiological, and chemical investigations. In addition the output of 17-ketosteroids and oestrogens is studied and the Thorn test for adreno-cortical function done. The pre-operative preparation consists in the correction of the blood state by transfusion and the administration of cortisone. In this series of patients cortisone only was used. There seemed to be no need for D.C.A. (deoxycortone) or for extra salt. Cortisone acetate is given in 100-mg. doses by intramuscular injection forty-eight, twenty-four, and one hour before the operation.

Post-operative.—During the operation and in the immediate post-operative period noradrenaline is used only if

there is a marked fall in the blood pressure. Noradrenaline is not used as a routine, only as an emergency measure. On the first post-operative day cortisone is given by injection in 100-mg. doses six hourly; this is reduced by a half on the second post-operative day; from the third to the fifth post-operative day 25 mg. of cortisone acetate is given by mouth six-hourly; this is further reduced to 75 mg. a day and finally to 50 mg. daily as a maintenance dose. Patients are given instructions about the need of extra cortisone during intercurrent illness or following an operation or an accident. Medullary failure occurs very rarely, sometimes several weeks or even months after adrenalectomy, and is corrected by noradrenaline.

The Operation

Bilateral adrenalectomy and oophorectomy can be done in one stage. The practice at present is to carry out bilateral oophorectomy and unilateral adrenalectomy in one stage and postpone the second adrenalectomy for seven days. The best approach to the adrenal is through the bed of the twelfth rib, the patient lying on her side, in the position usually adopted for renal operations. When the twelfth rib is small, it is necessary to remove the eleventh rib. The operation is technically simple, but the adrenal must be handled with care as it is friable, and in some patients there occurs a marked fall or rise in the blood pressure when the gland is manipulated. Haemorrhage is controlled by careful ligation of the adrenal veins, which show considerable anatomical variations, and with which the surgeon should be familiar. Accidents which can be guarded against are injury to the pleura, the renal vein, or inferior vena cava. In most patients convalescence is smooth, and the post-operative course gives rise to anxiety only in patients with pre-existing or pulmonary involvement by disease or following operative difficulties.

Mortality.—Of the 56 patients, 8 died following the operation, a mortality of 13.6%. The causes of death in these cases were: one from pulmonary embolus; one from cardiac arrest during the operation; two from renal failure on the sixth and twelfth post-operative days; one from cerebral metastases; and four from pleural and pericardial involvement by disease. A most careful study of these cases indicates that the very precarious state of the patient as well as the operative risk accounted for the deaths. It is interesting to note that there has been no operative death in the last 27 cases.

Failures.—Twelve patients derived no benefit at all from the operation: the disease progressed, and most patients died from it within a period of a few months. In 14 patients there was no alteration in the metastases, although some improvement in the general state of health and relief of symptoms was obtained. In four patients there was no relief of symptoms, although local improvement of the lesions was noted.

Successful Cases.—These patients have been studied as regards subjective and objective improvement. In 13 patients the results were remarkable, in the sense that bedridden patients with severe pain became ambulatory and no longer required pain-relieving remedies. The subjective improvement was accompanied by increase of weight and a return to a near-normal life. Objective improvement was assessed by healing of pathological fractures, alteration of osteolytic lesions to a normal bone structure, shrinkage of visible external tumours, such as the primary tumour, skin nodules, enlarged lymph nodes, and disappearance of metastases in the omentum, peritoneum, lungs, liver, and in the choroid. In one patient, nearly in extremis when adrenalectomized, with extensive destruction of the base of the skull, multiple cranial nerve palsies, and pleural, pulmonary, and intra-abdominal metastases, most lesions disappeared and the patient regained a near-normal state of health for a period of fourteen months, when the disease became active again

and the patient died fifteen months after adrenalectomy. So far, the longest survival period in this series is twenty-four months and the shortest six weeks. Examples reported here show regression of various types of lesions—skeletal, visceral, and soft tissue. Improvement can usually be noticed within a few days of the operation. If no improvement occurs within one week the case is likely to prove a failure.

Prognosis.—There is no method at present by which to forecast if adrenalectomy will be a success or a failure. Attempts have been made to correlate the results with the age of the patient, the extent of the disease, and the histological type of the primary growth. Both successes and failures were noted in all histological types, although Huggins and others think that the adenocarcinoma is more likely to regress than the carcinoma simplex or other varieties. The incidence of metastases in the adrenal is very high and reproduces accurately the histological variety of the primary growth. The Table shows the results in 48 patients.

Results in 48 Patients: Adrenalectomy for Breast Cancer

Illustrative Cases

The following successful cases illustrate the benefit which has been achieved by adrenalectomy in some patients with advanced and disseminated breast cancer no longer treatable by other methods. The cases chosen show the effect on skeletal, pulmonary, and soft-tissue metastases.

Case 1. Aged 50. Right radical mastectomy in January, 1950, for a carcinoma simplex with involvement of axillary lymph nodes. Post-operative x-ray therapy. In August, 1951, left radical mastectomy for a histologically similar tumour; lymph nodes in axilla involved. Post-operative x-ray therapy. In January, 1952, multiple skeletal metastases in spine, ribs, and skull. Testosterone propionate given by injection. In July, 1952, bilateral oophorectomy: both ovaries infiltrated by metastases. In November, 1952, the skeletal metastases had spread widely. Nearly all the ribs and all the vertebrae were involved. The sternum was the seat of a large tumour; 17-ketosteroid excretion: 6 to 7 mg./24 hours. Bilateral adrenalectomy performed. This was followed by immediate relief of pain and a fall in the 17-ketosteroid excretion to 2.5 mg./24 hours, and the Thorn test showed no fall in the eosinophil count. Both subjective and objective improvement was very marked. The effect on the skeletal metastases in the skull, sternum, and spine was a return of the bones to a normal structure. The patient remains well to date, twenty-four months after adrenalectomy. Fig. 1 illustrates the patient's present appearance; there is an alteration in her face (moon-shaped) due to the cortisone; marked increase in weight and complete relief from pain.

Case 2. Aged 42. Right radical mastectomy for a pleomorphic carcinoma of the breast in December, 1950. Post-operative x-ray therapy. In April, 1952, skeletal metastasis in lumbar and dorsal vertebrae. Pain relieved by x-ray therapy, but further metastases in the spine developed. From July to October, 1952, given testosterone propionate, but extensive skeletal

metastases found in right humerus (pathological fracture), skull, ribs, pelvis, femora; collapse of third lumbar vertebra. Patient was bedridden and in considerable pain on movement. 17-ketosteroids, 9.4 mg. 24 hours. Bilateral adrenalectomy performed on April 9, 1953. Both adrenals contained metastases. Skeletal pain relieved within twenty-four hours. Rapid recovery: healing of pathological fracture of humerus and other skeletal metastases. Fig. 2 shows the right humerus before adrenalectomy and ten months later; Fig. 3 shows extensive osteolytic lesions of the skull before and five months after operation. The patient is ambulatory and remained well seventeen months after adrenalectomy.

FIG. 1.—Case 1. Bilateral carcinoma of breast. Multiple skeletal metastases. Survival to date: 24 months after adrenalectomy. Marked increase in weight; regression of skeletal lesions. A, Moon-shaped face. B, Scars of bilateral adrenalectomy.

FIG. 2.—Case 2. Metastasis in humerus before and 10 months after adrenalectomy.

FIG. 3.—Case 2. Osteolytic lesions in right parietal and frontal bones. Before and five months after adrenalectomy.

FIG. 4.—Case 3. Pulmonary metastases from carcinoma of breast before and three months after adrenalectomy.

Case 3.—Aged 53. In September, 1952, mastectomy and post-operative x-ray therapy for an adenocarcinoma of the right breast. In August, 1953, patient noticed "flashes of light" in the right eye with progressive visual impairment. Seen by Mr. E. F. King at Moorfields Hospital and found to have a large choroidal metastasis in the right eye. X-ray examination of chest showed extensive bilateral pulmonary metastases (Fig. 4). Bilateral oophorectomy and adrenalectomy in October, 1953; the right ovary contained a metastasis; no metastases in either adrenal. Rapid improvement followed; complete disappearance of choroidal metastasis within three weeks and nearly complete regression of pulmonary metastases within three months (Fig. 4). Patient remains well to date, twelve months after adrenalectomy.

Case 4.—Aged 35. In November, 1951, radical mastectomy for an adenocarcinoma of the right breast with metastases in the axillary lymph nodes. Post-operative x-ray therapy. In July, 1952, metastases in the ribs and dorsal spine with destruction of several mid-dorsal vertebrae and marked kyphosis. X-ray menopause and testosterone failed to control the disease. In November, 1953, there was widespread involvement of the skull, pelvis, lower dorsal and lumbar vertebrae, ribs, both scapulae, and both femora. Sterna puncture showed numerous malignant cells in the bone marrow. Bilateral adrenalectomy performed on November 10. Rapid recovery; complete relief of bone pain. Increase in weight by 2 stone (12.7 kg.) and return to duty as a nurse in an administrative capacity. Improvement lasted nine months. Died twelve months after adrenalectomy.

Case 5.—Aged 43. Left radical mastectomy for a carcinoma simplex of the left breast in March, 1950. Two years later, local recurrence in scar (Fig. 5A) which was not controlled by radiotherapy. Bilateral oophorectomy and adrenalectomy in November, 1953. Rapid disappearance of lesion (Fig. 5B). Remains well to date, twelve months after adrenalectomy.

Case 6.—Aged 39. Radical mastectomy for a carcinoma simplex of the right breast in January, 1951. Post-operative x-ray therapy. In May, 1952, carcinoma of the left breast which did not respond to x-ray therapy. In December, 1952, there was a condition of carcinoma-en-cuirasse on the left side of the chest wall; enlarged supraclavicular lymph nodes. No improvement from testosterone. In February, 1953, bilateral oophorectomy was done with temporary improvement. In October, 1953, there were extensive local disease; an orbital metastasis causing proptosis of the right eye; skeletal metastases in the pelvis and the right scapula; and a pleural effusion. Bilateral adrenalectomy was performed on November 24, 1953. This was followed by remarkable subjective and objective improvement: relief of pain, return to a normal life, and complete disappearance of the lesion on the right side of the chest wall and supraclavicular gland. Remains well to date, twelve months after adrenalectomy.

Case 7.—Aged 40. Right radical mastectomy for a late stage II scirrhous carcinoma of the right breast in October,

FIG. 6.—Case 7. Enlarged lymph nodes in contralateral (left) axilla following right radical mastectomy. This patient also had multiple skeletal metastases. A, Before adrenalectomy. B, Five months after adrenalectomy.

1949. Post-operative x-ray therapy. Three years and three months later, in January, 1954, metastases in pelvis, femora, and opposite axilla (Fig. 6A). Bilateral oophorectomy and adrenalectomy in February, 1954. Both adrenals but not the ovaries involved by metastases. Uneventful recovery. Rapid disappearance of contralateral lymph node (Fig. 6B); complete relief of pain from skeletal metastases to date, eight months after adrenalectomy.

Summary and Conclusions

A series of 56 patients is reported on whom bilateral adrenalectomy was performed for disseminated breast cancer. Extended survival on cortisone maintenance has been obtained, so far up to 24 months. In a proportion of cases both subjective and objective improvement has been achieved which has never been accomplished before by any other method of treatment. Relief of pain from skeletal metastases, regression of visible and palpable lesions, reossification of skeletal metastases, and union of pathological fractures have followed adrenalectomy. There is no method, so far, to forecast if a patient will be benefited by the operation or not. Beneficial effects have been achieved in about 60% of patients; and in a proportion of these—23% of all cases—the improvement was quite remarkable and surprising.

The risk of the operation is reasonable and maintenance of life on cortisone simple. Although there is no likelihood of any permanent effect, the results are encouraging, and it seems justifiable to advise the operation at an earlier stage of the disease.

I would like to express my thanks to the Medical Research Council for the provision of cortisone and to my colleagues at Westminster Hospital for their help and co-operation, especially to Dr. F. D. Hart and Dr. C. J. M. Clark for the medical care of the patients, to Mr. A. Jessiman and Mr. G. Westbury for the help at the operations and post-operative care, and to Miss Worcester, the sister in charge of my wards, and her staff, on whom fell the burden of nursing care of these very ill patients.

PROBLEMS INVOLVED IN PREVENTION OF BACTERIAL COMPLICATIONS OF MEASLES WITH SPECIAL REFERENCE TO PROPHYLACTIC SULPHADIAZINE*

BY

G. I. WATSON, M.D.
General Practitioner

There is general agreement that sulphonamides and penicillin have contributed greatly to the fall in the mortality of measles in recent years (*British Medical Journal*, 1952), but the need for further study of the prevention of morbidity arising as a result of measles is also recognized (*British Medical Journal*, 1953). Since this essay was submitted, the *Lancet* (1954), in discussing the prophylaxis of measles complications, makes the following statement: "In this country quite satisfactory prevention of bacterial complications can still be obtained by the simpler and cheaper method of sulphonamide prophylaxis. This is one of the few forms—if not the only form—of routine sulphonamide prophylaxis that can be generally recommended." Two questions, however, have not yet been satisfactorily answered. The first is whether sulphonamides are, in fact, effective in the prophylactic as opposed to the curative treatment of the bacterial complications of measles. The second is whether the preventive dose, if effective, is sufficiently lower than the curative to warrant the expense involved by putting every case of measles on a prophylactic, even when no evidence of bacterial infection is present at the onset of the virus illness.

Historical

Haerem (1943) attempted to evaluate the effect of sulphonamides as antiviral rather than antibacterial agents in patients, probably mainly adults, admitted to a military hospital with measles. The dosage was 1 g. four times daily for four days. He found no significant differences in the duration of fever or the stay in hospital between treated and control cases, and he could find no previous mention of the use of sulphonamides in measles.

Begg *et al.* (1947) attempted to assess the total bacterial and haemolytic streptococcal counts in measles cases nursed in an L.C.C. hospital, and made a subsidiary study of the value of sulphadiazine in such cases. They concluded that sulphadiazine in a dose of 0.25 to 1 g. daily according to age was "of very doubtful prophylactic value," but were dissatisfied with their controls. The ages of the children are not given.

Badr El-Din (1951) attempted to assess the possible value of chlortetracycline ("aureomycin") "as an antiviral agent" in measles by attention to three things:

*Based on the Sir Charles Hastings Clinical Prize Essay, 1954.

(a) the increase or decrease of "catarrhal signs"; (b) the development and fading of the rash; and (c) the presence or absence of complications. The ages of only some, possibly the youngest, of the children are given. They were treated in hospital. Two out of 10 controls developed bronchopneumonia. No case of acute otitis media was reported, and no complications occurred in cases treated prophylactically, either with chlortetracycline or with combined penicillin and sulphadiazine. He found that chlortetracycline, given in the phase before the rash, diminished the catarrhal signs and also the intensity of the rash, if given early enough. He interpreted these as actions of chlortetracycline on measles virus, but other possible interpretations are discussed below.

No report has been traced of the use of sulphonamides or antibiotics in measles treated at home, nor of any attempt to assess the prophylactic value of these drugs in relation to the age of the child, to its past medical history, or to the presence or absence of bacterial infection at the onset of its measles. The present paper is an attempt to do this, as well as to define more clearly the limits of the problem, and to suggest what still remains to be done in any future, more extensive investigations.

Present Investigation

From December, 1950, to May, 1951, I attended 142 cases of measles in a rural partnership practice in the south-east of England, and the notes made at the time of seeing these patients, many of whom were treated prophylactically, mainly with sulphadiazine, have provided the material for this paper. As my notes were not then made with this particular research in mind, desirable details have sometimes not been recorded. Details of late complications after the children were out of the house from their attack of measles have not been analysed, as I was not then the only doctor seeing them. Particular care, however, was being taken during the epidemic to determine what signs of bacterial infection were present in each child at the onset of measles, and what evidence arose later in the illness to show that bacterial invasion had occurred. The details in this respect are therefore as accurate as circumstances allowed, and were all observed and recorded by me.

In defining the virus illness for myself, I took as its onset the first day of fever or typical symptoms, such as coughing or sneezing; and the end as the day when the rash had faded from the abdomen. At this stage a child was allowed up in the house, and outside on the next suitable occasion; but it was not returned to school or other crowds until three weeks after the onset of the rash, so as to minimize the risk of bacterial infection for that time. The episode which appeared to throw open the air passages of the head and chest to bacterial infection was the rash, first in the form of Koplik's spots. As the rash faded, so the mouth and eyes visibly healed, and one pictured the whole epithelium of the head and chest gradually recovering its resistance. Each of these stages in the virus illness might be defined more exactly in terms of changes in the leucocyte count, as is suggested below.

Information about the drugs used is incomplete in respect of dosage. The system I used for prophylaxis as a rule was a dose of tablets daily that totalled one more than the child's age in years, up to a total of six, in divided doses—that is, a child of 2 would have three tablets (each 0.5 g.) daily, in halves, while a child of 5 or over would have six tablets daily, one at a time. The duration of prophylactic treatment was from the day the child was first seen until at least the day the rash began to fade from the legs, sometimes until the rash had completely faded from the abdomen. I usually gave out the tablets at the time of my visit, working on this basis.

Results

The first case was seen on December 3, 1950, and the last on May 25, 1951. Table I shows that the peak of the epidemic came in February and that the proportion of children on prophylactic drugs rose to a peak then and fell away again.

TABLE I

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
On antibacterial prophylaxis	7	15*	38	25*	3	2	90
Not on drugs	13*	11	5	6*	2	4	41
On treatment for complications	1	1	2	2	1	0	7
On gamma-globulin	1	1	0	2	0	0	4*
Record of drugs missing	0	0	1	3	0	0	4
Total cases	21	27	46	36	6	6	142

* The four cases on gamma-globulin are shown in two places.

In later tables two cases on gamma-globulin alone are excluded from those receiving antibacterial prophylaxis, being shown as among those "not on drugs." Aspirin in some form was used for most children at the height of the fever. Details of the drugs used in the 90 cases receiving antibacterial prophylaxis are as follows: sulphadiazine alone, 74 cases; sulphadimidine alone, 10; "sulphatriad" suspension alone, 2; injection of penicillin alone, 1; sulphadiazine + sulphapyridine, 1; sulphadiazine + gamma-globulin, 1; sulphadimidine + sulphatriad suspension + gamma-globulin, 1.

Ages of Children Affected.—The epidemic began among the older schoolchildren of one village towards the end of term. From there it spread to their families and to other villages. Table II shows how, by February, it was the youngest schoolchildren and the older pre-school children

TABLE II.—Monthly Distribution of Cases by Age Groups (The Number on Prophylactic Drugs is Shown in Parentheses)

Age	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
1-2	1	1 (1)	0	5 (3)	2 (1)	0	9 (5)
3-4	3 (2)	2 (2)	1 (1)	8 (4)	1 (1)	0	15 (10)
5-6	1	4 (4)	6 (4)	7 (4)	2 (1)	1	21 (13)
7-8	1	3 (3)	4 (4)	3 (2)	0	1 (1)	12 (9)
9-10	1 (1)	4	9 (8)	1 (1)	0	2	17 (10)
11-12	2	3 (2)	10 (8)	1 (1)	0	1 (1)	17 (12)
13-14	5 (3)	5 (2)	3 (2)	2 (2)	0	0	15 (9)
15-16	3 (1)	1 (1)	6 (6)	3 (3)	0	0	13 (11)
17-18	0	1	0	4 (3)	1	0	6 (3)
19-20	2	1	2 (1)	2 (2)	0	0	7 (3)

Over 25	0	1	1 (1)	0	0	1	3 (1)
Total	21 (7)	27 (15)	46 (38)	36 (25)	6 (3)	6 (2)	142 (90)

who were being most heavily attacked. Not until March was the brunt of the attack borne by the youngest children at home. During April and May, which included the Easter holidays, the epidemic spent its force on the non-immune population.

Selection of Cases for Drug Prophylaxis

During December, and especially during January, as will be seen from Table II, drug prophylaxis was given particularly to the youngest children on the basis of the teaching in textbooks, as it was among them I expected the worst complications. Price (1947) states: "Measles is most fatal to infants and young children, 70% of the mortality occurring in children under 3 years of age." Gunn (1951) confirms this view, as follows: "Case fatality is highest under 1 year of age, but the greatest number of patients die in the second year because morbidity is much higher at this period." The two youngest children infected in this epidemic were each 14 months.

Children under 3.—The number of cases in infants was too small to allow more than a tentative opinion to be formed; but the impression gained from this outbreak was

that if bacterial infection was absent, prevented, or adequately treated in children under 3 years of age, who had been breast-fed and whose mothers had had measles, the illness due to the virus infection was less severe than in older children of, for example, 10-12 years, some of whom were amongst the most prostrated, even in the absence of complications. The mildness of measles in a group of children between 8 months and 3 years, to whom Badr El-Din (1951) gave chlortetracycline in the stage before their rash, he attributed to an action of the drug on the virus itself; it may, however, have been due solely to the antibacterial effects of this drug. The duration of benefit derived from maternal immunity should be studied again among a larger number of the very young.

Other "Poor-Risk" Groups.—In addition to any which might occur in very young children, complications were also expected to be particularly prevalent among two other groups—namely, those who started their measles with evidence of bacterial infection already upon them, and those who, though evidently free of such infection, had a bad past history of naso-bronchial catarrh.

Evidence of Bacterial Infection Present at the Onset of Measles

The nature and severity of any signs of bacterial infection present in every child examined, whether for measles or not, was being recorded in detail at that time even though no symptoms referable to these signs were mentioned. From those records the Tables which follow have been prepared. The term "acute chest" has been used in the sense of Fry's (1953) paper, but limited to conditions that are usually febrile. "Subacute chest" includes the afebrile cases and others with minimal abnormal signs.

In Table III the incidence and severity of such preliminary bacterial infection is shown, followed by details of the actual conditions allotted to each degree of severity.

TABLE III.—Monthly Incidence and Severity of Bacterial Infection Present at Onset of Measles

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total

% showing signs at onset	14%	15%	33%	55%	—	30%	31%
Severe	1	1	4	5	0	0	11
Moderate	1	2	6	9	0	2	20
Mild or doubtful	1	1	5	6	0	0	13

In the 11 severe cases the following conditions were present: both drums very red, 4 cases; one drum very red and "subacute chest," 3; one drum very red, 2; bronchopneumonia, 1; "acute chest" and symptomless otitis media, 1.

In the 20 moderate cases were found: both drums injected, 4 cases; one drum reddened, 3; one drum opaque, healing, or old otitis media, 4; one drum with red malleolus, 2; both drums injected, one or both eyes sticky, 2; one drum reddened and "subacute chest," 1; one drum injected and mucopus in throat, 1; both drums injected and chronic tonsillitis, 1; tonsils exuding pus, 1; "subacute chest," 1.

The 13 mild or doubtful cases included: one drum slightly or partly injected, 7 cases; earache but drums not reddened, 2; both drums slightly injected but with good light reflex, 1; one meatus and drum reddened by heavy rash, 1; grossly enlarged tonsils but no exudate, 1; doubtful "moist sounds" in chest, 1.

In case the differences in severity of bacterial infection might merely be because the patients were seen early or late in the virus illness, the records have been analysed to show the stage reached by each case and the severity when the signs were first seen. This has been done in relation to "R" day—the day the rash appeared; "R minus" includes those seen before, and "R plus" those first seen after the rash appeared.

Table IV demonstrates that the severe infections were not necessarily seen late in the virus illness and confirms that these children were entering their measles already harbouring in varying degree the often symptomless seeds of possible bacterial complications.

TABLE IV.—Severity of Bacterial Infection in Relation to Date of Rash

	Time First Seen			Total
	R—	R	R+	
Severe	4	5	2	11
Moderate	7	7	6	20
Mild	3	7	3	13

Table III also reveals that the peak of preliminary bacterial infections was reached slightly later than the peak of the measles epidemic; but the relative incidence of severe, moderate, and mild bacterial infections did not materially alter with the change of season. The need, therefore, for an effective antibacterial prophylactic was greatest at the height of the bacterial rather than of the virus epidemic. This fact was not appreciated at the time, and Table V gives the monthly distribution of cases receiving antibacterial drugs in relation to the stage of their virus illness.

TABLE V.—Cases Receiving Antibacterial Prophylaxis in Relation to "R" days, by Months

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
Total No. of cases	21	27	46	35	6	6	142
Prophylaxis:							
Starting on "R minus"	1	2	14	5	0	0	22
Starting on "R"	2	10	18	15	1	0	46
Starting on "R plus"	4	3	6	5	2	2	22
Total	7	15	38	25	3	2	90
% of monthly total	33	59	83	78	50	30	

It shows that the proportion of cases treated prophylactically more than doubled between December and February and that prophylactic doses of antibacterial drugs were being given earlier and to a slightly higher proportion of children at the peak of the measles epidemic in February than at the peak of the bacterial epidemic in March. The use of these drugs was evidently aimed more at preventing the complications of measles than at treating any bacterial infections which were found incidentally, though undoubtedly the latter factor was an influence.

"Catarrhal" Children

There were a number of children affected by measles in this epidemic who had suffered from recurrent previous attacks of respiratory infection often enough to merit being called "catarrhal" children. The number of such children seen is set out in Table VI, showing whether they presented with signs of bacterial infection as well as measles.

TABLE VI.—Monthly Incidence of Bacterial Infection at Onset of Measles Among Normal and Catarrhal Children

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
Total cases	21	27	46	36	6	6	142
Normal children	17	22	32	22	6	5	104
With bacterial infection at onset	2	2	8	7	1	0	20
Catarrhal children	4	5	14	14	0	1	38
With bacterial infection at onset	19	19	30	39	—	20	27
With bacterial infection at onset	1*	2	7	13	—	1	24

Severity of These Infections

	Severe	Moderate	Mild	Total
Normal	4	6	10	20
Catarrhal	7	14	3	24

* No percentages were calculated for a total of fewer than six.

Table VI shows that in this epidemic the incidence of signs of bacterial infection at the onset of measles was three times as great in catarrhal children as in children with normal histories; and a higher proportion of those infections in the catarrhal children were severe or moderate, as opposed to mild.

As the catarrhal state should be considered in relation to age, Table VII gives the age distribution of these infected children.

The numbers involved in Table VII are too small for conclusions to be drawn, but there is a suggestion of two separate peaks in the incidence of the catarrhal state; one

TABLE VII.—Ages of Catarrhal Children and Number Showing Signs of Bacterial Infection at Onset

	1-	2-	3-	4-	5-	6-	7-	8-	9-	10-	11-	12-	Over 20	Total

comes in the 4-5 age group, at the end of home contact before school begins, and the other in the 7-9 age group after several years of school contact. If this were shown to be generally true, it might be that the catarrhal state is brought about, at least in part, by undue contact with carriers of bacterial infection, at first in the home and later at school. Mawson *et al.* (1953) noted a variation by age groups with a peak at 6 years, in the incidence of acute otitis media, among children treated at hospital, and suggested that, after going to school, "exposure of the child to an alteration in its usual bacterial environment plays a part in the causation of this disease." This is a subject that would repay further research.

Complications Resulting from this Epidemic

Table VIII sets out the number of children who were free of infection at onset, and the percentage of these who at a later visit showed signs of bacterial infection, complicating their measles.

TABLE VIII.—Monthly Total of Children Free of Bacterial Infection at Onset of Measles, and Percentage of these Developing Complications Later

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
Total clear at onset	18	23	31	16	6	4	98
No. of these developing complications	5	6	8	4	2	0	25
% with complications	28	26	26	25	30	0	26

One should, however, differentiate between children with normal and catarrhal past histories in estimating the risk of complications arising in any particular child who is free of signs of bacterial infection when starting measles. This is done in Table IX.

Part A shows the high percentage of children with normal past histories who were clear of signs of bacterial infection at the onset of measles; more than three-quarters of these remained clear. On the other hand, it was found that the proportion of catarrhal children who started their measles clear diminished steeply from February onwards, and of all those who started clear one-half later developed signs of bacterial infection during their virus illness.

Badr El-Din (1951) reported that chlortetracycline, given in the phase before the rash, diminished the catarrhal signs of measles. He attributed this to an effect of the drug on the measles virus, but it is more probable that the effect was an antibacterial one. This raises the question of what abnormal signs in the chest in measles can be attributed wholly to the action of the virus and which are the results

TABLE IX.—Number of Complications Arising During this Epidemic of Measles

Catarrhal "	24	6	2	11	5

of any concomitant bacterial infection. Should any moist sounds, for example, be expected in the chest of a child with measles who is quite free from bacterial infection?

Part B of Table IX reveals at first sight a puzzling result—namely, that among 20 normal and 24 catarrhal children who started measles with signs of bacterial infection already present about half in each group showed a diminution or clearance of these signs during their virus illness. In discussing Table V, however, it was suggested that the presence of bacterial infection at onset had undoubtedly influenced the selection of cases for prophylactic treatment. This possibility is analysed in Table X, which shows separately, for both a pre-existing bacterial infection and a catarrhal history, how these factors influenced the selection of cases for prophylaxis.

It was shown in Table VI that signs of bacterial infection at onset were three times as common in catarrhal as in normal children during this epidemic. In Table X there is greatest

TABLE X.—Distribution of Prophylactics Among those With and Without Preliminary Bacterial Infection or a Catarrhal Past History

	Bacterial Infection at Onset		Past History	
	(1) Absent	(4) Present	(2) Normal	(3) Catarrhal
Total	98	44	104	38
No. on prophylactics	56 (57%)	34 (79%)	64 (62%)	26 (68%)

similarity between group 1 and group 2 with regard to the proportion on prophylactic drugs, while group 3 lies somewhere between those two and group 4, which had the largest proportion of children on prophylactics. In other words, the influence of selection for antibacterial prophylaxis was acting more strongly when I saw a case of measles in a catarrhal child with bacterial infection at the first visit, and was least active when I was dealing with normal children showing no early abnormalities.

The anomaly in Part B of Table IX now becomes understandable. Among those with signs at onset, whether with normal or catarrhal histories, such signs abated or disappeared in about half from each group because they were being given drugs in doses which were curative rather than prophylactic. The figures are too small for conclusions, but there is a further slight suggestion in part B of Table IX that, among catarrhal children, more often than among normal children, if the signs already present did not diminish, they were more likely to be aggravated than to remain *in statu quo* as a result of an attack of measles. In them the curative treatment had been insufficient.

What was the fate of those other children who were given drugs prophylactically, but who had shown no signs

of bacterial infection when first examined for their measles? This touches the crucial problem of prophylactic versus curative treatment. The results obtained in this epidemic are set out in Table XI. This Table shows an unexpected result: proportionately more fresh late bacterial infections were seen among those on prophylactic drugs than among those not taking any. In point of fact, 19 out of these 25 fresh late infections occurred during December to February, before the peak of the "bacterial infection at onset," shown in Table III.

One possibility certainly is that by giving sulphadiazine or similar drugs to otherwise healthy children at the start of measles one was lowering their resistance to bacterial infection, should this reach them during the period of their rash. I have heard an eminent consultant paediatrician express the opinion that, since measles produces a leucopenia and since sulphonamides tend to depress the white-cell count, therefore sulphonamides should never be given to children during measles. While this may well be wise advice, it is possibly not the whole explanation of the anomalies revealed in Table XI, for one would then expect more evidence of infection in these treated children at the peak of the bacterial epidemic. Furthermore, it was shown in Table IX that in some children sulphonamides had exerted a beneficial action during measles.

Another possibility is that during the early months of the epidemic one was examining the children more closely. If this were true it could perhaps explain the larger proportion of cases noted during the first three months, but the overall difference in complications rate would still remain to be explained.

This difference between the complications rate of prophylactically treated and untreated children becomes even more striking if the children are divided into those with normal or catarrhal histories, in order also to test whether there had been any unconscious selection of bad-risk cases among those on prophylactics. This difference is shown in Table XII.

TABLE XII.—Complications Rate in Prophylactically Treated and Untreated Children with Normal or Catarrhal Histories

	Total	No.	No. Untreated	Clear at Onset				Complications			
				On Drugs		Untreated		On Drugs		Untreated	
				No.	%	No.	%	No.	%	No.	%

Catarrhal histories	38	14	5*	8	57	4	90	3	40	—	—

* One record of drugs incomplete.

Of those clear at onset, 57% were given prophylactic drugs, whether they were catarrhal or not; there was evidently no increased tendency for catarrhal children to be given these drugs, so long as they were free of signs of bacterial infection at the time measles began (see discussion of Table X). Table XII also reveals that, whereas sulphonamides given to those who showed no signs of bacterial infection when they first attended for measles may have prevented complications among catarrhal children, these same drugs appeared to increase considerably the risk of complications occurring in normal children.

The distribution of complications among the age groups was studied to see whether there was any difference in this respect between treated and untreated children.

Table XIII shows that in the untreated group the three severe or moderate complications all occurred in younger children than did the five mild complications; while in the

TABLE XIII.—Number and Severity of Complications by Ages Among Prophylactically Treated and Untreated Children

treated group there were relatively more severe or moderate complications, and the 11 which occurred were at both younger and older ages than the six mild ones.

Discussion

In this epidemic the action of sulphadiazine appears to have been twofold. When given in near-curative doses to children, especially catarrhal children, who showed signs of active bacterial infection at the start of their measles, the drug acted beneficially by reducing the severity of the bacterial infection in about half the treated cases, while the remainder had probably received an insufficient dosage; but when sulphadiazine or another sulphonamide was given to normal children, apparently free of bacterial infection at the start of their measles, the drug appeared to confer no benefit, but rather to increase the rate and severity of complications as compared with similar untreated children.

If these findings were to be confirmed by other observers and in a larger series of cases, the whole question of the use of sulphonamides in any disease associated with leucopenia—for example, also influenza—would have to be re-examined. It might be possible to do serial white-cell counts throughout a sufficient number of cases of measles and influenza to determine the incidence and degree of leucopenia in relation to bacterial complications, both in prophylactically treated and in untreated cases. Penicillin and sulphonamides could be compared as antibacterial prophylactics in diseases associated either with leucopenia or with leucocytosis. It may be that when bacterial infection is already present at the onset of such a virus illness there is already a sufficient leucocytosis to offset any later drop in the white-cell count, due either to the superimposed virus infection or to drugs. In such cases sulphonamides may not be so harmful, though they are not necessarily to be preferred to penicillin.

Puckey (1941) reported a hospital case in which granulopenia had developed after a leucocytosis due to pneumonia, treated with sulphapyridine; measles and infective hepatitis developed during the treatment. At the end of the pneumonia, after ten days on sulphapyridine and three days after the measles rash appeared, the white-cell count was 25,000 per c.mm. In spite of stopping sulphapyridine the white-cell count dropped steadily to 4,600 per c.mm.

(24% neutrophils) on the fourteenth day after the rash. How much of this leucopenia was due to sulphapyridine, and how much to measles and infective hepatitis it is not possible to judge, but the question is one which undoubtedly needs to be examined again.

Conclusions

A fresh investigation of the problem of antibacterial prophylaxis in measles should be carried out soon by those with access to a large number of cases treated at home, bearing in mind the following conclusions which can be drawn from the present report of an outbreak in a country practice of 142 cases of measles, 90 of which were given prophylactics.

(1) The complications rate in untreated normal children during this outbreak was 4 out of 36 (11%), whereas in untreated catarrhal children it was 4 out of 5 (80%).

(2) Among all children, irrespective of age or past medical history, who were free of signs of bacterial infection at the onset of their measles, the complications rate was higher in those given sulphonamides prophylactically (17 out of 56=30%) than in the untreated (8 out of 41=20%).

(3) Some children already showed signs of bacterial infection when their measles began. This occurred in 24 out of 38 (63%) of catarrhal children, but in only 20 out of 104 (19%) of normal children.

(4) Twice as many such infections, already present, were graded as moderate or severe as opposed to mild in the catarrhal children, as compared with those in normal children.

(5) There was a seasonal variation in the amount of preliminary bacterial infection, especially among catarrhal children. In this outbreak the peak of such bacterial infection fell in March, though the peak of the measles epidemic passed during February.

(6) There was no evidence that the severity of the virus illness of measles was unduly marked in children under 3 so long as bacterial infection was absent; in fact, the impression was gained that such children suffered less from their measles than did some of their older siblings.

(7) There was evidence that the sulphonamides given had been acting curatively rather than prophylactically in those children who started measles showing signs of preliminary bacterial infection; but that in about half of these the dose had been insufficient.

(8) There was some evidence to suggest that the catarrhal state of a child was not something permanent, but that it might vary according to undefined circumstances both before and after the age of starting school.

(9) Since it appears from an analysis of the present observations that sulphonamides are of value to some children, but not to others, in preventing bacterial complications of measles, a further investigation is needed into the incidence, severity, and duration of any changes in the white-cell count of normal and of complicated measles, in both treated and untreated children, some receiving sulphonamides and some penicillin. Such an investigation might reveal ways of defining stages of the virus illness of measles in terms of leucopenia and the consequent risk of bacterial complications.

(10) Such an investigation, if also carried out in other diseases associated with leucopenia and apt to be followed by bacterial complications, such as influenza,

might further reveal a general principle of value in determining the choice of antibacterial drugs for prophylactic or curative use, especially in virus infections.

I wish to thank the librarian of the Royal Society of Medicine for his help in connexion with the references to previous work on this subject. Three colleagues, Dr. D. G. French, Dr. J. H. Hunt, and Dr. R. J. F. H. Pinsent, have offered valuable criticism of earlier drafts of this paper, and to them I would like to repeat my thanks.

Note.—Since this essay was presented, the College of General Practitioners has begun a two-year investigation into the value of sulphonamides and antibiotics in the prophylaxis of the bacterial complications of measles. The conclusions reached in this essay were made available to the College, which hopes to obtain records of 2,000 to 3,000 cases of measles by the end of 1955.

THE EARLY DIAGNOSIS OF SPINAL TUMOURS

BY

H. J. G. BLOOM, M.D., M.R.C.P.

Registrar, Meyerstein Institute of Radiotherapy, Middlesex Hospital; late Captain, R.A.M.C.

H. ELLIS, B.M., F.R.C.S.

R.S.O., Royal Infirmary, Sheffield; late Captain, R.A.M.C.

AND

W. B. JENNETT, M.B., F.R.C.S.

Surgical Registrar, United Liverpool Hospitals; late Captain, R.A.M.C.

(From the Military Hospital for Head Injuries, Wheatley, Oxford)

The first patient to be successfully treated for spinal tumour was a British Army officer who was operated on by Sir Victor Horsley in 1887 (Gowers and Horsley, 1888). He recovered from paraplegia and lived for twenty years before he died from an unrelated condition. Since this demonstration that at least some spinal tumours were surgically accessible, and indeed curable, it has been of the utmost importance to diagnose such neoplasms early in their course and to locate them accurately.

It is not the purpose of this paper to describe in detail the established clinical syndromes, excellent accounts of which already exist (Elsberg, 1941). Rather is it intended to make use of the opportunity afforded the Service medical officer of having patients under observation from an early stage, and to comment on the clinical picture and diagnosis at this stage. Failure to make an early diagnosis may lead to incomplete recovery or even permanent disablement, despite the removal of a benign tumour, due to prolonged cord compression.

This paper is concerned with primary and secondary tumours which involve the spinal cord or nerve roots: such lesions develop in the vertebrae or in the structures within the spinal canal. The material for the investigation consists of 36 verified cases of spinal tumour treated between January, 1940, and December, 1951, at the Military Hospital for Head Injuries, Oxford. During this period there were approximately 1,150 admissions with spinal symptoms, 813 bearing the label of prolapsed intervertebral disk. These cases were drawn from the three Services and therefore represent a special cross-section of the population in regard to age and sex. There were 32 males and 4 females, the ages ranging from 17 to 60 years, 30 of them being under 35 years (see Table III).

Pathology

The lesions met with in this series are given in Table I. The frequency of the histological groups may be compared with those in a civilian series of 275 cases reported

TABLE I.—Pathology

Present Series		Civilian Series (Elsberg, 1941)	
Tumour	No. of Cases	Tumour	No. of Cases
Neurofibroma	15 (41.6%)	Meningioma	73 (26.5%)
Metastatic	8 (22.2%)	Neurofibroma	64 (23.2%)
Vascular	4 (11%)	Sarcoma	31 (11.2%)
Ependymoma	3 (8.3%)	Glioma	14 (5%)
Glioma*	3 (8.3%)	Metastatic	14 (5%)
Osteoclastoma	2	Ependymoma	11 (4%)
Melanoma	1	Vascular	9 (3.3%)
		Others	59 (21.5%)

* Two histologically unverified.

by Elsberg (1941). Table I reveals two important differences between the two series in the relative incidence of these tumours. There are no meningiomas and there is a high proportion of metastases in the military series. These points require further comment.

Meningiomas are found most often in middle-age, and when they occur in the spine women are affected twice as often as men (Learmonth, 1927); this group of patients not being represented in the section of the population from which our cases are drawn thus accounts for their absence in this series.

Metastatic tumours occurred in no less than 22% (8 out of 36) of the patients in this series, mainly young adults; the oldest patient with a secondary tumour was 42, four patients were in the thirties, one was 19, and two were 17 years of age. However, the incidence of metastatic spinal tumours is doubtless underestimated in civilian series based on statistics from surgical explorations: many overtly metastatic tumours, frequently presenting in the terminal stages of malignant disease, never reach the neurosurgeon. Nevertheless, it is important to appreciate that a metastatic neoplasm cannot be ruled out on age alone, nor on the apparent absence of a primary growth.

In six patients (Cases 29–34) the histological sections of the spinal tumour revealed secondary anaplastic carcinoma, suggestive of bronchial origin. Although the presence of a primary bronchial carcinoma was later confirmed by a post-mortem examination in only one instance (Case 34), the available facts favoured a bronchial origin for the primary growth in all six cases. Pulmonary or hilar shadows were present in four of the five patients in whom x-ray films were available.

Another patient with a secondary neoplasm (Case 35) died elsewhere, and a post-mortem examination revealed anaplastic secondary carcinomatous deposits in the spine, liver, lung, and iliac glands; a primary tumour was not found. The final patient in this group (Case 36) had vertebral collapse associated with a tumour in the lower end of the humerus, the radiological diagnosis being "osteogenic sarcoma"; no further information about the pathology is available.

The proved or probable bronchial origin of six of the eight metastases indicates the importance of x-raying the chest of every patient suspected of having a spinal cord tumour. A carcinoma of the lung may, however, remain clinically latent or not be apparent radiologically for some time in the presence of spinal metastases (see Case 31, described below). Occasionally the primary growth may be very small and be revealed only after a careful search at the post-mortem examination (Turner and Willis, 1938).

Although we have emphasized the frequency of metastatic growths it should be stressed that essentially operable and benign tumours were present in 40% of the Service cases and in 48% of the civilian series. It is in these cases that early diagnosis is so important.

Symptoms

With primary spinal tumours the symptoms usually have a gradual onset, preceding physical signs by many months. As some 70% of them are situated posteriorly or posterolaterally in the spinal canal it is natural that sensory should precede motor disturbances as a rule. Spinal cord disorders usually occur later.

With secondary neoplasms, however, the course is characteristically rapid, paraplegia often developing within days of the first symptoms. In two cases in this series this interval was less than 10 days, whilst the longest history given by a case of secondary tumour was three months. All eight patients with metastatic lesions were unable to walk on admission, while this advanced picture was seen in only 6 of the 29 patients with primary spinal neoplasms. The rapid advance of some of these metastatic growths is illustrated by the following case.

Case 31. Extradural Metastatic Tumour with Three Weeks' History.—A trooper in the Life Guards, aged 17, was perfectly well until three weeks before admission, when he began to have backache. Pain down the right leg developed twelve days later, and three days before admission he rapidly developed a complete flaccid paraplegia below L4. Plain x-ray films of the spine showed only some doubtful erosion of the pedicle of D 11, but lumbar puncture revealed a manometric block and a cerebrospinal fluid protein of 1,000 mg. per 100 ml.; myelography showed the block to be at D 11. Laminectomy exposed an extradural tumour which was shown histologically to be a metastatic carcinoma, suggestive of bronchial origin. A chest x-ray film on the day of operation was clear. Later, supraclavicular, axillary, and intercostal glands became involved and a subcutaneous tumour which appeared over the scapula showed on biopsy the same appearances as had the spinal mass. The patient was transferred later to another hospital, where he was said to have developed cough and dyspnoea with signs of pulmonary collapse three weeks before his death, which followed three months after the laminectomy. A post-mortem examination was not made.

In contrast, the following case report illustrates the gradual onset of symptoms due to a benign spinal tumour.

Case 9. Dorsal Neurofibroma with Two Years' History.—An A.T.S. woman aged 26 first noticed numbness and a burning sensation in her right leg some two years before admission. For seven months she had experienced pain in the lower back and in both calves. During the four months before admission her gait had become increasingly unsteady, and for two months there had also been urgency and frequency of micturition. Examination revealed increased tone and weakness of the left leg, a sensory level at D 8, and bilateral extensor plantar responses. A spinal x-ray film showed erosion of the pedicle and scalloping of the body of D 7. Lumbar puncture revealed an almost complete spinal block and a cerebrospinal fluid protein of 120 mg. per 100 ml. She made a good recovery following removal of neurofibroma attached to the left seventh dorsal nerve root.

Pain is the commonest symptom, but it is not a constant feature. It occurred in 29 cases of this series (81%), which agrees with the findings of Craig (1936), who recorded pain as being present in 80% of 300 cases from the Mayo Clinic. Not uncommonly, and especially with tumours of the cauda

equina, there may be partial or complete temporary remissions of this symptom. Such remissions were found in five of our nine cauda equina tumours, and Allen (1930) reported remissions in 25% of 69 patients with tumours in this region.

Two types of pain are experienced: root pain and dull central backache. Root pain, which is the more common, was a manifestation in 24 of our cases (66%), and in 19 patients (53%) it was the initial symptom. That root pain is not confined to extramedullary tumours was pointed out as long ago as 1914 by Pearce Bailey. Indeed, such pain was found in nearly half the intramedullary growths studied by Kernohan and his colleagues (1931). In two of the five intramedullary tumours in the present series there was root pain, but in each case motor symptoms had preceded this by many months.

Root pain has certain characteristics. It may be aching or lancinating, is referred to the appropriate dermatome, and may be so severe as to require morphine for its relief. It is often accentuated, and sometimes precipitated, by raising the intrathecal pressure, as by straining and coughing; this is probably due to an alteration in the relationship of the tumour to near-by roots. It may be worse at night and be relieved by walking about or sleeping in a chair. Eaton (1941) suggests that this may be due to the lengthening of the spine which he has demonstrated experimentally to occur in recumbency. It is thought that the disks increase in thickness on lying down and that this is responsible for the pain by altering the relationship between the roots and surrounding structures.

Dull backache is common as a symptom of cauda equina tumours, but so frequently is this a complaint of other disorders that few sufferers should be suspected of having a spinal tumour on this account alone. It is backache which persists and fails to respond to rest that should arouse suspicion. Moreover, in the presence of a spinal tumour it is commonly accompanied by root pain; in only 4 of the 22 patients with backache in the present series was this the only type of pain. Though most constant in cauda equina tumours, backache is often a distressing feature of metastatic deposits in the vertebrae. It may even occur in intramedullary tumours, as evidenced by two patients in this series.

Pain was not a feature in seven patients (19%). This agrees with the figure of 20% reported by Craig (1936) and of 25% by Spurling and Mayfield (1936). The type of lesion present in our cases without pain varied, but included three examples of vascular malformation. There were two neurofibromas, one extradural secondary carcinoma of the bronchus, and one intramedullary tumour.

In other cases sensory disturbances apart from pain may be predominant, such as a sensation of tingling, pins-and-needles, burning, or numbness. These are common as early manifestations which occasionally occur alone, but more frequently are associated with backache and root pain.

Loss of power usually follows sensory disturbances, but it may occur as an initial symptom, and this is especially likely to happen with intramedullary tumours. In three of our cases this led to a diagnosis of poliomyelitis.

Sphincter Disturbance.—Although complete retention or incontinence of urine or faeces is a late manifestation, increasing constipation or some difficulty in micturition is not an uncommon symptom in patients with spinal tumour. Apart from 10 paraplegic patients who had incontinence or retention on admission, nine patients had experienced some difficulty in micturition, but in none was this a presenting feature.

Physical Signs

The presence of suspicious symptoms, such as root pain and persistent backache, warrants a thorough examination of the whole patient. In the majority of cases with spinal tumour this will yield further evidence of such a lesion. The spine is tested for local tenderness or deformity, muscle spasm, and limitation of movement. Spinal tumours in the lumbar region—that is, of the cauda equina—commonly

produce erector spinae spasm, a stiff spine, and even scoliosis. The range of straight-leg raising and the effects of jugular compression and of coughing are recorded. Careful examination of the nervous system will often indicate the level of the lesion fairly accurately, especially if the patient is paraplegic. Weakness, wasting, reflex changes, and sensory loss all contribute to this localization. The general examination should include in particular a search for the cutaneous pigmentation or tumours of neurofibromatosis and for angiomas of the skin or retina; and palpation of the abdomen, rectum, and breast for evidence of primary malignancy. The chest is x-rayed for primary or secondary neoplasms and to visualize any thoracic extension of dumb-bell tumours of the spine.

Dandy (1925) claimed that over 90% of tumours could be both diagnosed and located in this way, but he was referring to the established picture. Such signs may be minimal if the patient is seen at an early stage, and indeed in some cases when special investigations give definite evidence of a tumour. These investigations normally consist of plain x-ray films of the spine, lumbar puncture, and myelography. There were five cases in this series with minimal signs, and they are mentioned later in relation to the differential diagnosis from prolapsed intervertebral disk, which they all closely resembled. One may be noted here as an example.

Case 4. Neurofibroma of the Cauda Equina with Minimal Neurological Signs.—A major aged 60 complained of pain in the left buttock and thigh, accentuated by coughing and sneezing, for eleven months. He had massage and short-wave diathermy, following a diagnosis of fibrositis and osteoarthritis. Six weeks before admission he developed low lumbar pain. There was no weakness or sensory or sphincter disturbance even to direct questioning. The only signs on admission were a stiff lumbar spine, a slight depression of the left knee-jerk, and slightly impaired sensation, to pin-prick only, on the outer side of the left thigh. A preliminary diagnosis of prolapsed intervertebral disk was made. Plain x-ray films were normal, but a lumbar puncture showed a cerebrospinal fluid protein of 360 mg. per 100 ml., and myelography suggested a possible tumour at L 4. At operation a neurofibroma was removed from the left side of the cauda equina. He made a good recovery.

Though not a feature of any of our cases there may be no physical signs whatsoever, even when investigations reveal a tumour (Cohen and Kaplan, 1943; Toumey *et al.*, 1950). In all these reported cases, together with the five patients in this series with minimal signs, the tumour was situated in the cauda equina. Here the bony canal is relatively roomy, and this may be the explanation for the paucity of signs.

Ancillary Investigations

Radiography

Plain X-ray Films.—In 16 cases (44%) plain x-ray films of the spine showed appearances suggestive of spinal tumour. There may be gross vertebral destruction (three cases), but, more frequently, less well-marked changes occur such as erosion of the pedicles and laminae (10 cases), widening of the intervertebral foramina (three cases), and scalloping of the posterior aspect of the vertebral bodies (three cases). The value of such films is obvious, and in addition the changes produced by a primarily vertebral tumour or other spinal disease may be revealed.

Myelography. using ethyl iodophenylundecylate ("myodil"), was employed in the final localization of the tumour in 22 cases. Although myelography is by no means always necessary for the detection of a spinal tumour, it is invaluable in accurate localization, and may be the only way in which a neoplasm can be excluded in suspicious cases. Owing to oedema and secondary vascular effects the clinical level may be false, and at the best the clinician has only clues concerning the extent of the lesion. The myelogram may also suggest whether the neoplasm is intramedullary or extramedullary, the longitudinal extent of the lesion, or the presence of multiple tumours. It also gives the surgeon the opportunity to mark the lesion in relation to the spinous processes pre-operatively and so render exposure more

Lumbar Puncture

This procedure revealed an abnormality in every case in the present series. The changes were partial or complete manometric block, xanthochromia, and raised cerebrospinal fluid protein, though all three features were not always present.

Manometry.—Partial or complete manometric block was found in 26 of our cases (76%). So important is the detection of spinal block that manometry must be carefully carried out in every case. In patients with suspected tumour it has been our practice, where possible, to have two observers—one to apply bilateral jugular pressure and the other to watch the manometer. First, light compression of the neck is applied, as this may reveal an incomplete block, past which fluid could be driven by firm compression (Stookey *et al.*, 1925); normally a rise of 10–30 mm. is to be expected at this stage. Then firm pressure is applied for ten seconds, and this should, in the absence of a block, produce a steady rise up to 300 mm. with a more rapid fall on release. If there is a complete block there will be no rise at all, whilst any definite delay in either the rise or the fall indicates an incomplete obstruction. The application of a sphygmomanometer cuff to the neck with the pressure raised to approximately 80 mm. may be used as an alternative to manual jugular compression.

The patient must be warned to relax during the manometry, and in particular reassured about the neck compression, since if, as is natural, he reacts to it by holding his breath and tensing his abdominal muscles, this alone will produce a rise in the manometer reading even in the presence of a complete block. If no obstruction was demonstrable at the beginning of the test then manometry should be repeated after the removal of a few millilitres of fluid for analysis, before the needle is withdrawn.

It has been shown experimentally by Poppen and Hurxthal (1934) that manometric abnormalities are not to be expected until the diameter of the remaining patency of the spinal subarachnoid space is less than the diameter of the lumbar puncture needle used. Occasionally a block will be evident only after the removal of fluid, possibly due to the meninges collapsing down on to the tumour (Ayer, 1920). Repeated dry taps suggest obliteration of the subarachnoid space by a large cauda equina neoplasm; the needle may have entered the neoplasm.

Cerebrospinal Fluid Protein.—The cerebrospinal fluid was examined in 35 cases, and all showed a rise of protein from 50–6,000 mg. per 100 ml. (upper limit of normal taken to be 45 mg. per 100 ml.). Of the four cases with slight increases only (50–65 mg.), three had manometric evidence of block, so that the significance of the slight abnormality was not likely to be overlooked. Whilst the increase in protein is usually the result of a spinal block, it may occur in the absence of such obstruction, and is then thought to be due to exudation from the surface of the tumour. Raised protein from this cause may thus be found in those cases of cauda equina tumour in which the cerebrospinal fluid is withdrawn above the site of the neoplasm. Of the nine cauda equina tumours reported here, five were associated with over 1,000 mg. of protein per 100 ml.

Xanthochromia.—This was present in 16 of the 29 cases in which the appearance of the fluid was recorded. Whilst usually associated with a very high protein, whether below a block or above a cauda equina tumour, there was one case with xanthochromia but only 110 mg. of protein per 100 ml., and two others with 150 mg.

Cells.—In most patients there was no increase of cells in the cerebrospinal fluid, but in seven cases a slight increase in lymphocytes was reported (7–12 per c.mm.). This feature gave no hint of the type of lesion present, since it was found in cases of neurofibroma, angioma, glioma, and secondary carcinoma.

In view of the obvious diagnostic value of lumbar puncture, the question arises of how readily, or at what stage, should one recommend it. Two factors influence the

decision. The first is the appreciation that a spinal block may exist, due to a tumour, when neither plain x-ray films nor clinical examination of the central nervous system have shown any abnormality—or nothing diagnostic (see Case 20, described below). The second is the possible risk of the procedure, fear of which may dissuade investigators outside special units from pursuing their cases to this vital stage. During the past two years in this hospital over 2,000 diagnostic lumbar punctures have been performed safely without sequelae other than headache in a few cases. However, there are some cases reported from time to time of the precipitation or aggravation of the neurological signs after puncture in cases of spinal cord tumour. Because of this possibility, Horrax (1947) has suggested that lumbar puncture should be carried out in cases of suspected cord tumour only when there are facilities for proceeding, if necessary, to immediate laminectomy.

From a survey of our own experience and of cases in the literature, we think that the risk of lumbar puncture has been exaggerated, with the important exception of cervical cord tumours in which puncture may precipitate respiratory paralysis. In such suspected cases, and also in rapidly progressive cases, it is advisable to postpone this examination until the patient is in a special unit. Apart from these instances, we hold the view that if a patient complains persistently of backache or root pain for which there is no obvious cause, and the films of the spine are normal, a lumbar puncture should be performed, as this may be the only way by which a spinal tumour may be excluded with confidence. So common are these symptoms, and so uncommon are spinal tumours, that there clearly will be numerous investigations of this kind which will come to nothing, and it would be quite impracticable to restrict lumbar punctures to neurosurgical units.

The value of lumbar puncture is exemplified in Cases 3 and 20.

Case 3. Neurofibroma of the Cauda Equina; Minimal Neurological Signs.—A flying officer aged 22 gave a history of an attack of left-sided sciatica aggravated by coughing for a period of a fortnight, nine months before admission. The pain recurred during a bumpy car journey three months prior to admission, and two days later he went to bed for an unrelated condition (duodenal ulcer). While in bed the left-sided sciatica became worse, and a month before admission he also developed sciatic pain on the right. On examination he walked stiffly and there was slight weakness in both legs. No sensory loss was demonstrated and the reflexes were symmetrically brisk. Straight-leg raising was reduced to 20 degrees on each side. Plain films were normal, but lumbar puncture revealed partial block with xanthochromic fluid containing 950 mg. of protein per 100 ml. A myelogram showed a block at L 1. A cystic neurofibroma was removed from the cauda equina and he made a good recovery.

Differential Diagnosis

It is clear that in most cases the diagnosis of an intraspinal lesion is easy once the suspicion is aroused, although its exact nature may require special study. However, it will be apparent from the symptomatology that in the earlier stages, and in other cases in which neurological abnormalities remain minimal, a spinal tumour may readily be confused with other conditions. Some of the difficulties are well exemplified in the Services, where in general the patients come under medical observation early.

The average delay between first consulting a doctor and undergoing operation was 6.4 months in the present series. On the other hand, reports from civilian centres point to much longer delays; in one series the corresponding interval was seventeen months (Van Wagenen and Rossier, 1938). Specialist medical advice is particularly easy of access in the Services, and this probably accounts for the shorter delay. Late operations are due largely to the multiplicity of common conditions (see Table II) which can give rise to the same types of pain, and to the considerable rarity of spinal tumours. Added to this is the not infrequent paucity of abnormal signs in the central nervous system even in many long-standing cases. In the majority of cases there is

TABLE II.—Some Incorrect Diagnoses in 28 Patients

Diagnosis	Cases

for some time no specific neurological disability to draw attention to the central nervous system, whilst even in retrospect it is difficult to discern any single characteristic of the pain complained of, other than its persistence, that should have led to the suspicion of a spinal tumour as its cause. In short, we wish to stress that there is often a period of many months in the natural history of a spinal tumour when confusion with other conditions may readily arise, with consequent delay in surgical treatment.

Late diagnosis may prove disastrous to the patient with a benign spinal tumour. Irreparable damage may occur either from prolonged compression of the cord or from interference with its blood supply, so that even if a total removal is still possible recovery is slow and perhaps incomplete.

Although the possible differential diagnoses are legion certain conditions are more commonly simulated than others.

Prolapsed Intervertebral Disk

This diagnosis was made at some stage in 10 cases of the present series. The five patients already mentioned with minimal signs in the central nervous system closely simulated disk lesions, and two of them have been described (Cases 3 and 4). A further example illustrates the difficulty in diagnosis (Case 20).

Case 20. Ependymoma of the Cauda Equina Resembling Prolapsed Intervertebral Disk.—A man aged 28 had attacks of back pain for twelve months before operation. These would last five or six days and resolve with physiotherapy. A month before operation right-sided sciatica complicated an attack and he came into hospital. His pain increased in bed, but the only abnormal physical signs were flattening and rigidity of the lumbar spine and slight scoliosis, straight-leg raising was limited to 60 degrees bilaterally and there was a doubtful depression of the knee- and ankle-jerks on the right. In this hospital the diagnosis after x-ray examination, but before lumbar puncture, was of prolapsed intervertebral disk, as had been thought elsewhere. Further investigation showed, however, a complete spinal block and xanthochromic fluid containing 2,500 mg. of protein per 100 ml. A myelogram revealed a block at L 1, and at operation an ependymoma of the cauda equina was partially removed.

Two not infrequent features of tumour cases may render the simulation of the disk syndrome very close: (1) Temporary remissions of pain, which may even coincide with treatment applied for a supposed disk lesion and so be taken as confirming the suspicion. (2) Signs of disordered spinal mechanics—stiff spine with diminished straight-leg raising.

Although in most cases the history and evolution of the clinical picture are quite different in the two conditions, in some cases it may be impossible to make the distinction clinically, and Case 4 shows the value of lumbar puncture in settling the problem. Lumbar puncture is not everywhere a routine procedure before disk surgery is undertaken, but it would seem to be a wise precaution in the light of this experience. It has always been the practice in this centre.

"Backache"

There were 10 cases diagnosed at some stage as "fibrositis" or "rheumatism"—that is, non-articular rheumatism—on account of the complaint of backache alone. One of the cases (Case 20) had attacks of backache as the only symptom for eleven months, and, furthermore, these bouts

responded to physiotherapy. Case 1 illustrates that a long history cannot exclude tumour even when pain in the back remains the principal complaint.

Backache, especially if there is restricted spinal movement with muscle spasm, may raise the possibility of disease of the spine itself such as tuberculosis, ankylosing spondylitis, and osteoarthritis. A plain x-ray film usually disposes of these diagnoses.

Case 1. Neurofibroma of Cauda Equina—Prolonged Complaint of Backache without Neurological Disability.—A man of 32 was admitted in 1943 with a history of intermittent backache since 1935, when he had fallen, injuring his back. On that occasion he recovered after three weeks in bed, but two months later backache recurred and pain radiated down the left leg into the calf. There was no relief of symptoms in spite of five months in hospital, and he returned to work. In 1940 he joined the Army and, although able to manage a twenty-five-mile route march, he could not do physical training, and in 1942 "collapsed" with pain in his back during an assault course. Examination in hospital on several occasions did not reveal any obvious organic causes. On admission here he complained of backache and pain down the left leg which was continuous and aggravated by coughing. There were no other symptoms. Examination showed minimal sensory loss over the lateral aspect of the left thigh, slight diminution of the left knee-jerk, and an abnormal plantar response; no weakness could be detected. Straight-leg raising was normal, but jugular compression aggravated the pain. There was spasm of the erector spinae muscles with some limitation of spinal flexion. X-ray examination of the spine revealed

some flattening of the pedicle of L3. Manometry demonstrated a complete spinal block, the cerebrospinal fluid being yellow and containing 6,000 mg. of protein per 100 ml. Myelography showed a complete obstruction at the level of L3. At operation, eight years after the onset of symptoms, a neurofibroma was removed from the third left lumbar nerve root. He made a good recovery.

In this story there was nothing about the pain, apart from its persistence, which was suggestive of a tumour. The neurological signs, even after eight years, were not gross.

Visceral Diseases in the Thorax or Abdomen

Root pain is produced by many types of visceral disease, and this pain may be indistinguishable from that produced by irritation of the same roots by spinal neoplasm. Not uncommonly, abdominal operations of varying severity have been carried out for persistent pain before the correct diagnosis of spinal tumour has been made (Spurling and Mayfield, 1936; Craig, 1936).

Case 2. Neurofibroma of the Cauda Equina Resembling Visceral Disease.—An Army driver aged 27 had increasing pain in the left loin, radiating to the testicle and the front of the thigh, for eleven months; the pain was accentuated by coughing. It was thought to be of renal origin, but when intravenous pyelogram and urinary examinations were repeatedly negative he was referred to a psychiatrist, who diagnosed prolapsed intervertebral disk. The patient was transferred to this hospital, where examination showed slight weakness and depression of reflexes in the left leg and some diminution of sensation below L1 segment.

Lumbar puncture revealed a complete spinal block and a yellow fluid containing 1,600 mg. of protein per 100 ml. Myelography confirmed the block, and removal of a neurofibroma from the second lumbar nerve root completely relieved the symptoms.

Non-neoplastic Diseases of the Spinal Cord

In a few cases of neurological disease such as disseminated sclerosis, poliomyelitis, transverse myelitis, and motor neurone disease, clinical examination may suggest a focal spinal lesion, and if the cerebrospinal fluid protein is elevated the presence of a tumour may be suspected. It is in such cases that resort to myelography may be necessary. There were no cases in the present series in which a diagnosis of disseminated sclerosis was made after admission to this hospital. However, this is a common initial diagnosis in spinal cord lesions, and in these cases a lumbar puncture should always be carried out.

The importance of examining the blood and cerebrospinal fluid for the Wassermann reaction may be mentioned here; in relation to this it is interesting to remember that the original description of the Froin syndrome probably referred to three cases of syphilitic meningomyelitis (Greenfield and Carmichael, 1925).

Extradural Abscess

This is commonly simulated only by metastatic tumours, but the resemblance can be close. In this series three of the eight metastatic tumours were initially thought to be extradural abscesses, and emergency laminectomy was performed in one case (No. 34).

Case 34. Extradural Metastasis Resembling Extradural Abscess.—A man of 30, who had been treated for secondary syphilis three months previously, developed increasing weakness of the legs over three days. Examination showed a spastic paraparesis with pyramidal reflex changes, and a diagnosis of syphilitic meningomyelitis was made. Spinal x-ray films were normal, but a lumbar puncture showed a partial block with 120 mg. of protein per 100 ml. and 5 cells per c.mm. Paraplegia was rapidly progressing, and a neurosurgeon was consulted. A diagnosis of extradural abscess was made and an emergency laminectomy performed. A mass of pathological tissue was found extradurally which was said to be suggestive of a healing abscess, both macroscopically and microscopically. Two months later chest x-ray examination showed a hilar mass; only "congestive changes" at one base had been seen on a film a week before operation. Death occurred three months after laminectomy, and post-mortem examination showed a primary bronchial tumour with widespread secondary deposits, including those in the spinal dura.

These cases, then, illustrate the difficulties besetting the clinician confronted with a patient suffering from a spinal tumour. Two points emerging from a study of this series are, firstly, the value of lumbar puncture, and, secondly, the necessity for exploring the possibility of an intraspinal lesion in puzzling cases of backache or root pain and of periodic examination of the nervous system in search of minimal signs.

Treatment

Laminectomy should be carried out as soon as the diagnosis is established and the location determined. Complete removal of the tumour is, of course, the ideal procedure and is usually possible in cases of neurofibroma. Of the 14 neurofibromas operated on in this series all were totally resected and 11 made a complete recovery. The only unoperated case in the whole group was that of a dumb-bell fibroma with a large extraspinal mass in the neck, and the patient succumbed within nine weeks of admission (Case 15). The remaining tumours were only partly removed or else were left with decompressions, and the majority were then treated with radiotherapy. Incomplete removal followed by radiotherapy gave a satisfactory immediate recovery in two cases of ependymoma of the cauda equina. There was one operative death due to aspiration pneumonia. No long-term follow-up has been possible.

Conclusions

Spinal tumours in their early stages often present a difficult diagnostic problem. This is partly because the presence

of such a lesion may not be even thought of owing to its comparative rarity, and partly because it may simulate other more common disorders for many months or even years before there is total cord compression.

A variety of conditions may be confused with spinal tumour, the most frequent being "rheumatism," prolapsed intervertebral disk, neurosis, disseminated sclerosis, and visceral disease within the thorax or abdomen. However, a careful evaluation of the type of pain and a full neurological examination will in most cases of spinal tumour suggest the possibility of such a lesion. Furthermore, diagnosis is often possible, at a stage when neurological signs are minimal or debatable, by performing a lumbar puncture. Less often, plain x-ray films of the spine lead to detection.

Surgical treatment is often completely curative, but only if the diagnosis is made before irreversible pressure changes have occurred in the cord or nerve roots.

Summary

Service patients tend to come under observation early, and this opportunity has been taken to comment on the early clinical picture and diagnosis of spinal tumours based upon a study of 36 cases at the Military Hospital for Head Injuries, Oxford.

The average delay between the first consultation and operation was 6.4 months, which is shorter than in most civilian series. Common diagnostic errors were "fibrositis" or "rheumatism" in 28% of cases, prolapsed intervertebral disk or "sciatica" in 28%, and "neurosis" in 25%.

The most frequent complaint was backache and/or root pain, occurring in 81% of cases; in 61% it was the initial symptom. In five cases there were only minimal or doubtful neurological signs, although pain had been present for nine months or more.

The most frequent neoplasm was the neurofibroma (41%). An unexpectedly large number of metastatic tumours was present (22%), most of which appeared to be of bronchial origin; three of these tumours occurred in patients between 17 and 19 years of age. A metastatic lesion should be suspected if the history is short and the clinical picture advanced.

Reference is made to the ancillary investigations, and attention is drawn to the value of lumbar puncture in early diagnosis, especially in doubtful cases. Evidence of spinal block was obtained in 76% of cases, and in all 35 patients whose cerebrospinal fluid was examined the protein content was raised.

Lumbar puncture may be the only way of excluding a tumour with any confidence in patients with persistent back or root pain for which there is no obvious cause. The possible dangers of the procedure are negligible, except in rapidly progressive cases and those with suspected cervical tumours, the investigation of which should be delayed until neurosurgical aid is available.

We are indebted to the medical officers responsible for the detailed clinical notes, often made under considerable wartime difficulties, without which this study could not have been possible. We have received much encouragement from members of the staff of the Nuffield Department of Surgery, Oxford, and are particularly grateful to Mr. Joe Pennybacker for suggestions and to Dr. Peter Daniel for help with some of the pathological data. Above all, our gratitude is due to Mr. Walpole Lewin for much helpful advice and criticism at all stages in the preparation of this paper. We wish to thank the War Office for permission to publish these cases.

COARCTATION OF THE AORTA AND PREGNANCY

REPORT OF FIVE CASES

BY

LEONARD ROSENTHAL, M.D.

Physician, Geriatric Unit, Pontefract and Wakefield Hospital Groups; late Physician-Superintendent, Wakefield General Hospital

Coarctation of the aorta is an uncommon finding in adults and shows its higher incidence in males in a proportion of 3 males to 1 female (Abbott, 1928). The association of this anomaly with pregnancy must therefore be of some rarity. Benham (1949) was able to find records of only 53 cases in the literature and added three personal reports. To these can be added the following cases: Dieckmann (1941), 4; Magnin (1944-5), 1; Novak (1947), 1; Clark and Koenig (1947), 1; Cohen (1949), 1; Marcorelles (1949), 1; Money (1949), 1; Sundföer (1950), 3; Vander Veer and Kuo (1950), 2; Brown (1950), 4; Greig and Parker (1951), 1; Bond (1951), 1; Kerr and Sodeman (1951), 5; Soulié *et al.* (1951), 3; Notter (1952), 1; Miller and Falor (1952), 2; Stéphan (1952), 1; Peterson *et al.* (1953), 1; and Taylor and Pollock (1953), 1; making a total of 91 recorded cases.

In view of the infrequency of pregnancy complicating coarctation of the aorta the assessment of the risks involved and the prognosis and management of any individual patient become considerations of great importance and difficulty for the physician and obstetrician whose experience of this association of conditions must necessarily be limited. It would seem desirable that as many records as possible be reported so that a firmer basis for judgment may be provided. With this in view the following five cases are reported.

Case 1

The patient, aged 25, was referred from the local antenatal clinic at the third month of her first pregnancy for the diagnosis of a suspected heart lesion. A "rheumatic heart" was said to have been discovered when she was 5 years old, and from about the age of 10 she had had symptoms very suggestive of mild intermittent claudication. These lasted on and off for about five years. The only symptom of note after this had been mild dyspnoea on exertion, which she thought was probably a little more prominent since the beginning of her pregnancy. Except for this and very occasional "bilious attacks" (vomiting, mild headaches, but no eye symptoms) she was perfectly fit and well.

Examination showed the classical signs of coarctation of the aorta. Blood-pressure readings were: right arm, 170/100; left arm, 150/95; right leg, 120/100; left leg, 115/90. The heart size was within normal limits. She had a mild ichthyosis, mostly involving the skin of the trunk, upper arms, and thighs, and this had been present since childhood. She had no other abnormal physical signs. X-ray examination of the chest showed a poorly developed aortic knuckle and notching of the third, fourth, sixth, seventh, eighth, and ninth ribs of both sides. Blood counts, blood urea, and Wassermann reaction were normal. Intravenous pyelography studies and an electrocardiogram were within normal limits. The amylobarbitone test resulted in an average blood pressure of 130/95 compared with 155/100 before the test.

She attended the medical clinic regularly and the pregnancy proceeded uneventfully. At the 27th week a slight generalized enlargement of the thyroid gland was noted. She was admitted to hospital at the 36th week for a final rest prior to confinement. One week later she began to complain of nausea, hot flushes, palpitations, and precordial pain. Over the course of three hours her pulse rate rose from 80 to 115 a minute, the systolic blood pressure from 135 to 165 mm. Hg, and the diastolic pressure from 95 to 100 mm. Hg. It was decided to perform caesarean section at once. The lower segment operation was done under spinal analgesia, and a living infant weighing 5 lb. 6 oz. (2.4 kg.) delivered. The patient was not in labour and there was much bleeding from the thickened lower segment of the uterus. It was noted that the abdominal aorta was half normal size. The puerperium was uneventful, and she was discharged from hospital after three weeks.

The patient was seen again at the medical clinic three months later. She had remained fit and well with no complaints except for slight dyspnoea on exertion, which was no worse than before the pregnancy. There were no notable changes in the physical signs. She remained in good health for five months after delivery. One night, about one and a half hours after going to bed, she awoke, told her husband she felt "queer," rapidly became unconscious, and died within half an hour. A post-mortem examination was not carried out.

Case 2

A primipara aged 21 was referred from the local antenatal clinic for diagnosis of a suspected heart lesion. She had had no serious illnesses as a child and had played games and cycled as other girls of her age. She had no complaints of headaches or pains in the legs. Eighteen months previously she had been off work for three months with dyspnoea on exertion, lethargy, and ankle oedema. These symptoms returned when she became pregnant, but on stopping work she regained her former good health.

On examination she was found to be 20 weeks pregnant. The blood pressure in the arms was 165/85 mm. Hg, and the systolic pressure in the legs, by palpation of the dorsalis pedis artery, 105 mm. Hg. A systolic murmur could be heard at the base of the heart at the level of the second rib on the left side close to the sternum. A loud systolic murmur was heard over the whole posterior chest, maximal in the mid-zone on both sides. A systolic thrill was felt in the left supraclavicular region. X-ray examination showed the heart to be normal in size and configuration, though the aortic knuckle was not seen. Rib notching was not present.

The pregnancy continued uneventfully until the thirty-eighth week, when she was admitted with uterine haemorrhage. A central placenta praevia was diagnosed and a living infant of 5 lb. 14 oz. (2.7 kg.) delivered by lower segment caesarean section. No note was made of the size and pulsation of the abdominal aorta. Except for a mild pyrexia and anaemia the puerperium was normal. On the tenth day the cardiac bruits were unchanged. No collateral circulation could be felt or seen. The blood pressure in the arms was 150/75 mm. Hg, while that in the legs could not be determined. The femoral artery pulsations were not felt.

Case 3

A woman aged 43 was referred to the local maternity hospital because of a raised blood pressure, upper abdominal pain, and malaise three weeks before her fifth child was due. She had had four previous normal pregnancies and labours, and her past medical history was uneventful.

On examination, except for a blood pressure of 130/90 mm. Hg, no abnormalities were noted. The urine was free from albumin. For the next two weeks she did not complain, had blood pressures of 150/90 and 140/98, and the urine remained albumin free. She was admitted to hospital at term complaining of headache and vomiting, her blood pressure was 130/90, and a very faint trace of albumin was found in the urine. She was treated conservatively and the blood pressure varied from 140/90 to 170/110 with no albuminuria. One week after admission, with the blood pressure 190/130, labour was induced surgically. The next day her blood pressure was 120/70 and she was noted to be "bright and cheerful." In the afternoon she was allowed to walk around the ward in order to encourage the start of labour. Fifteen minutes later she dropped down dead.

Post-mortem examination showed the pericardial sac to be full of blood. Coarctation of the aorta was present at the origin of the left subclavian artery, and at this point the aorta measured $\frac{1}{2}$ in. (1 cm.) across. The ascending aorta was dilated to a diameter of 3 in. (7.6 cm.), and showed a split in the intima with a dissecting aneurysm which had ruptured through the adventitia into the pericardial sac. The left ventricular muscle was slightly hypertrophied. A bicuspid aortic valve was present. The uterus contained a normal full-term foetus, and except for congestion of the lungs all other organs were normal.

Case 4

A 1-para 2-gravida aged 24 was walking through the backyard of her home carrying her 15-months-old baby on her arm when she suddenly collapsed, quickly lapsed into unconsciousness, and died after about 30 minutes. No further history was available.

Post-mortem examination showed a small ruptured aneurysm at the bifurcation of the right middle cerebral artery. The subarachnoid haemorrhage was greatest around the optic chiasma, the brain stem, and between the cerebrum and cerebellum. It had tracked along the sulci and was present in the ventricles too. The skull was intact and there were no injuries of the scalp. The heart was slightly enlarged owing to hypertrophy of the left ventricle. The mitral valve showed some fibrosis and scarring, while the aortic valve had two functioning cusps only. Stenosis of the aorta was present at the junction of the arch and descending portions, and measured $\frac{1}{2}$ in. (1.3 cm.) at this point. The uterus contained a normally developed foetus $9\frac{1}{2}$ in. (24.2 cm.) long, corresponding to the pregnancy of 20 to 22 weeks' gestation. Except for venous congestion the remainder of the organs were normal.

Case 5

A woman aged 30 had been attending her local antenatal clinic for her first pregnancy and was said to have enjoyed perfect health both before and during her pregnancy. At about the 38th week she suddenly collapsed at home and died within a few seconds.

On post-mortem examination the pericardial sac was distended with blood which had poured through a small rupture in the posterior wall of the root of the aorta. The ascending and transverse parts of the aorta were very thin and were dilated to a point just behind the left subclavian artery. Here the aorta became narrow and "completely obliterated," while below this point the vessel was noted to be "abnormally narrow." There was marked hypertrophy of the left auricular and left ventricular muscles. The aortic orifice was very narrow and would not admit one finger. The uterus contained a normal 38-weeks foetus, while all other organs were macroscopically normal.

Discussion

The comparatively small number of cases on record do not allow of any valid conclusions of a statistical nature to be drawn from them. Many of the reports are deficient in important details; some are only mentioned in textbooks and articles. Again there is a tendency to report only the unusual and dramatic, and therefore no detailed statistical analysis is possible if an imbalanced picture is to be avoided.

Coarctation of the aorta in an adult carries with it well-defined risks, and the association of pregnancy increases these hazards, especially of rupture of the aorta. There are records of 11 patients with the anomaly whose death was directly associated with pregnancy, and in 6 of them death was due to rupture of the aorta just before term or during labour. In 9 out of the 11 cases the coarctation remained undetected during the pregnancy. Earlier diagnosis, and therefore appropriate supervision and management, may have a large part to play in improving the prognosis. However, perusal of the literature shows that many women have successfully negotiated repeated pregnancies without any demonstrable adverse effects in spite of the presence of coarctation, which in many cases remained undetected until after the pregnancy. One woman of 56 (Weber and Price, 1912) had produced 11 children and died 12 years after her last pregnancy, and another of the same age (Strassmann, 1922) produced seven children. While not diminishing the seriousness with which this association of conditions has to be regarded, these facts suggest that a uniformly gloomy prognosis for all cases is unwarranted. The records, however, give no indication of those women with coarctation of the aorta who are likely to be unaffected by pregnancy—information which might be a useful guide in the management of future patients. Comparative studies of blood-pressure readings or the degree of collateral circulation appear to have no value in deciding prognosis in an individual patient.

Antenatal supervision of pregnancies is now an established practice, and it is usual to examine the chest at least on the first attendance and to measure the blood pressure frequently throughout the pregnancy. These are unusually favourable conditions for detecting those patients who have an existing coarctation of the aorta, and routine palpation of the femoral pulses in all patients with hypertension, however mild, would undoubtedly disclose further examples of the associated conditions.

The advice regarding management of these patients has varied according to the personal experience of the physician and his reading of the literature at the time. Some have advised that all cases should have therapeutic abortion with sterilization (Mendelson, 1940), some have advised caesarean section at term with or without sterilization (Walker, 1943; Baber and Daley, 1947; Brown, 1950), while others have allowed labour to proceed normally (Soulié *et al.*, 1951). Surgical treatment of coarctation of the aorta has not only stimulated early diagnosis of the condition but will now influence the management of pregnancy cases. The patients of Marcorelles (1949) and Peterson *et al.* (1953) were both operated on successfully during their pregnancies, and Miller and Falor (1952) describe the case of a woman who was operated on three months after her first pregnancy and successfully negotiated a second a year later.

It is suggested that all patients in whom these conditions coexist should be referred to a thoracic unit, where the possibility of surgical intervention might be considered. A pregnancy of less than 20 weeks' duration should, in itself, be no contraindication to operation. Until more experience is available it would be wiser to defer surgery if the diagnosis of the coarctation is first made in the later months of pregnancy. Management otherwise is, in general, similar to that applied to pregnant women suffering from rheumatic heart disease. Undue enlargement of the heart, signs of aneurysmal dilatation of the ascending aorta, or symptoms suggestive of cerebral aneurysm indicate the advisability

of terminating the pregnancy. A rise of blood pressure in the last few weeks of pregnancy or during labour should be viewed seriously and caesarean section undertaken.

Summary and Conclusions

There are records of only 91 patients in whom coarctation of the aorta was associated with pregnancy. Five further cases are reported.

The association carries with it serious risks, especially of rupture of the aorta, but, in spite of these, many women have not been adversely affected by multiple pregnancies and have lived to an age well beyond the average expectation of life in coarctation of the aorta. Earlier diagnosis and surgical treatment of the coarctation offer means of improving the prognosis.

Diagnosis is not difficult, and depends mainly on the awareness of the examiner and routine palpation of the femoral pulses in all patients with hypertension. The antenatal clinic offers unusual opportunities for early diagnosis.

General principles in management of these patients are described and the importance of individual assessment and surgical treatment for the coarctation is stressed.

I thank Mr. J. M. McKiddie, who kindly allowed me to quote Cases 2 and 3; the late Mr. B. L. Jeaffreson, who operated on Case 1, and Dr. A. Green, who supplied the after-history; the late Professor P. L. Sutherland and Drs. D. E. Price and W. L. Rose for post-mortem reports; and Drs. G. Grimshaw and D. Gray for help with some of the translations.

It is recorded in the annual report of the Chalfont Colony for 1953-4 that an arrangement has been made with the National Hospital for Nervous Diseases whereby patients, either before or immediately after entering the Colony, will go to the Queen Square or Maida Vale Hospitals for full investigation and report. The executive committee believes that a certain percentage of cases now going to the Colony will be intercepted, treated at Queen Square or Maida Vale, and returned to normal life in a few weeks. The medical staff of the Colony will also receive guidance from the staff of the National Hospital about the treatment of those patients who are finally admitted to the Colony.

HAEMORRHAGIC GANGRENE OF THE SKIN IN CHRONIC LYMPHATIC LEUKAEMIA

BY

I. SARKANY, M.R.C.S., L.R.C.P.

AND

RUTH M. RANSOM, M.B., B.Ch., B.Sc.

(From the Peace Memorial Hospital, Watford)

In chronic lymphatic leukaemia both specific and non-specific skin lesions may occur, but distinction between the two often rests on the histological picture.

In a study of the dermatological manifestations of the lymphoblastoma-leukaemia group, Epstein and MacEachern (1937) found that out of 60 patients with chronic lymphatic leukaemia 27 (45%) had non-specific skin lesions. Of these, the haemorrhagic type was commonest (15 patients), and usually occurred in the terminal stages. Although Sutton and Sutton (1941) mention that purpura sometimes results in necrosis and ulceration of the skin and mucous membranes, we are unable to find any reference to the occurrence of haemorrhagic gangrene of the skin in chronic lymphatic leukaemia.

Case History

A 58-year-old male librarian was admitted on October 5, 1952, having been found unconscious in his garden. There was a past history of chronic bronchitis. A provisional diagnosis of subarachnoid haemorrhage was confirmed by lumbar puncture. During routine examination he was found to have moderate splenomegaly but no palpable glandular enlargement, and there were no other abnormal signs. A blood count showed: Hb, 92%; red cells, 4,680,000 per c.mm.; white cells, 12,900 per c.mm. (polymorphs 22%, eosinophils 0.5%, monocytes 1%, lymphocytes 76.5%); no primitive forms; platelets, 168,750 per c.mm.; E.S.R., 1 mm. in the first hour (Wintrobe); clotting-time, 6 minutes 30 seconds; bleeding-time, 3 minutes. A sternal marrow puncture showed a typical picture of chronic lymphatic leukaemia.

As it was uncertain whether the subarachnoid haemorrhage was in any way connected with the leukaemia, and as the leukaemia was symptomless, with the possible exception of being related to the subarachnoid haemorrhage, it was decided not to treat the patient at this stage. He was discharged in November, having made an uneventful recovery from the subarachnoid haemorrhage, and he was seen regularly as an out-patient.

In January, 1953, he was readmitted to hospital with a three-days history of fatigue with fever and the coughing up of sputum flecked with bright blood. On examination he was wasted and there were symmetrical localized areas of ecchymoses over both upper arms and both malar eminences. The only other abnormal physical finding was splenic enlargement, which was of the same degree as on the previous admission. A blood count at this time showed no marked change from the previous count, and the bleeding- and clotting-times were still within normal limits. The possibility of a leukaemoid reaction to generalized tuberculous infection was considered, and accordingly the sternal marrow was re-examined in February, 1953. No evidence of tuberculous histology was seen, and the appearance was still that of a lymphatic leukaemia. A chest x-ray examination showed extensive cavitation in the right upper lobe, but repeated sputum tests and examination of laryngeal swabs did not reveal any evidence of tuberculosis.

The skin lesions became more numerous. Each would start as a small patch of purpura which enlarged rapidly

and then developed superficial gangrene. Progressively and symmetrically they involved the pinnae, arms, forearms, buttocks, legs, and toes (see Fig.).

"Acthar gel," in a dose of 50 mg. 12-hourly intramuscularly, was begun, but two days later the patient went into coma and died on February 8.

Necropsy Findings.—External Examination: There was a dark-purple discoloration of ears and face, except for the circumoral area, with ulceration of both ears and cheeks. Dark-purple patches were present in the region of both nipples, on the outer side of both arms, with ulceration of the upper arms, on both buttocks, and on the outer side of both thighs and legs, with purpuric spots at the border.

Circulatory System: A large pericardial effusion was present

consisting of clear yellow fluid. **Respiratory System:** The lungs were emphysematous, with a cavity in the right upper lobe approximately 2 cm. in diameter, and an adjacent dark solid area with a hyperaemic border showing central softening. There was no macroscopic evidence of tumour.

Digestive System: The liver was enlarged (weight 2,326 g.) and extensively infiltrated with pale semi-translucent nodules. These swelled above the cut surface, and were approximately 1 cm. in diameter. **Haemopoietic System:** Lymph nodes around the coeliac axis and at the hilum of the spleen and para-aortic nodes were prominent. Cut surface was mottled, with reddish areas. The spleen (weight 1,162 g.) showed a pale cut surface with prominent Malpighian bodies. **Nervous System:**

An intact berry aneurysm arose from the anterior communicating artery of the circle of Willis. Adjacent to the aneurysm there was brownish discoloration of the arachnoid.

Histology.—Right Lung: An old infarct was present with central necrosis and peripheral haemorrhage and infiltration with lymphocytes and polymorphs. Elsewhere there were foci of lymphocytes. **Liver:** Lymphocytic infiltration had occurred and there were many deposits of irregular polygonal-celled trabecular carcinoma with a fine stroma. Mitoses were numerous. The appearances were those of metastases of an aplastic bronchial carcinoma. **Spleen:** Pulp spaces and sinusoids were distended with lymphocytes. **Coeliac Lymph Node:** Germ centres were no longer distinguishable, and the whole node was packed with lymphocytes of adult type. **Skin:** Both superficial and deep corium contained small recent haemorrhages, and in the same situation the veins contained organizing thrombi. The arteries appeared normal. There was no leukaemic infiltration.

Comment

Progress of the skin condition to extensive symmetrical gangrene had occurred as a terminal event, and it is difficult to assess the degree to which this contributed to the patient's death, particularly so when the double pathological condition found at necropsy is considered. Carcinoma, especially of the bronchus, is common nowadays, and

chronic lymphatic leukaemia is by no means rare, so that the association of the two conditions in the case here reported is probably fortuitous. Nevertheless, only 27 cases of carcinoma with leukaemia had been reported up to 1950 (Berk and Movitt, 1945; Even, Vibert, and Oury, 1950). In our case no primary growth was found in the lungs or in any other organ, but the histological appearance of the deposits in the liver was suggestive of primary carcinoma of the bronchus.

We wish to thank Dr. A. R. Kelsall for permission to publish this case.

THE EPIDEMIOLOGICAL APPROACH TO OBSTETRIC MEDICINE*

BY

A. M. THOMSON, M.B., B.Sc., D.P.H.

Research Lecturer, Department of Midwifery, University of Aberdeen

The annual report of a well-known teaching maternity hospital says that it had 1,413 admissions during the year 1950. These contributed 1,270 deliveries and 85 abortions. The stillbirth rate was 9.34 per 1,000 (an exceptionally low figure) and the neonatal death rate 17.32. In 31 tables are listed some of the features of numerous abnormal cases. How cases were chosen for admission and how they relate to the community as a whole are not indicated. The clinical detail presented is reduced to a bare minimum and there is no text or discussion whatever. The lay-out and scope of such annual reports are time-honoured, but make it very difficult to extract figures of scientific value. The time has surely arrived when all statistical reports should be drawn up according to the laws of epidemiology. Now that maternity services are organized on a regional basis, the leading hospital in an area might collate data from all sources and prepare reviews illustrating and discussing trends of morbidity and mortality in a defined population.

Maternity records are particularly suitable for systematic surveys because birth and death certification provides an automatic and accurate statistical framework for every administrative area. There is little difficulty, of the kind which arises in the study of chronic disease, in arriving at a biologically meaningful epidemiological "unit." A "maternity"—the cycle of pregnancy, childbirth, and recovery—is easily defined, and takes place in a limited and relatively constant period of time.

The group of maternities to be studied having been defined, the next step is to classify them. To reduce the population to a series of fairly homogeneous groups it is desirable to classify by legitimacy; by the maternity service to which a case has been booked, irrespective of the place of delivery; and perhaps by home address, if it is desired to limit the study to the residents of an area. Multiple maternities should be separated from single.

*Read in the Section of Preventive Medicine and Infectious Diseases at the Annual Meeting of the British Medical Association, Glasgow, 1954.

Photograph showing skin lesions in the early stages.

Most analyses will be carried out on groups of single legitimate maternities, which should be classified by age and parity.

Influence of Maternal Physique and Health

Since reproduction is a physiological function it is reasonable to suppose that maternal physique and health will be an important influence. It is, unfortunately, very difficult to assess health objectively, but a social classification is a useful indirect measure of the way of life of patients which is highly correlated with health and physique. Even better and more simple, it is useful to classify mothers by height. Height is associated statistically with social class and with general health. As one moves down the social scale, the proportion of small women and of unhealthy women increases (Baird, 1952b; Baird and Illsley, 1953). It has been shown that mothers in different height categories experience different rates of foetal mortality, prematurity, and difficult labour (Baird, 1949, 1952a, 1952b). The theory is that mothers who have been brought up in a satisfactory environment will grow to the maximum stature permitted by their genetic constitution, and will be in good general health, whereas those brought up in poor surroundings will be stunted and less healthy.

The Epidemiological Method in an Aberdeen Inquiry

I propose to illustrate the use of the epidemiological method in obstetrics by describing an inquiry made in Aberdeen into the nature and means of preventing unexplained deaths among mature babies. Accounts in greater detail have been published by Baird, Walker, and Thomson (1954), Walker (1954), and Walker and Turnbull (1953).

Prematurity has for long been recognized as a major cause of "unexplained" neonatal mortality. It is not so widely known that many babies which are mature by birth weight—that is, over 5½ lb. (2.5 kg.)—die for no very obvious reason. In a classification of obstetric deaths (stillbirths plus first-week deaths) by clinical cause (Baird, Walker, and Thomson, 1954) we distinguished two "unknown" categories, classified in terms of birth weight into "premature, cause unknown," and "mature, cause unknown." In both, pregnancy and labour were clinically uneventful, and at necropsy only uninformative conditions such as "prematurity," "atelectasis," "anoxia," and so on were found, the underlying cause of death being unexplained. Of 1,008 consecutive obstetric deaths in Aberdeen Maternity Hospital booked cases during the 15-year period 1938–52, 13.7% were classified as "mature, cause unknown."

A comprehensive analysis of these deaths by age, parity, and other factors was undertaken. Since booked hospital cases, especially multiparae, are more or less selected (Baird and Thomson, 1954), a study based on all city maternities, whether delivered in hospital or not, would have been preferable. Information on a city-wide basis has become available only recently, and in a relatively small city obstetric deaths are not numerous enough to permit dependable statistical analysis unless the results of many years are pooled. All stillbirths (not first-week deaths) in the city since 1938 could be classified by clinical cause, but complete information on age and parity was not available. In the booked hospital series, the stillbirth and first-week death rates behaved in relation to age, parity, and social class in much the same way as comparable national statistics, and long experience has shown that booked hospital primiparae at any rate may be regarded as a representative sample of first maternities in general; it was therefore believed that the behaviour of the obstetric death rate was fairly typical of the childbearing population as a whole.

The "mature, cause unknown" obstetric death rate was 6.3 per 1,000 total births in primiparae, 4.5 in second and third pregnancies, and 4.4 in fourth and later pregnancies. In primiparae, especially, there was a steady rise as maternal age increased—from 2.3 at age 15–19, to 19.0 at age 35 and

over. Obviously elderly primiparae (say 30 and over) form a high-risk group for deaths in this category.

Since the data were compiled from a 15-year series, during which time the overall obstetric death rates had fallen considerably, trends in the "mature, cause unknown" obstetric death rate were investigated in relation to time. In the hospital series this rate behaved rather erratically, and certainly showed no sign of a consistent fall such as had occurred in the rate from all causes. Examination of data for the whole of Aberdeen showed that the "mature, cause unknown" stillbirth rate fell from just over 7 per 1,000 in 1939–40 to slightly under 5 in 1944–5. During 1946–8, the period of the post-war rise in the birth rate, when there were relatively more first births and an increase of average maternal age, the rate rose to the pre-war level, falling again in 1949–51 to about 5 per 1,000 (Baird, Thomson, and Duncan, 1953).

Examination of the hospital data for primiparae by social class and maternal height showed no consistent trends.

"Premature, cause unknown" death rates, on the other hand, show consistent trends in the expected direction by social class and height: the rates fell steadily during the war and showed no post-war rise; the gradient by age in primiparae is not so steep and steady as in the "mature, cause unknown" group, and very young as well as elderly mothers seem to have a relatively high death rate. Excess deaths in the "premature, cause unknown" group seem to be statistically associated with poor social class, small stature, and poor general health and nutrition of mothers; this is by no means obvious in the case of "mature, cause unknown" deaths. Though the two groups no doubt overlap aetiologicaly, the distinction by birth weight—above or below 5½ lb. (2.5 kg.)—seems to be fairly effective in separating deaths of different character.

Obstetric Death Rate in Post-maturity

Clinically, we had the impression that many "mature, cause unknown" deaths took place when pregnancy was prolonged past term (40 weeks) and that death was frequently preceded by foetal distress—that is, marked irregularity or slowing of the foetal heart, or the passage of meconium. To check these impressions statistically it was necessary to have very detailed and uniform notes on the duration of pregnancy and on the occurrence of foetal distress during labour. That recent hospital records sufficed for a fairly accurate analysis shows that an interest in epidemiology has had the useful effect of raising the standard of clinical recording in the hospital to a very high level.

It has been known for some time that the stillbirth and neonatal death rates (especially the former) increase when pregnancy goes past term (Clayton, 1941, 1953; McKiddie, 1949). Analysis showed that the rise in the obstetric death rate in post-maturity could be attributed to two groups of deaths, "mature, cause unknown" and "trauma." The association of these two groups is not unexpected, since if a baby is liable to die without obvious cause it is presumably all the more likely to die if the stress of prolonged or difficult labour is added. Furthermore, it is known that the incidence of difficult labour increases after term.

Analysis of the incidence of foetal distress in labour showed that it behaves similarly to the "mature, cause unknown" death rate, increasing rapidly with maternal age in primigravidae and in post-maturity.

On the basis of these facts an attempt is being made to reduce the incidence of "mature, cause unknown" deaths by (a) routine induction of labour at the end of the forty-first week in all post-mature primigravidae over 25 years of age, and (b) more frequent resort to caesarean section when foetal distress, especially the passage of meconium, is noted during labour. Results to date are encouraging. Epidemiological research has thus pointed the way to a positive method of saving lives when the real cause of death is unknown.

It may be noted in passing that this kind of epidemiological research is possible only if very detailed clinical

information is available, and therefore ought to be undertaken primarily by clinicians rather than by statisticians. Some knowledge of statistical methods is useful, but it is much more important to tabulate accurate information sensibly and to interpret trends with insight than to calculate precisely the vagaries of chance among data which may be neither accurate nor meaningful.

Impaired Foetal Oxygenation

Finally, what is the cause of "mature, cause unknown" death and of foetal distress during labour? The association with post-maturity and the fact that anoxia is a common finding at necropsy suggest that impaired oxygenation of the post-mature foetus may be the immediate cause. This is supported by the work of Barcroft and Young (1945) on animals. Walker (1954) has undertaken a study of the oxygen content of human foetal blood and has found that the percentage saturation—that is, the content in relation to the capacity—falls after term in normal pregnancy, and is unusually low where there is foetal distress and in a second labour in cases in which the first pregnancy ended in a "mature, cause unknown" death. These findings confirm the hypothesis that impaired foetal oxygenation is the main reason for the excess foetal mortality after term; presumably the basic reason has to do with a decline in the functional efficiency of the placenta when pregnancy is unduly prolonged. We have yet to determine whether the high obstetric death rate in elderly primiparae is due to exceptionally low foetal blood-oxygen levels or to normal levels together with foetuses of low general vitality; it is not due to an unusually high incidence of post-maturity.

Summary and Conclusions

The study of morbidity and mortality statistics requires detailed clinical knowledge and good clinical case records if it is to be most fruitful. Statistics of maternity present many natural advantages for such a study, which should preferably be based on an administrative area. The scientific value of the traditional annual reports compiled by maternity hospitals is extremely limited.

The epidemiological approach in obstetrics is useful in providing insight into the nature and means of prevention of conditions which cannot be fully understood by detailed study of the individual case. Besides providing perspective, epidemiological research in a clinical unit increases precision of clinical observation, improves the quality of case records, suggests fruitful lines of laboratory investigation, and provides the means of checking the results of treatment.

The approach is illustrated by researches into the nature of unexplained stillbirths and first-week deaths in Aberdeen.

I am indebted to Professor Dugald Baird, Dr. James Walker, and other colleagues for valuable help and for allowing me to report these results of team research: to members of the Medical Research Council's Social Medicine Research Unit (Director, Dr. J. N. Morris); and to the Advisory Committee on Medical Research (Scotland).

THE TREATMENT OF SUBACUTE AND CHRONIC SUBDURAL HAEMATOMAS

BY

R. G. ROBINSON, G.M., M.B., F.R.C.S.

(From the Department of Neurosurgery, Dunedin Hospital, Dunedin, New Zealand)

Wilfred Trotter (1914) recognized that some of the poor results in treating chronic subdural haematomas were due to failure of the brain to expand after their evacuation. This observation has been confirmed many times. The head-down position, intravenous fluids, and drainage of the subdural space have been used to help the brain to resume its volume after removal of the compressing mass. LaLonde and Gardner (1948) showed that better results were got when saline was injected into the subarachnoid space to help the brain to expand. Since then no other series of cases so treated has been reported.

Details of Treatment

It is common practice to seek and treat subdural haematomas by making burr-holes in the skull. There is no value in raising an osteoplastic flap, and it may be detrimental. Improved methods of diagnosis have precluded cases in which a subdural haematoma was a surprise finding at craniotomy for a cerebral tumour.

The making of burr-holes is always done under local analgesia, no matter how restless the patient. The usual site for the initial burr-hole is in the mid-temporal region about 1½ in. (4 cm.) above the zygoma. Further burr-holes may be made in the frontal and parietal areas. The most useful site for the second burr-hole is in the posterior parietal region. While a fluid haematoma can be easily treated through one burr-hole, a clotted haematoma needs multiple explorations. Bilateral burr-holes are always made, as the haematomas are bilateral in many cases. Incision of the dura mater will allow the haematoma contents to gush out. A fine rubber catheter is introduced into the subdural space in all directions and irrigation is carried out gently with Ringer's solution, which is preferable to normal saline. The washing is continued until the returning fluid is clear. In favourable cases the brain will expand to fill the dead space left by evacuation of the haematoma. The skin incision is closed in two layers and no drainage tubes are inserted.

The intrathecal injection of Ringer's solution is used in every case in which the brain does not expand after removing the haematoma. Ringer's solution can be injected into the lumbar subarachnoid space or into the ventricles of the brain by way of one of the burr-holes. Ventricular injection may be difficult if the ventricles are collapsed, and some experience is needed for ventricular puncture. Lumbar puncture is easier, and is safe and effective. When the haematoma is unilateral the towelled patient is not greatly disturbed on being turned from the supine to the lateral position for lumbar puncture. It is unsatisfactory, however, to turn patients with bilateral subdural haematomas. This difficulty has been overcome by operating with the patient in the prone position. The head is held in a cerebellar head-rest, which is adjusted to the patient's comfort, no flexion of the head being needed. No respiratory embarrassment occurs in this posture if the chest is raised on the shoulder-pieces, as the tongue cannot fall back into the pharynx. The lumbar-puncture needle may be inserted before the burr-holes are made. The prone position gives good access to all parts of the head except the forehead. It is satisfactory also for making burr-holes in cases of acute head injury. The patient is in an ideal position if the posterior fossa has to be explored for a haematoma.

Between 50 and 200 ml. of Ringer's solution will be needed for brain expansion. The injection should be continued until the brain is in contact with the edge of the burr-hole. A recent case of bilateral subdural haematomas of infancy had 160 ml. of fluid injected by lumbar puncture without any adverse effect. When a single burr-hole is used as a means of treatment it is better to leave the catheter as a vent over the convexity of the brain until expansion has removed surplus fluid and air from the subdural space.

The after-treatment consists in keeping the patient flat and maintaining a good fluid intake. When the inflation method has been used it is desirable to do a daily lumbar puncture for at least four days. If the cerebrospinal fluid pressure is below 150 mm. H₂O Ringer's solution is injected to raise the pressure to this level. The state of consciousness and the absence of headache are reliable guides to clinical improvement.

Clinical Material

Twenty-eight cases of subacute and chronic subdural haematomas have been treated in the neurosurgical unit at Dunedin Hospital. Subdural haematomas of infancy and one case of chronic subdural haematoma in a child of 5 years with a successful outcome are excluded from the series. The subacute haematomas occurred between seven and twenty-one days of a known head injury. The chronic haematomas had a latent period of over three weeks, or a history of previous injury was unobtainable. The ages of the patients ranged from 17 to 77 years.

No fresh observations can be added to the well-known clinical picture. Many patients were seriously ill and had come long distances—often up to 500 miles by air ambulance. Eighteen had had lumbar puncture, mostly in other hospitals, and eight were made much worse by this procedure. In most cases the information gained by lumbar puncture did not materially assist in the diagnosis, and its danger in these cases cannot be too greatly stressed.

The diagnostic procedure of choice was carotid arteriography. When an arteriogram indicated a haematoma, an examination of the other side was not inflicted upon the patient, and a subsequent burr-hole was used instead. If the previous head injury was clear-cut or the condition of the patient with suspected haematoma was parlous, immediate burr-holes were preferred to any other diagnostic method. We have been reluctant to use arteriography in patients over the age of 65, and have not used it at all in those over 70. At this age there are few alternatives in the diagnosis of subdural haematoma, and the making of burr-holes is a benign matter.

In 1952 it was decided that the inflation method should be used whenever the brain did not expand after removal of the haematoma. Ten patients come under the old regime and 18 are in the new group. In 14 of the latter inflation was used. The subdivisions showed the same degree of neurological severity. However, there were four patients over 70 years and three with bilateral haematomas in the later group. This 10% incidence of bilaterality is at variance with the 30% incidence in most other series.

There was one death, and that was in the first group. The patient was a semi-comatose man who died 24 hours after burr-holes had been made. The necropsy showed that the brain had not expanded. Inflation might well have saved him.

The outstanding difference between the two groups was in the degree of recovery. Under the old regime, patients often remained confused and had headaches for several days—sometimes a week or more—and during that time gave cause for concern. There was one recurrence, and that was dealt with successfully. The new method brought a more rapid return to full consciousness. This improvement was often apparent on the operating table, and the post-operative period was less worrying. It was common for the headaches to disappear from the time of inflation. The greatest advantage was in elderly patients, who seem to be prone to develop dehydration and intracranial hypotension. While

it is impossible to be dogmatic, it is felt that a fatal issue was averted in several cases by the use of inflation. No ill effects from this treatment were seen.

When inflation was first used it was hoped that a single injection would be enough and that recurrences would be avoided. There were two patients over 70 years who made a dramatic improvement for a few days and then suddenly relapsed: further collections of fluid were successfully treated. Experience has shown that the only way to prevent recurrences is to do a daily lumbar puncture and to keep the C.S.F. pressure at 150 mm. H₂O by further injection as recommended by Munro (1952). The minimum period for this procedure is four days, and it must be continued until the patient's condition has stabilized.

Six patients had their inflation done by lumbar puncture and six had direct ventricular injection. The other two had combined lumbar and ventricular puncture. There is nothing to choose between the results of each method.

Discussion

The conclusions of LaLonde and Gardner (1948) on the value of injection of normal saline into the subarachnoid space or ventricles in the treatment of subdural haematomas are confirmed; but they did not give their results before using the method. Munro (1952) recommends the same treatment for all types of subdural haematoma. His use of repeated lumbar puncture to sustain the C.S.F. pressure is essential if recurrences are to be prevented.

The critical features in the train of events initiated by a subdural haematoma are compression of the brain, tentorial herniation by the temporal lobe of the brain, and intracranial hypotension. Jefferson (1938, 1951) has given good reviews of tentorial herniation, and intracranial hypotension has been reviewed by Page (1953) and Holmes (1953). In many cases removal of the haematoma leads to immediate expansion of the brain and rectification of these three complications; but they may persist singly or in combination and be responsible for a slow recovery or a fatal issue. The method of expanding the subarachnoid space and the cerebral ventricles, and also the brain, will counteract these adverse features. So long as there are no irreversible changes, the mortality should be lower and convalescence more rapid than with mere evacuation of the haematoma. This series, however, is too small for dogmatism regarding the mortality, though there is no doubt about the improvement which occurred in the recovery period when the injection method was used.

The method of brain expansion, whether ventricular or lumbar, does not make any difference to the end-result. The lumbar route is the easiest for the less experienced. The use of the prone position for the patient is an advantage for lumbar puncture and for access to the head.

Summary

The treatment of subacute and chronic subdural haematomas by the injection of Ringer's solution into the lumbar theca or cerebral ventricles is advocated.

Comparison is made between 10 cases before and 18 cases after this method was used.

Some of the pathological features of subdural haematoma are discussed in relation to treatment.

I wish to thank Mr. A. James for permission to use the cases admitted under his care and for access to the departmental records. He has given every encouragement in treating some of these cases and in writing this paper.

SPONTANEOUS RUPTURE OF OESOPHAGUS

REPORT OF THREE SUCCESSFUL CASES TREATED SURGICALLY

BY

JOHN BORRIE, F.R.C.S.

Surgeon-in-Charge, Department of Thoracic Surgery,
Dunedin Hospital, Dunedin; Senior Lecturer in
Thoracic Surgery, University of Otago

Spontaneous rupture of the oesophagus, until 1947 a fatal disease, can now be effectively treated by surgical means. The criterion for success requires that such a lesion be known about and kept in mind, that it may be recognized early and treated promptly. The general practitioner is as able to make the diagnosis as the specialist; and, like perforated duodenal ulcer, early recognition and treatment gives satisfying results (Borrie, 1953).

This paper reports three cases seen within an eight-months period at one Thoracic Surgical Unit dealing with a regional area of 250,000 people. In none of the three cases was the diagnosis at first suspected; in all, however, it was later established and operation was followed by complete recovery.

Case 1

A married woman aged 65 was an emergency admission to the medical wards of Dunedin Hospital on December 15, 1952, under Professor J. E. Caghey, with a diagnosis of haematemesis. Earlier that evening, while hungrily eating a fish meal, she tried to make herself sick because she thought she had swallowed a fishbone. She vomited copiously 1 pint (570 ml.) of bright blood-stained gastric contents, and was immediately seized with severe chest pain.

On examination she complained of pain behind the lower third of the sternum. It was severe and gripping, and came in spasms. There were no abnormal respiratory, cardiovascular, or abdominal physical signs, and no cervical emphysema. Her blood pressure was 180/110 mm. Hg, and her haemoglobin 90% (Sahli).

A diagnosis of haematemesis secondary to a foreign body in the lower third of the oesophagus was made, and she was referred to the ear, nose, and throat department. It was decided to keep her under close observation, with nothing by mouth, a rectal drip, penicillin, and "omnupon" to relieve her pain.

On the morning of December 16 she had ceased vomiting, looked better, but still had retrosternal pain. Later that day she could not swallow her sputum, and regurgitated blood-stained mucus. Oesophagoscopy was performed that evening by Mr. Alan Wardale, surgeon in charge of the ear, nose, and throat department. He found a considerable amount of dark blood lying in the oesophagus. The upper two-thirds of the oesophageal mucosa in particular was haemorrhagic. There was no foreign body. The possibility of rupture of the oesophagus at the junction of the middle and lower thirds was entertained, and on December 17 she was referred to the thoracic surgical department.

Clinically there was still no pleural effusion or cervical surgical emphysema. Radiopaque oil was given, and fluoroscopy showed a vertical rent on the left side of the lower third of the oesophagus, lying 1 in. (2.5 cm.) above the diaphragm. The diagnosis of spontaneous rupture of the oesophagus was established and left thoracotomy advised.

Operation.—Pre-operative oesophagoscopy confirmed haemorrhagic oedema of the entire oesophageal mucous membrane together with a vertical ragged area in the lower third of the oesophagus. Under general anaesthesia, the left

chest was opened through the bed of the resected left eighth rib. There was an extensive extravasation of blood-stained fluid under the mediastinal pleura and extending from the level of the oesophageal hiatus in the diaphragm up to the left inferior pulmonary vein, and midway between the necks and angles of the lower left ribs. Through a 3-in. (7.5-cm.) incision in the mediastinal pleura, the oesophagus was mobilized and retracted with a Jaques rubber catheter sling. On its left border was the vertical tear, approximately $\frac{1}{2}$ in. (1.9 cm.) in length. The points of dissecting scissors were easily introduced through the tear into the oesophageal lumen. The tear was closed with four interrupted twenty-day No. 1 chromic catgut sutures passed through all layers. The mediastinal pleura was not sutured. The left chest was closed over water-seal drainage, using interrupted catgut for the muscle layers and fine nylon for the skin.

The patient was allowed sips of water by mouth and over a period of three days gradually increased her intake by mouth to a fluid diet. She took solid food a week after operation. The intravenous fluid was discontinued on the third post-operative day, and the intercostal drainage was removed on the fifth post-operative day.

She was discharged, convalescent, three weeks after admission, swallowing normally. Subsequent fluoroscopy and oesophagoscopy showed no abnormality of the foregut. When seen 18 months after operation she remained well.

Comment.—This patient illustrates the typical onset following violent vomiting, and shows how a small tear need not be associated with rupture into the pleural cavities or with detectable emphysema. The constant retrosternal pain following vomiting alone suggests the diagnosis, which is further suspected after unusual findings at oesophagoscopy, and convincingly established by careful fluoroscopy with radiopaque oil. Untreated, she would undoubtedly have developed a serious mediastinal abscess.

Case 2

A bachelor aged 53 was brought to the casualty department of the Dunedin Hospital at 9 p.m. on June 29, 1953. Earlier that day he was well, and between 5 and 6 p.m. drank six pints (3.4 litres) of beer in a hotel. When the bar officially closed at 6 p.m. he staggered into the street and vomited copiously into the gutter. He started to walk away, but had just gone five paces when he suffered an agonizing retrosternal pain which radiated to the left shoulder and leg. He drove his car home with great difficulty, the pain becoming more intense and breathlessness more acute. There was no further vomiting.

When examined on admission he still had excruciating pain, was restless, and quite unable to find relief either by sitting up or lying down. He was convinced he would die. His pulse was 120 and blood pressure 170/110 mm. Hg. The casualty officer found the apex beat normal. What was believed to be a pericardial friction rub, crackling in quality, was detected. There were left basal crepitations. The abdomen was board-like, but with no definite tenderness. Although acute pancreatitis or rupture of the gall-bladder was entertained, these diagnoses were not supported by the general surgeon who was called to see him.

An E.C.G. showed T-wave inversion, with tall R waves in V₅ strongly suggesting left ventricular strain. With the diagnosis still in doubt, a chest radiograph was ordered. At this stage surgical emphysema above the suprasternal notch was noted, the correct diagnosis established, and the patient admitted to the thoracic surgical department. The chest radiograph showed left hydropneumothorax with air around the aortic arch and soft tissues of each side of the neck.

Operation.—At midnight, under general anaesthesia, the left chest was opened through the left ninth rib bed. The pleural cavity contained 1½ pints (850 ml.) of brown alkaline fluid. The mediastinum was emphysematous and the lacerated pleura had lifted from off the aorta and oesophagus. A catheter sling was passed around the oesophagus,

which was then lifted up for inspection. On its left side was a vertical rent 1 in. (2.5 cm.) long, and starting 1 in. (2.5 cm.) above the oesophageal hiatus in the diaphragm. Through this rent protruded oesophageal mucosa. After inserting mucosal stay sutures, the tear was closed with a series of interrupted chromic catgut sutures passed through all oesophageal layers. The chest wall was closed as in Case 1.

On July 1, because of sputum retention, aspiration bronchoscopy was performed and gave relief. The intercostal drainage was removed on the third post-operative day, and the skin sutures on the seventh day. The patient was discharged fit three and a half weeks after admission. The post-operative feeding regime was the same as in Case 1.

Subsequent barium study of the foregut revealed no pleural or oesophageal abnormality, but suggested a deformity of the duodenal cap without any definite evidence of active ulcer. Eleven months after operation the patient continued well and was working.

Comment.—This case illustrates the classical onset of symptoms first graphically described by Boerhaave in 1723 (Barrett, 1946). It illustrates their confusing severity, and how tell-tale cervical emphysema gave the key to diagnosis. Physical findings in the chest had been difficult to elicit and interpret, and an E.C.G. record was definitely misleading. It further shows how prompt surgical intervention materially altered the course of a catastrophe, with minimal convalescence and a most gratifying result.

Case 3

A farmer aged 52 was admitted as an emergency case to a county town hospital on July 20, 1953, suffering from severe epigastric and right chest pain. For years he had had an active duodenal ulcer; for four days before admission there had been an acute exacerbation of his ulcer symptoms, and he took only milk diet until 7 p.m. on July 20, when he ate a pear. Half an hour later he vomited twice and suddenly developed severe pain in the right chest, shoulder, and upper abdomen. The vomit was "coffee ground" material.

On admission he was distressed, with grunting respirations and slight cyanosis; pulse 120 and blood pressure 140/90 mm. Hg. The tongue was dry and furred. There was generalized abdominal rigidity, and absent bowel sounds. Examination of the chest at that time revealed no obvious abnormalities. A diagnosis of perforated duodenal ulcer was logically made, and the patient was prepared for operation—a Ryle tube being passed into the stomach and aspirated, and an intravenous drip being started.

First Operation.—At 11.30 p.m. that same night, under general anaesthesia with endotracheal intubation, laparotomy through an upper right paramedian incision showed the presence of a chronic duodenal ulcer in the first part of the duodenum and firmly adherent to the pancreas. There was no perforation, and the pylorus was patent. The large dilated stomach was further aspirated, 42 oz. (1,200 ml.) of brown fluid being removed. The abdomen was closed and the patient returned to the ward.

On the morning of July 21 a chest radiograph revealed a right-sided hydropneumothorax without tension phenomena. Spontaneous rupture of the oesophagus was established. Throughout the morning his condition gradually deteriorated, nor was it improved by aspirating a few millilitres of that same brownish fluid from the right pleural cavity. His pulse was 140 and blood pressure 55 mm. Hg. Plasma infusion, oxygen, and penicillin were given with no great improvement.

After telephone consultation with the thoracic surgeon in Dunedin, a Malécot catheter was inserted into the right pleural cavity and connected to water-seal drainage. His blood pressure steadily rose to 90 mm. Hg. A pint (570 ml.) blood transfusion was started and the patient was transferred 70 miles by ambulance.

At 11 p.m. on July 21 he was admitted to Dunedin Hospital, having withstood the journey well. Both the blood drip and the intercostal drainage were working satisfactorily. His temperature was 100.5° F. (38° C.), pulse 114, respirations 48, and blood pressure 110 mm. Hg systolic. A further chest radiograph showed little alteration, and the right lung was still partially collapsed.

Second Operation.—An hour later general anaesthesia was induced and the right chest opened through the ninth intercostal space. The pleural cavity contained $\frac{1}{2}$ pint (280 ml.) of brownish fluid. With positive pressure, the right lung was made to re-expand. Below the azygos arch was an irregular tear in the mediastinal pleura, with surrounding oedema. The oesophagus was isolated from the mediastinum and a catheter sling passed round it. Inspection revealed a vertical rent $\frac{1}{2}$ in. (3.8 cm.) long, starting 2 in. (5 cm.) above the diaphragm, and extending upwards to the azygos arch. This was closed with a series of No. 4 silk sutures, placed $\frac{1}{2}$ in. (3 mm.) apart and passed, as before, through all oesophageal layers. The chest was closed over water-seal drainage.

Post-operatively, bronchoscopy was performed and he was returned to the ward, where graduated continuous suction was applied to the water-seal drain. Fluids by mouth were restricted for four days, during which time intravenous therapy was continued. He was given penicillin and streptomycin.

A chest radiograph on July 24 confirmed that the right lung had re-expanded and was aerating satisfactorily. On July 27, however, there was evidence of a loculated basal pleural effusion, and on July 31 this was drained. The presence of a fistula and also staining after swallowing methylene blue solution confirmed that there was a leak from the oesophageal suture line.

On August 1 a second anterior pocket of pus in the right pleural cavity was cleared by intercostal drainage, and a Stamm gastrostomy performed. Progress thereafter was slow. The partially collapsed lung required a third apical intercostal drain and continuous suction for two weeks before it had re-expanded.

By September 30, almost two months after admission, the oesophageal fistula had healed and normal swallowing was again allowed.

On October 8 the gastrostomy tube was removed, by November 5 the anterior pleural sinus was healed, and by November 18, as the posterior sinus was negligible, he was discharged. He was last seen on March 10, 1954, when his sinuses were well healed and his swallowing was satisfactory.

Comment.—This is an interesting case of cause and effect. It demonstrates a further and unusual complication of duodenal ulcer—a complication which must always be kept in mind when sudden and severe abdominal symptoms follow vomiting. One can readily appreciate how the rupturing of the oesophagus into the right pleural cavity, with associated epigastric pain and rigidity, led to the possible diagnosis of perforated duodenal ulcer. Undoubtedly a pre-operative chest radiograph would have revealed the true diagnosis. This case, and two others not yet in the literature but known by me to have been explored as acute pancreatitis, induce me to plead for a pre-operative chest radiograph in all difficult acute abdominal cases. Nowadays, in such circumstances, a preliminary abdominal radiograph is common practice. The same film can well be adjusted to include the diaphragm and the lower chest, and thus avoid needless laparotomy. The case further illustrates how a patient in civilian practice, with pneumothorax and empyema made safe and temporarily relieved by intercostal drainage and by blood transfusion, can travel 70 miles by ambulance and be improved at the end of his journey.

Although Susman (1953) wisely points out that some cases of spontaneous rupture can recover without suture of the rent, and that Barrett's (1948) case of suture in fact leaked after surgical closure to produce a further oesophageal fistula and empyema, yet such conservative measures must

SPONTANEOUS RUPTURE OF OESOPHAGUS

BY

J. ROGER BOULLE, M.B., Ch.B.

Surgical Registrar, Taunton and Somerset Hospital

include adequate treating of the accompanying empyema. In a late case, with fully established empyema, to attempt to free the oesophagus and perform suture would be undoubted folly. In an early case, however, possibly up to 48 hours after perforation, the right attitude should be to explore and if possible suture the rent.

In this third case—with a long rent—there was a late leak. By performing a gastrostomy as an oesophageal bypass, and thus restricting swallowing purely to saliva, local pleural drainage together with gastrostomy ultimately gave sound closure.

Summary and Conclusions

Spontaneous perforation of the oesophagus is an acute emergency which must always be kept in mind and which may simulate many lesions. It can masquerade as coronary thrombosis, or acute abdominal catastrophes, especially perforated gastric ulcer, acute pancreatitis, and acute cholecystitis. Frequently the patient is too distressed to give a rational history.

As the oesophagus may perforate into the mediastinum alone, into the right or left pleural cavities, or into both, there is a diversity of signs and symptoms. Convincing chest clinical signs are often hard to elicit. Not all cases have cervical emphysema, but, if present, it is diagnostic. Chest radiographs, including, if necessary, the swallowing of radiopaque oil, confirm the diagnosis.

Pre-operative management embodies prompt relief of any tension pneumothorax, restriction of all food by mouth, intravenous fluids, passage of a Ryle tube to the stomach, and antibiotics.

Thoracotomy is then required, and wherever possible the rent should be sutured. In early cases, healing is sound and convalescence greatly shortened.

A plea is made to include a chest radiograph when faced with a difficult diagnosis of the acute abdomen.

I gratefully acknowledge help and co-operation with these patients from Professor J. E. Caughey, Mr. Alan Wardale, Mr. C. L. Tucker, Dr. R. L. Coulter, Dr. T. O'Donnell, and my resident staff in the Dunedin Hospital. I also wish to thank Dr. James Thomson, acting medical superintendent of the Dunedin Hospital, for permission to publish these records.

An observing station for measuring the smoke and sulphur dioxide pollution in the London atmosphere has been established in the Science Museum by co-operation with the Fuel Research Station of the Department of Scientific and Industrial Research. The station is one of a number that are being established to permit a more detailed examination of atmospheric pollution in London and elsewhere. The sampling equipment is displayed as a working exhibit in the Meteorology gallery. The smoke particles are captured on filter paper through which air is drawn from just above museum roof level by means of a small electric pump. As a result a grey stain appears on the filter paper, the intensity of which is a measure of the degree of smoke pollution. The same air is bubbled through a weak solution of hydrogen peroxide, where the atmospheric sulphur dioxide is dissolved to form an acid solution, the strength of which is measured by standard chemical methods. Observations of smoke and sulphur dioxide pollution are made daily by a member of the museums staff and reported to the Fuel Research Station, who are in charge of the investigation.

The following case of spontaneous rupture of the oesophagus is placed on record, even though treatment was unsuccessful, as this condition is still thought to be rather rare. The records of this hospital for the past six years, covering 28,725 admissions, show only one comparable case—that of an eclamptic patient who died thirty-two hours after admission—in which two perforations involving the lower end of the oesophagus were found: unfortunately the data about this case are too scanty for an accurate diagnosis to be made.

Increasing awareness of the condition seems to be bringing more cases to light. Mallam, Whitelocke, and Robb-Smith (1940) stated that the total number of published cases was 40. Barrett (1946), in a comprehensive review of the subject, put the figure at about 50 cases. Mauro (1952) discussed 103 cases in the literature. Barrett (1947) was the first to describe recovery following correct diagnosis and deliberate operation to repair the rupture. Frink (1947) published details of a successfully treated case of 1941, and Samson (1951) recorded two such cases mentioned by Graham in 1944. Nanson and Milnes Walker (1953) added the twenty-third recovery to the literature.

It would be wrong to publish only the successes in the treatment of this condition if a correct record of mortality rate is the aim. The mortality rate may be even higher and the disease commoner than the records would suggest, as up to 1949 only 16 cases had been diagnosed in life and the remainder at necropsy (Russell, 1953), and it may be possible to miss a ruptured oesophagus at necropsy unless one is looking especially for the condition (Barrett, 1946). Many cases of death in a period of hours to a few days after the onset of retrosternal pain, collapse, and perhaps vomiting must have been certified as being due to coronary thrombosis without necropsy confirmation, and these might well include a number of cases of spontaneous rupture of the oesophagus.

Summary of Case Notes

A 73-year-old widow, about to begin her tea, complained of severe upper abdominal pain which rapidly spread to both sides of the lower chest and back. After 30 minutes she vomited a little blood-stained fluid and then collapsed with pain. She was admitted to the medical wards, and after several hours was transferred to the surgical side. A long history of dyspepsia which she relieved by making herself vomit was obtained.

Examination.—Grossly obese, very shocked, and in great pain. Respirations 24, pulse 80, temperature taken rectally 99.8° F. (37.7° C.); blood pressure 150/90 mm. Hg. Tongue stained with altered blood. Marked surgical emphysema of front of neck. Equal aeration of both lungs and no detectable effusion or pneumothorax. Abdomen very fat, with large irreducible umbilical hernia; tender in right epigastrium but no guarding. A Ryle tube was passed and 90 ml. of thick bloody material was aspirated.

A provisional diagnosis of spontaneous rupture of the oesophagus was made and the patient was transferred to the x-ray department. Films of the chest were taken and then three mouthfuls of barium mixture were given to her to swallow before repeating the pictures. The following

information was obtained from these. The Ryle tube was folded on itself in the oesophagus. There was marked widening of the mediastinum and much free gas was present in it. There was slight collapse of the medial lung substance at both bases and a very little free pleural effusion on each side, but no pneumothorax. Barium was found to have passed into the posterior mediastinum to the left at the level of the lower part of the body of the seventh thoracic vertebra (see Fig.).

Radiograph showing barium in posterior mediastinum.

but the left side of the lower oesophagus could not be seen satisfactorily from this approach. The search was not prolonged, and a wide-bore stomach tube was passed without revealing the tear. The chest was closed after inflating the right lung, and two intercostal drainage tubes, leading from the mediastinum and the pleural cavity to underwater seals, were inserted.

After 36 hours her condition deteriorated and she died 48 hours after operation.

Post-mortem Examination.—The right lung was fully aerated and adhering to the parietal pleura; the mediastinum was dry and relatively clean. The left pleural cavity contained 2 pints (1,140 ml.) of clear brownish inflammatory exudate, but the mediastinal pleura was intact. The oesophagus had a vertical tear 2 in. (5 cm.) long on its left posterior aspect, the lowest part of the tear being 1½ in. (3 cm.) from the oesophago-cardial junction. The myocardium was pale and fatty and the right side of the heart was dilated; other organs showed evidence of congestive failure. Microscopical examination of many sections of oesophagus about the tear showed no evidence of pre-existing disease and the appearances were consistent with spontaneous rupture.

Discussion

Mackler (1952) distinguishes between rupture and perforation of the oesophagus, the term "rupture" applying when it occurs in a previously normal oesophagus and is not caused by direct trauma. Spontaneous rupture is usually associated with vomiting, but occasionally with other causes of increased intra-abdominal pressure. Mackler experimented with 65 oesophagi from fresh cadavers, by inflating them with air, and in all but three cases rupture took place as a longitudinal tear at the lower end of the oesophagus in its left lateral wall. McKenzie (1884) had also demonstrated this.

In the present case the tear was typical, as were the symptoms. The pleural cavity was not directly involved, as it often is (usually on the left side). No history of vomiting prior to the rupture could be obtained, though there was a long history of habitual voluntary vomiting.

Recent writers mention the value of radiography in the diagnosis. Dorsey (1951) states that the patient should be

given radiopaque material to swallow, and if none escapes from the oesophageal lumen no harm will follow; if it does escape, operation is indicated. Nanson and Milnes Walker (1953) used a barium compound, screening their patient; provided surgery follows if indicated, there can be no danger in using barium mixture. Priviteri and Gay (1951) prefer lipiodol to demonstrate the fistula, its site and extent.

In the above case barium mixture was used. It escaped only from the uppermost part of the tear, giving the impression that the tear was perhaps smaller and higher than it was eventually found to be.

Most writers are agreed that early diagnosis and immediate operation are necessary if there is to be recovery. Operation and drainage of the mediastinum, with the rupture of the oesophagus being adequately by-passed for some time, has been successful in a number of cases, and Jelliffe and Ferguson (1953) suggest that it may be sufficient. But most authors appear to feel that repair of the oesophageal defect increases the patient's chances of recovery. Mackler (1952) assesses the percentage of recoveries after drainage alone at 33%, and after definitive repair of the oesophagus at 69%.

Operation should preferably be performed at a centre with experience of operating in this field, but, as in the above case, the patient may not be fit to be transported any distance.

Summary

A case of spontaneous rupture of the oesophagus is briefly described.

The value of radiography and the use of radiopaque media as a swallow, to establish or confirm the diagnosis, is affirmed.

I should like to express my appreciation to Mr. L. Wynn Houghton for his advice and assistance with this case, and his permission to publish it.

A new British-American hospital, established to serve the constantly growing needs of the English-speaking community, has been opened in Madrid by Sir Ivo Mallet, the British Ambassador. The opening ceremony, attended by representatives of the Spanish Government and British and American residents, marked the end of three years' work to provide more adequate accommodation than that available in the 5-bed British-American nursing-home opened in 1923. Built on rising ground in the faculty of medicine area of Madrid's University City, the new 21-bed hospital stands on land leased free of charge for 50 years by the university authorities. A long, low, red-brick building on three floors, so constructed that three more floors can be added to meet future needs, it has a large garden and a wide view across the University City to the snow-capped peaks of the Guadarrama mountains north of Madrid. Several American firms gave medical and surgical equipment or sold it at cost, and an iron lung, said to be the only one in Spain for civilian use, was given by the U.S. Public Health Service. Equipment bought in England was shipped free of charge by a British mining company operating in Spain. The idea of building a new hospital for the British-American colony was proposed in June, 1951, by Sir John Balfour, then British Ambassador, in collaboration with Mr. Stanton Griffiths, an American businessman, who at that time was U.S. Ambassador to Spain.

BRUCELLOSIS AS A HAZARD OF BLOOD TRANSFUSION

BY

EILEEN E. WOOD, M.R.C.S., L.R.C.P.

Pathologist, West Cornwall Clinical Area

Since the introduction of low-temperature banks for the storage of blood, transmission of disease by transfusion has become negligible; Mollison (1951) and Whitby and Britton (1953) quote only syphilis, malaria, hepatitis, and some virus diseases as a possibility. Meno Brito (1948) refers to two cases reported at the second Mexican Brucellosis Congress in 1944, in which brucellosis was clearly transmitted by blood transfusion. Subsequently, during two years' work at a children's hospital he found five more instances in which brucella was isolated from the blood of donors, with no indication of clinical brucellosis, but whose blood on transfusion gave rise to the disease in recipients. He gives a table, showing the percentage of positive agglutinations against *Br. abortus* (1.31% in 2,899 donors) recorded at the hospital in 1945 and 1946, and states that, although a positive reaction is not sufficient for the diagnosis of active infection, he recommends that, in Mexico, tests should regularly be carried out to exclude the presence of agglutinins in the donor's blood. Brucellosis has a much lower incidence in this country, but the occurrence of the case described below shows the importance of questioning prospective donors and rejecting those whose state of health is unsatisfactory, particularly those who may be in the incubation stage of an infective disease.

History of the Donor

A married woman aged 53 was a regular donor who had never before felt any after-effects, but who returned home from her donation on October 11, 1952, feeling "very unwell." She did not consult her doctor for 10 days, but complained afterwards that she had been ailing all this time, and a fortnight later, on November 5, she was admitted to Southmead Hospital, Bristol, with undulant fever. On November 7 her serum agglutinated *Br. abortus* to a titre of 1:1280. A blood culture taken at the same time was sterile after 14 days' incubation.

In view of the history and the diagnostic level of the titre four weeks after donation, it seems likely that this woman's blood would have shown a bacteraemia at that time.

History of the Recipient

The recipient, a man aged 27, had lived a "transfusion life" since 1946, when he developed a complete red-cell aplasia shortly after painting with "aeroplane dope." On October 17, 1952, he received his usual weekly transfusion of one pint (570 ml.) of blood, and early in November a report was received from the Regional Transfusion Centre that the donor was suffering from brucellosis. Questioned at his next visit, the patient admitted that he had had a cold, but his temperature was normal and his serum agglutination tests were negative, as they were on three subsequent occasions up to December 28. Indirect questioning failed to elicit any other complaint, and it was not until January 17, 1953 (13 weeks after the transfusion), that he admitted feeling unwell; he then complained of malaise, worse in the morning, slight sweating, also more pronounced in the morning, anorexia, some diarrhoea, and vague pains in the limbs. His temperature was 99° F. (37.2° C.), and examination showed a purpuric rash on both limbs; the liver and spleen were just palpable. His

liver function was known to have been depressed since a homologous serum jaundice in 1949, and there was a severe transfusional haemosiderosis. On January 18 his serum agglutinated *Br. abortus* to a titre of 1:2,560; he was treated with chlortetracycline ("aureomycin"), 250 mg. six-hourly for six days, and his temperature fell to normal. He remained depressed, however, and failed afterwards to attend regularly for transfusions.

He was unable, or unwilling, to give an account of the beginning of his illness, and a visit was paid to his home in the hope of obtaining some information. His mother remembered that he first complained of nausea and abdominal discomfort towards the end of October, when he thought "the jaundice was coming back"; she bought him some medicine from a chemist but did not consult a doctor. Jaundice did not, however, develop. It was decided that he had "gastric flu," and he was in bed, on and off, for several weeks. By Christmas he was very unwell, eating little and feeling increasingly depressed, but by the middle of January his illness was, in his mother's opinion, abating. His milk-drinking habits were investigated, and it seemed certain he took very little milk, and that scalded, in tea and milk puddings. A report from Mr. H. G. L. Harvey states that in his opinion the weight of evidence points to the absence of brucellar abortion on the farm supplying the milk; unfortunately only one of the two cows owned at the time could be traced, but tests on this animal were negative.

Discussion

Spink and Anderson (1950) discuss the transmission of brucella through the blood of an asymptomatic but bacteraemic individual; they believe that, although a scanty inoculum of brucella will remain viable up to six months at 4° C., from a practical point of view the likelihood of transmitting disease by this route is remote because the organism would be destroyed by the blood or tissues of the recipients. That patients with active disease have relatively few organisms is shown by the difficulty of blood culture and the few colonies generally obtained.

In the above case the recipient had been suffering from a severe regenerative anaemia and was dependent on transfused red cells for his continued existence. His reticulo-endothelial system was known to be damaged, and it is tempting to speculate that as a result of this he was less competent than a normal individual to deal with the small number of organisms transfused. Agglutinins in this man developed late, but ultimately were in high titre, and it is recognized that a delay of weeks or months may occur even in the normal individual—indeed, that the whole process may pass without any detectable agglutinins being formed at all (Evans, 1934). Hardy *et al.* (1938), studying cases diagnosed in New York whose onset can be accurately dated because the entire milk supply to the city is pasteurized and infection by this means can result only from visits outside the Metropolitan area, stress the insidiousness of onset of the disease and the uncertainty regarding the early symptoms in the patient's own mind. They showed that the prodromal period is often measured in weeks rather than days, and gave the mean incubation period computed to the onset of earliest symptoms as ten weeks and to severe symptoms as 13 weeks (the time at which the disease was diagnosed in the above case). Morales Otero (1930), in experimental inoculation of volunteers, found that symptoms ordinarily causing attention took 28 to 35 days to develop, but he did not use the intravenous route. Unfortunately no clinical details are given in Meno Brito's paper, for it might be expected that symptoms develop more rapidly when infection occurs through the blood stream.

No evidence was found to incriminate milk as a source of infection in the above case, but there was, unfortunately, some difficulty and delay in tracing the two cows responsible for the patient's milk supply at the time. It would, however, seem to be pressing coincidence rather far to postulate a milk-borne source of infection developing

concurrently with exposure to infection through the blood of an individual known to have been in the bacteraemic stage of the disease.

Summary

A case of brucellosis diagnosed 13 weeks after transfusion with blood from a donor in the bacteraemic stage of the disease is described. If accepted, it is the first time that such an infection has been reported in this country, but such cases have been confirmed in Mexico.

Its occurrence illustrates the importance of questioning prospective donors about their health and rejecting those who might be in the incubation stage of an infectious disease.

The insidious onset of symptoms in undulant fever and the delay which may occur in the development of the antibody response are demonstrated.

I would like to express my thanks to Sir Weldon Dalrymple Champneys and to Professor Robert Cruickshank for their interest in this case; to Mr. Geoffrey Harvey, M.R.C.V.S., for investigating the patient's milk supply; to Dr. G. H. Tovey, of the Regional Transfusion Centre; and to the donor's medical attendant, Dr. R. C. Clifford, of Portishead, for his helpful notes. My thanks are also due to Dr. C. T. Andrews, physician to the West Cornwall Clinical Area, for permission to publish this case.

Medical Memoranda

Lactation from Axillary Tail of Breast

Studying the literature on polymastia, which is taken to include supernumerary breasts, polythelia, and accessory aberrant or ectopic breast tissue in any form or situation outside the normal gland, one is impressed by the universal complaint of those few authors who have interested themselves in these interesting developmental anomalies that the subject has been somewhat neglected by medical writers.

In view of the relative rarity and the paucity of recorded cases, it was thought worth while publishing the following case, especially as no record of an identical one could be found, that of Anderson (1930) being closest in similarity.

CASE REPORT

A 25-year-old primigravida was on October 1, 1953, delivered normally at term of a live female infant weighing 7 lb. 2 oz. (3.2 kg.). On October 4 both breasts were engorged and tender. With expression, they were improved by the next day, but the patient became aware of moisture running down from the right armpit. On closer inspection this proved to be milk, and she was found to have bilateral moderately tender axillary breasts continuous with the main organs. Gentle pressure over the right-sided one caused milk to exude from a skin pore. The swellings were in the situation and relation of the axillary tails of Spence. The one on the left was of the same consistency but slightly smaller, and from it no milk could be expressed through the skin. There was no vestige of nipple or areola related to either swelling or elsewhere in the "milk line." The main breasts were normal, and satisfactory feeding was soon established, with subsidence of engorgement of the axillary tails. These had at no time caused gross discomfort.

Upon discharge from hospital on October 10, the axillary swellings were about half the size initially observed, and

non-tender. Milk could still be expressed from the one on the right, but no longer ran out spontaneously. The infant had regained its birth weight. The patient was seen again on October 21, when the findings were the same as on the day of discharge.

Her mother, who has five children, had not been able to feed any of them, lactation failing in each case at the end of the lying-in period. She has no form of polymastia.

The patient has one sister, aged 24. She attended the antenatal clinic on October 27, when she was about 10 weeks pregnant, expecting her first child, and was found to have a unilateral swelling in the left axilla in the same situation as that of her sister. It was of the same consistency as the main breasts, but with no palpable communication with the one on that side, which was decidedly smaller than the right breast. On the right she has two rudimentary nipples in the "milk line," 3 in. (7.5 cm.) above and below the nipple of the main breast respectively.

COMMENT

Cases of axillary breast previously reported in which milk secretion occurred through a skin pore differ from the above case in that no connexion with the main breast was described (Anderson, 1930; Storey, 1936; de Cholnoky, 1939, 1951). More commonly, cases have been reported in which no milk-secreting duct opened on the surface of axillary breast tissue (Anderson, 1930; Christie, 1938; de Cholnoky, 1939, 1951; Masor, 1952). Some of these had been shown to communicate with the main breast by an isthmus of mammary tissue, others not. Most of these swellings had presented for the first time in the puerperium with the establishment of lactation, and most were very uncomfortable to the patient. De Cholnoky noticed that subjective complaint is much less where there is a connexion with the breast, as the secretion is discharged to and through the normal channels. None of the cases described, however, in which a communication with the main breast could be demonstrated, had milk coming through a skin pore over the axillary swelling.

In order that the presence of axillary breast tissue should not be missed, perhaps a suggestion that the best time to look for it is at or before the first post-natal examination would not be out of place. Storey's criteria are most useful.

I am indebted to Mr. C. W. F. Burnett, under whose care this patient was, for permission to publish the case report.

Case of Kaposi's Varicelliform Eruption (Accidental Vaccinia)

The following case shows the possibility of accidental vaccinia in a mother from contact with her vaccinated baby.

CASE REPORT

A 10-months-old child was vaccinated on April 2, 1953, in the upper and outer part of the thigh. This was successful, and the usual reaction followed. On April 18 the mother, who had never been vaccinated, developed a papule on the lower part of the left cheek and a sore in the left nostril in the naso-facial angle. A papule appeared on the following day on the posterior aspect of the terminal phalanx of the left index finger and also one on the interscapular part of the back. On April 22 the papules became pustular and there was a tendency towards umbilication. Considerable left infraorbital oedema developed with sub-maxillary adenitis. The temperature rose to 101.4° F. (38.6° C.) and the patient felt ill generally. As there had been several cases of smallpox in the North, a suspicion

arose about this case, and the medical officer of health was informed about it on April 23. A complement-fixation test of the pustular content was negative for vaccinia.

Dr. J. P. Marsden, Home Office Consultant, who saw the patient on April 24, was of the opinion that this was a case of accidental vaccinia, which he thought was rather rare. The accompanying photograph, taken on the same day, shows the typical appearance of the lesions and the facial oedema. A repeat complement-fixation test on egg membrane on April 27 proved positive for vaccinia, and so was

Photograph showing typical appearance of lesions.

an egg culture. Crusts began to form on the pustules on the 27th and the oedema was beginning to subside. The crusts separated about a week later, and small slightly depressed scars were left on the cheek and nostril.

This was a definite case of Kaposi's varicelliform eruption, as it fulfils the two requirements: (1) it was acquired by contact with a vaccinated person, and (2) it was definitely due to vaccinia virus, as proved by the complement-fixation test and egg culture.

COMMENT

Considering the large number of vaccinations performed, the number of reported cases of accidental vaccinia is comparatively very small; and although this case ran a benign course, the possibility of serious complications and sometimes of a fatal issue should be borne in mind. Finn *et al.* (1952) report a case of accidental generalized vaccinia in a child 6 months old, contracted from another child admitted thirteen hours previously into a cot adjacent to the patient's and who had had an active vaccination sore for ten days. The patient developed lesions twelve days later and died after ten days, in spite of treatment. Good and MacLachlan (1950) report a case of accidental generalized vaccinia in a boy of 6, who played in bed with a recently vaccinated infant; the boy died in hospital nine days later from vaccinia.

Vaccinia may also develop in a person who has been vaccinated, as illustrated in a case reported by Blattner (1951) of a child who developed impetiginous lesions after a smallpox vaccination. Vaccinia changes were demonstrated in the material taken from the lesions fifteen days after vaccination. According to Blattner *et al.* (1946), humoral antibodies to vaccinia begin to appear at the end of the first week following cutaneous vaccination; they increase in amount during the second and third weeks and reach their maximum at the end of the third week.

Bigler and Slotkowski (1951) maintain that the microscopical changes in vaccinia are identical with those of variola. It is believed that vaccinia and variola are caused by the same virus. When variola is inoculated into cattle and carried through several transfers in these animals the virus (variola) becomes attenuated and approaches the nature of vaccinia. The changes in the Malpighian layer of the epidermis consist of swelling, cytoplasmic degeneration and liquefaction, formation of multilocular vesicles, and eosinophilic inclusion bodies—Guarnieri's bodies—which are swollen nucleoli that have migrated from the nucleus into the cytoplasm.

It would therefore seem advisable to issue warnings about the possibility of accidental vaccinia from undue contact with recently vaccinated persons. The risk appears to be greater in people who have never been vaccinated.

I would like to express my thanks to Dr. J. P. Marsden, consultant, Joyce Green Hospital, for his kind help and advice about the case, and to Dr. J. C. Birchall, assistant medical officer of health for Croydon, for his great interest in the case and for the repeated complement-fixation tests and cultures done through him in the virus laboratories.

A. FRY, M.R.C.S., L.R.C.P., D.M.R.

Torsion of Gall-bladder

Torsion of the gall-bladder is a relatively rare emergency, which can occur only in those cases in which the gall-bladder is suspended from the liver by a mesentery. Bean and Symond (1953), in a review of the literature, found 100 cases reported up to 1953. The first case was reported by Wendel in 1898. In his case there was a floating gall-bladder, with a long cystic duct, and a floating kidney, with cholelithiasis and perforation of the gall-bladder. Brewer (1899), in 100 consecutive dissections, found only five cases in which the gall-bladder had a mesentery. A mesentery is only one of the several possible congenital anomalies of the gall-bladder. Recht (1952) reported a case in which he found a double gall-bladder, one part of which had undergone torsion. According to Maingot (1948) most cases of torsion occur during later life—that is, at the age of 60–70. Short and Paul (1934) estimated that 84% of cases occur in females. A further case is here presented.

CASE REPORT

On admission the patient, a woman aged 71, complained of severe abdominal pain, mostly in the upper part and down the right side of the abdomen. She stated that the pain had started in her neck, and seemed to pass down her chest to settle in her stomach. She had vomited several times prior to admission. There were no other symptoms of note. Her own doctor had diagnosed angina pectoris. She stated that for the past two years she had had severe breathlessness on slight exertion.

On examination she was noted to be a frail, thin, ill-looking old lady, obviously in severe pain. She was edentulous. The tongue was clean and moist. No abnormal physical signs were detected on examination of her chest, apart from the fact that the apex beat was $1\frac{1}{2}$ in. (3.8 cm.) outside the nipple line. There was no abdominal distension; only slight movement with respiration was noted, and the abdomen was rigid down the right side, where it was also very tender. A distinct zone of maximal tenderness was noted about $1\frac{1}{2}$ in. (3.8 cm.) above and to the right of the umbilicus, this area being approximately 1 in. (2.5 cm.) in diameter. No mass could be felt and no loss of liver dullness was detected. Her temperature was 99° F. (37.2° C.), pulse 95 and regular, and blood pressure 290/120.

A provisional diagnosis of perforated duodenal ulcer was made and the patient prepared for operation.

A laparotomy was performed through a right upper paramedian incision. When the peritoneum was opened a pyriform black mass presented, which, on further inspection, was found to be a gangrenous gall-bladder. The gall-bladder was suspended from the liver by a mesentery and had undergone torsion in an anticlockwise direction. The mesentery extended from near the fundus to the proximal part of the cystic duct and was $\frac{1}{2}$ in. (1.3 cm.) across its widest part. The torsion involved the proximal half of the cystic duct, which was longer than usual. The gall-bladder was easily removed after the cystic duct and artery had been identified

and divided, only the mesentery remaining to be dealt with. A drainage tube to the gall-bladder bed was brought out through the upper part of the wound, which was then closed in layers. The patient's general condition remained satisfactory during and after the operation. Her general condition improved considerably during the next twenty-four hours; she continued to make good progress until her discharge from hospital on the fourteenth post-operative day.

COMMENT

One very interesting clinical sign in this case was the distinct zone of acute tenderness over a small area. This had previously been noted by Case (1951). The gall-bladder was relatively free and mobile, but when torsion occurred it became relatively fixed and firmly abutted against the anterior parietal peritoneum. The small zone of maximal tenderness therefore corresponds fairly accurately to the area in contact with the gangrenous gall-bladder.

The patient's convalescence was without incident, which is not only gratifying but interesting; Arthur (1937) estimated the mortality to be 16%.

I wish to thank Mr. G. Townsley for permission to report this case.

Successful Femoral Embolectomy 17 Days After Acute Coronary Occlusion

Instances of successful removal of large emboli are not numerous. In a series of 19 femoral or iliac embolectomies performed during a five-year period (1946-51) at the Cook County Hospital (Klingensmith and Theis, 1952) only one patient was discharged with a surviving embolectomized leg. 15 died in the hospital, and 3 were discharged with an above-knee amputation. There are other reports in the literature claiming better results than this, but, even so, the percentage of successes is small.

A common cause of peripheral embolism is mural thrombus following myocardial infarction. Boas and Boas (1949) state that such thrombi are found in about 50% of cases of myocardial infarction that come to necropsy. Hellerstein and Martin (1947) found that the incidence of clinically detectable thrombo-embolic lesions in myocardial infarction in 1,600 cases was 11.5%. The incidence of embolism in the extremities was 5.5%.

CASE REPORT

A woman aged 64 was admitted to hospital on March 24, 1953. She was brought in by ambulance after an attack of severe substernal pain, which came on suddenly while she was walking.

On admission she was not shocked; pulse 82, irregular owing to extrasystoles; blood pressure 145/85. The heart sounds were normal, no murmurs or pericardial rub were heard, and there were no signs of cardiac failure. A diagnosis of myocardial infarction was made. This was confirmed by an electrocardiogram, which showed a recent anterior coronary occlusion. The patient was treated by rest in bed. No anticoagulants were used.

Satisfactory progress was made, apart from some chest infection, until April 10, when she complained of sudden onset of pain, first on the left side of the abdomen, and then, shortly after, by very severe pain in the right leg. On examination the right leg was pale, cooler than the left, and no arterial pulses were palpable. After ten minutes the limb had become mottled and blue. She was treated with

morphine, $\frac{1}{4}$ gr. (16 mg.), tolazoline hydrochloride, 50 mg. intravenously; heparin, 10,000 units; and ethyl biscoumacetate, 900 mg. After one hour the limb was still cold and cyanosed, but the pulsation of the external iliac artery had become palpable.

Three hours after the onset of pain an operation was carried out under local analgesia. No premedication was given, as the patient had had morphine for her pain.

One per cent. procaine was infiltrated and an incision made over and in line with the right femoral artery, in the femoral triangle. The artery was freed. Its wall was not thickened or calcified. Tapes were applied around the artery, which was opened between the tapes. Several small clots were removed. By releasing the pressure on the proximal tape, a thrombus 50 mm. long shot out of the lumen of the vessel. A ureteric catheter was inserted in the distal part of the artery, and 5 ml. of sodium citrate and 1 ml. of heparin was injected through the catheter. The incision was closed with an arterial suture. The sheath of the artery was not closed. The deep subcutaneous tissues were closed with plain catgut. The skin wound was closed and a firm bandage applied.

At the end of the operation there was a marked improvement in the circulation. The pulsation of the popliteal, dorsalis pedis, and posterior tibial arteries was palpable. The limb, however, remained mottled and cyanosed for some 12 hours post-operatively. At the end of the operation the patient complained of pins-and-needles in the toes.

An intermittent venous occluder was applied to the limb in the mid-thigh and left on for 24 hours, after which it was discontinued, as the circulation appeared to be normal.

Heparin therapy, 10,000 units eight-hourly, was given for 24 hours, and ethyl biscoumacetate, controlled by prothrombin times, was given daily for three and a half weeks.

Post-operative progress was uneventful. The patient was allowed up after four weeks, and was discharged quite well on May 16, five weeks after the embolectomy.

Our thanks are due to Mr. J. Thompson Fathi for his help and encouragement in the preparation of this article, and to Dr. P. J. Mills for his permission to publish this case.

The Diagnosis of Mongolism in Infancy: Small Auditory Meatus

It was pointed out in a previous publication (Wallis, 1951) that the diagnosis of mongolism in infancy is made easier by the observation of Brushfield's spots. In Brushfield's (1924) own words these are: "Speckled white or very light yellow clearly defined pin-points near the outer margin, generally placed at regular intervals in a ring and appearing to be placed on the iris. I have not been able to find these in the brown iris."

Observation of a further 10 cases has confirmed my surmise that at birth all mongols have blue eyes and show Brushfield's spots. Unfortunately some normal children show the spots as well. However, at least if a newborn infant has not got them we may be sure that it is not a mongol.

Another sign which has come to light is the smallness of the external auditory meatus. In all 10 cases it has been found impossible to insert an auriscope speculum of 3 mm. diameter into the ear, and in fact in not one of them could the drumhead be seen on either side. This is merely an expression of the general lack of development of the basal bones of the skull, but it has not apparently been recorded previously.

Reviews

THE BRAIN IN EPILEPSY

Epilepsy and the Functional Anatomy of the Human Brain. By Wilder Penfield, O.M., C.M.G., M.D., F.R.S., and Herbert Jasper, M.D., C.M. Chapter XIV by Francis McNaughton, M.D., C.M. (Pp. 896+xv; 314 illustrations, 8 coloured plates. £5 15s.) London: J. and A. Churchill Ltd. 1954.

This large volume, which is a sequel to *Epilepsy and Cerebral Localization*, written by Penfield and Erickson in 1941, presents material collected at the Montreal Neurological Institute since Dr. Jasper joined Dr. Penfield there in 1938. It deals, through detailed fact and copious illustrations, with the experimental neurosurgery and human electrophysiology that these workers have undertaken in that time. The historical background of their subject is also summarized.

The importance of the work can be judged from the fact that before the second world war, when this work began, to record directly from the cortex of man was a remarkable event and to stimulate it electrically an isolated experiment. Dr. Penfield's greatest achievement has probably been to secure such close co-operation from hundreds of patients who, having simply local analgesia of the operation area, have been able to describe their experiences under cortical stimulation and to help in hours of clinical and electrophysiological recording. Everyone who is concerned with cerebral physiology will wish to study the detailed observations included in this volume. As the methods and circumstances of recording are also fully described they can be collated and interpreted by the reader himself. This must have been the authors' intention, as they suggest in the preface, for such a wealth of fact, including the invocation by stimulation of every sensation, most movements, and some of the emotions which man experiences, cannot be interpreted by one school or in one era.

Roughly, the first part of the book considers epilepsy, especially from the neurosurgeon's point of view; the last sections deal with clinical, surgical, and electrophysiological techniques; and the larger middle portion presents the observations made by Dr. Penfield and his team of workers. The method employed is to illustrate a chapter with relevant case histories, though these differ from those usually found and from clinical texts in their intimate nature. They include photographs of the stimulated brain at operation, with verbatim accounts of important observations made by the patient or one of the team. Epileptic experiences are reproduced and past events invoked by cortical stimulation, and the psychologist and philosopher can make of it what he will. That this wealth of accumulated observations cannot yet be logically integrated is apparent in those sections of the book dealing with memory or the concept of a centrencephalic mechanism.

Although "the dedication of this book to Hughlings Jackson is prompted by the knowledge that many of the conclusions reported here were long ago the surmise of the founder of the English School of Neurology," there is surely still a long way to go before the facts presented can lead to consistent conclusions which would have been acceptable to him. It is this rather than any conclusions suggested which makes the book so valuable and provocative. It is particularly welcome to those who have followed Dr. Penfield's work through the years, for its publication coincides with his retirement from the Chair at McGill.

DENIS WILLIAMS.

ATOMIC MEDICINE

Atomic Medicine. Edited by Charles F. Behrens, M.D. Second edition. (Pp. 632+xiv; illustrated. 84s.) London: Baillière, Tindall and Cox, Ltd. 1953.

The development of atomic energy has introduced entirely new medical problems in connexion with many of its potential uses and abuses. The atomic industries require health

precautions of a novel kind which are already highly developed; the clinical and experimental use of isotopes and of nuclear radiations is constantly yielding new methods of investigation and therapy; and nuclear weapons can cause widespread radiation hazards in a variety of different ways. This is the broad subject, or rather the group of subjects, which is designated "Atomic Medicine" and discussed in detail in the second edition of a valuable work originally produced in 1949, largely by members of the medical and scientific staff of the United States Navy.

In many ways this is an important book, and particularly for its account of severe radiation injury and for the practical survey of health precautions in atomic industries. These are unfamiliar fields of medical responsibility on which it is useful to have the available information so well assembled. The section on particular isotopes is sometimes rather more superficial, perhaps because a large field, which has been the subject of several excellent textbooks, is here attempted in a few chapters. The bibliography of some chapters shows signs of inadequate revision since the 1949 edition, although in the work as a whole both the references and the tabulated material are of considerable value for reference. Inevitably in a composite work by different authors there are reduplications and omissions, but the planning and editing are usually careful and good, considering the rather disconnected subjects that the book attempts to cover. Parts of the chapter on "Survival Methods in Atomic Disaster" are somewhat trivial or naive, but a picture emerges which is coherent and practicable. Readers of this book will, incidentally, enjoy the conception of "the World War II figure of the 'air-raid warden' idly swinging his baton or flash-light during an 'alert' or a 'blackout,'" and agree that this figure needs replacing.

This book is important to those concerned with nuclear radiation and shows clearly to what extent the biological hazards are serious and are controllable.

E. E. POCHIN.

TROPICAL MEDICINE

A Manual of Tropical Medicine. Edited by Thomas T. Mackie, M.D., Colonel M.C., A.U.S. (Retired), George W. Hunter III, Ph.D., Colonel M.S.C., U.S.A., and C. Brooke Worth, M.D. Second edition. (Pp. 907; illustrated. 60s.) Philadelphia and London: W. B. Saunders Company. 1954.

In tropical medicine the size of a textbook has always been of special importance, for those working in this field are likely to travel and to need a textbook while doing so. A volume which covers the subject-matter in the minimum of space has therefore a very special appeal. This one is intended not to be a voluminous work of reference, but to contain sufficient detail to be an authoritative guide to those practising tropical medicine. It is of readily transportable size, it is packed with up-to-date, well-presented information of a high degree of accuracy, and it covers all the diseases likely to be encountered by a practitioner in the Tropics. To deal in detail with such a wide range of diseases is now beyond the scope of any small group of authors, and the editors are to be complimented on calling upon twenty-four contributors to help them.

As is right in an American publication, special emphasis is given to diseases of the tropical parts of the New World. American enthusiasm for the use of antibiotics has in places been allowed to obscure the value of older but highly effective standard remedies. Thus it is said of emetine bismuth iodide, which outside America is regarded by the majority of workers as being the most effective drug for the treatment of amoebic dysentery, that it and similar preparations are now seldom necessary or desirable.

Diseases of military importance are also given special attention, and the fact that the work is up-to-date is emphasized by a section on the recently described epidemic haemorrhagic fevers. Unfortunately nutritional diseases, which to tropical peoples are of tremendous importance, are dealt with inadequately. Sprue is classed as a nutritional disease, and to it and all other diseases in this section a mere

twenty-two pages are devoted. To macrocytic anaemia and kwashiorkor, which together probably affect many millions of tropical inhabitants, less than one page is devoted, as compared with six pages dealing with epidemic haemorrhagic fever, of which only a few hundred cases have so far been reported. In spite of these shortcomings, however, the book is a good one, and it is certain to be warmly received. The printing, paper, and the 304 illustrations are excellent.

A. W. WOODRUFF.

AN ANATOMICAL ATLAS

Atlas of Descriptive Human Anatomy. By J. Sobotta. Edited and translated by Eduard Uhlenhuth, Ph.D. Volume III. Blood vessels—Nervous system—Sense organs—Integument and Lymphatics. 5th English edition. (Pp. 390+xix; 164 coloured and 142 black and white illustrations on full page plates and additional 67 partly coloured figures in the text. £6 5s.) New York: Hafner Publishing Company Inc. London: Lange, Maxwell and Springer. 1954.

The late Professor Sobotta was not only a distinguished teacher of topographical anatomy but also famous for his many accurate investigations in the field of early mammalian development. His contributions to the study of the maturation, fertilization, and cleavage of the ovum of the mouse are regarded as classics. The present volume of his *Atlas of Anatomy* is the fifth English edition of this now famous book, first produced in German in 1904. After an absence of nearly ten years this edition will be welcomed by teachers and students alike. The first English edition was prepared by Professor McMurrich, of the University of Toronto; the fifth has been edited and translated by Professor Edward Uhlenhuth, of Baltimore. As in earlier editions, arteries, veins, and nerves are shown together in a single illustration. This has many advantages in that the student is able to see the relationships of these structures as they are found in the body and not as separate entities when they are illustrated in separate diagrams. The only criticism I would make is that in several of the illustrations too many fine branches of nerves and arteries have been shown, and in certain figures such detail obscures the essentials. The text is clear and concise. The atlas is one of the best available to-day and can be recommended with confidence.

W. J. HAMILTON.

CARDIOVASCULAR SURGERY

Cardiovascular Surgery. By Gerald H. Pratt, M.D., F.A.C.S. (Pp. 843; 358 illustrations, 4 coloured plates. £5 10s.) London: Henry Kimpton. 1954.

The rapidly increasing scope of cardiovascular surgery makes it difficult to condense the sum total of our present knowledge into a reasonable space. Dr. Pratt has, however, achieved this end and has given a concise and yet comprehensive account of the subject in one volume. Diseases of the heart and blood vessels are becoming increasingly important in a society whose expectation of life is steadily improving, and surgery in this field has, therefore, a similarly increasing significance, even though only a proportion of the disorders are amenable to treatment.

The book is divided into sections, starting with a classification and the general examination of the patient, and passing via anaesthesia, fluid balance, and the like to surgery of the heart, of the arteries, of the veins, and of the lymphatics and thence to special technical procedures. Each section has an adequate, though not complete, bibliography, and there are numerous well-chosen illustrations to amplify the text.

In the chapters on heart surgery the description of mitral stenosis and its treatment is very satisfactorily handled. Other cardiac lesions suitable for surgery are more briefly, though adequately, discussed. Occlusive arterial disease is described in detail, and not only are surgical procedures well illustrated, but conservative measures, including dietary instructions, are given in a practical manner. The treatment of threatened and actual diabetic gangrene is similarly dealt with. Arterial thrombosis, embolism, aneurysm, and

arteriovenous fistula are discussed with a wealth of detail that is based on the author's considerable experience and makes valuable reading.

There is little that the author has omitted in his comprehensive survey of the whole subject, and if there is a certain unevenness in some sections it is a very minor criticism of a book which must well remain for some time a standard work on this complex subject.

T. HOLMES SELLORS.

ANGIOGRAPHIC STUDY OF PATHOLOGY

Atlas Postmortaler Angiogramme. By J. Schoenmackers and H. Vieten. (Pp. 203; illustrated. D.M. 57.) Stuttgart: Georg Thieme. 1954.

This most original volume consists of a series of radiographs taken from cadavers after injection of the blood vessels with opaque material, thus enabling a large number of pathological conditions to be studied from a very unusual point of view, often with surprising results. The technique employed is described in detail, and the superb radiographs which have been obtained are a proof of its success. The skill and labour involved must have been very great, but they were fully justified by the result.

Every region of the body has been covered and in a large variety of pathological conditions. Each print is accompanied by a full description and frequently by an explanatory diagram. At the end of each section a summary is given in four languages, but in general the plates speak for themselves. They number in all 131, and in every case the production is perfect. Perhaps the most interesting are those of the lungs and of the heart. Angiograms of the lungs include acute infection, asthma, emphysema, tuberculosis, silicosis, and carcinoma, while those of the heart are devoted to the coronary arteries, showing variations of the utmost significance.

The importance of this laborious study as a background will be realized when the great development of such radiographic study of the living in clinical practice is considered. Comparison of a clinical angiogram with the corresponding plate in this atlas should greatly facilitate an appreciation of its meaning and assist in diagnosis. But perhaps it is the pathologist himself who will best appreciate these superb plates and the perfect technique which their production demanded.

HENRY SOUTTAR.

PHYSIOLOGY OF THE MOUTH

The Physiology of the Mouth. By G. Neil Jenkins, M.Sc. (Liverpool), Ph.D. (Cantab.). (Pp. 288; 53 figures. 30s.) Oxford: Blackwell Scientific Publications. 1954.

The physiology of the mouth and dental tissues has not in the past received the attention it deserves, and it is most useful to have a modern work on the subject with very excellent references collected together in one volume. Although written primarily for undergraduate students, for whom it will be most valuable, its greatest value will probably be to the postgraduate student and those interested in research in this field, since it deals with current aspects of research which may be somewhat beyond the basic training of the dental student. The author is to be congratulated on producing a most interesting book.

A. MACGREGOR.

Alumni Cantabrigienses, compiled by J. A. Venn, is a biographical list of all known students, graduates, and holders of office at the University of Cambridge from the earliest times to 1900. The four volumes of Part I covered from the earliest times to 1751, and the sixth and final volume of Part II (from 1752 to 1900) has recently been published, the names in this volume running in alphabetical order from Square to Zupitza. The compiler and publishers (Cambridge University Press) are to be congratulated on successfully completing this immense biographical task. The cost of the final volume is the same as that of its predecessors, £10 10s.; and the whole set of ten volumes can be bought for £89 5s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 1 1955

ADRENALECTOMY FOR BREAST CANCER

Most of our present-day knowledge of the aetiology of breast cancer is based on animal experimentation. Although as early as 1919 Loeb and his co-workers had demonstrated the carcinogenic potency of the ovaries in mice with a high susceptibility to breast cancer, it was not until 1932 that Lacassagne¹ finally established the relationship between the ovarian factor and mammary neoplasia. His discovery that oestrone induces breast cancer in male mice, which normally never develop it, was important because oestrogen was proved to be the first substance originating in the body which causes cancer. Further research into the biological activities of the sex hormones showed that administration of the male sex hormone could prevent the development of mammary cancer in female mice belonging to high cancer strains. These results produced a wave of optimism, for many then took the view that cancer which arose in organs under endocrine control could be prevented, or at least held in check, by administering a hormone antagonist.

Loeser² was one of the first in the clinical field to try testosterone therapy in cases of inoperable breast cancer, and Adair and Hermann,³ among others, reported later on this form of treatment. Haddow and his colleagues,⁴ Nathanson,⁵ and Stoll and Ellis,⁶ relying on the depression of pituitary function and hence inhibition of ovarian secretion in preference to a hormone antagonist, used massive doses of oestrogen for treatment of breast cancer in women. These different forms of treatment gave variable results. Some breast neoplasms were temporarily held in check, others failed to respond. Apparent recovery, however, was extremely rare, and reactivation of tumour growth invariably occurred. This is probably due to the fact that when an endocrine imbalance is created, either by the surgical removal of an organ or by the administration of a hormone,

the anterior pituitary gland stimulates other endocrine organs to make up for the deficiency. Thus the adrenal cortex might be stimulated to secrete both oestrogens and androgens, the ovary to secrete androgens, and the sertoli cells of the testes to secrete oestrogens sufficient in amount according to some authors⁷ to induce cancer of the male breast.

Huggins,⁸ working on the assumption that steroid hormones of the adrenal cortex might be responsible for reactivation of tumour growth, was the first to advocate bilateral adrenalectomy combined with castration in cases of breast cancer which had failed to respond to other forms of hormone treatment. He has recently published a review⁹ of these results, and Sir Stanford Cade makes another important contribution in the opening pages of this *Journal* to the knowledge being gained about this method of treatment. Nearly 20% of deaths from cancer in women in Great Britain are from mammary carcinoma, and the importance of the recent work must be judged against this background, but both Huggins and Cade are emphatic in claiming only that this form of therapy controls the growth of the disease rather than cures it. The operative mortality, considering the physical state of the patients, is very low. Post-operative adrenal insufficiency is made good by the administration of cortisone acetate. Those with skeletal metastases obtain immediate relief from pain, and begin to gain weight. Cade reports on 56 patients who had bilateral adrenalectomy for disseminated breast cancer. The results have been good in 60% of these cases, including 23% which showed remarkable improvement, regression of palpable lesions being accompanied by reossification in skeletal metastases. Survival so far has been up to 21 months. Huggins, in his recent review, reports that out of 17 patients subjected to adrenalectomy for mammary cancer in May, 1951, there was only one post-operative death. Six patients were alive two to three years after the operation, and secondary deposits had regressed in all of them. One patient, three years after the operation, has apparently recovered and has returned to work. Unfortunately only some breast cancers respond to this treatment: in fact there appear to be three distinct types, none of which with any certainty can be histologically diagnosed. There are those tumours which are adrenal-dependent for sustained growth and respond to adrenalectomy. The second type are those which are ovary-dependent, and these likewise respond to the combined operation of castration and adrenalectomy. Growths of the third type, which are rarer, are hormone-independent and fail to respond to any form of hormone therapy. This resistance may possibly be due to a factor of hypophyseal origin. Since there are no reliable means

whereby it can be ascertained beforehand whether a breast cancer is hormone-dependent, the results obtained by adrenalectomy must remain unpredictable.

Admittedly there are many gaps in our present knowledge of the functional inter-relationships of the endocrine system, and until a method of controlling the activity of the anterior pituitary gland can be found the treatment of mammary cancer by hormone therapy will remain incomplete and often unsatisfactory. Nevertheless, as Sir Stanford Cade rightly states, "No method of treatment has as yet achieved control of disseminated, widespread, and often terminal stages of breast cancer comparable to that following adrenalectomy."

YELLOW FEVER IN AFRICA

Until the early years of this century yellow fever had been one of the great plagues of the Tropics and sub-Tropics for more than two hundred years. In 1900 the discovery of the transmission of the disease by the mosquito *Aedes aegypti* was the first of many important advances, and since then epidemiological investigations have led to methods of control so efficient that a major epidemic need no longer occur anywhere. At first it was believed that yellow fever was essentially an urban disease carried only by *A. aegypti*, but experiments in 1928 showed that certain other mosquitoes could transmit it under laboratory conditions. In 1932, in Brazil, a rural epidemic was studied in which *A. aegypti* was not the vector, and similar outbreaks, in which secondary cases were much less common than in urban areas, were noted in populations living in or close to uncut forest. These facts suggested the existence in the jungle of a transmission cycle involving a mosquito and an animal host, human infection being only incidental. This theory was supported by the presence of protective antibodies in locally captured monkeys, and in 1944 it was confirmed by the recovery of yellow fever virus from a wild marmoset and from the forest mosquito *Haemagogus spegazzinii*.¹

In Africa the study of rural yellow fever has been actively pursued in the Bwamba forest of Uganda since 1936, and there a similar epidemiological pattern was found. In Brazil jungle yellow fever was contracted mainly in virgin forest, but in the Bwamba area infection mainly occurred in farm clearings in the forest. As the local epidemiology was elucidated it was found that the main sylvan hosts were monkeys

living in the treetops and never descending to ground level. The virus was carried between them by *Aedes africanus*, a night-biting, treehole-breeding species which also lived in the tree canopy.² A further link was required to bring the disease to man. This was provided by other species of monkeys which rested in the trees at night where they could be infected by *A. africanus*, but during the daytime they raided farms and were then bitten by *Aedes simpsoni*.³ This species fed during daylight on both monkeys and man, and it bred in the leaf axils of banana and colocasia plants in the edges of clearings and forest fringes. By this chain of transmission in the Bwamba forest the virus is transported from the tree canopy to man at ground level and can then be carried to towns, where man-to-man transmission by *A. aegypti* may result. The epidemiology requires clarification, however, in some other African areas where there are insufficient monkeys to support continued transmission of the virus and where a prolonged dry season eliminates or reduces the vector population to a very low level for some months. In this connexion it may be significant that protective antibodies have been demonstrated in wild African lemurs living in savannah country. It has also been shown that certain mites and ticks can ingest and conserve yellow-fever virus for days or weeks, though transmission by their bites has not been effected.⁴ Infection of a sandfly has also been recorded in nature.⁵

Modern methods of controlling yellow fever are based on the specific epidemiology of the disease. In urban areas transmission is prevented by eliminating *A. aegypti* by means of larval control and residual insecticidal spraying of houses, or by reducing its density below that necessary for epidemic spread. Control of the sylvan form of transmission is a much more difficult problem because no practical means exist of attacking the insect vectors or the monkey hosts. A method of prophylactic treatment of man by live attenuated virus is, however, available. Two vaccines are in use, 17D vaccine produced by the Rockefeller Foundation by culture in denervated chick embryo, and a vaccine prepared by the Institut Pasteur in Dakar from infected mouse brain. The former is administered subcutaneously, while the latter can be given either subcutaneously or by scarification, in which case it may be combined with smallpox vaccine. The period of protection given by both preparations is officially recognized as six years, and is probably longer. Reactions following 17D vaccine are rare and mild and many millions of people have been protected by it. The Dakar vaccine in a small proportion of cases causes neurotropic reactions, but it has been used extensively in French West Africa,

where more than 38 million doses have been administered.⁶ The results of this method of control have been excellent. In treated areas sylvan yellow fever is no longer seen in the human population, or occurs only exceptionally, usually in remote localities in persons who have escaped vaccination. The spread of sylvan yellow fever from the permanent foci to urban areas can thus be prevented, while *Aedes* control in towns obviates epidemic transmission if the disease is introduced and reduces the risk of its export to other parts. *Aedes* control on airfields and the use of insecticides in aircraft are necessary to prevent the carrying away of infected vectors. There still remains a risk of spread from centres so far unrecognized, but this is becoming more remote as immunity surveys delineate more accurately the endemic zones and foci of the disease.

SEQUELAE OF ERYTHROBLASTOSIS

Rhesus incompatibility is a risk run in about one-eighth of pregnancies, with harmful antibodies developing only in about one in two hundred. A further 20% of maternal sera contain anti-A or anti-B agglutinins incompatible with the infant's cells,¹ though haemolytic disease complicates only a small proportion of these cases. The most important complication of the disease is kernicterus; before the introduction of exchange transfusion it was reported in up to 30% of cases. Deep jaundice is accompanied by such signs as head retraction, eye rolling, squint, opisthotonos, hyperpyrexia, convulsions, and terminal respiratory failure. A hypotonic phase usually follows in the one-third who survive the acute stage, and this is generally succeeded by choreo-athetosis with or without deafness, in some cases accompanied by mental retardation. Minor abnormalities may also occur in jaundiced babies in the first few days, such as lethargy, reluctance to feed, and vomiting, sometimes with increased muscle tone or mild cerebral irritation, but such cases apparently carry a better prognosis, and several have been reported as being entirely normal at the age of a year.² A correlation between hyperbilirubinaemia and kernicterus was suggested by the identification of the staining pigment as bilirubin,³ the discovery that the indirect type has a special affinity for the basal ganglia,⁴ and by the experimental kernicterus produced by bilirubin infusion in animals.^{5,6} Thus it has been established that kernicterus is rare if the serum bilirubin level remains below 18 mg. per 100 ml.⁷ Exchange transfusion removes the source of approximately 1,000 mg. from the infant's blood and is therefore indicated if there is anaemia with cord haemoglobin below 15 g.

per 100 ml., prematurity, or a history of a previous affected sibling; otherwise it is given if the bilirubin level rises above 18 mg. per 100 ml.¹ Armitage and Mollison last year reported⁸ the results of a therapeutic trial encompassing about 450 liveborn infants wherein alternate anaemic babies with haemoglobin below 15.5 g. per 100 ml. were treated by exchange and simple transfusion. In the whole series there was still a 9% overall mortality from kernicterus up to the end of the first year, while a further 5% of 350 tested survivors were backward or showed neurological abnormality in a 1-3-year follow-up. In spite of effecting a reduction of 50% in the mortality from kernicterus, a single exchange transfusion did not avert this complication in 11% of anaemic full-term babies and 35% of anaemic premature babies. Better results are attained by repeating the exchange transfusion if further jaundice or hyperbilirubinaemia develops, which measure succeeded in reducing the immediate mortality from kernicterus to 2% in 250, mostly full-time, sensitized babies.⁹ One case is also worth recording of an infant who received exchange transfusion subsequent to the onset of acute kernicterus and later apparently developed normally.⁹

Apart from the sequelae of frank kernicterus, there remains the question whether blood group incompatibility can lead to mental retardation in cases where there is no evidence of acute or subsequent neurological damage. Creak and Durward¹⁰ found normal distribution of intelligence in the 45 physically normal survivors of 50 children originally treated at Great Ormond Street for the neonatal effects of rhesus incompatibility. Another method of investigation has been to determine the rhesus blood groups of undifferentiated mental defectives and their parents. Yannet and Lieberman,¹¹ comparing the blood groups of neurologically normal mental defectives whose defect was of unknown aetiology with the blood groups of their mothers, found an increased incidence of rhesus incompatibility as compared with aments of known aetiology, but numerous later investigators¹²⁻¹⁴ have failed to confirm these findings or similar ones for ABO incompatibility.¹⁵ More satisfactory have been two

well-controlled mental and neurological follow-up studies by Day and his colleagues on babies known to have had haemolytic disease of the newborn without having developed clinical signs of acute kernicterus or any subsequent neurological deficit. Gerver and Day¹⁶ reported a normal average I.Q. of 102.7 in a series of 68 such babies, but the sibling controls were on the average 11.8 points higher, while five of the affected babies and none of the siblings had I.Q.s below 70. In a second study, after the introduction of exchange transfusion, Day and Haines¹⁷ reported that deeply jaundiced babies with severe anaemia suffered a significant depression of 23 points, as opposed to the entirely normal intelligence found in babies with absent or moderate jaundice. This danger from deep jaundice, which was also present to a lesser degree in cases without severe anaemia, could presumably be reduced but not entirely prevented by the prophylactic use of exchange transfusion repeated as often as necessary, though the new threshold level of bilirubinaemia has yet to be determined.

Deafness afflicts 30% or more of survivors from kernicterus,¹⁸ though haemolytic disease itself does not account for more than 3% of cases of congenital perceptive deafness.¹⁹ The deafness is usually of high frequency type, similar to that occurring after prematurity or birth hypoxia, which raises the question of a common factor in pathogenesis. Haemolytic disease accounted for 15% of a large series of infants with obstructive jaundice,²⁰ but the prognosis is good, and permanent obstruction of the bile ducts does not occur, though rare cases of cirrhosis of the liver are reported. Congenital malformations and hepatolenticular degeneration are now known not to be connected with blood group incompatibility. In conclusion, it is heartening that 95% of the Armitage and Mollison series and 90% of Creak's series showed entirely normal mental and physical development on follow-up.

THE NUFFIELD FOUNDATION

The Nuffield Foundation, which was established nearly twelve years ago, in the middle of the war, has issued two progress reports.^{1,2} One of them is technically an annual report, but the work supported by the Foundation is largely long-term and cannot be fitted into a single year, some of it not even into a five-year period. The annual report is really a report of what has been done during the last quinquennium and a prospectus of what it is proposed to do during the next. The other volume gives the list of the grants made over the last ten years, amounting to well over £4m. Research has been subsidized in many laboratories and university and other departments at home and overseas, the subjects ranging from nuclear physics to the effects of ageing, from dental health to soil science, from foetal physiology to

the impact of television on children, from studies of the aborigines of Arnhem Land to the health services of the Aden Protectorate, from malnutrition of children in Uganda to the insect fauna of the game reserves of South Africa, and so on almost interminably.

The first grant of the Foundation in the medical field—£100,000 over ten years—resulted in the establishment of the Institute of Child Health of the University of London. Then industrial health departments were promoted in three universities in industrial areas of Great Britain, help being given to a total of £150,000. Dental health claimed attention, and a chair of oral medicine was set up in the University of Durham and research units in preventive dentistry in Leeds and Manchester. The Foundation has not concerned itself with particular diseases, with the exception of rheumatism; and on research in rheumatism, assisted by what is known as the Oliver Bird Fund, it has spent a total of £228,693 since the initiation of the Manchester centre in 1947. The care of the aged is another of the objects enjoined upon the Foundation by its trust deed. To the National Corporation for the Care of Old People it has contributed over half a million pounds in five years, and another half-million has been given by the Lord Mayor's National Air-raid Distress Fund. Finally, there is a large scheme of fellowships, scholarships, and bursaries, for residents both in the United Kingdom and in other parts of the British Commonwealth, to the number of several hundreds, about one-third of them in medicine. Seventy pages of this ten-year chronicle are devoted to a bibliography of published research attributed in whole or in part to the Foundation's grants and awards. Under the heading of research in the field of rheumatic diseases alone there are well over 100 entries, and that is only a selected list.

In the other volume, which is described as the ninth annual report, it is stated that during the last five years the Foundation has set aside nearly £400,000 for projects outside the United Kingdom. In the overseas parts of the Commonwealth private aid is "more keenly needed, sought, and valued" than in the United Kingdom, because in this country there is increasingly generous provision for scientific and medical research from public funds supplemented by industry. The Foundation's main concern during the next five years will be with the natural sciences (giving preference to biology), with continued support for research in rheumatism and some other medical projects, and with the social sciences. It will assist research and practical experiment in the employment of elderly people, and the various fellowship schemes will also be continued into the next quinquennium, but perhaps not all of them throughout the period. Some may be replaced by new schemes, for the Foundation is not committed to a rigid formula of beneficence. Indeed, apart from the scale of its benefactions, its chief characteristics seem to be its adaptability, imagination, and capacity for adventure—qualities also favoured by the great industrialist who provided this immense capital fund of £10m. for the advancement of health and of social well-being.

² *The Nuffield Foundation—Report for the Year ended March 31, 1954*, London.

THE GUT PROVOKED

"Diagnostic roentgenologists basically are organologists," says Friedman,¹ and in the interests of their search of the gut for growths, ulcers, polyps, and so on they usually do their best to soothe and console the patients committed to their rays. Friedman did exactly the opposite. By what he calls "superficial psychic probing" he provoked an emotional disturbance in patients under radiological examination, and claims thereby to have demonstrated the appearance of a "deficiency" or "motor dysfunction" pattern in the small intestine of persons in whom it was absent when they were in a state of composure. This is the pattern typically seen in pictures of the small intestine in cases of steatorrhoea, provided barium capable of flocculating is used. Friedman's patients were not suffering from steatorrhoea, and the illustrations of the small-intestine pattern before and after provocation are impressive. The main interest, however, of this study lies in its dual approach, the use of physical and psychological methods to study intestinal function.

A perusal of the work of Cannon² and the later studies of Wolf and Wolff^{3,4} and their colleagues, aided perhaps by a little intelligent self-observation, must convince all but the most hard-boiled of organologists that the digestive apparatus may be profoundly upset in states of emotion. But whether these disturbances are of importance in the aetiology of so-called organic disease is a vexed question, for the technical difficulties of proving or disproving such a thesis seem at present almost as great as the philosophical ones in such questions as, Can mental events cause physical disease?

In the meantime the observation and measurement, when possible, of changes in function during emotional states is of value both for its own sake and to define more clearly the normal limits, thus to prevent these changes from being misinterpreted as evidence of structural disease. Friedman has shown that radiological methods can be used successfully for this purpose in the gut, but the danger of excessive irradiation must seriously limit the scope of the method. Colonic movement, for instance, has been studied in animals by means of serial x-ray pictures, and would appear to be an admirable subject for this kind of observation in man were it not for the excessive amount of irradiation necessary to obtain an adequate serial record of the movements of the colon.

Perhaps one of the most interesting aspects of this study is to illustrate how the old distinction between "organic" and "functional" in the sense of physically or mentally determined is breaking down. Is the disturbance which appears on x-ray plates as the "deficiency" or "motor dysfunction" pattern organic or functional? Perhaps the question does not make sense, and what we should ask in this, as in all changes of function in living persons, is: How far can this behaviour be explained by physical methods, and how far by psychological? The further applications of such a

dual approach to gut function, whether by means of x rays or not, may well bring information of clinical value, and at the same time further illuminate gut-mind relationships.

UNEQUAL TRANSRADIANCY OF THE LUNGS

Chest radiographs showing one lung to be more translucent than the other are commonly seen when pulmonary distension has occurred to compensate for lobar or segmental collapse of a lung. A similar radiological picture is seen when partial bronchial occlusion has led to obstructive emphysema, and more rarely when an abnormality of the chest wall, such as loss of breast tissue following amputation, or congenital absence of the pectoral muscle, gives the illusion of abnormal translucency. Recently Macleod¹ drew attention to a group of patients whose radiographs showed abnormal transradiancy of one lung but in whom none of the usual causes were apparent. In nine such cases care had been taken to exclude abnormalities of the bronchi by bronchography and bronchoscopy. Most of the patients investigated suffered from increasing shortness of breath; cough was uncommon, but many of the patients were troubled by wheezing. Physical examination demonstrated diminished chest movement and reduced breath sounds on the affected side. Rhonchi, when present, were evenly distributed over both sides of the chest. Radiographs taken in inspiration showed increased translucency of one lung, the mediastinum being displaced towards the affected side in six of the patients. On expiration the difference in transradiancy was increased, and mediastinum shifted towards the normal side. Bronchograms showed that the finer bronchial radicles scarcely filled with oil and that there was almost no alveolar filling at all; there was, however, no abnormality in the calibre or distribution of the main bronchi.

These features made it clear that the patients were not suffering from obstructive emphysema, bullous emphysema, or cystic disease of the lung. In seeking an explanation for the underlying abnormality, only clinical evidence was available, since in no case had morbid anatomical or histological examination been possible. Macleod thought it unlikely that there was a congenital basis to these cases. He thought that some of them might be examples of unilateral emphysema, and measurements of the intrapleural pressures in one patient were in keeping with this diagnosis. The six cases in which the mediastinum was displaced to the diseased side were more difficult to explain. Here, Macleod thought the most likely explanation was that the affected lung had, during the time when growth was taking place, been affected by some disease which temporarily retarded its development. Later, when the primary disease had abated, the affected lung was stretched beyond its normal capacity in an effort to fill the hemithorax. It is quite conceivable that such a sequence of events could take place as a result of primary tuberculosis with transitory partial bronchial obstruction. The natural history of this disorder needs further observation before it is fully understood.

¹ *Thorax*, 1954, 9, 147.

HEALTH OF SCHOOLCHILDREN

Since the end of the war children's mortality rates for infectious diseases have startlingly diminished, and even for diseases less susceptible to antibiotic attack they have shown a gratifying fall. The death rate per 100,000 for children aged 5-9 was, for infectious diseases (including tuberculosis), 22.7 in 1946 and only 6.5 in 1952. For children aged 10-14 the fall was from 19.6 to 4.9.¹ Rates for other causes combined fell to about two-thirds of their 1946 values. It is against this background that the Chief Medical Officer of the Ministry of Education can report² that in 1953 the health of schoolchildren was everywhere satisfactory. The general condition of the children examined at medical inspections was found to be "good" in just under 45%, "fair" in 53%, and "poor" in just over 2%. Diphtheria is now an uncommon disease owing to the immunization campaign. There were fewer outbreaks of food-poisoning, and probably no increase in the prevalence of rheumatic fever—possibly a fall. But in contrast to the great improvement in response to serious disease the C.M.O. has to record deterioration in other respects, though the diseases concerned are milder or relatively trivial. Perhaps most notable is the increase in dental caries. Indeed, "the figures of all areas show a substantial increase of caries in 1953 as compared with 1948." The most likely cause seems to be the almost incessant consumption of sweets, chocolate, and buns³ that has become habitual to the children of far too many ignorant or over-indulgent parents. In spite of modern pesticides, over 300,000 children were found to be verminous, a figure that the report concedes to be disappointing even though it is the lowest so far recorded. No doubt education has a large part to play here, for in some sections of the population lice are looked upon as more or less normal commensals, and lousy parents provide a constant supply of fresh reserves as the lice infesting their children are wiped out. More and better co-operation between school doctors and general practitioners is a happy feature of the report, and by and large relations with hospitals seem to be cordial. But as Dr. C. W. W. Jeremiah, of Nottinghamshire, is quoted as recording: "Co-operation is a matter of personal relationship and cannot be dictated by 'powers that be,' be they national or parochial."

AGENE TREATMENT TO END

Last week the Minister of Food announced in Parliament⁴—some would think rather belatedly—that the agene treatment of flour is to end after December 31, 1955. Almost five years ago the Ministries of Health and Food concluded that the use of nitrogen trichloride (the agene process) for improving flour ought to be discontinued, and, as this *Journal* commented at the time,⁵ "it is disquieting that not until over three years after a possible danger to health was shown to exist have steps been taken to combat it." Now that those steps have

plodded on for another five years—and are to continue for almost twelve months more—the disquiet may at last give way to congratulation that the care of Parliament for its subjects' and of industry for its consumers' health has caught up with a scientific discovery made eight years ago. It was in 1946 that Sir Edward Mellanby reported in this *Journal*⁶ that agenized bread is a cause of canine hysteria, and a year later he found that it could cause the same symptoms in ferrets.⁷ In 1950 Mellanby, together with his colleagues P. N. Campbell and T. S. Work, isolated a crystalline toxic factor from agenized flour which on administration to ferrets caused severe epileptiform fits.⁸ It was apparently the same as a product obtained independently by a team working in the laboratory of the British Flour-Millers Association. Mellanby *et al.* emphasized that the poison was cumulative in effect: a fatal toxic reaction was produced by feeding to ferrets over five to ten days doses that were only a fraction of those that caused an immediate toxic response.

While animal experiments showed that the product of agenization is exceedingly poisonous to some animals, no satisfactory evidence has been adduced that it is harmful to man. The presumption is nevertheless reasonable that a substance so poisonous to some mammals ought not to be incorporated in human food, especially in such a staple food as bread. Popular taste may well demand "improved" flour, and limits of storage space necessitate it, but the replacement of agenization by another process can only be welcomed. What the best method will be is still under investigation. The chief chemist of J. Lyons and Co. recently referred to some of them,⁹ and in particular to a new method of mixing the dough so as to oxidize the flour by means of aeration. To anyone who has a healthy scepticism about adding chemicals to food this line of research would seem to be well worth following up.

EMERGENCIES IN GENERAL PRACTICE

The first of a new series of articles in the Refresher Course for General Practitioners appears in this issue at page 39. The articles will all be concerned with emergencies in general practice—medical, surgical, obstetric, and psychiatric—and will range in subject from such common disorders as cardiac asthma, discussed this week by Dr. J. G. M. Hamilton, to the accidental swallowing of poisons by children, and from post-partum maternal collapse to acute lumbago and sciatica. Articles previously printed in the Refresher Course series have proved popular in book form, two volumes having so far been published and the third, *Clinical Pathology in General Practice*, being in the course of preparation. The aim of the new series on emergencies is to provide reliable, up-to-date, and practical advice, bearing in mind the nature of domiciliary practice and the special problems of the general practitioner.

EMERGENCIES IN GENERAL PRACTICE
CARDIAC ASTHMA

BY

J. G. M. HAMILTON, M.B., F.R.C.P.Ed.

Physician, Royal Infirmary, Edinburgh

The term "cardiac asthma" is applicable to a clinical syndrome—paroxysmal dyspnoea due to heart failure—with a range of severity extending from urgent acute pulmonary oedema to transient nightly attacks of cough, wheezing, and breathlessness, though used by some to refer only to the latter. Although such paroxysms sometimes occur in the presence of mitral stenosis, they are most commonly an expression of left ventricular failure in hypertensive, coronary, or aortic valvular disease. A sudden attack of intense dyspnoea is not infrequently caused by acute myocardial infarction, and the occasional absence of the characteristic pain or the overshadowing of pain by the intense dyspnoea may result in the basic lesion being missed.

Clinical Picture

The patient is most commonly in the second half of life and may or may not be known to suffer from hypertension or coronary disease. He is awakened from sleep, or roused from quiet, recumbent rest, by cough and breathlessness which may rapidly reach urgent severity so that he is obliged to sit up gasping for breath and hardly able to speak. Soon some frothy, watery sputum appears, becoming in the most severe attacks profuse and pink through blood-staining. Wheezing may be prominent. The patient's distress is often accentuated by the occurrence of Cheyne-Stokes periodic respiration. During the phases of apnoea he may fall back on his pillows and close his eyes in thankful comfort, only to be roused in a few seconds by terrifying distress as the phase of hyperpnoea develops. The tantalizing repetition of the cycle may be almost unbearable.

In less severe attacks of breathlessness with cough and wheezing the intensity of the symptoms may decline spontaneously after the patient has been sitting up for 20 to 30 minutes and he may return to sleep without medication. While a severe attack is sufficiently alarming for medical help to be summoned, in the case of the lesser attack the patient commonly consults his doctor only after several disturbed nights. He may be free from breathlessness by day or admit only to some effort distress if questioned. The described picture of cough, wheezing, and breathlessness all too often leads to an erroneous diagnosis of bronchitis or bronchial asthma and the prescription of an ineffectual expectorant or linctus, or the administration of isoprenaline or adrenaline.

The patient taken urgently ill in the night is seen to be sweating and cyanosed, with cold extremities. The heart is accelerated, while the rhythm, commonly regular, may be disturbed by extrasystoles or auricular fibrillation. The blood pressure is usually elevated, often grossly, pulsus alternans being often observable, but may have fallen from a previously hypertensive level to a normal or low level either because of the severity of the heart failure or because the attack has been precipitated by the occurrence of acute myocardial infarction. A complaint of gripping, crushing, or burning retrosternal pain, severe or slight, prior to or coincident with dyspnoea may draw attention to this possibility, which is of more than academic interest, even in the middle of the night, for in several respects treatment should be varied according to whether or not infarction has or seems likely to have taken place. Cardiac enlargement is almost invariably to be found and should be looked for by palpation of the apical impulse, for this provides the necessary conclusive evidence of the existence of organic cardiac

disease, and, in the presence of a normal or low blood pressure and the absence of aortic valvular disease, establishes that hypertensive heart disease underlies the condition. Further valuable evidence of heart failure is provided by the finding on auscultation at the apex of triple or gallop rhythm. The neck veins are often somewhat engorged, but oedema of ankles or sacrum is generally absent, since attacks of cardiac asthma usually antedate the appearance of right heart failure and indeed may cease to occur when right ventricular failure supervenes.

Although respiration may be noisy with wheezing rhonchi, crepitations are to be heard over both lungs, in severe cases in all areas to such an extent and in such profusion that the lungs seem waterlogged, in less severe cases predominantly at the lung bases.

In the case of the patient examined between milder attacks similar evidence of heart disease will be found—hypertension, cardiac enlargement, and basal crepitations, although these last may be scanty at such a time.

The need to elicit these signs of heart disease has been stressed, since there is no little chance that hasty consideration of the symptoms of cough, wheezing, and dyspnoea, and the finding of harsh respiration with rhonchi and crepitations, may focus attention on the respiratory tract and lead to a diagnosis of bronchitis.

Paroxysmal dyspnoea of this type—cardiac asthma—except in the instances in which it is actually precipitated by myocardial infarction or paroxysmal tachycardia, occurs for the most part at night before or during sleep. It may be the first clear manifestation of heart failure in the hypertensive subject, though it often comes after a decline in effort tolerance has set in. Cardiac asthma, however, seldom develops for the first time in patients already under adequate treatment for hypertensive heart failure unless it is due to the occurrence of some complication such as infarction or a paroxysmal arrhythmia. Severe nocturnal attacks may follow unduly vigorous exertion during the preceding day, or an injudiciously large meal in the evening, or high excitement, including intercourse.

Cause of the Dyspnoea

The symptoms of cardiac asthma are immediately due to pulmonary engorgement. Quiet rest in bed with its decline in physical effort and reduction in metabolism is associated with reabsorption of tissue oedema fluid, even where this has not been manifest, and therefore with an increase in circulating blood volume. The recumbent posture results, owing to the removal of the influence of gravity, in an increased venous return to the right side of the heart which, through increased venous filling pressure, is a stimulus to increased ventricular output. In the presence of hypertension or aortic valvular disease or coronary sclerosis, whose main detrimental influence is upon the left ventricle, this chamber, beginning to reach the stage of dilatation and failure, may be less able to respond to such a demand for greater effort and output than the less directly burdened right ventricle. The vascular bed between these chambers—that is, the pulmonary capillaries and venules—is congested therefore to accommodate the excess of the right ventricle's output over that of the left, tiny though that excess may be at each stroke.

Pulmonary congestion and the resulting transudation of oedema fluid into the alveolar walls and cavities progressively reduce the vital capacity, while the emergence of this fluid on to the sensitive bronchial epithelium touches off

the cough reflex. Either the dyspnoea of reduced vital capacity and stiff congested lungs or the cough wakens the patient. The intense effort of the dyspnoea and cough constitutes very vigorous exercise which itself aggravates the cardiac embarrassment. An additional factor operating in some cases is general peripheral arteriolar constriction. The increase in arterial pressure which this causes throws a sudden additional load on a left ventricle already prejudiced by established hypertensive disease, coronary ischaemia, or both, and precipitates left ventricular failure. In such cases the blood pressure is found to be elevated well beyond what is known to be that patient's customary level.

In the mild or moderate case the assumption of the erect posture when the patient sits up in bed, or better still in a chair with his feet on the floor, may break the vicious cycle of pulmonary engorgement→dyspnoea and cough→exercise→further pulmonary engorgement→worse dyspnoea, by allowing a reduction in venous return so that the labouring left ventricle can gradually overtake its debt and clear the pulmonary congestion below the critical level. Then the attack may end spontaneously. In the worst cases the vicious cycle progresses and the patient dies, drowned by his own pulmonary transudate.

Partial ischaemia and anoxia of the respiratory centre resulting from diminished arterial output from the overloaded left ventricle, combined probably with a measure of cerebral vascular stenosis, especially in the elderly, is the cause of Cheyne-Stokes respiration in cardiac asthma. It is not to be attributed to uraemia in the circumstances under discussion.

Immediate Treatment

Treatment of cardiac asthma resolves itself into the handling of the emergency and the long-term management of the underlying disorder with the object of rendering less likely the repetition of such disturbing and dangerous crises which are almost certain to recur if the crisis is taken on its own and sustained treatment neglected.

In the emergency morphine should be administered immediately the diagnosis of cardiac asthma has been made. The object here is twofold: first, to reduce the sensitivity of the cough reflex and of those respiratory reflexes having their origins in the stiffened congested lungs, whereby the intensity of the effort of coughing and breathing may be diminished, and, secondly, to calm the apprehension, even panic, and the restlessness which a severe attack of cardiac asthma causes in even the most phlegmatic person. With these effects achieved venous filling pressure on the right heart and therefore right ventricular output are reduced and the left ventricle given an opportunity of partially clearing the congested pulmonary vascular bed. The effects must be achieved with the maximum certainty and without delay, since any severe attack of this condition must be regarded as critical and immediately endangering life. For a patient of average or over-average weight morphine sulphate, $\frac{1}{2}$ gr. (15 mg.), should be injected intravenously and the same quantity subcutaneously. In the presence of acute heart failure absorption of the whole dose from a subcutaneous injection is undesirably slow, and if intravenous injection is for any reason impracticable, half of the total dose of $\frac{1}{2}$ gr. (30 mg.) should be given by intramuscular injection. In the case of patients of under-average weight the total dose can be reduced to $\frac{1}{4}$ gr. (20 mg.), but again half of this dose should be given intravenously. When the attack is of only moderate severity the ordinary subcutaneous injection of morphine, $\frac{1}{2}$ gr. (15 mg.), may suffice.

Many practitioners combine a dose of atropine sulphate with the subcutaneous injection of morphine or even give atropine alone. This habit is based upon a misconception that the excessive fluid in the respiratory passages is due to excessive bronchial secretion. However, the fluid is in reality transuded oedema fluid whose production cannot be controlled by paralyzing by atropine the bronchial secretory glands. If atropine has any action in cardiac asthma it is by depressing vagus-mediated reflexes involved in the pro-

duction of dyspnoea. Atropine is better omitted altogether, since the dryness of the mouth which it induces makes the patient demand fluid to drink which he would be better without.

Although Cheyne-Stokes respiration, if present, may be expected to be aggravated by the injection of a large dose of morphine, this must not deter the physician from giving morphine in an adequate dose. The distressing dyspnoea (which is what immediately matters) of the hyperpnoeic phases will be suppressed. The periodicity of the respiration, however, can usually be rapidly relieved by an intravenous injection of aminophylline, 0.5 g. Such an injection should be given in all severe or moderate cases, even in the absence of Cheyne-Stokes breathing, for its vasodilator and bronchodilator action.

The patient should be propped securely on a high bank of pillows or made comfortable in an easy chair.

Other Measures

The question of the administration of digitalis or digitalis glucosides requires rather more careful consideration in each case. When the patient is known not to have been taking digitalis or digoxin for at least a week before the attack, and when there is no reason to suppose that acute myocardial infarction has occurred, digoxin, 1 mg., should be injected intravenously directly after the administration of morphine. It may be combined with the injection of aminophylline. When the patient is known to be fully under the influence of an adequate maintenance dose of digitalis or digoxin already, it is wise to assume at the time of the acute episode that the attack is due to the occurrence of myocardial infarction and withhold the intravenous injection of digoxin. Such should also be avoided, even in the undigitalized patient, when the features of the case strongly suggest that an infarction has precipitated the crisis. The risk of inducing paroxysmal ventricular tachycardia or even fatal ventricular fibrillation is not negligible. Reliance should then be placed on intravenous morphine and aminophylline for the emergency and digoxin, 0.5 mg., given by mouth as the starting point of a more gradual process of digitalization.

Where there is a strong clinical indication that acute myocardial infarction has taken place, early and rapid anticoagulant therapy with heparin may prevent an immediate extension of the infarct, with serious and perhaps fatal results. Heparin, 10,000-15,000 units (100-150 mg.) according to body weight, should be given intravenously and repeated six hours later, after which it can be decided whether a full course of anticoagulant therapy is to be undertaken.

If oxygen is readily obtainable it should be used. It is desirable that a flow-meter should be employed and a flow of 6-8 litres a minute administered by double nasal catheter or by a light plastic nose-and-mouth mask. The patient should be allowed to go to sleep with this in place, but naked lights should not be permitted near the oxygen cylinder or the mask.

If in a severe case dyspnoea does not subside within 10 to 30 minutes of the injection of morphine, venous tourniquets should be applied on the proximal parts of all four limbs to reduce venous return. They should be tight enough to hamper the venous outflow from the limbs but not tight enough to impede the arterial inflow. After about an hour the tourniquets should be slowly released one at a time to avoid a sudden augmentation of venous return which would again overload the recovering heart.

Rapid venesection of one pint (570 ml.) through a wide-bore needle, or by simply slashing a vein, may be usefully employed instead of the above "bloodless phlebotomy," especially in plethoric patients.

When a striking rise in blood pressure is observed, suggesting a hypertensive crisis, the use by intravenous injection of powerful vasodilators and hypotensive agents such as tolazoline and the methonium compounds has much to

commend it on theoretical grounds. In patients suffering from severe acute left ventricular failure due to hypertension the rapid reduction of an extravagantly high blood pressure may so reduce the load on the failed left ventricle as to contribute importantly to the interruption of the vicious cycle. Beneficial effect has been obtained in many such cases, but the use of methonium compounds by intravenous injection is fraught with risks and is better avoided except by those with experience of their use in this and other fields.

Long-term Management

On the morning after the severe attack the long-term measures should begin. Arrangements should be made for the patient to be confined to bed, well propped up at night, or to bed and a chair in his room according to the severity of the condition, in the "uncomplicated" case for about two weeks, but of course for longer when myocardial infarction has been diagnosed. Mersalyl, 2 ml., should be given by intramuscular injection, to be repeated two days later, twice weekly for two to three weeks, and weekly thereafter, even though manifest peripheral oedema be absent. A more cautious approach to the use of full doses of a mercurial diuretic—for example, mersalyl, 0.5 ml. for the first dose and 1 ml. for the second—is indicated where previous symptoms of prostatic hypertrophy suggest the possibility of acute retention being precipitated by the sudden massive diuresis of the full dose. The process of thorough digitalization should be continued by ordering, for example, digoxin, 0.25 mg. thrice daily by mouth. Later, when a full digitalis effect has been achieved, as indicated by the appearance of anorexia and squeamishness, the dose should be adjusted, after 24 to 48 hours' "desaturation-holiday," to one suitable to maintain an optimum digitalis effect for the rest of the patient's life. The occurrence of cardiac asthma should be the signal in the untreated patient for the institution of the "digitalis life."

Moderation of salt intake should be arranged by the prohibition of salty foods and added salt, the limitation of salt in cooking, and the avoidance of sodium-containing medicines. If severe sodium restriction can be achieved and if a mercurial diuretic is regularly given the patient can be permitted a normal fluid intake.

For three or four nights after the acute attack of cardiac asthma morphine, $\frac{1}{4}$ gr. (15 mg.), should be given subcutaneously and for a week thereafter an opium-containing hypnotic given by mouth, such as:

Chloral hydrate	gr. 20 (1.5 g.)
Tincture of opium	min. 20 (1.2 ml.)
Liquid extract of liquorice	min. 10 (0.6 ml.)
Water	to fl. dr. 2 (7 ml.)

It is important that until the full effect of digoxin, mersalyl, and rest has been obtained the patient be protected by opium against a recurrence of the nocturnal crisis.

In the case of the patient complaining of recurrent milder attacks of cardiac asthma at night an opium-containing hypnotic is indicated for seven to ten nights. For this purpose a mixture like the above, but with 30 gr. (2 g.) of chloral hydrate and 30 min. (1.8 ml.) of tincture of opium, is suitable, half the dose being given in the last few nights of the period or for a few further nights if required. He should be advised to use extra pillows and to avoid slipping down to a low position if he can. While the patient is thus protected against the nocturnal attacks he should be brought fully under the influence of digoxin in the usual way and a permanent maintenance dose established. Again, even in the absence of manifest oedema, intramuscular injections of mersalyl, 2 ml., should be given in the morning twice a week for two or three weeks, and weekly thereafter.

The other measures called for in the treatment of cardiac failure—salt limitation and modification of habits in respect of physical and mental effort—will if necessary be inaugurated at the same time. In the milder cases under consideration, unless there are manifest features of chronic heart failure or frank evidence of serious coronary disease, it is seldom necessary to confine the patient to bed for more

than perhaps a day or two, though a week or two off work with modified rest about the house is desirable while the full effect of treatment is being attained.

Conclusion

There must be few acute disorders in the non-surgical realms of adult medicine in which treatment is so immediately rewarding as in cardiac asthma. The utter relief of the acutely dyspnoeic patient, or the achievement of nights blessed by sound sleep undisturbed by attacks of wheezing breathlessness in the less severely ill patient, does, for me at any rate, amply reward the night-call, the bloody mess of the venesection, or the early morning injection of mersalyl. However, it cannot be too often or too forcibly emphasized that the foundation of the emergency treatment of this serious and dangerous disorder is its recognition as heart failure and not bronchitis, and the use of morphine, aminophylline, and digoxin, and of its prevention the permanent treatment of hypertensive and coronary heart disease with digoxin, mersalyl, and salt restriction.

THE SWEEP-FREQUENCY METHOD OF MAKING SCREENING TESTS OF THE HEARING OF SCHOOLCHILDREN

STATEMENT PREPARED BY PROFESSOR A. W. G. EWING AT THE REQUEST OF THE M.R.C. COMMITTEE ON THE EDUCATIONAL TREATMENT OF DEAFNESS*

In a recent investigation it was found that approximately 70% of pupils in English schools for the deaf and partially deaf have suffered from their handicap since before the age of 2 years. From the Ministry of Education's returns and from the results of recent surveys it seems that nearly all deaf children are admitted to special schools by the age of 7 years, but that the ascertainment of partial deafness as a cause of educational retardation is at present less effective among children under 7 than among those who are older.

The sweep-frequency technique has been shown to be a reliable and efficient method of making screening tests of the hearing of 5- and 6-year-old schoolchildren. A pure-tone audiometer is used, and, when the range of frequencies that are used is extended from 250 to 6,000 cycles per second, early symptoms both of conductive and of perceptive deafness can be detected. It has been established that a sweep check over this range of frequencies at 15 decibels above normal threshold of detectability is more thorough and reliable as a screening test than the use of word material (as in the test by gramophone audiometer), the loudness of which cannot be monitored satisfactorily for this purpose. The fading-intensities, called-number test has been shown to be sometimes ineffective for the detection of high-tone deafness.

*Sir Frederic C. Bartlett (chairman), Mr. T. E. Cawthorne, Professor A. W. G. Ewing, Mrs. J. R. Ewing, Dr. D. B. Fry, Mr. C. S. Hallpike, Mr. D. Lloyd James, Mr. J. Lumsden, the late Mr. J. Spalding, Mr. A. B. Swayne, and Professor R. C. Oldfield (secretary).

Audiometricians who have been trained to work with young children are able to make a sweep check of auditory acuity, as an individual test, at a rate of three minutes per child. It has been shown that extraneous noise in a room in which a screening test of hearing is to be made should not exceed about 30 decibels. The sweep-frequency test can be made in a small room. When it is necessary to make screening tests of children's hearing in school buildings it is much less difficult to find small rooms that are quiet, in schools, than large rooms.

The sweep-frequency test can be made immediately or soon after children are first admitted to school, whereas the gramophone audiometer test, as normally administered, is a group test, in which children are required to write down numbers that they hear. It cannot therefore be used with children younger than 8 years. The sweep-frequency test is very valuable in screening out children who are likely to need hearing-aids and special educational treatment, before they have been exposed to the risk of educational subnormality as a result of defective hearing.

A comparative study of the relative reliability of the sweep-frequency and gramophone audiometer tests, when both were administered to 6-year-old children individually, showed the sweep-frequency test to be superior. The called numbers that are used in the gramophone audiometer test involve a constrained context and are therefore often recognizable by children suffering from loss of hearing to a significant degree.

BLEEDING, CUPPING, AND PURGING

When Roderick Random, newly qualified, was seeking a position as an assistant to a well-established practitioner, he was faced with the pertinent question: "Can you bleed and give a clyster, spread a plaster, and prepare a potion?" From the beginning of history these three arts—together with that of providing more active counter-irritation by the seton or by the cautery—had formed the basis of the doctor's technique. In his recently published FitzPatrick Lectures for 1950-1* Dr. William Brockbank discusses authoritatively as much of the vast history of these subjects as can be fitted into the compass of a volume of reasonable size, and he has added an interesting summary of the history of intravenous injection. There is no similar work which covers the same field.

The enema, or clyster—for though philologically distinct the words are practically synonymous—has a very ancient history. Pliny appears to have been the originator of the myth that the black stork of Egypt used its long beak to give itself an enema of Nile water. Mediaeval illustrations show the bird carrying out the operation. But in fact the bird is probably only taking oil from its preen gland to preen its feathers. No modern observer has ever seen a bird acting as in Pliny's account.

The antiquity of the enema is shown by its distribution among primitive peoples. For example, the Eskimos use a

*William Brockbank, M.A., M.D., F.R.C.P.: *Ancient Therapeutic Arts. The FitzPatrick Lectures delivered in 1950 and 1951 at the Royal College of Physicians*. London: William Heinemann Medical Books, Ltd., 1954. Pp. 162. Price 25s. net.

portion of the gut of a seal, into one end of which a bone nozzle is bound. The simple enema tube was used by the Aztecs of Mexico and by the Maya of Yucatan. Other ancient races, such as the Peruvians, fitted a bulb to the enema tube, the bulb being often formed by the bladder of an animal. Both in Africa and in America gourds are commonly used as enemata at the present day, and a reed is frequently fitted to the narrow end of the gourd.

Excelsior

From the very earliest times the use of the enema has been cursed by an erroneous motto—*Excelsior*—on the part of its adherents. The Babylonians tried to reach the whole of the intestinal tract by giving their nauseous mixtures both by mouth and by the rectum at the same time. The ileo-caecal valve was not known until 1588, and much damage must have been caused by those appliances which attempted to drive the injection round the bowel by force. The most powerful apparatus of this type was finally invented by Equisier in 1848. In this apparatus the fluid was injected suddenly by means of a powerful spring.

In general all practitioners up to the mediaeval period used what might be termed "rectal polypharmacy," and many an inflamed colon must have been violently irritated by the drugs employed. Avicenna was the first to use soap and water as the common basis. John Arderne, who practised surgery at Newark-on-Trent in the second half of the fourteenth century, wrote a celebrated treatise on fistula, and he gave a description and illustration of his enema apparatus. Arderne used a swine's bladder to inject the fluid. (There is, incidentally, no justification for calling him, as Dr. Brockbank does, John of Arderne.) The piston syringe as a means of propelling the injection is shown in a fifteenth-century carved-wood apothecary's sign which was presented to the Museum at Bruges in 1880; but the syringe may have been in use earlier, since such a method is employed by certain primitive races, notably the Catawba Indians of North Carolina.

At certain periods patients appear to have been shy of allowing themselves to be treated by this method, while at other times they were just the opposite. Ambroise Paré seems to have been the first to introduce an enema syringe by using which the patient could administer the enema to himself. De Graaf and others invented similar types of apparatus, and in the eighteenth century the enema stool became popular. Molière and the Roi-Soleil unintentionally popularized the use of the enema, and from that time onwards it appeared in cartoons and on the canvases of the great artists. In 1695 Dekkers published a practical manual at Leyden, and in this he devoted nearly 100 pages to the use of the enema. In 1480 Louis XI, suffering from apoplexy, was relieved by an enema, and from then on he had his pet dogs treated by this method. Early in the nineteenth century an engraving was published showing a pet dog receiving an enema under the supervision of learned physicians. Satirists such as Rowlandson and Gillray frequently introduced the enema in their political cartoons. The rubber bulb attached to an enema tube seems to have been used in the Amazon region from early times. It was brought to Europe by the Portuguese shortly after 1740, and its use spread widely. Higginson invented his syringe about 1850.

Cupping Horns

Cupping has also an ancient history. The ends of animal horns are still used by primitive races, and in the Wellcome Collection there is the equipment of the personal physician of Cetewayo, the Zulu chief. It contains no fewer than thirteen such cupping horns. Dry cupping is performed by inverting over the skin a glass vessel which has been exhausted by a flame. It is an interesting and harmless experiment to carry out this simple operation on oneself. I have never seen the method used on a patient,

but as a student its use was demonstrated to me as a method which had practically died out. Dr. Brockbank also says he has never seen a patient cupped; but he quotes very appositely George Orwell's description of his treatment for pneumonia in a Paris hospital in 1929—six cupping glasses, followed by scarification of the blisters, reapplication of the cups, and then a mustard poultice. This was really wet cupping, in which the aim was to draw blood into the evacuated cups. Paré introduced the mechanical scarifier, a devilish instrument which produced at once up to eighteen incisions within the area of the cup. These scarifiers were used until well into the nineteenth century. In some instruments the movement of the blades is so rapid that it is quite invisible.

Dr. Brockbank deals with the subject of leeching less fully than one might have expected. He might have said something about the bloody war which raged in France during the 1830's. On the one side Broussais, on the other P. C. A. Louis. In nine years (1824-33) the teaching of Broussais increased the number of leeches used in France from 3 to 40 million annually. It was at this period that a physician at the Val-de-Grâce was in the habit, when he arrived at the hospital for his visit, of asking how many patients had been admitted. He thereupon ordered 30 leeches each before he had examined them. There is a well-known satire which shows Broussais ordering a further ninety leeches for a moribund patient—"and continue the diet." Dr. Brockbank gives a most interesting account of the variations in the number of leeches used in the Manchester Infirmary between 1782 and 1882. These variations correspond with those described by Marshall Hall at the General Hospital, Nottingham.

On the subject of counter-irritation by other means Dr. Brockbank is very interesting. Cantharides as a blistering agent is of course of great antiquity, and, as the "fly-blisters," was used in the early years of the twentieth century, and may indeed still be used. The seton is essentially a cord of silk or cotton inserted through the soft parts and left to drain away the resulting pus for a period of a year or more. Very frightening were the instruments for the insertion of setons invented by Paré, Glandorp, Bartisch, and others. An issue, or fontanelle, was a pea or a metal cylinder inserted in the superficial tissues to produce supuration. It disappeared from practice early in the nineteenth century, and the seton a few decades later. A moxa was a cone of *Artemisia moxa* which was applied to the skin and slowly burned to produce a blister. This Chinese method of counter-irritation came to Europe in the seventeenth century and had been discarded before the middle of the eighteenth.

Dr. Brockbank's very readable and valuable book would be enhanced by the addition of an index. It is well produced—though the style of production may be rather modern to suit everyone. Some may still think that the best place for a caption is below its illustration and not on the opposite page. In this, as in some other "modern" books, the "title-page" can no longer be termed such, for it has been shorn of one-third of the title of the book. The erring word has wandered over to the reverse of the page traditionally known as the "half-title." The bibliographer will have to revise his terminology.

E. ASHWORTH UNDERWOOD.

A study group set up by the World Health Organization to consider the identification and classification of the snail vectors of bilharzia found that confusion existed not only in the nomenclature of the species but even in the delimitation of the genera and the family to which snails belong. It was therefore unanimously agreed that the family name should be "Planorbidae" and that the intermediate hosts should be placed in the two subfamilies "Planorbinae" and "Bulininae." *Wld Hlth Org. techn. Rep. Ser.* No. 90, 1954, Geneva.

Preparations and Appliances

A FOOT EXERCISER FOR USE WITH A THOMAS SPLINT AND A TULLOCH BROWN U-LOOP

Dr. R. C. LEMON, accident and orthopaedic registrar, Royal Buckinghamshire Hospital, writes: All leg splints to-day have attachments for the prevention of foot-drop. The two exercisers in use at this hospital were designed not only to prevent foot-drop but also to enable the patient to plantar-flex his foot actively and against a spring resistance. They are easy to make, are simple in construction, and have been a great aid in keeping up the tone of the patient's leg muscles. They have been used in fractures, and in cases of arthroplasty of the hip in which traction has been deemed advisable by means of a Tulloch Brown U-loop. Both exercisers are basically the same in construction. The first can be used on any Thomas splint or its Pearson attachment (Figs. 1 and 2). It consists of a foot-rest, in this case made of aluminium, which can be adjusted up or down by means of a screw-bolt so that its curved upper end is at the level of the metatarsal heads. The foot-rest is attached to an axle which clamps to the side bars of the splint, the axle itself having a telescopic device so that it can be adjusted to any width of the splint (Fig. 2). The resistance is obtained by a spring attaching to the bottom of the foot-rest and to a clamp which can be screwed to either side bar of the splint at any required distance from the foot-rest to increase or diminish the resistance against which the foot has to work.

In the case of the exerciser for the Tulloch Brown U-loop, advantage has been taken of the Nissen foot-plate already provided with the splint. The foot-rest has been made adjustable up and down by means of a screw-bolt again.

FIG. 1.—Tulloch Brown U-loop exerciser. The side bars of the splint are seen in the bottom of the picture.

FIG. 2.—Thomas splint exerciser. The black lines indicate the side bars of the splint.

Mobility is attained by cutting off the flanges on the side pieces. The attachment for the spring is made by fixing a rigid steel bar vertically downwards from the foot-rest (Fig. 1).

The exercisers are placed against the foot and the spring tension is adjusted so that when at rest the foot is held at 90 degrees. Plantar flexion can then be carried out with the greatest of ease.

A thick woollen bed-sock is used on the foot to prevent any sores developing and to facilitate movement of the foot against the foot-exerciser. Padding attached to the foot-exerciser itself interferes with the movement.

I am indebted to Mr. G. Platt for his helpful criticism and advice; to Mr. Dudley, who made the exerciser to my design; and to Mr. Mason for the photographs.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Changes in the Mental Health Services

SIR.—Dr. J. B. S. Lewis (*Journal*, December 4, p. 1354) and Dr. J. Gibson (*Journal*, December 18, p. 1484) strongly advocate the abolition of mental observation wards, but a mental observation ward attached to a general hospital and administered by a general physician can do valuable work, for these reasons: (1) Facilities for laboratory tests and consultant medical and surgical opinions being more easily obtained at a general hospital, the investigation and treatment of physical causes for mental illness can conveniently be carried out there. In my own observation ward a large number of people have been admitted as mental cases when their illness was entirely due to physical causes such as pneumonia, empyema, meningitis, cerebral tumour, G.P.I., bromide intoxication, hypoglycaemia narcolepsy, myxoedema, Addison's disease, Simmonds's disease, and many other conditions.¹ The early detection and treatment of these organic cases is surely of importance and more easily done by a man who is in daily contact with acute medical work. (2) In a general hospital many patients with medical or surgical illnesses may develop mental symptoms—the delirious pneumonias, the head injuries, and others. If there is an observation ward attached to the hospital these people can continue treatment under the doctors that know their case without being transferred to mental hospital. It is also most beneficial to the other patients in a general ward if their mentally disturbed fellows can be temporarily moved out of the general ward. (3) The unfortunate compartmentation of medical from psychiatric work is lessened, particularly if an appointment is established where one man has charge of both general medical and mental observation cases. (4) For teaching a mental observation ward is invaluable. The assessment of the acute psychotic case and the early detection of organic causes for mental illness are just what are needed by students. (5) There are many people with mental illnesses that only last a few days, and it is an advantage if these people can be managed in an observation ward without their having to go to mental hospital. (6) Where the assessment of a suspected case of mental illness is difficult, it is far easier to judge the patient if he is under observation for a few days rather than decide at a short interview in his home. A fair decision as to his sanity is hence more easily made when the question of certification arises, and for other patients the choice of voluntary status, temporary order, or discharge can be more wisely made.

For all these reasons I think that observation wards ought to continue and that the L.C.C. are right in recommending this to the Royal Commission. To argue, like

Drs. Lewis and Gibson, that they should be abolished because some of them are overcrowded or badly staffed is not very sensible; some general hospitals are overcrowded and badly staffed, but one could not reasonably suggest abolishing all the general hospitals in the country for that reason. It is more logical to suggest that the staffing and equipment of observation wards should be improved where it is inadequate.

Observation wards are not always the places of noisy, nightmare horror your correspondents suggest. Often after a patient with delirium from pneumonia has been transferred to the mental observation ward from the general side I have, when he has begun to recover, said, "You can go back to the other side now," to be told, "I think I'd rather stay here, doctor—it's so much quieter."—I am, etc.,

London, N.W.10.

Premedication of Children for Tonsillectomy

SIR.—The summary of Dr. Christine M. Rendell's article (*Journal*, December 11, 1954, p. 1397) indicated that in methylpentynol had been found an almost ideal drug for pre-operative sedation of children prior to tonsillectomy. This appraisal is not, I contend, justified by the text, with the findings of which I am largely in agreement, though not with Dr. Rendell's evaluation of them. In a smaller series than Dr. Rendell's a clinical impression has been gained by me that methylpentynol is in fact a very unsatisfactory pre-operative sedative.

Everyone would agree that some premedication is helpful in allaying fear, and in my series it was entirely "verbal" and carried out by the ward sister or anaesthetist, the only pre-operative drug used being atropine 1/100 gr. (0.65 mg.) prior to guillotine tonsillectomy. Our experience indicates that with this preparation alone the apprehensive or frightened child is rarely encountered—rather less often than once in ten cases. At the present time an investigation is under way to test this impression on a scientific basis. In the light of this clinical impression, then, Dr. Rendell's claim for the success of methylpentynol is open to doubt, and is rather weaker than for cases where only atropine was used. Methylpentynol did not rob the procedure of psychic trauma; Dr. Rendell admits that an inquiry after the children's discharge established that "many . . . retained a vivid and unpleasant memory" of the induction despite the statement that at the time they were "peculiarly happy and co-operative." It is hard to reconcile these two observations, since surely distaste on recollection of the event must imply the same feelings at the time. I cannot endorse Dr. Rendell's assertion that children find the "oblivion elixir" pleasant to take. All of my series were questioned immediately prior to induction, at a time when a favourable reply might have been expected. Only two in fifty-six children admitted liking the preparation, one, I suspect, out of politeness; the remainder disliked it intensely.

Dr. Rendell states that "in about a tenth of the cases the induction, always slower than after barbiturate premedication, was delayed by vomiting the elixir." On the first point I concur wholeheartedly; the effect is most noticeable. As to the incidence of vomiting (the summary states that unpleasant side-effects were not observed), I have been more fortunate in having only two such cases, but even this incidence I regard as highly unsatisfactory when one has not oneself, nor one's colleagues, encountered a single case of vomiting during induction in many hundreds of guillotine tonsillectomies where atropine alone was the premedicant. Post-operative vomiting following methylpentynol was almost invariable.

It is asserted that the children settled quickly post-operatively, a statement at variance with the implication that "nepenthe" was needed frequently post-operatively. This bears out my own observations to the extent that ward staffs actively disliked the use of methylpentynol on account of the almost universal post-operative restlessness and lack of co-operation that accompanied its use, after which nepenthe was invariably required. This by contrast to children who, having had atropine alone pre-operatively, very rarely require any post-operative sedation at all following ethyl chloride for the guillotine operation. My clinical impression on this point is that, whereas the non-drug-sedated child is soon completely "round" after the operation and after suitable explanation and reassurance will lapse into quiet sleep,

a child who has had methylpentynol is still confused and incapable of appreciating the situation, and thus reacts accordingly. This variation between the two groups, at the same operating sessions, has been most striking, and in the latter instance has certainly increased rather than decreased the nursing care required post-operatively.

Dr. Rendell points out that in fact the ill-behaved or frightened child, whom surely it is most important to sedate, is best premedicated with a barbiturate. Despite the fact that methylpentynol was liked by ward staff and anaesthetists its use was discontinued. My own impression of methylpentynol as a sedative, which bears out Dr. Rendell's recommendation above, is that its effects are, not surprisingly, as varied and to some extent as unpredictable as the more familiar ethyl alcohol when indulged in by persons of varying temperament and mood.—I am, etc.,

Portsmouth.

N. G. P. BUTLER.

SIR.—Using methylpentynol as a premedicant before tonsillectomy, Dr. Christine M. Rendell (*Journal*, December 11, p. 1397) found approximately 15% of children either tearful and apprehensive or screaming and resistant, and 85% calm and co-operative. The state of apprehension before premedication is not recorded, nor is there a comparable control series. Dr. Rendell concludes in her summary that methylpentynol "successfully diminished pre-operative apprehension." It may be argued just as reasonably, or unreasonably, that the failure rate showed pre-operative apprehension to be unaffected or increased. Indeed, the latter conclusion may be nearer the truth, as many observers will argue that these figures compare unfavourably with those following atropine premedication alone.

Dr. Rendell found that 10% of the children vomited during induction and a still greater proportion vomited in the theatre at some stage. Such vomiting may endanger life, and be distracting and disagreeable to both surgeon and anaesthetist. In the text of her article Dr. Rendell attributes this vomiting to gastric irritation induced by the drug. It is therefore a surprise to learn that the second conclusion in Dr. Rendell's summary (only too often the only part read when attempting to keep abreast of the literature) is that with this drug "unpleasant side-effects were not observed." It is unfortunate and misleading that this summary should contain such unsubstantiated conclusions divorced from Dr. Rendell's earlier statements that the drug "fell short of the ideal" and that she had since abandoned the method.

Finally, Dr. Rendell found that methylpentynol when compared with other premedicants prolonged the induction period, and that many children retained a vivid and unpleasant recollection of their experiences. Furthermore, in this series the children awaiting operation were allowed to observe the return from the theatre of their comrades, never a pleasant sight even under ideal conditions. May I be allowed to doubt yet another of Dr. Rendell's contentions, that "the importance of psychic trauma has long been realized"?—I am, etc.,

Portsmouth.

R. J. HAMER HODGES.

SIR.—The old question of premedication for tonsillectomies in children is a perpetual recurrent. Atropine gr. 1/100 (0.65 mg.) by injection and a kind and calm nursing staff is the safest and most satisfactory premedication there is. After all, any premedication swallowed gives increased gastric motility and increased risk of vomiting and its sequelae, any morphine derivative depresses respiration and makes it difficult to obtain the required depth of anaesthesia, and most children object more to rectal injections than a gas tactfully given. All the barbiturates make the children restless and difficult to control post-operatively unless there is a nurse for each patient. I give anaesthetics for upwards of five ear, nose, and throat lists a week, and I remain convinced that the best and safest premedication is atropine 0.65 mg. and nothing else.—I am, etc.,

Kew, Surrey.

D. B. HALSTEAD.

Appendicectomy in Chronic Appendicitis

SIR.—Professor J. Chassar Moir (*Journal*, December 11, p. 1415) has done well to draw attention to the paper by Mr. Iain McLennan and Mr. Kennedy Watt in which they claimed that the incidence of alleged chronic appendicitis is between three and four times as great in women of the menstrual age as in other females and of males of all ages.

This disparity is enough to justify strong criticism of the correctness of the diagnosis in females of the reproductive age. If it were true it would indicate a special vulnerability of the appendix as a result of the physiological processes of menstruation, but we know that the appendix and the pelvic organs have no specific association, for they belong to different parts of the body. Apart from the waste of time and energy, not to emphasize the distress caused by an unnecessary laparotomy, the patient suffers two other hazards which are even more serious. Only too often we hear after the operation that the right ovary was removed with the appendix. The general surgeon, who chiefly performs these operations, naturally cannot have the same specialized knowledge of the female pelvic organs as a gynaecologist of experience. On finding, as so frequently, a normal appendix that shows no evidence of previous inflammation, he is tempted to seek a further source of the patient's pain. The right ovary is near by and is easily picked up. It will usually contain a follicle cyst or corpus luteum, perhaps some old unruptured follicle, and is thereby incriminated and removed. The ovary seldom is the seat of pain. Perhaps in endometriosis, but not always, possibly if prolapsed with a varicocele of the pampiniform plexus of veins, and as a part of salpingo-oophoritis. It is a serious matter to remove a normal ovary from a young or not so young woman, but it is a common part of the unnecessary operation for so-called chronic appendicitis.

A second hazard is a diagnosis of "adhesions" to explain the recurrence of the old pain after a few months, which may lead to a further operation or even more than one. And thus in some introspective types of feeble personality is laid the foundation of the "chronic abdominal woman." When I was a house-surgeon one of my chiefs used to warn us "never to open the abdomen for pain alone." Unless there are some other symptoms, physical signs, a significant history, or positive tests, the surgeon will usually draw a blank. So few of these women who are diagnosed as cases of chronic appendicitis, especially the young ones, can show any supporting evidence of true appendicitis.—I am, etc.,

London, W.1.

ALECK BOURNE.

SIR.—It is a fortunate thing that the lower abdominal pain and tenderness, which is so frequently associated with chronic inflammation of the cervix uteri, is rather more common on the left side than on the right. There is no doubt that this is the reason why more women than would otherwise be the case have been able to preserve their normal appendix from its surgical removal.—I am, etc.,

Glasgow, S.W.1.

JAMES MAIR.

SIR.—General practitioners naturally see things differently from those whose work is limited to hospitals, and as a G.P. I am afraid that I must disagree profoundly with several of Professor J. Chassar Moir's laudable attempts (*Journal*, December 11, 1945, p. 1415) to lay down the law about chronic appendicitis. But, before I do so, may I suggest that "a more plausible explanation" is not necessarily more correct, and certainly not more scientific, especially when its plausibility lies in assuming the other fellow to be wrong. But in fact the chart of age incidence, to which he refers, has very little validity from which to argue as he does, for any general practitioner of experience knows how frequently patients deny that they have had pain or other symptoms previously until confronted with his written record of such occurrences, often years before.

From the data given the chart should be more correctly construed (with a slight shift to the right) as a chart of the time at which the patients came to operation. If this is done, several suggestions seem reasonable, the first being that the sudden increase at the age of 16 (if the relatively small numbers justify any conclusion, though they accord with my impressions) represents the time when the girls leave school and become more able to decide their destinies for themselves. Also, if the pain is at all serious it interferes with their earning capacity and makes operation more desirable. After a woman has begun to have a family she finds it increasingly difficult to get away for an operation, and all practitioners are familiar with the way women struggle on with all sorts of disabilities. Until these personal and family factors are taken into consideration it would be risky to draw even the most "plausible" conclusions from the chart, particularly as we do not know what proportion of the younger age group were treated at children's hospitals.

Professor Chassar Moir's final paragraph, "facing the facts," is quite contrary to my thirty-odd years' experience here, during which we have had the inestimable advantage of being able to operate on any case which seemed to require it. Pain may be completely absent in cases of chronic and even pretty acute appendicitis, and if present it may be felt far from the right iliac fossa or the umbilicus; there may be no apparent history of gastric disturbance. An enormous amount of time, money, and energy is consumed by "complete investigations," which are mostly unnecessary, for a patient's sensations are much more delicate than most tests, and a thorough clinical investigation on old-fashioned and, alas, outmoded lines, which paid careful attention to these, would in most cases lead to a correct diagnosis, even where the investigations are negative, as they so frequently are. Tests are most valuable in research, but in appendicitis anyhow a doctor should be above all a clinician and not a signpost to a clinical laboratory.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Infantile Scurvy

SIR,—The reminder by Drs. G. Howells, P. E. S. Palmer, and W. H. St. John-Brooks that infantile scurvy is not extinct, and should not be forgotten in differential diagnosis, is timely (*Journal*, November 13, p. 1143). Three weeks ago a 15-month-old male infant was admitted to the Evelina Children's Hospital, under the care of Dr. B. Buckley Sharp, suffering from this disease, with a two weeks' history of painful lower limbs and a classical clinical picture. The gums were bluish, swollen, and bleeding; tender swellings were present at the lower ends of both femora and just above both ankles; and the skin was generally scaly with perifollicular hyperkeratosis on forearms and legs. There was pitting oedema of both feet and a palpable scorbutic "rosary" was present. In contradistinction to the cases quoted by the above authors, this infant was undernourished and weighed only 15 pounds (6.8 kg.). The relatively late onset was also of interest. Although the mother had had three children previously who had all maintained good health, this was the only one she had been unable to breast feed. The diet from the age of 2 months consisted of boiled cows' milk with cereals, with the addition of some orange juice diluted with boiling water.

The diagnosis was confirmed by the characteristic x-ray appearances in the long bones, a 24-hour urinary ascorbic acid excretion of 1.4 mg., and by the satisfactory response to treatment by injection of ascorbic acid 200 mg. intramuscularly on alternate days. Other biochemical features were the low levels of serum calcium (8 mg./100 ml.), and of inorganic phosphate (2.2 mg./100 ml.), and of serum alkaline phosphatase (4.5 King Armstrong units). Rickets was suggested as an additional diagnosis despite the low alkaline phosphatase. Vitamin D was also given, and these biochemical anomalies were quickly rectified (serum calcium 9.4 mg./100 ml., serum inorganic phosphate 3.4 mg./100 ml., alkaline phosphatase 26 King Armstrong units).—I am, etc.,

London, S.E.1.

S. E. LEVIN.

Cantharidin Poisoning

SIR,—With reference to the last paragraph in your leading article on cantharidin poisoning (*Journal*, December 11, p. 1405), you state that Craven and Polak say "there are no grounds whatever for retaining preparations of cantharidin in the *Pharmacopoeia*." In fact, cantharidin and its preparations have not appeared in the *British Pharmacopoeia* since the edition of 1932, and you misquote Craven and Polak in having mentioned the *Pharmacopoeia* in the paper to which your leading article refers. In it they simply say that "since cantharidin preparations have no special virtue but are highly dangerous they should no longer be made available for therapeutic purposes"—a statement with which I heartily agree.—I am, etc.,

D. M. DUNLOP,
Chairman,
British Pharmacopoeia Commission.

Edinburgh.

SIR,—In the leader entitled "Cantharidin Poisoning" (*Journal*, December 11, p. 1405) a statement is made that "it (cantharidin) survives in the *British Pharmaceutical Codex* to-day in six preparations for use as counter-irritants . . ." and later that "there are no grounds whatever for retaining preparations of cantharidin in the *Pharmacopoeia*." During the recent revision of the *British Pharmaceutical Codex* it was decided that the monographs for cantharidin and its preparations should not be retained in the *Codex*, and so they have been omitted from the *B.P.C.*, 1954, which was published on October 29, 1954.—I am, etc.,

K. R. CAPPER,
Editor,
British Pharmaceutical Codex.

London, W.C.1.

Chlorpromazine

SIR,—I have been re-reading the articles and letters about chlorpromazine (*Journal*, August 21, p. 439, and September 4, pp. 560 and 565), in the light of my own, very limited, recent experience in general practice. This leads me to suppose either that my patients have been particularly unfortunate or that the sentence in your leading article (p. 581), "The drug seems to be relatively non-toxic," needs revision.

I have now given "largactil" to 18 patients, nearly all of them psychoneurotics with marked emotional tension. In no case has the dose exceeded 25 mg. three times daily or the period of administration been more than five weeks. Despite this, three patients have developed clinical jaundice. In none of these three was there any evidence in the history to suggest previous liver damage. One man of 56, who had only been taking the drug for eight days, became deeply jaundiced and remained so for over a week; he also had severe initial symptoms of vomiting, anorexia, and nausea. In the two other cases, a girl of 20 and a woman of 53, the jaundice was transient; both had been taking 25 mg. three times daily, the former for 10 days and the latter for about four weeks. In these three cases chlorpromazine therapy was stopped and has not been resumed.

One other patient had to stop taking the drug because of a severe febrile reaction after only a few days of treatment. Two others asked for therapy to be discontinued because of other side-effects. In three cases the treatment was stopped after two to three weeks because no benefit had been obtained. Five patients seem to have been helped by chlorpromazine; one of these developed jaundice and expostulated bitterly when the drug was withheld. The remaining few patients are still under treatment, the effect of which cannot yet be assessed.

In view of the anti-emetic and emotional effects of chlorpromazine, it is very tempting to use the drug in cases of hyperemesis gravidarum. In view of the danger of liver damage, I feel that this temptation should be resisted. I gave one girl with hyperemesis 40 mg. daily in divided doses. She asserted very vehemently that her vomiting was made much worse. This statement was somewhat borne out by the rapidity with which she settled down when the therapy was discontinued.

In general, my experience of chlorpromazine has been disappointing. It is not such a stand-by for the G.P. as its admittedly valuable and interesting properties would lead one to suppose.—I am, etc.,

Huddersfield.

J. BRYAN EAGLES.

Flourpaper Tuberculin Jelly Test

SIR,—In the recent correspondence on tuberculin testing, it has been argued that there is some urgency to evaluate the Heaf multiple puncture test. We have been using this test in Cardiff for the past four years for child contacts, hospital staff, and, this year, as a single tuberculin test prior to giving B.C.G. vaccine to "school-leavers." When introducing our school-leaver scheme we were anxious to give B.C.G. vaccine following a single tuberculin test. For the first term we used the Heaf multiple puncture test with P.P.D. tuberculin (2 mg. per ml.) on the left arm, and the Mantoux test using P.P.D. tuberculin (10 I.T.U.) on the right arm. The results were as follows:

	Positive	Negative	Doubtful	Total
Heaf test	325	620	6	951
Mantoux	323	620	8	951

It is thus seen that in this series of children there is greater agreement between the Heaf and Mantoux tests when using P.P.D. (10 I.T.U.) than in the series reported by Dr. H. G. Calwell (*Journal*, November 27, 1954, p. 1292), when a dose of 100 units of old tuberculin was used. As Dr. Calwell has pointed out, some of the results that are regarded as positive are in fact false positives. We have retested and given B.C.G. vaccine to a number of contacts who were negative to the Heaf test but were originally regarded as positive when retested with a dose of 100 units of old tuberculin. In these contacts we have not had an accelerated or untoward reaction to the B.C.G. vaccine. As Dr. R. Stevenson Doig (*Journal*, December 4, 1954, p. 1357) points out, the advantages of the Heaf multiple puncture test are many, particularly as it can be used as a single test prior to vaccinating "school-leavers."—I am, etc.,

Cardiff.

P. M. BOWEN.

Spontaneous Rupture of the Spleen

SIR,—In view of the recent discussion on the association between perforation of a peptic ulcer and rupture of the spleen, we feel that the following case throws further light on this condition.

A man aged 55 years was admitted to Poplar Hospital and operated on 10 hours after the perforation of a chronic peptic ulcer. The perforation, which was on the anterior wall of the duodenum, was closed and covered with omentum. Post-operatively the patient developed a productive cough with an evening pyrexia to 102° F. (38.9° C.), and this responded to the exhibition of sulphamethazine and streptomycin for five days. From the fifteenth day he had evening rigors for which no cause could be found. Examination of the blood showed no malarial parasites. On the twenty-first post-operative day he suddenly collapsed and died within a few minutes. Post-mortem findings: the peritoneal cavity contained three pints (1.7 litres) of blood with evidence of recent clotting. A small abscess surrounded the splenic pedicle, and there was a septic thrombophlebitis of the first inch of the splenic vein. The spleen was softened and twice the normal size, with a large subcapsular haematoma of the lower pole and an irregular tear in the capsule. The ulcer was satisfactorily sealed by omentum.

This case is similar to that recorded by Babson and Morgan.¹ Their patient, a man of 49 years, collapsed five days after an operation for the closure of a perforated duodenal ulcer. After conservative treatment, continued for six days, laparotomy was performed. The peritoneal cavity was found to contain eight litres of blood, and the spleen, with the laceration on its superior border, was removed. The patient recovered.

Mr. Blair Thompson (*Journal*, November 20, p. 1209) reported that in his case, at laparotomy, the spleen had a large subcapsular haematoma and the splenic vein contained clots. We agree with him that the progress in these cases

is most likely: (1) perforation of the peptic ulcer, (2) local inflammation and thrombosis of the splenic vein, (3) congestion of the spleen leading to a subcapsular haematoma. It is difficult to imagine that severe muscular rigidity suggested by Mr. J. A. Shepherd² can damage an organ which is normally protected by lower ribs. The effect of coughing suggested by Babson and Morgan is similarly unlikely. The case described by Mr. Shepherd does not fall into this group: blood was not found in the peritoneal cavity until after the perforation had been discovered an inch from the oesophageal opening. It is possible that this case may come into another category—namely, traumatic rupture.

We wish to thank Mr. Alan Perry, M.S., F.R.C.S., under whose care this case was admitted, for permission to publish these details.—We are, etc.,

ANTHONY R. ANSCOMBE,
D. J. CROWTHER.

Chicken-neck-wringer's Finger

SIR,—The digital occupational deformities described as window-cleaner's finger by Mr. P. J. Moir (*Journal*, September 25, p. 757) and paper-folder's fingers by Dr. M. W. Partington (*Journal*, November 13, p. 1166) prompt me to record this case seen in the out-patient department at the Royal Free Hospital in 1940.

The patient was a lady aged 45 who had worked in Smithfield market from the age of 14 until she was 36 at the occupation of killing chickens. The bird was placed

across her lap, the wings and legs being held in her left hand, and, by stretching the neck with the right hand, she dislocated the cervical vertebrae with her middle finger. She stated that she could kill a bird up to the size of about 11 lb. (5 kg.) weight. She gave up the occupation when she was 36 owing to an increase in domestic duties, and the condition was quite painless until she was 45 years old, when she first noticed some pain in the joint and came to hospital.

X ray showed subluxation and osteoarthritis of the distal interphalangeal joint of the right middle finger. She was seen again a few weeks ago, at the age of 59; the condition is very little worse and gives her no trouble in her household duties.—I am, etc.,

London, W.1.

GEORGE QVIST.

Professional Secrecy

SIR,—Dr. E. C. Dawson's richly informative discussion (*Journal*, December 18, 1954, p. 1474) of the doctor's duty as witness and informer may be supplemented by reference to a related problem concerning the psychiatrist. It happens, for instance, that litigants in divorce actions try to exploit the analytical treatment received by the other party, or a family member, and propose that the therapist is called as a witness and be subjected to cross-examination. It is thus hoped to elicit personal particulars damaging, or at least embarrassing, to the other party.

All persons consenting to unreserved communication in the interest of their treatment do so because they have been reassured as to the unconditional secrecy of the whole material thus disclosed. Without this absolute belief in the therapist's integrity, few people might seek this type of

treatment; and certainly very few would make satisfactory progress. Many in the legal and medical professions may not realize the widespread damage bound to result if the Press reported that a psychotherapist had been compelled to divulge anything entrusted to him by his patient, who had been made to believe that such a betrayal was impossible.

On two occasions I was approached for advice by colleagues pressed and intimidated by solicitors desirous of involving them in the lawsuit. I advised my friends to reply that the evidence thus enforced might easily result in harm to their clients' interests, and almost certainly be of no benefit to them. I have so far not heard of a case of a psychotherapist being actually forced to give evidence in such repugnant circumstances. But, if ever a psychiatrist finds himself in such a situation, ought he not to risk going to prison and cause public indignation, rather than yield to pressure and destroy the trust we psychotherapists enjoy and so much need in our professional activities? Otherwise, how could he afterwards face his current patients, or reassure new ones as to the absoluteness of professional secrecy?

We understand that ministers of religion are in practice not asked in court to divulge confessional secrets. I think this is so because the clergy would at any rate refuse to submit. This legal attitude should be extended to those handling intimate psychiatric material, even though members of the medical profession are unlikely to defend the principle in question with the same intransigence as manifested by priests. The refusal by the psychotherapist to testify would be certainly the only moral alternative where no crime or serious harm is to be prevented by divulging the patient's secrets.—I am, etc.,

London, N.W.4.

S. Lowy.

SIR,—The day the Association alters its present views on professional secrecy we shall see headlined in the Press: "Doctors Can Divulge Your Secrets" (and, in smaller print) "Under Certain Circumstances." Once this has happened irreparable harm will have been done to the profession. Let us not meddle with high principles, but rather let us strive to attain them.—I am, etc.,

London, S.E.2.

PETER H. SHERWOOD.

Renal Complications after Sulphonamides

SIR,—It was purely by chance that, in looking up a past reference in your *Journal*, I saw the correspondence on renal complications due to sulphonamides. Ever since seeing a case of incipient obstruction due to the use of sulphathiazole in the Tropics in 1943 a special routine was evolved, since when a case of renal complication from the use of sulphonamides (including sulphanilamide, sulphathiazole, sulphadiazine, sulphamerazine, "sulphatriad," sulphaguanidine, and sulphadimidine) in doses up to 30 gr. (2 g.) four-hourly for many days has not been encountered. Two precautions were necessary: (1) All sulphonamides except the sulphaguanidine type were given as a mixture containing as well sodium citrate 60 gr. (4 g.), the mixture being taken in a large glass of lemon squash. (2) Fluid intake was not used as a criterion, but each specimen of urine was kept and examined, the last specimen being thrown out of the clear glass container just before passing urine. A yellow coloration indicated not enough fluids (whatever the fluid intake chart said), and a very pale light green to colourless was considered just right. This was acting on the principle that it is not the fluid intake which really matters but the fluid output.

Adhering strictly to these two principles, I have not seen any case of renal complications using sulphonamides even in the Tropics, and would be very interested to hear from correspondents who have had any failures, not due to the failing of this routine itself.—I am, etc.,

Kuala Belait, Brunei State.

K. F. D. SWEETMAN.

Obituary

ELIZABETH CASSON, O.B.E., M.D., D.P.M.

Dr. Elizabeth Casson, founder and medical director of Dorset House School of Occupational Therapy, Oxford, died at Bristol on December 17, 1954, at the age of 73.

Elizabeth Casson was born at Denbigh on April 14, 1881, the third daughter of Major Thomas Casson, J.P., who brought an original mind to organ building, and brother of Sir Lewis Casson, the well-known actor. After leaving St. Mary's College, Paddington, she became interested in housing estate management and worked under Miss Octavia Hill from 1908 to 1913. During this time she was secretary of Red Cross Hall at Southwark. At the age of 30 she took up the study of medicine at Bristol University, graduating M.B., Ch.B. in 1919 and proceeding M.D. in 1926. After holding a resident appointment at the West Herts Hospital in Hemel Hempstead she took the D.P.M. in 1922 and joined the staff of the Royal Holloway Sanatorium at Virginia Water. It was while she was a

medical officer there that she called a meeting of medical women who were interested in psychological medicine, and from this beginning grew the Standing Committee in Psychological Medicine of the Medical Women's Federation, as well as an informal group of medical women with interests in this field who have met at intervals ever since. Dr. Casson gained the much-coveted Gaskell Prize and Medal of the Royal Medico-Psychological Association in 1927, and she later founded the Gaskell Club, the members of which are past winners of the medal. The club has met yearly for many years to welcome new medallists, to dine, and to discuss matters of common interest. Dr. Casson was always an outstanding personality at the dinners, taking the chair at the last meeting a few weeks ago.

In 1929 she returned to Bristol as medical officer in charge of a residential clinic for mental disorders, and she was also in due course appointed to the staffs of the Bristol General Hospital and the Walker Dunbar Hospital. In 1930 she founded the first school of occupational therapy in this country. It was opened at Dorset House, on the Promenade, Clifton. Dr. Casson herself wrote that the importance of occupational therapy was impressed on her when she was in hospital one Christmas and found the enormously improved atmosphere in the hospital ward was directly due to the interest of the patients in preparing the Christmas decorations. She acknowledged that her first introduction to occupational therapy came from a description by Dr. David (now Sir David) Henderson of the small department he had opened at Gartnavel Hospital, Glasgow. During the first three years of the existence of this school the training given was chiefly for mental hospital work, but in due course an occupational therapy department was opened at the Bristol General Hospital for the treat-

ment of patients with physical disease. Occupational therapists are nowadays able to take the diploma for either physical or mental work or the combined diploma for both. In the early years of the school Dr. Casson herself gave the lectures to the students on anatomy and physiology. During the war the school moved to Barnsley Hall Hospital, Bromsgrove, Worcestershire, but after the war ended it was attached to the Churchill Hospital, Headington, Oxford, where Dr. Casson was a frequent and welcome visitor. She was elected an honorary fellow of the World Federation of Occupational Therapists, and in 1951 was awarded the O.B.E. for her work as founder of the Dorset House School of occupational therapy.

In the years before the war Dr. Casson worked actively for the B.M.A. and represented her Division at nine Annual Meetings. She also took a keen interest in Bristol University and was a member of the university court. Her whole heart was in her work, and what she gained in knowledge she put to the service of others. But that was not all, for apart from her work she was affectionately devoted to innumerable friends, patients, and students and to a wide family circle. During the war her home in Bristol was bombed, and since then she had lived in Clevedon.

The death on November 19, 1954, of Dr. P. H. J. TURTON, of Heanor, Derbyshire, removed an outstanding personality from the district. He was 59 years of age. Philip Henry Job Turton was the son of the late Dr. William Henry Turton and, like his father, was a native of Heanor, where he was born on August 13, 1895. He interrupted his medical studies at Edinburgh University to serve in the R.A.M.C. in the first world war, returning to graduate M.B., Ch.B. in 1921. Four years later he proceeded to the M.D., receiving a high commendation for his thesis on the aetiology of endemic goitre, based on his own observations in Heanor. In 1929 he obtained the Manchester D.P.H. When his father, who was part-time medical officer of health for Heanor for 54 years, died in 1942 he succeeded to the appointment, which he retained until his death. For many years he was also honorary physician to Ilkeston Hospital and Heanor Memorial Hospital. He retained his particular interest in the incidence of "Derbyshire neck," and in 1933 read a paper before the Section of Epidemiology and State Medicine of the Royal Society of Medicine on the distribution of simple goitre in Derbyshire. Dr. Turton was a man of many parts who brought a keen and inquiring mind to all branches of medicine.

J. S. and T. B. F. write: It was always stimulating to attend a patient with Dr. Philip Turton. His knowledge of up-to-date research in medicine was quite striking in one who was so busy in his practice. His annual reports as medical officer of health were a delightful mixture of classical quotations and solid facts on the health of the district. He bore his recent severe illness with great fortitude and never lost interest in the people of the district, whom he served so well. To his widow and family goes our sincere sympathy in their loss.

C. M. E. writes: It was a privilege to work as Dr. Philip Turton's assistant, and, later, as his junior partner. He was outstanding as a general practitioner, being a brilliant diagnostician, and he never spared himself in the service of his patients, who thought of him not only as their doctor but as their guide, counsellor, and friend.

Dr. MARY A. T. RITCHINGS died on December 9, 1954, at her home at Swansea, where she had been in practice for over fifty years. She was 77 years of age. The daughter of a herbalist, Mary Ann Thompson Ritchings was born on July 20, 1877, and was educated privately and at Glasgow University, where she graduated M.B., Ch.B. in 1903. After

graduation she held the appointment of resident medical officer at Drumcondra Hospital, Dublin, before settling in general practice at Swansea. In 1918 she was appointed M.B.E. for her work as medical officer in charge of the Y.M.C.A. auxiliary hospital at Swansea during the first world war. The first woman general practitioner at Swansea, Dr. Ritchings built up an extensive practice, mostly among her own sex, and was greatly loved and admired by her patients. Although she did not accept service under the National Insurance Act of 1911 or under the National Health Service Act of 1946, she was keenly interested in the latter during its initial stages. Of a retiring disposition and in the last few years not very active, Dr. Ritchings was not known to many members of her profession or to many of the general public, but as a young woman she was a frequent speaker on political platforms. She is survived by two sisters.—J. C. O.

SIR WILLIAM HASLETT, who died at his home at Weybridge on December 17, 1954, at the age of 88, was not only a specialist in mental and nervous disorders, but also a man who contrived to devote much time to public and political work over many years. William John Handfield Haslett was born on September 10, 1866, the son of Dr. S. Torrens Haslett, of Laghey, Co. Donegal, and was educated at the Academical Institute, Londonderry, receiving his medical training at Trinity College, Dublin, where he won first-class honours in anatomy, and at Sir Patrick Dun's Hospital, Dublin, Meath Hospital, and the London Hospital. After qualifying M.R.C.S., L.R.C.P. in 1889, he held appointments at Meath Hospital, the Poplar Hospital for Accidents, and St. Luke's Hospital for the Insane. In 1892 he became resident medical superintendent of Halliford House, a private mental hospital at Shepperton-on-Thames, in which he had a proprietorial interest, and soon afterwards began to take an active part in public affairs. This work included membership of the Staines Board of Guardians, the Middlesex Insurance Committee, and the Sunbury Urban District Council, and later he was for some time a commissioner for income tax. From 1913 to 1928 he was a member of the Middlesex County Council, and as chairman of the committee for the care of mental defectives did valuable work in connexion with the establishment of special colonies for defectives. He was also a justice of the peace. In professional circles he was a member for many years of the British Medical Association, the Royal Medico-Psychological Association, whose certificate he obtained quite early in his career, the Windsor and District Medical Society, of which he was a past president, and the Kingston Medical Society. He was chairman of the South Middlesex Division of the B.M.A. from 1914 to 1919 and represented the Division at the Annual Representative Meeting held in London in 1917. Earlier, he attended the first Annual Meeting of the Association to be held in Canada—at Montreal in 1897—and read a paper on the influence of physical upon mental disease before the Section of Psychology. In 1938 he was created a knight for his political and public services in the Spelthorne Division of Middlesex, having been for many years president of the local Conservative and Unionist Association. Just before the last war he gave up his appointment at Halliford House, but continued to render useful service as consulting physician, and some six years ago he left Shepperton to go to live at Weybridge, just across the Thames. He married Miss Norah Macan in 1922 and had one son and three daughters.

P. M. J. writes: Having just had the unusual experience of reading the obituary notices (*Journal*, December 11) of two men to whom I have been secretary, may I add a little to what has already been said of them? My outstanding recollection of Dr. N. S. GILCHRIST during the 1930's is his tremendous capacity for work—nothing stood in its way for him. He would often start out at eight in the morning in order to be with "the other side's doctor" when the latter finished his morning surgery, and he would continue driving

and examining all day and well into the evening. In those days cases in the provinces provided his recreation, because he would enjoy the change of scenery. He was a perfectionist, and had a great gift for wording his reports in such a way that the layman had no difficulty in understanding them. During the 1940 blitz it was not uncommon for him to drive through the debris and over hosepipes whilst dictating his report on the last case we had visited.

I worked for Dr. A. C. ROXBURGH only during the last three years of his life, his previous secretary having been with him for 24 years. During that time, however, I realized how much his patients loved him. His ability as a skin consultant is known by all, but only those who knew him personally appreciated that his courtesy, humour, kindness, and great humility were not a façade for his patients and the medical profession only, but they pervaded his dealings with all and sundry, even his secretary. A day or two before he died I suggested that the forthcoming publication of the tenth edition of *Common Skin Diseases* might provide something of a record. His reply was, "Oh, I don't know; let's see," and he led me to his bookcase. He always marvelled—never boasted—that his private practice kept at such a level for so long after his retirement from his hospital appointments. Indeed a great man, and a great loss to all.

Medical Notes in Parliament

Agene in Flour to be Discontinued

Mr. HEATHCOTE AMORY, Minister of Agriculture and Food, announced on December 21, in answer to a question by Mr. N. DODDS (Dartford, Lab.), that he had received a report from the subcommittee set up under the chairmanship of the Chief Medical Officer of the Ministry of Health to consider the question of flour improvers.

A detailed experimental study had been made under the aegis of the Medical Research Council, he said. The methods of flour improvement which had been examined were agene, chlorine dioxide, potassium bromate, ascorbic acid, and an aeration process. The experiments had confirmed that agene-treated flour when fed in large quantities caused fits in dogs, and had shown that none of the other improvers tested did the same. Since other methods of flour improvement existed which had not produced these symptoms in animals, the Government was of opinion that, although no ill effects in man due to the use of agenezed flour had been established, effect should now be given to the decision taken in 1950 to discontinue agene. In view of this decision, the National Association of British and Irish Millers had agreed to recommend their members to discontinue the use of agene and to give an undertaking that the equipment for treating flour in this way would be removed from their mills by December 31, 1955. Some delay was inevitable, because new equipment had to be obtained to treat flour by other means. The National Association of Flour Importers had similarly agreed to recommend their members to ensure that no flour treated with agene would be imported by them. The further investigations undertaken by the Medical Research Council had revealed some differences between the effects on flour of the other methods of improvement, but the effects demonstrated were not sufficient to require the discontinuance of any of the other four improving processes. These methods of flour improvement would continue to be kept under close scrutiny, in collaboration with the milling and baking industries.

Medical Evidence on Mrs. Christofi

The HOME SECRETARY was questioned by several M.P.s on December 20 about the reasons why he had decided not to advise the Queen to exercise the prerogative of mercy and reprieve Mrs. Christofi. Sir LESLIE PLUMMER (Deptford, Lab.), who asked why he had refused to see a deputation of M.P.s, also asked if the Home Secretary would

publish all the medical evidence he considered in making his decision; and Mr. S. SILVERMAN (Nelson and Colne, Lab.) asked what opportunities Dr. T. Christie, principal medical officer at Holloway Prison, had of forming an opinion about the mental condition of Mrs. Christofi, what opinion he formed, and in what circumstances other medical evidence was sought, obtained, or provided.

Major G. LLOYD-GEORGE stated in reply that Parliament had on many occasions recognized the undesirability of pressing the Home Secretary to disclose the reasons why he did or did not tender advice to the Crown with regard to the exercise of the Prerogative of Mercy in a capital case. So far as concerned the particular case of Mrs. Christofi, the principal medical officer at Holloway Prison stated in a report dated October 5 that after observation of the prisoner since July 30 he had formed the conclusion that she was insane, but was medically fit to plead and to stand trial. A copy of that report was furnished to the defence. At the trial, which began on October 25, the defence did not raise the issue of insanity.

After the dismissal of the prisoner's appeal to the Court of Criminal Appeal (he continued) it fell to him to consider the case. In view of Dr. Christie's report he appointed three distinguished and experienced doctors to conduct an inquiry in accordance with statutory provision. The three doctors reported that the prisoner was not insane, and they added that in their view she did not suffer from any minor mental abnormality which would justify them in making any recommendation on medical grounds relevant to the question of a reprieve. After very full consideration he regretfully came to the conclusion that there were no sufficient grounds for recommending any interference with the due process of law. It would be contrary to long-established practice, and open to considerable objection, to disclose any advice tendered to the Home Secretary in a case of this kind by the trial judge, or to disclose the terms of the medical report submitted by the statutory inquiry, and he was not prepared to make these documents available.

Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) asked what results were obtained from electroencephalographic examination of Mrs. Christofi while she was in custody. Major LLOYD-GEORGE said that there was no such examination in this case, as the prisoner would not agree to the examination being made.

Local Medical Committees

Mr. JOHN RANKIN (Glasgow, Tradeston, Lab.) asked the Secretary of State for Scotland on December 21 who was responsible, under his regulations, for setting up the local medical committees, and what was their purpose in the administration of the general medical service. Mr. J. STUART replied that these committees were formed by the medical profession themselves, and were accorded statutory recognition by the Secretary of State. They appointed medical members to the local executive council; they must be consulted by the council on certain specified matters, and were normally consulted on other matters, affecting the general medical services; and they had a number of specific functions under the regulations, including particularly the investigation of excessive prescribing.

Mr. RANKIN said there was widespread dissatisfaction with the manner in which many of the committees were carrying out their functions, and that they were tending by their attitude to limit the doctor's right to give the type of treatment he considered necessary. As they were assuming something of a judicial attitude, should not a doctor be represented when he appeared before one of these committees? Mr. STUART said he would like to look into that. He did not wish any dictatorial attitude to be adopted by these committees. He thought they were working very well.

Mr. RANKIN said that one of the interviews to which a doctor was called started by the chairman informing him that he need not worry because on this occasion he would not be fined. Mr. STUART said he was not aware of that. If Mr. Rankin would give him details he would look into them.

Industrial Health Survey

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked the Minister of Labour on December 21 whether he was satisfied that the Advisory Committee on Industrial Health would have all the powers and resources necessary to enable them to carry out an effective survey, so as to make clear the main deficiencies of the existing health provisions in industry. Mr. HAROLD WATKINSON, the Parliamentary Secretary, stated that the committee would be an advisory body. The scheme for the development of industrial health services, including any necessary surveys, would be carried out through the Factory Inspectorate, which possessed wide powers under the Factories Acts. Mr. BLENKINSOP asked if the Minister was satisfied that they had powers to inspect conditions in some of the smaller factories, where there was most need. Mr. WATKINSON pointed out that the committee was only working at the moment on premises which came under the Factories Acts.

Mr. BLENKINSOP asked if the Minister had completed his discussions with interested bodies on the composition of the advisory committee and whether he had agreed to the inclusion of persons with experience of local government work. Mr. WATKINSON said "No." Further requests for membership of the committee had been received, and the whole subject was still under consideration. Mr. BLENKINSOP pressed the Minister to give public health authorities some place on this committee in view of their heavy responsibilities. It was fantastic, he said, not to include representation from this important section. Mr. WATKINSON replied that local authorities had only limited responsibility in industrial health. That did not prejudice the Minister's decision, which had yet to be taken.

Clinical Experiments

Mr. S. SWINGLER (Newcastle-under-Lyme, Lab.) asked the Minister of Health to what extent clinical experiments were being carried out in hospitals under the regional hospital boards; what regulations governed the conditions of such experiments; and on whose authority, and under what circumstances, clinical experiments on infants in hospital, such as that to which his attention had been drawn, were permitted to be carried out. Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, replying on December 20, stated that hospital authorities were given power to conduct research by Section 16 of the National Health Service Act, 1946. Individual clinical investigations were undertaken on the authority of the clinician in charge of the case, and the Minister had not complete knowledge of the extent of all the work in progress at hospitals. Such investigations involved medical and ethical problems which were not susceptible of control by regulations.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Raymond Horton-Smith Prize for 1953-4 has been awarded to Dr. P. A. G. Monro.

In Congregation on November 13 the following degrees were awarded:

M.A.—W. E. Hick, M.D., Reader in Experimental Psychology; Bernard Towers, M.B., Ch.B., University Demonstrator in Anatomy; Christopher Parish, F.R.C.S., Associate Lecturer in Thoracic Surgery; L. M. Rouillard, F.R.C.S.Ed., Associate Lecturer in Plastic Surgery.
M.B., B.Chir.—P. Gortval.
M.B.—E. Burkinshaw.

Dr. A. P. Waterson has been elected into a Research Fellowship at Emmanuel College.

*By proxy.

UNIVERSITY OF LONDON

The following candidates at the Institute of Psychiatry have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PSYCHOLOGY.—Section D: Patricia M. Bannister, H. R. Beech, Marian Black, Genevieve L. Castrodale, Esther R. Gottstein, D. Hall, J. H. G. Hewlett, V. F. W. Newham.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 11 (No. 49) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Scottish Life Tables

The remarkable decline in mortality rates of young people during the last eight decades in Britain is reflected clearly in the life tables for Scotland based on the 1951 census.

The expectation of life at birth in 1871 was 39.8 years for males and 42.0 for females; in 1951 it was 64.4 for males and 68.7 for females. But for those people who reached the age of 60 the increase was much less striking—from 13.3 to 14.3 years for males and from 14.8 to 16.8 years for females.

Middle childhood is the age at which mortality has been most sharply reduced. At age 10 mortality in 1951 was only 9% for males and 6% for females of mortality in 1871. At age 60 it was 79% for males and 58% for females of mortality in 1871, while at age 80 mortality was slightly worse in 1951 for males, being 105% of the 1871 rate and 100% for females.

The mortality of married persons is lighter than that of single or widowed for men in all age groups, and lighter for younger women; the mortality of older women is much the same in all three categories. In the twenty years between 1930-2 and 1950-2 a change has been noted in the mortality rates of single and married women. In 1930-2 the single women's mortality rates were less than those of married women; in 1950-2 they were some 60% greater on average. Two probable reasons are advanced to account for this. First, the risks of childbirth were greatly reduced; secondly, marriage rates were high, with the result that those who remained unmarried included an unusually high proportion of women who were unmarried because of ill-health. (*Life Tables 1950-2*. Supplement to the 99th Annual Report of the Registrar-General for Scotland. H.M.S.O. 1s. 3d.)

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ———. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

In England and Wales during the week ending December 11 a fall was recorded in the number of notifications for scarlet fever of 184, from 893 to 709, 109 for whooping-cough, from 2,156 to 2,047, and 106 for dysentery, from 463 to 357, and a rise of 281 was recorded for measles, from 6,017 to 6,298.

The largest increases in the incidence of measles were 137 in Cheshire, from 304 to 441, 83 in London, from 390 to 473, 72 in Yorkshire West Riding, from 408 to 480, and 63 in Staffordshire, from 162 to 225, and the largest fall was 71 in Nottinghamshire, from 207 to 136. The largest falls in the number of notifications of scarlet fever were 32 in Yorkshire West Riding, from 100 to 68, 30 in London, from 69 to 39, and 29 in Lancashire, from 132 to 103. The largest variations in the returns of whooping-cough were a rise of 47 in Kent, from 114 to 161, and a fall of 53 in Lancashire, from 271 to 218. 15 cases of diphtheria were notified, being 2 more than in the preceding week. The largest returns of diphtheria were Liverpool C.B. 5, and Birmingham C.B. 3.

43 cases of acute poliomyelitis were notified during the week. These were 1 more for paralytic and the same for non-paralytic cases as in the preceding week. The largest returns were Yorkshire West Riding 5 (Leeds C.B. 3), Lancashire 5 (Manchester C.B. 3), Cheshire 4 (Wallasey C.B. 2), and London 4.

The number of notifications of dysentery was the lowest for the past ten weeks. The largest centres of infection were Lancashire 96 (Oldham C.B. 24, Liverpool C.B. 21,

Morecambe and Heysham M.B. 11), London 67 (Hackney 25, Islington 10), Yorkshire West Riding 37 (Sheffield C.B. 25), Staffordshire 27 (Stoke-on-Trent C.B. 17), and Norfolk 22 (Norwich C.B. 17).

56 deaths were attributed to influenza in the great towns. The number of deaths is at a higher level than in recent years; in the past month there have been 156 deaths, compared with 56 in 1953 and 65 in 1952 during the corresponding period.

Week Ending December 18, 1954

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 798, whooping-cough 1,833, diphtheria 18, measles 6,523, acute pneumonia 736, meningococcal infection 24, acute poliomyelitis 36, dysentery 340, paratyphoid fever 9, typhoid fever 1.

Medical News

Royal Society.—Once again the medical profession is honoured by the fact that both the president of the Royal Society and one of the four vice-presidents are medical men. Dr. E. D. ADRIAN, O.M., was re-elected president at the annual meeting in December, and among the members of the council are Sir EDWARD MELLANBY, a vice-president, Sir ALAN DRURY, and Professor J. H. GADSDON. The Royal Society has awarded Locke Research Fellowships to Dr. M. DE BURGH DALY, lecturer in physiology at University College, London, to support work on the haemodynamics of the pulmonary circulation, and to Dr. J. C. F. POOLE for work at the Sir William Dunn School of Pathology, Oxford, on the effects of fat absorption on blood coagulation and thrombosis.

Psychoanalysis at McGill University.—With the appointment of Dr. W. CLIFFORD SCOTT as associate professor in the department of psychiatry, a full psychoanalytical training programme will now be offered at McGill University, Montreal, for the first time. Dr. Scott graduated at Toronto in 1937, and then studied under the late Professor ADOLF MEYER and Professor MACKIE CAMPBELL. Until recently Dr. Scott was director of the London Clinic of Psychoanalysis and chairman of the Board of Directors of the Institute of Psychoanalysis. He was also on the staff of the Bethlem Royal and Maudsley Hospital. Applications for psychoanalytical training should be made directly to Dr. SCOTT, Allan Memorial Institute, McGill University, Montreal.

Impressions of the Russian Doctors.—Before they left on December 23 at the end of their three-week tour the group of Soviet doctors who have been visiting Britain gave their impressions of medicine here (see *Journal*, December 11, p. 1431, and December 18, p. 1495). Professor A. N. SHABANOV, who led the delegation, said that they were leaving England with a good deal of satisfaction at all the things which they had seen, and about which they would tell their colleagues on their return. This exchange of scientific information was of great importance, because it gave a true understanding of the work being carried out in each country. He hoped that there would be exchange of technical information in the future, and that the contacts which the delegation had established in this country would lead to further invitations to Soviet scientists to come to Britain. Professor Shabanov then announced that he had invited British surgeons to a conference of surgeons to be held in Moscow next month, of which he was a member of the organizing committee. The Soviet doctors, Professor Shabanov continued, left with a good impression of all the medical institutions which they had visited. One specific feature of medicine characteristic of this country was the system of general practitioners, which seemed popular. It was at first very difficult for the

visitors to understand the National Health Service. They had got to know quite well that part which was administered by local government, but they had seen less of the part administered by the Ministry of Health. Britain had not such a unified health service as in the U.S.S.R., where all institutions were under the Health Ministry. All the doctors whom they saw were carrying out their work with a sense of responsibility. In the medical centres and institutions which they had visited the work being done was of a high standard. A woman member of the delegation, Dr. Z. M. DZHAMALOVA, deputy Minister of Health, Uzbek Republic, an obstetrician and gynaecologist, said that the antenatal clinics were well organized in Britain and the obstetrical departments were very good. Methods of anaesthesia in childbirth differed from those in the Soviet Union, where pain in childbirth was alleviated by psychological preparation and drugs and a short application of ether in the second stage where medically indicated.

Hostel for Deaf Children.—The Astor Shield, presented by Lord Astor for outstanding work in the field of infant welfare, has been awarded this year to the Royal National Throat, Nose, and Ear Hospital in recognition of its work in opening a hostel for deaf babies and their mothers. Dr. D. H. GEFFEN, vice-chairman of the National Baby Week Council, made the presentation at a small function at the hospital on December 15. The hostel is at Ealing and provides for the accommodation of mothers who can stay with their deaf babies and very young children in order to learn to apply a deaf aid to a child at a time when there is a readiness to listen and later to talk. Dr. Geffen described this as the finest concept in child welfare that his council had come across during the last few years. If young children were to learn to talk it must be through the mother, and this was the only way of really doing something for a sadly neglected portion of the population—namely, congenitally deaf children. Miss EDITH WHETNALL, director of the audiology unit of the hospital, whose lecture on the management of deaf children was reported in our last issue (December 25, p. 1542), said that mothers and babies were kept at the hostel for from three weeks to a month. The house had been bought by the hospital, but the Nuffield Foundation was responsible for the salary of the teacher, the mothers receiving a grant from the Ministry of Health, if needed, to enable them to take advantage of its facilities.

Anatomical Society of Great Britain and Ireland.—At the annual meeting at Guy's Hospital Medical School on November 26 Professor W. J. HAMILTON and Professor F. GOLDBY were re-elected president and secretary respectively. Professor E. W. WALLS was elected treasurer in place of Professor T. NICOL.

Wright-Fleming Institute of Microbiology.—Professor ROBERT CRICKSHANK has been appointed Principal of the Wright-Fleming Institute of Microbiology in succession to Sir ALEXANDER FLEMING, who retired on December 31, 1954. Professor Robert Crickshank will continue to hold the chair of bacteriology in St. Mary's Hospital Medical School.

Wellcome Historical Medical Museum.—For the past seven years the Wellcome Historical Medical Museum in London has been carrying on its activities at 28, Portman Square. It has now moved to the Wellcome Research Institution at 183-193, Euston Road, London, N.W.1 (Tel. Euston 4688). Exhibitions dealing with primitive medicine and with child welfare through the ages are open to the public in the new premises (Monday to Friday, 10 a.m. to 5 p.m.).

News in Brief.—Sir LIONEL WHITBY will be visiting professor of medicine at the New York State University College of Medicine this month.

Oxytetracycline ("terramycin"), and preparations of it, intended for parenteral injection, have been brought under the Therapeutic Substances Act, 1925, by Regulations

coming into force on January 1. The provisions relating to insulin under the Therapeutic Substances Regulations, 1952, have also been amended.

At the Swedish National Medical Congress in Stockholm last month a new Swedish vaccine against poliomyelitis was announced. It is reported to be less likely to give rise to allergic reactions than the corresponding American product.

The inaugural meeting of the Polarographic Society was held in London recently. The society is open to all interested in polarography. The secretary is Mrs. B. LAMB, 25, Grittleton Avenue, Wembley.

COMING EVENTS

Institute of Diseases of the Chest.—Open clinical demonstrations on various aspects of chest disease are given on Fridays at 5 p.m. in the lecture room of the Institute (in the grounds of the Brompton Hospital, Fulham Road, London, S.W.3). These demonstrations are intended for candidates for higher qualifications. They are open without fee to medical practitioners on signing the attendance book. The next series will begin on January 7 and end on April 1.

London County Medical Society.—Annual dinner on January 18 at the Talbot Restaurant, 64, London Wall, London, E.C.2, at 7 for 7.30 p.m. Dr. ROBERT FORBES, secretary of the Medical Defence Union, will speak on "Recent Developments in Medical Litigation." Tickets 11s. 6d., from Dr. A. M. RAMSAY, Royal Free Hospital, Lawn Road, London, N.W.3.

Israeli Scientific Publications.—The exhibition at the Consulate of Israel, 18, Manchester Square, London, W.1, will remain open until January 7.

Goulstonian Lectures.—Dr. G. M. BULL will lecture at the Royal College of Physicians, Pall Mall East, at 5 p.m. on January 18 and 20 on "The Uraemias."

Pan American Congress of Ophthalmology.—Fifth congress in Santiago, Chile, January 15–22, 1956. Details from Dr. RENE CONTARDO, Huerfanos 930—Of. 74, Santiago, Chile.

Association of Industrial Medical Officers.—The association will be celebrating the 21st anniversary of its foundation by holding a special anniversary meeting in London from September 25 to 29, 1956.

NEW ISSUES

Archives of Disease in Childhood.—The next issue (Vol. 29, No. 148) is now available. The contents include:

IDIOPATHIC HYPERCALCAEMIA IN AN INFANT. I. M. P. Dawson, W. S. Craig, and J. J. C. Petera.
THE INVESTIGATION OF A LARGE FAMILY AFFECTED WITH VON WILLEBRAND'S DISEASE. J. C. W. MacFarlane and M. J. Simpkins.
NORMAL RENAL FUNCTION IN THE FIRST TWO DAYS OF LIFE. R. A. McCance and E. M. Widdowson.
THE INFLUENCE OF EVENTS DURING THE LAST FEW DAYS IN UTERO ON TISSUE DESTRUCTION AND RENAL FUNCTION IN THE FIRST TWO DAYS OF INDEPENDENT LIFE. R. A. McCance and E. M. Widdowson.
PROGNOSIS IN IDIOPATHIC THROMBOCYTOPENIC PURPURA OF CHILDHOOD. G. M. Kornfower and G. B. Watson.
CHRONIC GENERALIZED OEDEMA AND HYPOPROTEINAEMIA OF OBSCURE ORIGIN. R. S. Illingworth and E. Finch.
TEMPORARY GENERALIZED OEDEMA OF OBSCURE ORIGIN. R. S. Illingworth and E. Finch.
COLLOIDION SKIN OF THE NEWBORN. O. D. Fisher and Kathleen G. McKee.
CONTROL OF THE BLOOD SUGAR LEVEL IN THE NEONATAL PERIOD. James W. Farquhar.
FIVE CASES OF ACUTE INFECTIVE POLYNEURITIS (GUILLAIN-BARRÉ SYNDROME) IN CHILDREN. Pamela Aylett.
THE TREATMENT OF TICS IN CHILDHOOD. David M. Zausmer.
THE RETINOPATHY OF PREMATURITY. J. D. Kerr and G. I. Scott.
A CONTROLLED INVESTIGATION ON THE EFFECT OF DIET ON ACUTE NEPHRITIS. R. S. Illingworth, M. G. Philpott, and John Rendle-Short.
TRICHORHEZOA. F. C. Friedlander and P. Kushlick.
RADIOIODINE (¹³¹I) IN JUVENILE MYXOEDEMA DUE TO ECTOPIC THYROID TISSUE. E. M. McGirt and James H. Hutchison.
NEONATAL ASCITES ASSOCIATED WITH URETHRAL OBSTRUCTION. N. E. France and E. H. Beck.
CHRONIC MYELOGENOUS LEUKAEMIA IN INFANCY. Edward G. Fox and Janet L. P. Hunter.
NON-ENDERMIC GOITROUS CAETINISM. A. D. M. Jackson.
THE TREATMENT OF HYPOPLASTIC ANAEMIA AFTER CHLORAMPHENICOL. R. McLaren Todd.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Medical and Biological Illustration.—The new issue (Vol. IV, No. 4) is now available. The contents include:

SOME CONDITIONS OF THE NAILS. Part of a Teaching Display from Westminster Hospital Medical School.
JOSEPH LEIDY. W. J. Bishop.
THE VALUE OF GRAPHICAL MATERIAL. M. D. Vernon.
MOTION STUDY. John Hall.
THE PHOTOGRAPHY OF PAPER CHROMATOGRAMS. J. P. Berry, J. D. Cheshire, and L. I. Wood.
SELF-CONTAINED UNIT FOR KINEMOGRAPHY WITH BUILT-IN EXPOSURE DEVICE. H. M. Dekkinge.
EQUIPMENT AND METHODS:
THE "MICROMAG" FOCUSING DEVICE.
THE LEDA NUMBERING MACHINE.
EQUIVALENT FOCAL LENGTHS.
THE BRUBACKER-HOLINGER 16 MM. ENDOSCOPIC MOTION PICTURE CAMERA.
KENTMERE REFLEX TRANSPARENT FILM PAPER.
PLASTIC STORAGE CABINET.
ABSTRACTS.
BOOK REVIEWS.
MOTION PICTURES.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged for a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, January 3

INSTITUTE OF DERMATOLOGY.—Fourth of a series of semi-permanent exhibitions from January 3 to 21, by Dr. J. A. Milne, on Histology of Acute Vascular Disease of the Skin.
INSTITUTE OF NEUROLOGY.—5 p.m., Sir Geoffrey Jefferson, F.R.S.: Benign and Malignant Tumours of the Gasserian Ganglion.

Tuesday, January 4

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: Skin Lesions with Deeper Significance.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson: Demonstration by Dr. G. D. Lumb: Some Pathological Aspects of Ulcerative Colitis.

Wednesday, January 5

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Parapsoriasis, Psoriasis, and Mycosis Fungoides.
INSTITUTE OF LARYNGOLOGY AND OTITIS.—5.30 p.m., Professor F. C. Ormerod: Indications for the Use of Antibiotics in Otolaryngology.

Thursday, January 6

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Centenary Lecture by Dr. Muriel Robertson, F.R.S.: Sir David Bruce—An Appreciation of the Man and His Work (lantern slides).
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Mr. J. M. Potter: Angiomatous Malformations of the Brain: Their Nature and Prognosis.
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases.

Friday, January 7

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. J. E. M. Wigley: Psoriasis.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Congenital Abnormalities of the Chest.
● ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. I. Anderson: Electrolyte Balance.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., clinical meeting. Members of the Stratford Division, B.M.A., are invited.

Saturday, January 8

MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, 3 p.m. Dr. J. Morrison Smith: Polythene Plombage; Dr. P. A. Thorn: Gastrectomy and Tuberculosis; Dr. R. G. May: Some Observations on Segmental and Lobar Opacities in Primary Tuberculosis in Children.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Blend.—On December 18, 1954, at the London Hospital, London, E., a daughter, wife of Dr. David Blend, 22, Compton Terrace, London, N. a son—Jonathan William Eliot.

DEATHS

Bryce.—On December 13, 1954, at 2, Kennedy Gardens, St. Andrews, Fifeshire, William Henderson Bryce, M.B., C.M.
Cameron.—On December 12, 1954, at Kingston, Jamaica, John Joseph Cameron, M.D., aged 72.
Eunson.—On December 3, 1954, Leonard Harvey Eunson, M.C., M.B., Ch.B., of Dudley Port House, Tipton, Staffs., aged 58.
Goodwin.—On December 15, 1954, Edward Knox Goodwin, M.R.C.S., L.R.C.P., of 2, Marten Road, Folkestone, Kent, aged 86.
Hes.—On December 12, 1954, at Starcross, Devon, John Hyde Hes, M.B., Ch.B., aged 76.
Saaler.—On December 9, 1954, at Golders Green, London, N.W., Bruno Carl Saaler, M.D., aged 71.
van Someren.—On December 4, 1954, in hospital at Newcastle, Staffs., Gerald Antony van Someren, M.R.C.S., L.R.C.P., D.P.M., of Mount St. George, Second Avenue, Porthill, Stoke-on-Trent, Staffs., aged 43.
Wallace.—On December 13, 1954, at Simpsons, Glenalmond, Perth, Alexander Frank Wallace, M.C., M.D., formerly of Northern Rhodesia.
Watson.—On December 13, 1954, at an infirmary, Glasgow, Henry Currie Watson, M.C., M.B., Ch.B., of 187, Neilston Road, Paisley, Renfrewshire.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Risk of Agranulocytosis with Sulphonamides

Q.—What is the incidence of agranulocytosis with the commoner sulphonamide preparations? Are any more dangerous than others in this respect, and is there a maximum dosage which if not exceeded is likely to prevent the occurrence of this complication?

A.—It is not possible to give a precise figure for the incidence of agranulocytosis during sulphonamide therapy, since many cases are either not recognized or are not reported. It is probably of the order of one in a thousand to one in ten thousand of cases treated. There is no convincing evidence that one sulphonamide is more likely to produce agranulocytosis than another, but sulphadiazine and sulphadiazine are probably safer in this respect than sulphathiazole and sulphapyridine. Most of the reported cases have arisen after heavy dosage for a week or more, or after the prolonged use of small doses as in the prophylaxis of acute rheumatism. As a crude guide it may be said that the total dose should not exceed 50 grammes nor the period of administration twenty-one days. If these figures are exceeded the patient should have weekly total and differential white cell counts carried out. Administration of a sulphonamide should be immediately stopped in any patient showing drug fever or developing a sore throat, and the blood picture should be investigated.

Treatment of Agranulocytosis following Drugs

Q.—What is the best treatment for agranulocytosis following drug therapy? How may the prognosis be assessed?

A.—Many substances, including pentose nucleotide, pyridoxine, folic acid, liver extracts, and A.C.T.H. and cortisone, have been used in the treatment of the agranulocytosis following drug therapy. However, there is no convincing evidence that any of these remedies has a specific effect in stimulating leucopoiesis under these circumstances. The transfusion of leucocytes is likewise of little or no value. Fortunately, as for instance in thiouracil agranulocytosis, the dangerous phase of acute granulocytopenia usually lasts only for a few days and seldom persists longer than one week. After stopping the responsible drug at once, all that is necessary, therefore, is for the patient to be kept under observation in bed so that any septic lesions which develop may be vigorously treated by an appropriate antibiotic.

The prognosis can be assessed by marrow puncture. This may show signs of leucocyte regeneration a day or two before the neutrophil count in the peripheral blood starts to rise. If the marrow puncture also reveals depression of erythropoiesis and thrombopoiesis, as in sensitivity to chloramphenicol, the outlook is much more serious than when leucopoiesis alone is depressed.

Mechanism of Blood Clotting

Q.—What is the modern view of the mechanism of blood coagulation?

A.—The following is an outline of the modern theory of blood coagulation. Blood clots when the protein fibrinogen is changed to fibrin. This change is brought about enzymatically by thrombin. Thrombin does not exist normally in blood *in vivo*—if it did the blood would clot in the blood vessels; it is formed from a precursor, prothrombin. It is

the processes which result in the activation of prothrombin to thrombin that have been the subject of the greatest controversy and research in recent years.

It is now believed that the activation of prothrombin is brought about by "intrinsic" thromboplastin, and that this thromboplastin is formed as the result of the interaction of at least five factors in the presence of ionized calcium. Four of the five factors exist normally in the plasma—anti-haemophilic globulin, the Christmas factor, and Factors V and VII; the fifth factor is derived from blood platelets as the result of contact with a water-wettable surface.

Strongyloidiasis

Q.—I have a male patient who became infected with *Strongyloides stercoralis* while in a Japanese P.O.W. camp. This condition persists in spite of intensive treatment with gentian violet, and he has frequent attacks of urticaria and pruritus. What further measures can be taken? Would phenothiazine be of any value?

A.—It is now generally agreed that there is no effective treatment for infection with *Strongyloides stercoralis*. There is no evidence that phenothiazine is of any value in such infections. Fortunately, these worms very seldom give rise to symptoms, and patients harbouring them may generally be reassured and encouraged to ignore the fact that they have a worm infection. In the case in question it is possible that the urticaria is the result of sensitivity to the worms and their products, but other causes of urticaria should be excluded. If it is decided that the *Strongyloides stercoralis* are responsible for the urticaria, symptomatic treatment should be employed.

Skin Ink

Q.—Can you give me the prescription for an efficient skin dye for the pre-operative marking of varicose veins? Those that I have already tried are immediately removed by the application of surgical spirit.

A.—An efficient skin ink for the pre-operative marking of varicose veins is a solution made up as follows:

B. Pyrogallol	1 g.
Methylated spirit	20 ml.
Liquor ferri perchlor. ..	2 ml.
Acetone	10 ml.
Hydrochloric acid	1 drop

After the patient has been shaved and bathed, he should stand in a good light while the veins are marked by a pledget of cotton-wool dipped in the ink and held in dissecting forceps. The longer the interval between the application of the skin ink and the pre-operative skin preparation the more indelible the ink becomes. An interval of 12–18 hours is advisable, and even then spirit must not be scrubbed over the markings or some will be removed. The dye gradually wears off during the usual post-operative desquamation once baths are resumed.

Scarlet Fever and Nephritis

Q.—Is it correct to treat scarlet fever cases, however mild, by rest in bed for at least two weeks in order to reduce the incidence of nephritis? If this is so, should not all cases of haemolytic streptococcal sore throat be treated in the same way for the same reason?

A.—Post-scarlatinal nephritis is regarded, probably correctly, as a toxic-allergic manifestation. There is no conclusive evidence that patients allowed up early are in greater danger of developing nephritis. When the disease was common and dangerous, nephritis occurred even in the most carefully nursed cases, but only rarely in those efficiently treated with antitoxin. Nevertheless, it is probably unwise to submit to strain and overactivity organs that have recently

been subjected to a toxic or bacterial attack, and for this reason alone it is wiser to allow reasonable rest after the temperature has subsided.

Many authorities allow the discharge of patients from hospital about one week after onset of the disease; it is commonplace to release patients in from 10 to 12 days. And this would not be practised if it were thought that a greater risk of nephritis would result.

Not all streptococcal throats are caused by scarlatinal strains, and some scarlatinal strains are poor toxin producers. The nephritic reaction is almost certainly linked with the specific toxin. Furthermore, the patient with a scarlatinal streptococcal tonsillitis may have a high immunity to the toxin. It is probable, therefore, that streptococcal throats without rash are even less likely than scarlet fever to end in nephritis.

This answer is taken from the third book of *Any Questions?* Copies of both the second and third books of *Any Questions?*, each containing some 200 expert answers, are available from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller, price 7s. 6d. a copy (postage 6d.). The third book contains a cumulative index.

Virtues of Hair-oil

Q.—In India hair-oil is used practically by everyone, partly as a fashion and partly owing to the popular belief that oil is necessary to protect the hair. It is also believed that oil protects the head against the heat and thus helps to prevent sunstroke. During my stay in England I saw that hair-oil was used very little. Is there any truth in the fact that oil is beneficial to the hair, particularly in the Tropics?

A.—It would seem that the use of hair-oil to-day by Indians, as with many other races, is essentially for cosmetic reasons and is practised as a toilet routine with little other purpose.

There is a natural tendency to maintain a definite "head" of sebaceous secretion in the skin, and this is soon restored if grease is removed from the skin, so that the addition of more oil would not seem to have any physiological value. Climatic conditions, particularly heat, determine the normal secretion of sebum, and the natural output of the skin and scalp is no doubt adequate for all protective purposes. The coloured races secrete much larger quantities of sebum in their native climate when in good health. Ill-health is commonly indicated by a loss of greasiness of the skin, and this may have led to the idea that the addition of oil, even in health, is of value.

Furthermore, from the earliest times there has been an association between the anointing with oil and the driving out of evil influences, the conferring of divine grace and blessing, and a general sense of protection. This ritual may perhaps underlie the widespread use of oil on the hair. It is doubtful if there is any physical benefit resulting from the practice.

Hypercholesterolaemia

Q.—What are the present views on the aetiology of hypercholesterolaemia, its relationship to coronary thrombosis, and treatment by dieting and the administration of oestrogens?

A.—The cholesterol level in the blood depends upon the amount eaten in the diet and formed in the body on the one hand, and upon the amount excreted in the faeces and metabolized on the other. Although in animals overfeeding with cholesterol produces atheroma, it is now thought that in man the amount of ingested preformed cholesterol is less important in influencing the blood level than the amount being synthesized and metabolized in the body.

There is an association between premature arteriosclerosis and diseases characterized by hypercholesterolaemia such as occurs as a familial disorder of lipid metabolism in familial xanthomatosis, in nephrosis, and in diabetes. There

is little doubt that coronary thrombosis relatively early in life can be correlated in many instances with abnormally high and fluctuating serum-cholesterol levels.

In some subjects, but not in all, a cholesterol-free diet may lower the plasma cholesterol level, and there is evidence that in women the cholesterol concentration fluctuates throughout the menstrual cycle, the lowest levels being found at the time of maximum oestrogen secretion. Whether a cholesterol-free diet or oestrogens will prove of value in preventing atherosclerosis by lowering the plasma cholesterol level remains to be proved.

Corns Between the Toes

Q.—I should be grateful for advice on the treatment and prevention of painful soft corns between the toes in an elderly woman.

A.—In very many cases soft corns between the toes are the result of fungus infection. A careful search should therefore be made for the organism and if it is found appropriate treatment instituted. Failing this, treatment should aim at keeping the interdigital folds slightly separated and dry. The skin between the toes should be washed night and morning with soap and water, swabbed with surgical spirit, and freely dusted with talcum powder. A few thicknesses of gauze will keep the opposing surfaces apart.

A Case for Thoracoplasty

Q.—A man of 48 years suffered from tuberculosis of the left apex with cavitation which has responded satisfactorily to rest and chemotherapy, but for which it is considered that a thoracoplasty should now be made. The left lower lobe, however, invariably produces showers of persistent unchanging fine crepitations. On radiography, screening, bronchography, and bronchoscopy no abnormality is detected. The right lung is apparently normal. The patient has no sputum. Vigorous physiotherapy has not altered the signs. What is the nature of the disturbance in the left lower lobe and is it safe to perform thoracoplasty on that side?

A.—A shoal of fine crepitations is sometimes an early indication of a spread of disease which has not yet become apparent radiologically. Occasionally it indicates a minor degree of fibrosis. Before considering operation it might be advisable to wait for several weeks to see if there are any radiological changes. On the assumption that there is no change it should be possible to carry out a thoracoplasty in slow stages (2 to 2½ ribs at a session). The main risk would be basal atelectasis, but if bronchostenosis has been excluded by bronchoscopy and bronchograms this should not be allowed to weigh unduly. Antibiotics should be used before and during surgery.

NOTES AND COMMENTS

Health Education.—Dr. JOHN BURTON, medical director of the Central Council for Health Education, writes: In contrast with the Hospital Service Group at the Central Council for Health Education Summer School for 1954 (see *Journal*, November 27, p. 1263), groups concerned with public health accepted in principle the need for a trained health educator. In one case it was suggested that this officer should be on the staff of the M.O.H. and responsible to the latter.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Altology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. Highest peak concentrations and sustained therapeutic effect with 'ESKACILLIN' the palatable liquid oral penicillin

Some authorities stress the value of high, if intermittent, peak penicillin serum concentrations; others favour lower, but sustained, plateau levels. With 'Eskacillin' the advantages of both patterns are available. A very high peak concentration is achieved within about one hour of the first dose, succeeded by a more than adequate therapeutic level sustained for several hours.

Transvasin

brings the esters of NICOTINIC ACID
SALICYLIC ACID
p-AMINO BENZOIC ACID

to the focal point of
soft-tissue rheumatism

The esters in Transvasin, a new preparation developed by Hamol S.A., our Swiss associates, readily pass the skin barrier in therapeutic quantities and enable an effective concentration of the drugs to be built up where they are needed. Transvasin not only induces vasodilation of the skin with a superficial erythema, but also brings about a deep hyperaemia of the underlying tissues. It is non-irritant, and can be safely used on delicate skins.

It is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible cream base ad	100%

Transvasin is available in 1 oz. tubes, basic price 2/6 plus 7½d P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD., 11 Waterloo Place, London, S.W.1 WHITEhall 8654/5/6

Transvasin is the registered trade mark of Lloyd-Hamol Ltd.

induction of sleep . . .

. . . one of the 44 uses for
short-acting

Nembutal
REGD.

What yardstick do you use to determine the drug you write on your prescription? If the drug is a barbiturate—such as short-acting NEMBUTAL—you can measure it, compare it, and sum it up in these four short sentences:—
NEMBUTAL can produce any desired degree of cerebral depression—from mild sedation to deep hypnosis.

The dosage required is small—only about half that of many other barbiturates. Hence, there's less drug to be inactivated, shorter duration of effect, wider margin of safety and little tendency towards morning-after hangover. In equal oral doses, no other barbiturate combines quicker, briefer, more profound effect.

Perhaps that's why, after nearly 25 years, more and more prescriptions call for NEMBUTAL (Pentobarbitone Sodium B.P.)

TREATMENT OF PHENYLKETONURIA WITH A DIET LOW IN PHENYLALANINE

BY
L. I. WOOLF, Ph.D., B.Sc. RUTH GRIFFITHS, M.A., Ph.D.

AND

ALAN MONCRIEFF, C.B.E., M.D., F.R.C.P.

(From The Hospital for Sick Children, Great Ormond Street, London)

Phenylketonuria is one of the very few conditions in which mental deficiency is associated with a demonstrable metabolic error. It has been suggested that the mental defect is due to an intoxication by phenylalanine or one of its metabolites, and that the mental deficiency may be relieved by feeding a diet low in phenylalanine (Woolf and Vulliamy, 1951). Such a diet must be adequate to permit normal health and growth.

All dietary proteins are about equally rich in phenylalanine (Block and Bolling, 1951), and a suitable diet can therefore be devised only by supplying the bulk of the nitrogen as a mixture of amino-acids. While it would be possible to mix pure amino-acids to obtain such a diet, the cost would render any long-term treatment of even a few cases impossible. Protein hydrolysates have been commercially available for some years, and it is known that they can be freed from phenylalanine, tyrosine, and tryptophan by passing through a column of charcoal (Schramm and Primosigh, 1943). It seemed likely that a suitable amino-acid mixture could be obtained at a reasonable cost by passing an acid hydrolysate of casein through charcoal and adding tyrosine and tryptophan. This was suggested by one of us (L. I. W.) to Dr. H. Bickel, who at that time had a suitable phenylketonuric patient under his care. Bickel carried out the preparation of the suggested diet, fed his patient on it, and reported a very marked improvement in the child's mental condition (Bickel, Gerrard, and Hickmans, 1953). No psychometric measurements were made, and it seemed worth while repeating this work, making as objective and as accurate measurements as possible of intelligence level before feeding the diet and at intervals after. Electroencephalograms were used as a second objective measurement.

The findings are described for two children, both aged 2 years 8 months at the start, who have been fed a diet low in phenylalanine for nine and ten months respectively; marked intellectual improvement resulted, and the E.E.G. became normal in the one case in which it was previously abnormal. A third child, aged 5 years 5 months, has been fed this diet for a shorter period, but presents interesting features, and the preliminary finding of intellectual improvement is described.

Diet

The major dietary components (Table I) were fed as a soup made by cooking the starch in the milk and water,

adding the other components, and homogenizing. In the first stage (till the urine was free from phenylpyruvic acid, two to ten days) milk was omitted and the other ingredients were increased. In the second stage the amount of milk fed was gradually raised till phenylpyruvic acid became just

TABLE I.—Daily Dietary Intake for a 3-year-old

Casein hydrolysate*	26.5 g.
DL-Tryptophan	1 "
L-Tyrosine	5 "
Wheat starch	28 "
Glucose	85 "
Calcium hydrogen phosphate (CaHPO ₄)	1 "
Iodized salt (NaCl)	2 "
Kosher vegetarian margarine	70 "
Arachis oil	3.5 ml.
Milk	240 "
Water	300 "

* Low in phenylalanine, tyrosine, and tryptophan.

TABLE II.—Daily Vitamin Intake

As tablets:	
Aneurine hydrochloride	1.5 mg.
Riboflavin	1.5 "
Pyridoxine	1 "
Nicotinamide	10 "
Calcium pantothenate	3.5 "
Ascorbic acid	50 "
α-Tocopherol	1 "
Acetomenaphthone	1.5 "
Meso-inositol	50 "
Biotin	0.5 "
Lactose	q.s.

As liquid:	
Crude liver extract	6 ml.
Choline chloride	25 mg.
"Adexolin"	10 drops

TABLE III.—Daily Mineral Intake

Potassium chloride (KCl)	1.5 g.
Magnesium sulphate (MgSO ₄ .7H ₂ O)	0.324 g.
Zinc sulphate (ZnSO ₄ .7H ₂ O)	0.0017 g.
Ferrous sulphate (FeSO ₄ .7H ₂ O)	0.069 g.
Manganous sulphate (MnSO ₄ .4H ₂ O)	0.00111 g.
Cupric sulphate (CuSO ₄ .5H ₂ O)	0.00393 g.
Hypophosphorous acid	0.05 ml.
Water	11 ml.

detectable in the urine; then it was dropped to a level at which no more phenylpyruvic acid was excreted. The wheat-starch is a protein-free preparation as fed to children with coeliac disease. The soup was fed in divided feeds four or five times daily.

Vitamins were added in tablet form, made up in the pharmacy of The Hospital for Sick Children, supplemented by a liquid crude liver extract containing added choline chloride and by an oily solution of vitamins A and D (Table II). Minerals (other than calcium phosphate, sodium chloride, and iodine) were added as an aqueous solution (Table III).

Water, orange juice, and glucose water were allowed *ad lib*. Biscuits, composed of wheat starch, kosher margarine, sugar, and flavouring, were also allowed up to 50 g. a day.

Clinical Summaries

Case 1

The parents of this child are Irish and unrelated. Five elder brothers and both parents are normal and have no phenylpyruvic acid in the urine. Pregnancy was normal except that the mother had high blood pressure; the birth was rapid but otherwise normal; he was jaundiced for about a week. His "milestones" were all passed late; he did not hold up his head until he was 6 months old. He began to have "fits" at the age of 6 months, and at 19 months was thought to be deaf by his parents; this led to a medical examination, when his mental retardation was noted, but he had had otitis media, which might have contributed to his deafness. At 2 years 3 months his "fits" had increased in frequency, and his backwardness was more obvious; he could not stand by himself, was incontinent of urine and faeces, and made only unintelligible sounds. Phenylpyruvic acid was found in his urine and he was admitted for dietary treatment when 2 years 8 months old.

Physical examination showed a slightly small skull, 18 in. (46 cm.) in circumference. There were no signs of abnormality in the cranial nerves or central nervous system and the disks were normal. The Wassermann reaction was negative. His "fits" consisted of transient losses of consciousness when, if sitting up, he fell forward.

An E.E.G. on October 2, 1953 (before starting the diet), was reported as "abnormal and diagnostic of epilepsy." There were frequent sustained outbursts, bilateral and synchronous, consisting of irregular high-voltage slow activity associated with spikes. The special diet was started on October 9. His weight then was 31 lb. (14 kg.) and there was some initial loss, but within three weeks the weight curve was climbing steadily.

He was readmitted on January 18, 1954. No "fits" were seen and an E.E.G. showed "none of the previously recorded high-amplitude slow wave and spike." His weight was 32 lb. 8 oz. (14.7 kg.).

In May an E.E.G. showed "a medium-voltage dominant rhythm of about 5 cycles per second. From this background occasional brief high-voltage specific epileptic outbursts occurred, having generalized distribution and consisting of slow waves associated with spikes. There was considerable general improvement over the first record of October 2, 1953."

An E.E.G. on August 3, 1954, showed a medium-voltage activity of 5 cycles per second dominant, but no well-sustained rhythmical runs of activity. No specific epileptic activity was seen. The weight was only 32 lb. 8 oz. (14.7 kg.) and there had been some difficulties at home. On ward "discipline" he gained nearly 2 lb. (0.9 kg.) in a few days, and was later transferred to the branch hospital at Tadworth, where a further weight gain was recorded.

An interesting observation was that his hair, which was almost ash-blond when he was admitted, became noticeably darker during the special diet period.

Case 2

One older brother of this child is a proved phenylketonuric ament. The parents are of normal intelligence, do not excrete phenylpyruvic acid, and are unrelated; one parent comes from Yorkshire and the other from Cheshire. The pregnancy was normal and delivery normal at full-term. The child appeared to recognize her mother at the age of 6 to 8 weeks. She was 1 year of age before sitting up, stood at 2 years, and walked at 2 years 4 months. She had had no illnesses and there had been no fits.

At the age of 2 years/7 months the state of mental retardation was confirmed, phenylpyruvic acid was found in the urine, and she was admitted for dietary treatment. This was started on October 21, 1953, when her weight was 33 lb. 4 oz. (15.1 kg.). There was a slight initial loss, which was quickly regained. Nearly a year later, after a continuous period of the special diet, she weighed 38 lb. 11 oz. (17.5 kg.).

The skull was a trifle small, measuring 19 in. (48 cm.) in circumference; the fontanelle was closed. There was no evidence of disease in the central nervous system other than the mental backwardness. The disks were normal. An E.E.G. was considered to be within normal limits; there was no evidence of epilepsy.

The hair, very pale originally, became darker during the year of treatment.

Case 3

One older brother of this child is a proved phenylketonuric ament, an older sister is mentally normal and does not excrete phenylpyruvic acid. The parents are Irish, unrelated, of normal intelligence, and do not excrete phenylpyruvic acid. The pregnancy was normal and delivery normal at full-term. Nothing abnormal was noted during the first three months of life and then it was thought the child did not recognize her parents. She could sit unsupported by 1 year, and by 15 months showed signs of recognizing her parents.

At this time (1951) she started having "fits" of a petit-mal type and occasional major attacks in which she screamed and fell forward unconscious, the attack lasting two or three minutes. Phenylpyruvic acid was found in her urine. The Wassermann reaction was negative. An E.E.G. showed generalized spike-and-wave discharges.

At the age of 18 months an attempt was made to assess her intelligence in Guy's Hospital, and her mental age was put at 8 months. She was given a trial of glutamic acid for six months, but showed no improvement (Woolf and Vulliamy, 1951). Aloxidone was given for the fits, resulting in partial control, but the fits ceased abruptly when amphetamine sulphate was added in December, 1953. At the age of 3 years she could stand when holding a support. She was admitted for dietary treatment at the age of 5 years 4 months.

Physical examination showed that she was well developed for her age. She would not sit erect and preferred a flexed posture, making frequent rocking movements and dribbling saliva. There was a divergent strabismus, but no other signs of abnormality in the cranial nerves or central nervous system. An E.E.G. on April 30, 1954, showed, when sleeping, generalized slow spike-and-wave complexes.

The phenylalanine-free diet was started on May 3, when her weight was 35 lb. (15.9 kg.). There was an immediate gain, followed by a steep fall. Then she showed a steady gain except during the acute episodes described later. On September 16 she weighed 40 lb. (18.1 kg.).

After 25 days on the diet low in phenylalanine (May 28) she had a curious attack of unconsciousness with severe twitchings of arms and neck. Similar episodes lasting an hour or so at a time continued for three days, and cardiac failure then developed with persistent tachycardia. Digoxin, primidone, aloxidone, and amphetamine sulphate were given, the fits came under control, the general condition of the heart and circulation gradually returned to normal, and digoxin was stopped.

This child's hair also darkened considerably during the period of the special diet—even more so than in the other two patients.

Psychological Observations

The scale of tests used for these investigations is the "Griffiths mental development scale for testing infants from birth to 2 years." This scale was recently devised and standardized on a fairly representative sample of about 600 babies ranging in age from 2 weeks to 2 years (Griffiths, 1954). The severe retardation of the cases to be studied brings them well within the range of these tests in spite of their higher chronological ages. The scale consists of 260 finely graded items placed in strict order of difficulty on a percentage basis. The items are classified and divided into five subscales which measure separately five significant aspects of development: A, locomotor-development; B, personal-social development; C, hearing and speech

development; D, hand and eye co-ordination; and E, performance. These five subscales are very closely equal in difficulty at each month of age throughout the scale. It is therefore possible to compare a child's level of attainment in several directions at once and watch the changing development as the child's interests swing from one aspect of learning to another.

Case 1

First Test

October 6, 1953, and before treatment began. Chronological age (C.A.), 137½ weeks; mental age (M.A.), 27½ weeks; general quotient (G.Q.), 20.

The child was excessively fatigable, and could concentrate for only very brief periods.

The profile, with the trough at C (Table IV), is suggestive of deafness. The child made no responses to auditory stimuli—bells, tuning-fork, the human voice. Subsequent results go to show, however, that this boy now hears quite well, and we can safely regard this early lack of response to sounds as functional rather than organic. All the results at this time showed a low-grade defective level with general quotient 20.

The child could sit in his cot among pillows and take his weight a little when held on his feet, but could not lift his head when lying in the dorsal position, roll from back to stomach, or make any attempt towards crawling. (Q.A. 21.)

He could smile and laugh, recognize his mother, stop crying when talked to, look at himself in a mirror, etc. (Q.B. 20.)

There was some slight vocalization and one-syllable cooing, but no definite response to auditory stimuli. (Q.C. 8.)

He was somewhat better at manipulation, but thumb opposition was not yet complete and he could manipulate only one object at a time; when offered a second, he immediately relinquished the first. He could pass a cube from one hand to the other, and did this continually with objects given to him. He played with paper. (Q.D. 25; Q.E. 25.)

Second Test

January 20, 1954, three months after diet was started. (C.A., 151½ weeks; M.A., 34½ weeks; G.Q. 23.)

As before, there was very slight ability to respond or concentrate. Some progress in the total result had been achieved, particularly in the direction of speech (Table IV). The total quotient had risen by three points to 23 and the profile had become more even, the trough at C being very largely corrected.

Some slight progress was recorded in regard to locomotor development. His lower limbs were still feeble and underdeveloped; there was no attempt at crawling. He could lift head and shoulders in the dorsal position, sit alone on the floor, make stepping movements when held up, and almost stand when held. (Q.A. 24.)

He was taking more notice of people, beginning to return affection, and responding more definitely to situations. (Q.B. 23.)

Quite remarkable progress had taken place in the direction of speech. He was now able to shout, make sing-

ing noises, respond and listen to sounds (bell, tuning-fork, stop-watch). He was making more noises but no clear syllables yet. (Q.C. 21.)

There was practically no progress yet in scales D or E. (Q.D. 24, Q.E. 22.)

Third Test

April 7, 1954, six months after diet was begun. (C.A., 162 weeks; M.A., 44½ weeks; G.Q. 28.)

This test indicated definite progress in each of the five scales. The improvement at speech was being maintained and accelerated. Also scales D and E showed definite movement forward (Table IV).

The total quotient had risen by five points, to 28, since the previous test. Considerable progress had been made all round. Manipulation of objects was increasing and becoming more effective.

At this time the child could sit himself up from both prone and dorsal positions, walk round the railings of his cot and playpen holding on, pivot on the floor, and roll over to get about. He was not yet crawling. (Q.A. 29.)

The child was also reacting more normally to the presence of people; he looked at them more definitely and co-operated in activities better. (He gave the impression that he had "become a human being.") (Q.B. 26.)

At speech he was making slow but definite progress. Most significant was the improved capacity to attend to sounds (active listening). (Q.C. 25.)

A gain of as much as six and seven points was recorded in scales D and E respectively. Thumb opposition had become complete. He showed preference for the right hand and was handling toys and materials with more interest and more efficiently. (Q.D. 30; Q.E. 29.)

Fourth Test

August 4, 1954, ten months after diet was begun. (C.A., 179½ weeks; M.A., 53½ weeks; G.Q. 30.)

This test showed quite dramatic progress in this child on scales A, B, and C, but practically no movement on scales D and E, on which he made such remarkable improvement between the second and third tests. This produced again a changing profile (Table IV).

The total quotient had again risen somewhat, though not so much as during the previous period. None the less, the results suggest that further and most important stages had been reached in several directions.

The boy could not only balance on his feet and stand alone but had begun to walk alone. He demonstrated this by taking half a dozen steps between the mother and the psychologist in the ward. This brought him well into the second year for locomotor development. From this time on he no longer sat endlessly in his cot, but was eager to be moving about the room. (Q.A. 33.)

He was much more alert and aware of people. He obeyed simple commands, played pat-a-cake, and tried to "help" with dressing. His facial expression had become quite different, alive, watching people, laughing at the examiner's approach, and wanting to be lifted up. He accepted and returned affection. He helped to hold the cup when drinking, but could not yet manage a spoon to feed himself. (Q.B. 29.)

TABLE IV.—Case 1

Test No.	Chronological Age (Weeks)	Mental Age (Weeks)	General Intelligence Quotient	Subscale A Locomotor		Subscale B Personal-Social		Subscale C Hearing and Speech		Subscale D Hand and Eye		Subscale E Performance	
				Mental Age (Weeks)	Q.A.*	Mental Age (Weeks)	Q.B.*	Mental Age (Weeks)	Q.C.*	Mental Age (Weeks)	Q.D.*	Mental Age (Weeks)	Q.E.*
1	137½	27½	20	28½	21	26½	20	11½	8	35	25	35	25
2	151½	34½	23	36½	24	35	23	31½	21	36½	24	33½	23
3	162	44½	28	46½	29	41½	26	40	25	49	30	47½	29
4	179½	53½	30	59½	33	52½	29	57½	32	49	27	49	27

* Q.A., Q.B., Q.C., Q.D., and Q.E. are the intelligence quotients (subquotients) calculated on subscales A, B, C, D, and E respectively.

Speech showed improvement greater than in any other direction. He could say two clear words and produced much meaningful babble. He tried to sing, knew his own name, and enjoyed and recognized familiar rhymes. (Q.C. 32.)

At the sitting stage he had made a remarkable spurt in scales D and E (between the second and third tests), but now that he was on his feet this new activity claimed his interest, together with his newly found skill at verbal expression. (Q.D. 27; Q.E. 27.)

Case 2

First Test

October 16, 1953, immediately before the diet was started. (C.A., 138½ weeks; M.A., 58½ weeks; G.Q. 42.)

The child was much less severely retarded than Case 1 and was already walking. As with Case 1 this child showed great fatigability and sleepiness.

The results produce an unusual profile (see Table V). The child did best at locomotor development. She was walking alone but with an unusual gait, her feet rather wide apart and swaying from side to side, like a child of 14 to 15 months just learning to walk. (Q.A. 54.)

She showed friendliness and liked attention from adults, but became easily excited when noticed. An affectionate child, she put her face up to her mother, but, like a 12-months-old baby, she was unable to kiss. She could hold a cup for drinking, take off her shoes and socks, etc. She liked her mother to show pictures to her, but was not able to recognize objects in pictures. (Q.B. 49.)

Her level at speech was very low. The mother reported that the child used to say one or two words but had ceased to do so. There was no indication of deafness. She enjoyed rhymes and responded to auditory tests including the voice. (Q.C. 36.)

Her hands were developed only to a 12-months level. She could point with her index finger, and thumb opposition was complete. She held a pencil and made a slight mark with it. (Q.D. 39.)

At performance she did poorly. She could rattle a box and crumple paper, but had no other interest in objects except to carry them to her mouth or send them to the floor. (Q.E. 32.)

Second Test

January 18, 1954, three months after diet was started. (C.A., 152 weeks; M.A., 70½ weeks; G.Q. 46.)

Genuine improvement in the child's condition had taken place since she was first seen. Although progress was slow, it was definite and noticed in all directions. She was more active and alert, and firmer on her feet. The general quotient had risen by four points to 46.

Locomotor development was at this time still somewhat ahead of the other scales. She was trotting about like a child of 18 months, able to climb into chairs and climb up stairs (but not down), and had improved in balance and liked pushing a pram, etc. (Q.A. 52.)

In personal-social development she "showed shoes" on request, pointed out "hair" and "hands," and had begun to use a spoon. Her relationship to people was developing. (Q.B. 47.) Speech, still poor, was developing very slowly. (Q.C. 38.) At manipulation, considerable improvement was

shown. She had learnt to roll and throw a ball, to scribble on paper, and to play a little with toys, pushing cars, etc. (Q.D. 51.) At performance she not only rattled the boxes, but opened them and explored the contents, and did the first two items of the form-board series. (Q.E. 44.)

In this case, as with the first, the profile is seen to change as the child begins to progress and take interest in her surroundings.

Third Test

April 14, 1954, six months after diet was started. (C.A., 164 weeks; M.A., 77 weeks; G.Q. 47.)

The third test showed the child maintaining progress at her new level and developing more in relation to speech, the general quotient remaining approximately the same. The profile has become more even (see Table V).

Only slight progress was made in regard to walking. She was at this stage more competent on stairs and climbing about more. (Q.A. 50.) In social development also there were very few gains, only five weeks' progress being achieved in the three months. (Q.B. 47.) At speech, however, very great progress was made, 16½ weeks' progress being recorded. At this stage she had a vocabulary of about 10 words, clearly and consistently used, and could identify objects by name. (Q.C. 45.)

Only slight progress was recorded on scales D and E. (Q.D. 47; Q.E. 44.)

Fourth Test

July 14, 1954, nine months after dietetic treatment began. (C.A., 177 weeks; M.A., 86½ weeks; G.Q. 49.)

This examination showed the child maintaining the improvement achieved earlier, and the general quotient was again slightly improved (Table V). The general shape of the profile is much as it was in the previous test, and is still fairly even, except that scales A and B still tend to be somewhat higher than the other scales.

The child had ceased to climb stairs on hands and knees and was able to walk up and down holding the banisters. She could run and jump. (Q.A. 53.) She was learning self-help to some extent, could open doors, feed herself with a spoon more competently, and point out three parts of the body. (Q.B. 51.) She had a vocabulary of about 16 words, recognized pictures, and was beginning to name them. (Q.C. 48.) Only slight progress could be reported on scale D. (Q.D. 45.) She showed more definite interest in performance material. She did form-boards and brick boxes to a 20-months level. (Q.E. 48.)

Case 3

This little 5-year-old girl was seen before treatment was started, and given the Griffiths scale. She was seen again after periods of 9 weeks and 21 weeks on the diet. This child being older than either of the other two cases, the severe retardation produces a still lower quotient.

First Test

April 21, 1954. (C.A., 278½ weeks; M.A., 30½ weeks; G.Q. 11.)

When seen in April this child was in most respects like a child of about 7 months' mental development (see Table VI). She was somewhat more advanced than this in locomotor development and less advanced in regard to hearing and speech.

TABLE V.—Case 2

Test No.	Chronological Age (Weeks)	Mental Age (Weeks)	General Intelligence Quotient	Subscale A Locomotor		Subscale B Personal-Social		Subscale C Hearing and Speech		Subscale D Hand and Eye		Subscale E Performance	
				Mental Age (Weeks)	Q.A.*	Mental Age (Weeks)	Q.B.*	Mental Age (Weeks)	Q.C.*	Mental Age (Weeks)	Q.D.*	Mental Age (Weeks)	Q.E.*
1	138½	58½	42	74½	54	68½	49	50	36	54	39	45	32
2	152	70½	46	79½	52	72	47	58	38	77	51	67	44
3	164	77	47	82	50	77	47	74½	45	77	47	72	44
4	177	86½	49	94½	53	89½	51	84½	48	79½	45	84½	48

* Q.A., Q.B., Q.C., Q.D., and Q.E. are the intelligence quotients (subquotients) calculated on subscales A, B, C, D, and E respectively.

The child could sit alone, and sat rocking back and forth in the cot. She twisted her rather thin limbs about in unusual positions. She could roll over and turn around on the floor, but could not crawl. She could not pull herself up to stand, or balance holding on to a support. She could make stepping movements when held in a standing position and encouraged to try to walk (an eighth-months item). (Q.A. 14.)

She appeared indifferent to strangers, but gradually began to co-operate to some extent in the examination. She reacted to her mirror image, smiling and turning the mirror over as if in search of the child in it. She was not yet drinking from a cup but was still on the bottle. (Q.B. 10.)

She could make a few vague noises and blow bubbles like a young baby. She had a vocabulary of four vague sounds (er-er, ah, m-m-m, g-g-g). She listened to the tests with bells, tuning-fork, and voice. (Q.C. 8.)

Manipulation was very poor. She could attend to only one small object at a time. She could not retain two cubes; when offered a second one she invariably dropped the first. She could pass a toy from one hand to the other, and did this continually. Thumb opposition was complete. (Q.D. 11; Q.E. 11.)

Second Test

June 23, 1954, nine weeks after treatment started. (C.A., 287½ weeks; M.A., 40½ weeks; G.Q. 14.)

The child showed marked improvement in appearance. She seemed to be more active mentally, and definitely more able to co-operate. Dropping of saliva had ceased. She looked at the examiner and appeared to remember (see Table VI).

Some slight progress had been made in locomotor development, the child being more active on the floor, rolling, lying, and sitting, frequently changing her position in order to secure toys beyond her reach, but without actually crawling. She could still not pull herself to standing. (Q.A. 15.)

Social progress was quite good. She had learned to drink from a cup instead of the bottle previously used. She turned her head to people talking and took more interest in her surroundings. (Q.B. 13.)

The child was now able to pay better attention to sounds—bells, tuning-fork, watch, etc.—and listened to the voice of the examiner, but the simpler, clearer sounds of the instruments gave definite pleasure. She herself could make many sounds and noises; no definite speech, nor prolonged babble, but cooing, cooing, squeaking noises, much like a young baby makes. She tried to sing. (Q.C. 12.)

On the manipulative scales D and E progress was most pronounced. The right hand had become dominant. She was handling objects more freely, still spending much time passing toys from hand to hand and back again. She accepted the third cube, and watched the scribble but did not handle the pencil. She could take the lids off the test boxes and remove the bricks. She did not understand the first form-board. (Q.D. 15; Q.E. 16.)

Third Test

September 15, 1954, 21 weeks after start of diet. (C.A., 299½ weeks; M.A., 42½ weeks; G.Q. 14.)

The child's reactions during this third test were very similar to those made at the second test. She passed only

six new items. After the rapid progress made between the first and second tests, there was in this second period a slowing up of development. At the same time there was no deterioration. On the contrary, her progress was sufficient to maintain the slightly higher quotient that she showed at the second test. Her progress rate over the entire period of 4½ months was 55.5.

At locomotor development she had gained two points (Q.A. 15). No progress can be reported on scales B (Q.B. 12) or C (Q.C. 12), where her mental ages remained the same; but slight gains were made on scale D, hand and eye development (Q.D. 16) and scale E, performance (Q.E. 16).

[NOTE ADDED DECEMBER 16, 1954.—The three children continue to progress: Case 1, at C.A. 44½ months, had M.A. 14 months, G.Q. 31, and no epileptic activity; while Case 2, at C.A. 191 weeks, had M.A. 100 weeks, and G.Q. 52.]

Chemical Investigations

In each case at least one 24-hour specimen of urine and a corresponding specimen of blood were obtained before starting the diet. Once the child was placed on the diet single specimens of urine were obtained daily until it went home, in addition to one or more complete 24-hour specimens of urine and corresponding blood specimens once the diet was stabilized. At home the parents collected single specimens of urine at weekly intervals and sent them, preserved with chlorbutol and acetic acid, to the laboratory. Every three months, when the child returned for an intelligence test, a complete 24-hour urine specimen and a specimen of blood were obtained.

The blood specimens and the 24-hour urine specimens were examined by paper chromatography for amino-acids (Woolf, 1951b). In addition there was determined, on the 24-hour specimens of urine, phenylpyruvic acid (Berry and Woolf, 1952), phenylacetylglutamine (Woolf, 1951a), and phenylalanine and phenyllactic acid (Kapeller-Adler, 1932; Woolf, unpublished). The daily or weekly single specimens of urine were used for a qualitative ferric chloride test for phenylpyruvic acid.

In Cases 1 and 2 phenylpyruvic acid could no longer be detected in the urine by the tenth day after starting a completely phenylalanine-free diet. Then 8 oz. (230 ml.) of milk was added daily for nineteen days; no phenylpyruvic acid could be detected in the urine either by the direct ferric chloride test or by the far more sensitive method of Berry and Woolf (1952). The milk was increased to 10 oz. (285 ml.) daily, phenylpyruvic acid remaining undetectable in the urine for 28 days, when it became just detectable by the direct ferric chloride method. The milk was then dropped to 8 oz. (230 ml.) daily and kept there, no more phenylpyruvic acid appearing in Case 2. In Case 1 occasional weak positive reactions and, later, strong ones were obtained from urine specimens sent from his home. The mother admitted that he had occasionally been fed food not included in the diet.

On the diet phenylalanine quickly dropped to a low level in both blood and urine, but remained a little above the normal; phenyllactic acid, and the unidentified phenolic keto-acid (Berry and Woolf, 1952) vanished, and phenylacetylglutamine dropped to the normal level.

TABLE VI.—Case 3

Test No.	Chronological Age (Weeks)	Mental Age (Weeks)	General Intelligence Quotient	Subscale A Locomotor		Subscale B Personal-Social		Subscale C Hearing and Speech		Subscale D Hand and Eye		Subscale E Performance	
				Mental Age (Weeks)	Q.A.*	Mental Age (Weeks)	Q.B.*	Mental Age (Weeks)	Q.C.*	Mental Age (Weeks)	Q.D.*	Mental Age (Weeks)	Q.E.*
1	278½	30½	11	40	14	28½	10	23½	8	31½	11	30	11
2	287½	40½	14	41½	15	36½	13	36	12	42½	15	45	16
3	299½	42½	14	45	15	36½	12	36	12	47½	16	46½	16

* Q.A., Q.B., Q.C., Q.D., and Q.E. are the intelligence quotients (sub-quotients) calculated on subscales A, B, C, D, and E respectively.

In Case 3 the withdrawal of phenylalanine from the diet produced more dramatic results, all phenylpyruvic acid vanishing from the urine by the third day. Milk (10 oz. (285 ml.) daily) was added to her diet on the fourth day, but phenylpyruvic acid did not reappear in the urine. The blood phenylalanine level dropped to normal by the third day after withdrawal of phenylalanine and continued to drop, being below normal by the eighteenth day and completely absent on the twenty-eighth day, in spite of the presence of phenylalanine in the diet; later the phenylalanine levels in blood and urine returned to normal. Phenyl-lactic acid, phenylacetylglutamine, and the phenolic keto-acid had dropped to normal levels by the tenth day after starting the diet.

Discussion

The results of the psychological testing prove conclusively that there is at least in some cases considerable intellectual improvement in phenylketonurics fed a diet low in phenylalanine. The increase in the general intelligence quotient, from 20 to 30, in ten months in Case 1 is highly significant, as is that in Case 2 (from 42 to 49 in nine months). It is extremely unlikely that such an improvement, as indicated by mental testing, would ever occur spontaneously in children with phenylketonuria. The changes in these two children have been dramatic. The boy (Case 1) lay inert, sleepy, unaware of much that was going on around him and subject to frequent slight epileptic attacks. Unable to do more than sit among pillows, and endlessly finger-fanning or twisting his limbs about, with eyes half-closed, unable to roll over or sit himself up, with no speech other than the murmured vocalization of a very young baby, his general level was that of a child of 6 months. After ten months of treatment he is upon his feet, walking, has begun to talk, and is developing in all directions. This development goes forward irregularly, swinging now in one direction and now in another, but the total quotient shows the degree of mental growth that is definitely taking place. The girl (Case 2), not quite so severely handicapped, just beginning to walk when treatment was started, and without speech other than a few babbled phrases, is now able to run about more normally and has a small vocabulary of clearly spoken words, and has also developed socially.

Mental age plotted against chronological age for Cases 1 (J.J.) and 2 (G.W.). For discussion see text. (O) = Result of test on the Griffiths scale. ↑ = Point at which diet was started.

This improvement could result only if the mental deficiency were due to an intoxication by phenylalanine or one of its metabolites; there is evidence that the toxic agent is not phenylalanine itself (Woolf and Vulliamy, 1951), but more work is needed to prove its identity.

The concept of progress rate is particularly useful in evaluating the results of the diet. The progress rate is the increase in mental age divided by the increase in chronological age between tests multiplied by 100. Thus over a period of 43 weeks the mental age of Case 1 increased from 27½ to 53½ weeks; his progress rate over the period is $\frac{53\frac{1}{2} - 27\frac{1}{2}}{43} \times 100 = 60$. The progress rate can be defined as the slope of the curve of mental age plotted against chronological age and multiplied by 100 (see Chart). In the majority of children in whom the quotient is constant, the

progress rate is equal to the I.Q. and does not vary with time. An increase in progress rate to a new steady level indicates a mind that has improved and is maintaining its improvement. In such a case the new progress rate will be higher than the intelligence quotient, which will steadily rise. The I.Q., being a ratio, is always affected by the magnitude of the chronological age at the beginning of treatment.

The notation of the infinitesimal calculus can be used with advantage; if M represents the mental age, Q the intelligence quotient, t the chronological age, and R the progress rate,

$$\text{then } Q/100 = M/t$$

$$\text{and } R/100 = dM/dt;$$

$$\text{therefore } M = 1/100 \int_0^t R \cdot dt$$

$$\text{and } Q = 1/t \int_0^t R \cdot dt$$

$$\text{If } dR/dt = 0, \text{ then } Q = R.$$

If, at a chronological age t_1 , the progress rate changes from R_1 to R_2 , and these are constant from birth to t_1 and from t_1 to t_2 respectively, then, at the age of t_2 ,

$$Q = 100 \cdot M/t_2 = 1/t_2 \left(\int_0^{t_1} R_1 \cdot dt + \int_{t_1}^{t_2} R_2 \cdot dt \right)$$

$$\text{Therefore } Q = 1/t_2 (R_1 \cdot t_1 + R_2 (t_2 - t_1))$$

In the Chart the mental ages of Cases 1 and 2 are plotted against chronological age. It is assumed that the progress rate was steady from birth (when the mental age was presumably zero, these children being normal at birth) to the time of withdrawing phenylalanine from the diet immediately after the first psychological test; it is not unlikely that the curve should be convex to the abscissa over this period—that is, decreasing progress rate—but we have no evidence in these or other cases that it should be concave or irregular. The three determinations of mental age after starting the diet in each case clearly lie on a new straight line of slope—that is, progress rate—considerably greater than that before the diet. The kink in each curve is sharp and would be even sharper if the curve before starting the diet were convex to the abscissa; it occurs at the time of starting the diet. From the curves the progress rate in Case 1 has increased from the assumed consistent value of 20 to 64, and in Case 2 from 42 to 76. The actual ratio between the total increase of mental and chronological age between the first and the fourth test gives a progress rate of 60 in Case 1 and 71 in Case 2.

The intellectual improvement has been maintained at a fairly steady rate over nine and ten months respectively and is therefore not a matter of a sudden spurt followed by a return to the previous rate. This sudden jump in progress rate to a high but fairly steady level and the consequent steady improvement in the intelligence level is just what would be expected if the brain were continuously under the action of a depressant that did not cause any irreversible damage to the brain tissue. It must be remembered that post-mortem examinations have failed to show any consistent changes in the brains of phenylketonurics (Corsellis, 1953).

In Case 3, though the result can only be regarded as preliminary, the initial improvement in progress rate, even though this dropped again, is so striking that it strongly suggests that even at the age of 5 years the brain has suffered relatively little permanent damage. The appearance, for the first time, of major epilepsy soon after this child was placed on the diet is unlikely to be due to coincidence. A possible explanation is that the cerebral cortex, for over five years under the action of a depressant, began functioning more actively once this agent was withdrawn, and at first cortical activity was poorly co-ordinated. This child is of interest for another reason: she shows clear evidence of a deterioration in intelligence before being placed on the diet. When first seen she was 15 months old and had an estimated mental age between 6 and 9 months (Woolf and

Vulliamy, 1951, Case 5), and her mental age was assessed at 8 months when she was 18 months old. Her mental age had not increased when seen at the age of 5 years 5 months, and her I.Q. has therefore dropped very considerably.

Petit mal is far more frequent among phenylketonurics than among the population as a whole, and an association of petit mal with phenylketonuria is generally accepted. The cessation of attacks of petit mal (formerly very frequent) in Case 1 and the change of the E.E.G. from a typical spike-and-wave pattern to a normal pattern when placed on a diet low in phenylalanine is particularly interesting; it suggests that the petit mal is due to the same intoxication as the mental deficiency and, like it, yields to withdrawal of the toxic agent.

In Case 1 the diet was not very strictly adhered to at home, particularly from the sixth to the tenth month. It seems probable that the reversion of the E.E.G. from normal to a rather improved epileptic pattern, and the decrease in the progress rate over this period, are associated with these dietary indiscretions.

The profile varies in an interesting way from test to test and from child to child. It is as though the small amount of mental energy available to these children becomes, at a particular stage, almost completely absorbed in one dominant phase of development.

The prognosis for these three children can be made only tentatively. If the intoxication theory is correct the improved progress rate may be maintained. The I.Q. at the age of 14 would then be about 70 for Case 2, and about 60 for Case 1. Either of these children may eventually reach an educable level. It may be possible to improve the diet in such a way as to raise the progress rate still further. However, the present progress rate, being below 100, may possibly indicate true, though relatively slight, long-term damage to the functioning of the brain. Only repeated psychological testing throughout childhood can settle this point.

The difference in final I.Q. tentatively predicted for the two children is the result of their differing progress rates, and their different mental and chronological ages when placed on the diet. These differences are in themselves interesting; presumably the children, had they not had this error of metabolism, would have had differences in innate intelligence—that is, different progress rates; the differences in mental age are, however, far greater than those to be expected for individuals chosen at random, and it is necessary to postulate a difference in degree of intoxication, whether due to differing concentrations of the toxic agent or to differing susceptibilities.

The difference between the mental and the chronological age at the time treatment is started is a "time lag" that may never be made good. The child who at 5 years has the mental age of a 7-months-old infant has to learn to babble and then to speak, and then to walk, omitting nothing of the developmental sequences before babyhood is passed. Even if, as the result of treatment, his progress rate became 100 at this age, this would enable him to make the same amount of progress in a year as would be made by a normal baby between 7 and 19 months of age. Then at 7 years his mental age would still be only 2½; only at 9½ would he reach a mental age of 5 years and be ready to start formal education, and then he would presumably progress at the normal rate for a 5-year-old. This raises special educational problems, such a child being clearly distinguished on the one hand from children of similarly low intelligence whose progress rate is constant and as low as their I.Q., and on the other from normal children. His educability should not be judged on the basis of his I.Q. but on his progress rate, starting formal education at a mental age of 5 years so far as administrative difficulties allow. Of course the progress rate of Case 1 is only 64, and that of Case 2 76, but their educability should have been more accurately assessed by the time these children reach a mental age of 5 years. It is, at present, useless to speculate

on the mechanism of learning for a brain structurally more mature than one corresponding to its mental age, or on the more distant problem of the age at which increase in mental age will cease.

Presumably the improvement in intelligence in these patients can be maintained only while a diet low in phenylalanine is adhered to, and any return to a normal diet would be likely to lead to re-intoxication. The economic aspects of this form of "treatment" must be considered. It has been estimated that the incidence of phenylketonuric amentia is about 4 for every 100,000 of the population. This gives a figure of about 1,600 patients for England and Wales—and without treatment most of these will eventually reach an institution, where the cost each week is said to average at least £5. The special dietary constituents—casein hydrolysate, tryptophan, tyrosine, the vitamin tablets (made in the pharmacy of The Hospital for Sick Children), the liver extract and choline (see Tables I and II)—cost 10s. 9d. a day at present prices. If all the phenylketonuric aments came under "treatment" and some form of central manufacture of the special diet ingredients could be organized, the cost would fall considerably.* The grades of many of these patients might be raised so that the ineducable become educationally subnormal and the E.S.N. group might get accepted at ordinary schools, thus saving the cost of institutional care. Later on, society may gain productive members. These financial considerations must, however, not be allowed to influence decisions on the treatment of afflicted individuals. The most important point is that if costly treatment is to be justified it must be started early. *This means that the urine of every baby or young child in whom there is the slightest suspicion of mental retardation must be tested for phenylpyruvic acid.* This is an extremely easy screening method: a few drops of 5% ferric chloride solution are added to the fresh urine; the appearance of a deep green colour (sometimes an opaque deep blue-grey owing to precipitated phosphates) within five minutes is a positive result. In phenylketonuric aments the test should be positive by the age of 3 weeks at latest.

The Diet

The diet has to supply adequate amounts of total nitrogen, the essential amino-acids, carbohydrates, fats, minerals, and vitamins. The bulk of the nitrogen is supplied as the charcoal-treated casein acid hydrolysate (hereafter called casein hydrolysate) now commercially available as a dry powder. Casein is a protein of quite high biological value—that is, it contains adequate amounts of all the essential amino-acids; an acid hydrolysate, unlike an enzymatic hydrolysate, is free from peptides which might complicate the removal of phenylalanine. L-Tyrosine and DL-tryptophan are added to the casein hydrolysate; L-tyrosine is not normally an essential amino-acid, but, since in phenylketonuria phenylalanine cannot, or can only very slowly, be converted to tyrosine (Jervis, 1947, 1953; Udenfriend and Bessman, 1953), tyrosine should be an essential amino-acid in phenylketonuria. DL-Tryptophan is harmless, has about 70% of the dietary value of L-tryptophan, and costs only one-tenth as much.

Phenylalanine is an essential amino-acid, the minimum requirement for a normal adult being 1.4 g. a day (Harte and Travers, 1947). A diet containing less than this causes a negative nitrogen balance, loss of appetite, and rapid loss of weight. The minimum daily requirement of phenylalanine for a young child is unknown. Phenylalanine is very rapidly converted to tyrosine in normal individuals (Woolf and Edmunds, 1950), but since this metabolic path is closed in phenylketonuria, less dietary phenylalanine should be required for anabolism by a phenylketonuric than by a normal person. The success of the diet depends wholly on this point; in effect an "unbalanced protein" with a deficiency of phenylalanine is being fed, and in a normal

* Reductions in the prices of the casein hydrolysate and of the other amino-acids had reduced the daily cost to 7s. 4d. at the time when proofs of this article were received.

individual this would result in reduced protein utilization and excessive nitrogen excretion, but the dietary amino-acids are balanced for a phenylketonuric. It follows that the best daily intake of phenylalanine in our cases could only be determined empirically. Phenylalanine is added in the form of whole milk, which contains 42 mg. of phenylalanine per oz. (1.35 mg. per g.) (Block and Bolling, 1951).

Since the diet is almost entirely synthetic, it seemed advisable to feed a salt mixture (similar to that fed by Rose, Johnson, and Haines, 1950), a comprehensive selection of vitamins as well as a liver extract, and arachis oil to supply arachidonic acid. *p*-Aminobenzoic acid was originally included in the vitamin mixture, but later excluded on the grounds that there was no proof that it played any part in human nutrition, and it might, at some future date, have complicated the sulphonamide treatment of an acquired infection. Tomato purée and agar-agar (to supply "bulk") were at one stage included in the diet, but they appeared to have no beneficial effect.

The mental ages of all three children being initially below 1 year, the diet was fed in the form of a soup. As their mental ages increased some of the starch, sugar, and fat was presented as biscuits or bread. Our latest patient (not included in this paper), with a mental age of over 2 years, has potatoes, carrots, and cabbage with, instead of the soup, a thick gravy flavoured with tomato purée; the phenylalanine in the vegetables is allowed for by reducing the amount of milk, which she has separately with a breakfast cereal; she eats fruit, jam tarts, and bread with butter and honey (both made with protein-free wheat starch), and even an egg may be allowed occasionally if the amount of other protein is correspondingly reduced.

The amount fed was varied with age according to the accepted desirable intakes of calories and protein nitrogen.

A careful watch was kept for any signs of incompleteness of the diet. While the children were in hospital they were weighed daily and their appetites watched. Their blood haemoglobin content and erythrocyte count were determined fairly often. Only when it was considered that they were thriving satisfactorily on the diet were they sent home, and they returned for examination at intervals. The weight loss while on a diet completely free from phenylalanine was expected; once phenylalanine was added to the diet (as milk) the children started gaining weight satisfactorily and their blood haemoglobin levels remained normal. It appears that the diet is adequate in all respects for normal health and development.

Choice of Subjects

Two factors suggested that children should be as young as possible when placed on the diet low in phenylalanine: (a) if the mental deficiency is due to an intoxication starting in the neonatal period and continuing throughout life, the brain may possibly become permanently damaged by prolonged exposure to the toxic agent; and (b) removal of the intoxicant would probably result, at best, in a child with the ability to learn and the intellectual content of a normal infant of the same mental age. There are, however, considerable difficulties in detecting mental retardation in the very young. It is worth emphasizing again that in every instance of mental retardation the urine should be tested for phenylpyruvic acid.

It may be argued that if a patient of initially relatively high level of intelligence is chosen, a socially useful person is more likely to result. On the other hand, a patient of initially low level would be expected to show a more clear-cut and dramatic effect. In practice, however, the number of children under 3 years of age in whom phenylketonuria is diagnosed is so small that there is little opportunity for choosing them on other grounds.

Where experimental therapy is prolonged, as in this case, the child will, in general, have to be treated at home. The parents must be able and willing to feed the child this rather complicated diet, and in accepting a child for treatment this had to be taken into account.

Summary

An economically practicable diet low in phenylalanine has been devised.

Three phenylketonurics (two idiots and one imbecile) have been fed this diet for four and a half to ten months. Their mental ages have been measured before and at intervals after starting the diet.

The rate of increase of mental age of all three rose markedly on the diet, their I.Q.s have risen, and they may reach educable levels.

One child ceased having attacks of petit mal and his E.E.G. became normal soon after starting the diet.

The other child with petit mal developed major epilepsy and status epilepticus on the diet, but later improved.

Otherwise normal physical health and growth were maintained.

It is concluded that the mental deficiency in phenylketonuria is due to intoxication by phenylalanine or one of its metabolites and can be relieved by decreasing the dietary content of phenylalanine. The petit mal may also be due to this intoxication.

We wish to thank Dr. P. R. Evans for permission to quote Case 3; Miss Dilliston for working out details of the diets; Dr. W. W. Payne, Mr. Rae, and Mr. Philips for helpful discussions; Mrs. S. Zisman and Mr. A. Jarrett for technical assistance with the laboratory investigations; Dr. D. A. Pond and Dr. C. C. Evans for the E.E.G. reports; the nursing staff for their intelligent co-operation; and the Research Committee of The Hospital for Sick Children for financial support.

Delivering the Florence Blair Memorial Lecture before the Liverpool Medical Institution on December 1, 1954, Sir CHARLES DODDS, F.R.S., spoke on two human menaces— infection and cancer. After briefly reviewing current theories on cancer, Sir Charles turned to the question of infection, a hundred years ago a scourge of equal mystery and seriousness to cancer. He wondered whether a lesson could be learnt from that study. The problem of infection had been solved by Pasteur's realization that the question of spontaneous generation must be settled finally before a real advance in biology could take place. It was his demonstration that the development in broths, etc., of living creatures was due not to their spontaneous generation but to their introduction from outside. This fact, that the air contained living organisms, was the basis of Lister's work which indicated clearly that infection of wounds came from outside. It might well be, Sir Charles continued, that a solution of the cancer problem would come from the application of some principle discovered as a result of general research. Also the possibility of what might be termed "a piece of luck" should not be entirely lost sight of.

DISAGREEMENT BETWEEN OBSERVERS IN AN EPIDEMIOLOGICAL STUDY OF RESPIRATORY DISEASE

BY

R. S. F. SCHILLING, M.D., D.P.H., D.L.H.

J. P. W. HUGHES, M.D., D.P.H.

AND

I. DINGWALL-FORDYCE

(From the Nuffield Department of Occupational Health,
University of Manchester)

The investigation of the incidence and severity of a disease in a community may depend on the clinician's skill in taking histories and observing physical signs. The less opportunity there is of using objective measurements, such as x-ray films, blood pressures, and blood counts, the more does the clinician have to depend on his skill and on the memory and veracity of the patient.

In a study of byssinosis in Lancashire cotton-workers the investigators had to depend almost entirely on their clinical observations and on the patients' histories, because, unlike most industrial pulmonary diseases, byssinosis shows no specific x-ray changes in the lungs. In its later stages the clinical picture is often that of chronic bronchitis with emphysema, which is endemic in Lancashire. The diagnosis is made on an odd but characteristic history of chest tightness and breathlessness on Mondays, gradually extending, as the disease progresses, to other working days (Schilling, 1952).

Cochrane *et al.* (1951) and Fletcher (1952) have shown that clinical observations in respiratory disease may be very unreliable. In this study, therefore, it seemed to be necessary for two investigators to examine each worker independently to see if the method of diagnosing byssinosis was reliable. The two examinations also made it possible to assess the reliability of a number of other clinical observations and of patients' histories.

This paper deals with the disagreement between observers, and shows that there was fair agreement in diagnosing byssinosis on the history, but some of the clinical data were so unreliable that they cannot be used to indicate the nature or the severity of disease.

Procedure

The subjects studied were 187 men aged between 40 and 60 years exposed to fine cotton dust in 27 mills and 88 men (the controls) of similar ages who worked in two factories in which there was no known hazard of industrial pulmonary disease and who had never been exposed to cotton dust. The survey was made between March and December, 1953. Each observer examined about half of the subjects in the first part of the survey and saw the other half in the second part. There was an interval of approximately four months between the two examinations of each worker. Practically all the 275 men were examined at their place of work, but a few were seen at their trade union office. All were seen privately and usually in a reasonably quiet room. Neither observer knew of the other's findings until the field work was completed.

An occupational history and a record of previous illness were taken at the first examination. Both observers asked detailed questions about chest complaints and examined each man for the following signs: clubbing of fingers;

cyanosis; movement of chest *en bloc*—in which the chest wall moves up and down as a whole, without showing the normal progressive expansion (Hart and Aslett, 1942); kyphosis graded as normal, moderate, severe; Hoover's sign—in the early stages of emphysema the subcostal angle remains constant during inspiration; as the disease progresses the subcostal angle is narrowed on inspiration; the observer's thumbs are placed symmetrically along the costal borders as indicators (Hoover, 1913); absence of apical impulse; abnormal chest sounds. Chest expansions and systolic and diastolic blood pressures were also recorded.

Results

Diagnosis of Byssinosis in the Cotton-workers

Both observers graded the men for byssinosis as follows: Normal no chest symptoms. Grade I chest tightness and/or breathlessness on Mondays only. Grade II chest tightness and/or breathlessness on Mondays and other days.

TABLE I.—Comparison of Byssinosis Grading in 183* Cotton-workers

	Grade	Observer A		
		Normal	I	II
Observer B	Normal	72	6	—
	I	6	47	17
	II	1	14	20

* Complete agreement in 139 men (76%). Agreement on the presence or absence of byssinosis (139:14, 17:179 men (93%).

* Four men could not be compared because their working conditions had changed completely when they were seen on the second occasion.

The observers disagreed in their findings in 24% of the subjects* (see Table I). On the actual presence or absence of byssinosis there was only a 7% disagreement, which was not due to one observer diagnosing byssinosis more readily than the other.

Clinical Signs

For signs recorded as either present or absent the observer error was considerable, and ranged from 30% in absent apical impulse to 4% in cyanosis (Table II). These figures, however, tend to exaggerate the reliability of the observers in detecting those abnormalities which were found infre-

TABLE II.—Observer Error in Clinical Signs in 275 Men

Clinical Sign	Agreement		Disagreement			
	Found by		Found by		Observer Error	Significance

Cyanosis	265	0	10	0	10 (4%)	A > B P < 0.001

quently. For example, Observer A found 10 men with cyanosis and B none. Comparing the disagreement on the positive cases, A found significantly more men with kyphosis and cyanosis, and B significantly more men with an absent apical impulse and movement of chest *en bloc*.

The different findings of each observer for the cotton-workers and controls are compared in Table III. Observer A found similar incidences of abnormalities in both groups, and Observer B found consistently a higher incidence among the cotton-workers. A likely explanation of the different standards of diagnosis of the two observers is that either Observer A was biased against or Observer B was biased

* These percentage disagreements will from now on be referred to as observer error.

One observer appeared to be biased against and/or the other towards finding abnormalities in the cotton-workers. The same observer bias occurred in taking histories of symptoms.

The importance of observer error in epidemiological studies and possible methods of reducing it are briefly discussed.

We are grateful to the Medical Research Council for a grant to study byssinosis. We have had much helpful advice and criticism from our colleagues inside the Department and others, particularly from Dr. J. C. Gilson and his colleagues in the Pneumoconiosis Research Unit, and from Dr. C. M. Fletcher. The lateral x-ray films were read for kyphosis by Dr. J. C. Gilson and Dr. W. E. Miall. To all the above we gratefully acknowledge our indebtedness and to the many workers and employers whose co-operation has made this work possible.

CLINICAL EXPERIENCE OF THE INSULIN ZINC SUSPENSIONS*

BY

J. M. STOWERS, M.D., M.R.C.P.

Department of Medicine, University of St. Andrews, Dundee

AND

J. D. N. NABARRO, M.D., M.R.C.P.

Assistant Physician, The Middlesex Hospital, London,
formerly of the Medical Unit, University College
Hospital Medical School, London

In introducing the insulin zinc suspensions, Hallas-Møller *et al.* (1952) claimed that they enabled the majority of diabetics requiring insulin to be controlled with a single daily injection. By mixing in different proportions the relatively quick-acting amorphous and the longer-acting crystalline forms, insulins with a wide range of prolonged action could be obtained. These mixtures were consistent in their effect, unlike, for example, those of protamine zinc (P.Z.I.) and soluble insulin (S.I.). The Danish workers found that a mixture of seven parts crystalline with three parts amorphous was suitable for most patients; this was placed on the market as "lente insulin" and is known in this country as insulin zinc suspension (I.Z.S.). The amorphous and crystalline forms are also available separately as insulin zinc suspension (amorphous)—I.Z.S.(A)—and insulin zinc suspension (crystalline)—I.Z.S.(C). It was claimed, too, that the absence of any foreign protein and the use of thrice-recrystallized insulin in the preparation of the insulin zinc suspensions reduced the incidence of sensitivity reactions. Preliminary studies in this country (Lawrence and Oakley, 1953; Oakley, 1953; Murray and Wilson, 1953; Nabarro and Stowers, 1953a, 1953b) confirmed these

*The results in this paper formed the basis of a communication given at the Annual Scientific Meeting of the British Diabetic Association on July 16, 1954.

findings, and the new insulins were made generally available in Great Britain in October, 1953. We have now used them in the routine management of 240 diabetic patients in the clinics at University College Hospital and in the Dundee area, and this report is a critical review of the results we have obtained.

Results

Patients already on insulin were selected for trial of the new preparations only if their previous regime was proving unsatisfactory. They therefore do not represent a cross-section of all diabetics requiring insulin, but rather some of the more difficult ones. A series of 205 patients already taking insulin have been tried on the insulin zinc suspensions, and the indications for transfer and the results obtained are shown in Table I. The term "poor control—hyper-

The sum of the number of indications exceeds the total number of patients because in a proportion multiple indications were present.

glycaemia" is used for patients with diabetic symptoms (thirst, polyuria, or unintentional loss of weight) or in whom the blood sugar was found to be over 250 mg. per 100 ml. on an ordinary day. Of the patients transferred because their previous regime involved multiple injections, 81% were satisfactorily controlled with a single injection of the new preparations. About 80% of those who had hyperglycaemia, diabetic symptoms, or repeated hypoglycaemic attacks were improved. Of those in whom the results of transfer have so far proved unsatisfactory, the trial was discontinued in 10 for reasons that are given in a subsequent paragraph. In the remainder further adjustments of the proportions of I.Z.S.(A.) and I.Z.S.(C.), as well as alterations of the diet, are being tried to improve the control of the diabetes.

The alterations in dose that were required when the patients were transferred from different insulin regimes to the insulin zinc suspensions are shown in Table II. Patients who had been taking two or three doses of S.I. usually

TABLE II.—Alterations of Dose in Transfer to I.Z.S.

needed little if any change in dosage, whereas those previously on a single dose of P.Z.I. required on an average 40% more. The difference between these two figures is highly significant, being five times the standard error. Patients previously using globin insulin (G.I.) or P.Z.I. plus S.I. required usually a slight increase in dose, but the differences do not attain the level of statistical significance. The alterations of insulin requirements that follow transfer from P.Z.I. or S.I. to the insulin zinc suspensions can to some extent be explained by the pharmacological properties of these insulins. P.Z.I., if given in a dose large enough to control postprandial hyperglycaemia in the day, is virtually certain to produce hypoglycaemia in the night or early morning. Therefore patients on P.Z.I. alone usually have to take a

smaller dose of it than of an insulin which acts mainly in the day and less at night, like I.Z.S. S.I., on the other hand, has a rapid hypoglycaemic action, which is apt to bring into effect counter-regulatory mechanisms for raising the blood sugar, and, to control this, extra S.I. may need to be given at the next injection. With some patients on two or three doses of S.I. this leads to an increase in the apparent insulin requirement. The moderate increase of dose in the case of patients previously taking G.I. or P.Z.I. + S.I. may reflect in part the closer attention accorded by the physician in an attempt to obtain optimal control with a new preparation. FitzGerald *et al.* (1954) found that four out of eight patients transferred from two doses of S.I. to the same total dose of I.Z.S. suffered a deterioration in control, and although this experience has proved exceptional in our series, it illustrates the variability in individual response in the same circumstances. It is such variations that require adequate numbers of cases to be studied before reliable conclusions can be drawn.

In deciding the initial dose to be given when transferring a patient to the new insulins the previous regime must be taken into consideration. If the patient was on P.Z.I. alone we now suggest an increase of 20% for the initial dose of I.Z.S., with patients on G.I. or P.Z.I. + S.I. an increase of 10%, and for those who had been taking two or three doses of S.I. the same total dose as before, assuming that the patient had been having an optimal dose of the previous insulin.

The present insulin dose of patients transferred to the insulin zinc suspensions is shown in the Chart. Most cases fell into the group requiring 30 to 70 units a day, but a

Chart showing the final dose of I.Z.S. in 230 diabetics.

number were well controlled on a single dose of over 100 units, and one patient takes 160 units. We have previously pointed out (Nabarro and Stowers, 1953b), that patients needing large doses may require more I.Z.S.(C.) than in the standard 3:7 mixture (I.Z.S.). On the latter these patients, despite the exclusion of a bed-time snack, tended to get early morning hyperglycaemia, and any attempt to increase the insulin dose resulted in the development of hypoglycaemia during the day. In this series we have so far found that about 14% of the patients required the addition of extra I.Z.S.(C.) to the standard I.Z.S. mixture, whereas only 2.5% needed extra I.Z.S.(A.). It therefore appears that, although 3:7 is the ratio most commonly required, a significant proportion of diabetics need a modification of the standard mixture. Results from other British clinics (Oakley, 1953; Venning, 1954) have differed to some degree regarding the proportions of patients needing more or less crystalline zinc suspension than is present in the I.Z.S. (lente) mixture. Such differences are probably based mainly on different distribution of the diet and a different timing of the blood

and urine tests. Where mixtures other than the standard I.Z.S. have been indicated, we provide them already mixed in sterile phials, or the more capable patients prepare them themselves. Since the 80 units per ml. strength of I.Z.S.(A.) and I.Z.S.(C.) has become available, it has been possible to provide special mixtures for patients with high insulin requirements.

It is our practice when transferring patients to the new insulins to review the distribution of the dietary carbohydrate. I.Z.S. acts most strongly between about 12 noon and 6 p.m., and therefore the carbohydrate content of the lunch and tea meals should be considerable. The usual distribution used for these patients is shown in Table III. A few tended to get hypoglycaemic before lunch, and in these the carbohydrate content of the mid-morning snack was increased. Dietary adjustments have proved a valuable help in improving control in patients taking the insulin zinc suspensions. The patients were advised to take their insulin

Lunch	..	32%			

three-quarters to one hour before breakfast when possible, in order to prevent the postprandial hyperglycaemia which occurs if the interval is shorter.

Nine patients were tried on the new insulins because they were getting sensitization reactions at the site of injection of their previous insulin, and in six there was a considerable improvement. One had been getting local reactions to P.Z.I. and continued to do so with the British I.Z.S.; they ceased, however, when Danish I.Z.S. was used.

The trial of the insulin zinc suspensions was abandoned in 10 cases. In one this was because local sensitization reactions were unimproved and the patient asked to return to his previous insulin, and in six there was a considerable improvement. One had been getting local reactions to P.Z.I. and continued to do so with the British I.Z.S.; they ceased, however, when Danish I.Z.S. was used. In the remaining eight cases the transfer to I.Z.S. was followed by a steep increase in insulin requirement, and in two ketosis developed. It was not an uncommon experience for the diabetes to escape from control following transfer, if the initial dose of I.Z.S. was the same as that of the previous insulin, especially if the latter was a single injection of P.Z.I. To regain control a large increase of dose was required, sometimes supplemented with S.I. In the cases mentioned above the trial of I.Z.S. was discontinued because the patient, and on occasion the physician as well, became alarmed at the increase of insulin requirement.

The steep increase of dose needed to regain control if the initial dose of I.Z.S. at the time of transfer had been inadequate has also been noted in patients well balanced on I.Z.S. whose stabilization has been upset by an intercurrent infection. When a patient on I.Z.S. becomes unbalanced the insulin dose must be increased more boldly to control the hyperglycaemia and avert ketosis than is the case with patients on S.I. or G.I. Three of our patients have developed ketosis after being satisfactorily balanced on I.Z.S. After treatment with S.I. two of them were re-balanced on I.Z.S. and needed a dose very similar to that taken before the episode of ketosis. This danger of the insulin zinc suspensions has so far not been emphasized. It is important to realize that if thirst and polyuria develop during an intercurrent infection the insulin dose should at once be increased by about 20%, and if the symptoms persist S.I. should be given before the later meals of the day.

In addition to the 205 patients already on insulin 35 new diabetics have been given the insulin zinc suspensions. In the more severe cases which required admission to hospital the symptoms were first controlled with S.I. and in the remainder the insulin zinc suspensions were used from the

start. These new preparations proved very satisfactory for the management of fresh cases of diabetes, and the final doses required are shown in the Chart. One of these patients has had mild local reactions at the site of the injections.

Discussion

Colwell (1954), in a recent editorial discussing the insulin zinc suspensions, suggested that "before new preparations are introduced it should be clearly apparent that they possess decisive advantages over those now available." If the value of the insulin zinc suspensions is to be assessed, the advantages and disadvantages of the insulins previously available must be reviewed briefly and compared with those of the new preparations.

Soluble Insulin.—S.I., with its quick action, is very valuable for emergency use in diabetic ketosis, and for conditions in which the insulin requirement is changing rapidly and is unpredictable—for example, in the presence of an acute infection or after surgery. On the other hand, if it is to be used for the day-to-day routine management of patients, at least two and often three injections are needed.

Protamine Zinc Insulin.—This form is suitable for the treatment of very mild cases, and the exact timing of the injection in relation to breakfast is relatively unimportant. However, its action is slow and the total duration prolonged (up to thirty hours or more). It acts as strongly by night as by day, and, in all but the mildest diabetics, if enough is given to control the daytime blood sugar, hypoglycaemia is apt to occur in the early hours of the morning. For this reason it is often necessary to supplement its action with a dose of S.I. given before breakfast, either mixed with the P.Z.I. or by a separate injection. If the mixing technique is used, inconsistent effects may result from variable degrees of mixing and from the variable excess of protamine present that tends to combine with the S.I. Diabetics requiring doses of 60 units or more may escape from control in the evening unless another dose of S.I. is given before supper. This means that the treatment is somewhat complicated, involving two or three injections daily and two kinds of insulin which have to be varied independently according to the timing of any hypoglycaemic attacks or hyperglycaemic peaks during the twenty-four hours. Regimes with P.Z.I. plus S.I. seldom lead to hypoglycaemic attacks in the late afternoon, a period that is rather difficult for working men with the small tea meal followed by the journey home. Patients taking P.Z.I. and S.I. in the morning and S.I. in the evening are able, when necessary, to vary both the time and the amount of the latter, and this may be very convenient for those who make a practice of dining out. Local reactions at the site of the injection are quite common, and these are usually due to the protamine content of the preparation.

Globin Insulin.—Diabetes of mild or moderate intensity may often be treated by a single daily injection of this insulin, and severe "brittle diabetics" may be well controlled by two injections—one given about three-quarters of an hour before breakfast and the second before tea or supper. Severe diabetics cannot be controlled with a single injection because its action is too short and the blood sugar rises in the evening and during the night. Hypoglycaemia tends to occur in the late afternoon and a large tea meal is required. Sensitivity reactions to the globin in this preparation are not uncommon.

Isophane (N.P.H.) Insulin.—This modification of P.Z.I. has only recently been made available in this country, although it is at present the most popular insulin in the U.S.A. It is designed to exert its hypoglycaemic action for twenty-four hours, and, since it contains no excess protamine to combine with the insulin, it can be mixed with S.I. without significantly modifying the rapid action of the latter. Apparently in a proportion of cases its action fails to last for the full twenty-four hours, and early morning hyperglycaemia may be troublesome. Like P.Z.I., it contains a foreign protein and, as would be expected, produces local sensitivity reactions in a number of patients.

The insulin zinc suspensions overcome many of the disadvantages of these preparations. The duration of action of the I.Z.S.(C.) is more than twenty-four hours, and during the day this can be reinforced by the addition of I.Z.S.(A.). The actions of mixtures of these two preparations are consistent and predictable, being those of the two insulins given separately. Most diabetics are well controlled on the 3:7 mixture—I.Z.S.—but a few require a different ratio. The insulin zinc suspensions cannot be mixed with S.I. because the acid in the latter overcomes the weak buffer in the suspensions, and, by lowering the pH, may modify the particle size and lead to unexpected alterations in the duration of action. This is not a serious disadvantage, because I.Z.S.(A.) and S.I. come into action at much the same rate and if it is necessary to accelerate the action of I.Z.S. it can be done by adding extra I.Z.S.(A.). The morning injection of I.Z.S. should probably be given three-quarters of an hour to one hour before breakfast, and this may be a disadvantage in later risers. The maximal hypoglycaemic action of I.Z.S. is in the afternoon; and if hypoglycaemic attacks at that time are to be avoided a good lunch and tea are required; some patients find this difficult to arrange.

The theoretical advantages of the insulin zinc suspensions have been borne out by our finding that 80% of the more difficult diabetics attending our clinics have benefited from being transferred to them. At the same time they have been in general use in this country for only one year, and it is possible that further experience will reveal shortcomings. We are a little apprehensive about the difficulty in regaining control with them once it has been upset by, for example, an intercurrent infection.

Summary

The results of a trial of the insulin zinc suspensions in 240 diabetic patients are described. Thirty-five were new patients and satisfactory stabilization was achieved. The remainder were transferred to the new insulins because their previous regime had disadvantages. Over 75% of these cases benefited from the transfer. Patients previously on a single injection of protamine zinc insulin needed a 40% increase in dose, those on other programmes with long-acting insulins needed smaller increases. Patients having two or three injections of S.I. were balanced on a similar total dose of the insulin zinc suspensions. When patients are being transferred to the new insulins it is necessary to take into consideration the type of insulin the patient had been using when assessing the initial dose of insulin zinc suspension to be given.

In the majority of patients insulin zinc suspension (lente), with the ratio three parts amorphous to seven parts crystalline, proved satisfactory: 14% needed a larger proportion of the crystalline and 2.5% a larger proportion of the amorphous.

The comparative advantages and disadvantages of the current British insulins have been reviewed. It is concluded that the insulin zinc suspensions have definite advantages over the other preparations, and that probably over 90% of all diabetics requiring insulin can be satisfactorily controlled by a single daily injection of suitable proportions of crystalline and amorphous insulin zinc suspensions. Attention is, however, drawn to the difficulty in regaining control with these preparations if the balancing of the diabetes is upset by an intercurrent infection.

Grateful acknowledgment is made to Dr. K. Hallas-Møller and to Evans Medical Supplies Ltd. for making supplies of I.Z.S. available to us before their general release, and to Dr. W. M. Wilson (Perth), Dr. R. McNeil (Maryfield Hospital, Dundee), and the physicians working in the Diabetic Clinic at University

College Hospital for their co-operation in this trial. We wish to thank the Lund Research Fund of the British Diabetic Association for a grant towards the work done at University College Hospital.

R. D. LAWRENCE, M.D., F.R.C.P.

Physician in charge of Diabetic Department

(From the Diabetic Department, King's College Hospital)

The clinical assessment of the new insulin zinc preparations introduced by Hallas-Møller *et al.* (1952a, 1952b) has necessarily been divided into two stages. The first, in which detailed observations were made on a small number of diabetic patients in hospital under controlled conditions, was necessary to verify their metabolic activity and provide familiarity with their clinical potentialities. Our own initial observations (Lawrence and Oakley, 1953; Oakley, 1953) have been confirmed by those of Drury (1953), Murray and Wilson (1953), Nabarro and Stowers (1953), and Venning (1954), all of whom obtained satisfactory results. From this preliminary work it was evident that in carefully selected and well-treated groups of patients a considerable measure of success could be obtained using insulin zinc suspension ("insulin lente"; I.Z.S.) in a single daily injection.

The second and equally important stage in its evaluation was the study of a large number of diabetics in conditions of everyday life. Variations in diet and activity, exposure to intercurrent disease, and the inevitable spontaneous day-to-day fluctuation in the diabetic state might lead to results at variance with those obtained in the earlier studies.

Present Study

This paper is based on our observations on 479 patients seen in the Diabetic Department of King's College Hospital, treated with I.Z.S. in the period July, 1953, to June, 1954. The length of treatment ranged from three months to one year, the majority having been maintained on I.Z.S. for over six months. When out-patients were changed to the

new insulin, readmittance was demanded during the first six weeks at intervals of a week or a fortnight. Special notes were kept with records of the night and morning urine tests for sugar and ketone bodies, blood sugar, weight, hypoglycaemia, local reactions, the patient's subjective observations, and alterations in diet. Some degree of selection was inevitable, as cases already on insulin tended to be chosen because they were judged likely to do well on I.Z.S., and those with insulin requirements of over 80 units a day were usually excluded. A relatively larger proportion of patients were, for instance, on protamine zinc (P.Z.I.) rather than soluble insulin (S.I.). Almost all new patients seen during this period were tried on a single injection of I.Z.S., those with severe ketosis being first treated with S.I. We must emphasize that at this time it was our policy not to alter the treatment of well-controlled diabetics, and only about 10% of insulin cases attending the clinic were changed to I.Z.S. The frequency of visits also made big demands on the patient's co-operation, and those who could not attend as often as we required were not permitted to change. The total of patients treated at King's College Hospital on I.Z.S., I.Z.S. amorphous ("semilente"), or mixtures of the latter with I.Z.S. crystalline ("ultralente") is now well over 700, and we think that enough clinical experience has been gained to justify a definite decision on their value.

Criteria of Control

There are no clear-cut criteria by which the clinical superiority of any type of insulin can be assessed. We have analysed our results so as to take into account both subjective and objective factors, and have compared these with the degree of control previously achieved using other types of insulin.

Subjective.—By this we mean the opinion of the patient concerning his well-being and freedom from hypoglycaemia and diabetic symptoms, as compared with his condition either before any form of insulin was started in new cases or on his previous regimen. Since the patient's attitude to any new form of therapy is likely to be biased this information is of limited value.

Objective.—To assess *absolute control* we have taken into account (A) the degree of night control as indicated by the early morning urine tests; (B) day control, judged by the blood sugar before the midday meal; and (C) alterations in weight. Night control was regarded as good when on at least 75% of examinations the early morning Benedict's test was blue or green (3+; one plus). Day control was accepted as satisfactory if the capillary blood sugar was under 200 mg. per 100 ml. (Folin and Wu). Changes in weight of ± 2 lb. (0.9 kg.) were ignored, and only larger variations were deemed significant. When both night (A) and day control (B) were good, and when weight was static or had increased (C), control was considered excellent and the A B C classification applied. As in many patients a slight loss of weight was desirable, we have grouped those with A B C and A B classifications together and described the control as good. When only one or two of the criteria were satisfied control was assessed as fair, and if none were satisfactory it was assessed as poor and recorded as O.

Comparative control was assessed in the same way by comparing the results achieved with I.Z.S. with those over a similar retrospective period of treatment with other insulins, and classified as better, the same, or worse.

Analysis of Results

In order to facilitate discussion we have divided our cases into the following groups:

Adults:	{ O'd insulin cases	..	..	312
	{ New cases	..	..	122
Children:	{ O'd cases	..	..	30
	{ New cases	..	..	15
I.Z.S. abandoned, including adults and children				46

Table I shows that 433 of the 479 cases receiving I.Z.S. remained on it at the close of the trial, and that in only 32 was this form of treatment regarded as a failure.

TABLE I.—Proportion of Successes and Failures in 479 Cases Treated with I.Z.S.

	No. Treated	Maintained	Abandoned	
			Failed	Other Reasons
Old cases	342	299	30	13
New ..	137	134	2	1
Total	479	433	32	14

Adult Old Cases

In the 312 adult old cases I.Z.S. was abandoned in 43, of whom only 30 were assessed as failures. The age distribution of the 269 patients who remained on I.Z.S. is shown in Fig. 1. Their previous insulin arrangements were as follows: S.I., 75; S.I. + P.Z.I., 94; P.Z.I. alone, 89; and globin, 11.

FIG. 1.—Age distribution of adult cases.

Subjective assessment (Fig. 2) showed that 43% (117) felt better on I.Z.S. than on their previous treatment, while 55% (147) noticed no change, and only 2% (5) felt worse. In this latter group objective control was, however, not necessarily any poorer. Assessment of control was equally satisfactory from both the *absolute* and the *comparative* point of view. Night control was good in 174 (65%), but bad in 83 (31%), whilst the renal threshold was sufficiently low in 12 to invalidate the urine tests. Day control was good in 179 (67%) and unsatisfactory in 90 (33%), proportions very similar to those for night control, though not necessarily

FIG. 2.—Analysis of results in adult old cases.

in the same patients. The correlation of these factors is mentioned later. There was a weight gain in 108 (40%), no change in 88 (33%), and a loss in 66 (24%), whilst in 7 (3%) the weight was unreliable because of oedema or significant alterations in diet. As shown in Fig. 2, absolute control was good in 53% (143), and bad in only 9% (29). Comparison with the degree of control on their previous insulin arrangements showed that 32% (84) were better, and that in 64% (172) control was the same. There were only 4% (10) in whom control was worse.

Alteration in Insulin Dose.—It is important to know whether this general improvement was in fact due to the superior action of I.Z.S. *per se* or merely to an increase in the total insulin dose compared with that administered

previously. The changes in dose are shown in Table II, an increase of over 10%, being made in 61%, whilst in only 28% was no significant alteration ($\pm 10\%$) necessary. Analysis according to the type of insulin previously administered showed that there was a dose increase of 10% or more in approximately the same number of patients on two injections of S.I. as on a mixed dose of S.I. and P.Z.I. It was in the group on P.Z.I. alone that the highest proportion

TABLE II.—Adult Old Cases—Change in Dose on Transfer to I.Z.S.

Dose Change	Original Insulin				Total	
	Two Injections of S.I.	S.I. + P.Z.I.	P.Z.I.	Globin	No.	%
Less	8	16	5	1	30	11
Same $\pm 10\%$	24	30	17	4	75	28
+25% ..	17	22	19	3	61	23
+50% ..	20	18	25	2	65	24
+75% ..	3	5	6	—	14	5
+100% ..	3	—	6	1	10	4
>100% ..	—	3	11	—	14	5

(75%) needed more insulin, and it was among these patients that the 100% rises occurred. This is probably because the dose of P.Z.I. was limited by the danger of nocturnal hypoglycaemia, control during the day being poorer than that achieved with an increased dose of I.Z.S., with which there is less risk of insulin reactions at night. From these

FIG. 3.—Absolute control on I.Z.S. in relation to previous types of insulin.

FIG. 4.—Comparative control on I.Z.S. in relation to previous types of insulin.

figures it can be seen that most patients needed a larger dose of I.Z.S. than of other types of insulin. In order to decide which patients could best be changed to I.Z.S. the results were analysed according to their previous insulin arrangements (Figs. 3 and 4). Our figures show that the proportion of patients in whom better control was achieved was remarkably similar in all groups. There was no evidence that improvement was directly related to increase in insulin dosage. It is, however, true that patients on very large doses of S.I. were rarely changed, and the highest dose of I.Z.S. that was used with success was 104 units.

Hypoglycaemia in Adults.—I.Z.S., like any other insulin may produce hypoglycaemia. The symptoms and signs are of the usual type, palpitations, sweating, and tremor being

the most common. The times at which reactions most commonly occurred are shown in Table III. Insulin reactions were reported by 119 of the 269 adult old insulin cases and by 35 of the 122 new cases. Only 5 experienced

TABLE III.—Incidence of Hypoglycaemia in I.Z.S.-treated Cases

	Old Cases	New Cases
Breakfast to lunch	84	28
Lunch to evening meal	55	7
Night to breakfast	32	5
No. of patients reporting reactions	119	35

severe reactions with loss of consciousness; the majority occurred between breakfast and lunch, with a smaller proportion between 4 and 6 p.m. It did not appear that I.Z.S. was particularly liable to cause hypoglycaemia or that the reactions were in any way different, more severe, or more difficult to prevent by carbohydrate buffers.

Adult New Cases

This group consisted of 122 patients, of whom 55 were men and 67 women. The age distribution shows a surprisingly high proportion in the third decade (Fig. 5).

FIG. 5.—Age distribution of adult new cases.

The treatment of new cases presents a less difficult problem because they are relatively insulin-sensitive, pay more attention to their diet, and usually do well in the early stages. The satisfactory nature of these results is shown in Table IV. To find out whether these results were

TABLE IV.—Comparison Between Control in I.Z.S. New Adult Cases and a Series on Other Insulins

	I.Z.S. Group	Control Group

Subjective assessment:		
Better ..	112	102
No change ..	8	18
Worse ..	1	2

better than with other types of insulin we have analysed the degree of control in a consecutive series of 122 new diabetics treated in a corresponding period in 1952 and 1953. It is impossible to obtain two strictly comparable groups, but it can be seen that subjective assessment showed little difference, slightly favouring the I.Z.S.-treated group. There was a higher proportion of objective successes with I.Z.S., particularly in day control, and the same proportion of patients gained or remained constant in weight in both groups. Since the control series included many combinations of S.I. and P.Z.I., nothing is to be gained from analysis of the incidence of hypoglycaemia, but reactions were slightly more frequent in the I.Z.S. group, in 28% of patients as compared with 23% in the controls.

Children

Under this heading we have included patients of 15 years or younger; the total of 45 is made up of 30 old and 15 newly diagnosed, the youngest being 2 years old. As with the adult patients, about 10% of the children attending the clinic were changed to I.Z.S., but a higher proportion were tried on I.Z.S. because previous control was poor. At least three were difficult diabetics in whom treatment by other means had been unsatisfactory.

Old Cases.—Subjective assessment of these 30 children based on their own and their parents' opinions revealed that half felt better on I.Z.S. and none felt worse. Assessment of absolute control was also satisfactory, being good in 12 and fair in 17, whilst in only one was treatment inadequate; this lad did not respond as well as was hoped to over 80 units of I.Z.S. a day, but control was slightly better than with two injections of S.I. Assessment of comparative control suggested that in no case did I.Z.S. give poorer results; 11 had improved and 19 remained unchanged. Gain in weight was often striking, and indicated that frequently there was room for improvement in previous régimes. Our observations accord with those of Engelson (1953), who found all 22 of his diabetic children improved by I.Z.S., but we would not agree that it is always as effective in what he terms the "brittle" cases.

New Cases.—During the past nine months we have used a single injection of I.Z.S. in all new cases, though we have treated no infants under the age of 12 months. These results, as with adults, have been encouraging. Absolute control was good in 12 and fair in 3.

Hypoglycaemia.—In this group of 45 children insulin reactions were experienced by 19, the incidence being high before lunch, lower in the afternoon, and most infrequent after supper or before breakfast. It did not appear that hypoglycaemia was unduly frequent or that the effect of physical activity or missed meals was any greater than with other insulins. Insulin reactions in children are apt to develop suddenly, and it is not surprising that they were severe in three patients.

Treatment Abandoned

At the close of the trial 46 (9%) of the 479 patients were no longer taking I.Z.S., but not all were failures. Only 3 of the 137 new patients had abandoned it, against 43 of the 342 old patients (see Table I).

The actual number of failures was as low as 32 (7%) of the whole series. The most common reason for failure was poor control, yet in many instances this bore favourable comparison with that achieved previously. Among the 20 patients with bad control, only 2 were worse on I.Z.S., the remainder being equally bad on both types of treatment. Seven patients in the failed group were unsatisfactory because of poor subjective assessment in spite of reasonable objective control, of whom five complained of diabetic symptoms and two of troublesome hypoglycaemia. The proportion of failures in patients transferred from two doses of S.I. and from mixed doses of S.I. and P.Z.I. was similar, but there were no failures among those changed from P.Z.I. alone. In most cases the dose of I.Z.S. had been raised by 20 to 100% before failure was acknowledged, and it seemed that lack of success was due to insulin insensitivity or inadequate dieting rather than to any primary fault in the insulin. Previous control had often been poor, and there was no doubt that in many such patients there was a definite improvement with I.Z.S. Five patients returned to their previous insulin arrangement after inadequate trial, in spite of apparently good control, sometimes because of undue alarm at the increase in glycosuria shortly after transfer, and also because of personal preference for the flexibility of two injections. It is a tribute to the value of I.Z.S. that no case in this trial had to be admitted to hospital because of ketosis due to the change-over, and that a reasonable dose never failed to correct loss of control due to minor infections.

Local Reactions

Local reactions were never bad enough to cause cessation of treatment, but in one case the injections were thought to be more painful than the previous mixed dose of S.I. and P.Z.I. Erythema and pain are often troublesome for a few weeks in any newly treated diabetic, and the impression has been gained that I.Z.S. is less irritating than the more acid soluble insulin. There were five patients in whom local reactions appeared to be worse on British preparations of I.Z.S. than on the original insulin lente, but to all intents and purposes there is nothing to choose between either preparation. It is too early to draw any conclusions about the incidence of fat atrophy or insulin tumour formation.

Discussion

These observations, coupled with a general clinical appreciation, have left us in no doubt that I.Z.S. is a valuable preparation. We can also confirm the opinion of Hallas-Møller that the proportion of I.Z.S. amorphous to I.Z.S. crystalline of 3 to 7 is a satisfactory one for routine use. It has not been possible to predict which cases are most likely to need significantly more of the new insulin, but some increase is usually found to be necessary, especially in patients changed from a single dose of P.Z.I. No patient should be changed to I.Z.S. without adequate supervision. An increase in glycosuria is very common for the first three or four days, until the prolonged action of the crystalline component is fully available, and patients should be warned of the possibility of this. When thirst or polyuria is troublesome a small additional evening dose of S.I. may be advisable for a few days. If after a week the urine tests are still bad, an increase of at least 10% should be made, with still further additions in the following week if necessary. We now usually prescribe a 10% larger dose of I.Z.S. from the start, and the patient is warned not to be disappointed at having to take more insulin.

Progress can be adequately followed by the usual tests provided the renal threshold is normal. For routine purposes the urine should be tested before breakfast and again before lunch, tea, or the evening meal, whichever gives the best result. Clearly it is unsafe to increase the dose of insulin if the urine is sugar-free at any of these times, and in this respect treatment with a single mixed preparation, such as I.Z.S., allows rather less latitude than varying mixtures of S.I. and P.Z.I., or I.Z.S. amorphous and crystalline. It is helpful to modify the dietary arrangements at the time of the change, or in new cases to give at least 160 g. of carbohydrate daily without restriction of fat or protein. A suitable distribution is as follows: Breakfast, 30 g. carbohydrate; mid-morning, 10 g.; midday meal, 40 g.; tea, 30 g.; supper, 30 g.; bedtime, 20 g.

Such a basic diet can usually be increased by the addition of more carbohydrate, especially at breakfast and the evening meal. Since I.Z.S. amorphous comes into action about half an hour later than S.I., it is wise, when convenient, to give the injection one-half to three-quarters of an hour before breakfast; the risk of hypoglycaemia is slight, and the immediate postprandial rise in blood sugar is controlled better.

When these precautions are taken a high proportion of patients on two doses of S.I. as well as those on a mixed dose of S.I. and P.Z.I. with a total daily dose of up to 80 units a day can be safely changed to I.Z.S. Once the dose has been properly adjusted, and an increase is to be expected, about one-third of the patients ought to secure better control of their diabetes. Provided the dose is increased sufficiently, nearly every patient on P.Z.I. alone does well, and there is no doubt that the blood sugar during the day runs at lower levels. Our experience over the last year has shown that I.Z.S. is a reliable insulin, certainly superior to P.Z.I. alone, and in many cases the equal of a mixed injection, or of S.I. alone, without the necessity of two injections. There is no reason why it should not be widely used in the future. Newly discovered diabetics, both

children and adults, should always be given the benefit of a single injection of I.Z.S. once severe ketosis has been dealt with. S.I. still remains indispensable during surgical operations, pregnancy, periods of severe ketosis, and in the treatment of diabetic coma.

Summary

I.Z.S. has been used in the treatment of 479 diabetic patients. The degree of control has been assessed both subjectively and objectively, the latter both from an absolute standpoint and in comparison with that achieved with previous forms of therapy.

In less than 7% of cases I.Z.S. was a failure, whilst 31% of adults and 37% of children previously treated with insulin were found to be improved.

I.Z.S., as at present constituted, is considered to be a satisfactory preparation which should enable an increasing number of diabetics to be adequately controlled on one injection of insulin a day.

Some practical points in the use of I.Z.S. and in the management of the patients are discussed.

We are indebted to Dr. Hallas-Møller and the Novo Laboratories in Copenhagen, as well as to Evans Medical Supplies Ltd., Liverpool, for generous supplies of Novo lente insulin. We also wish to thank the nursing, laboratory, and clerical staff of the Diabetic Clinic, particularly Sister Maureen Tomlinson, our out-patient sister, Mr. H. R. Millar, our chief technician, and Miss E. P. Comley, secretary to the department.

ADDENDUM.—Since we made the above analysis of our results with I.Z.S. our views on its usefulness and application to the treatment of diabetes have been modified by further experience. We are now convinced that there exists a recognizable group of patients in whom I.Z.S. fails to control hyperglycaemia and prevents ketosis. These cases are relatively insensitive to all the long-acting insulin preparations and cannot successfully be treated for any length of time without the use of S.I. Temporary control may sometimes be achieved with the use of large doses of I.Z.S., but this is poorly maintained, or completely lost, when infection or intercurrent illness further reduces insulin sensitivity. It is now our practice not to attempt to change over such cases to one injection of I.Z.S., but rather to leave them on some arrangement which includes the use of S.I.

At Barrow-in-Furness, as elsewhere in towns which have room to spread, new housing estates have developed on the outskirts. The additional child-welfare clinics which are needed to serve these new estates cannot yet be built, and the medical officer of health, Dr. James MacLachlan, has got over the difficulty by establishing a mobile clinic service in a second-hand single-deck omnibus at a cost of £1,500. The clinic contains three rooms, the rearmost being a waiting-room with accommodation for ten mothers; then comes the nurse's room, containing baby-scales and a weighing machine; and the third room is the doctor's, which has an examination couch, washbasin with gas water-heater, instrument stand, sterilizer, and desk. The rooms are warmed by convection heaters, specially modified for use with calor gas, and there are electric extractor fans in the roof of the vehicle. The water supply is carried on the roof, and waste water is collected in a tank under the floor. The staff consists of a doctor, a health visitor, and an ambulance driver. The usual clinic facilities are provided, including immunization and vaccination.

CRYING IN INFANTS AND CHILDREN*

BY

R. S. ILLINGWORTH, M.D., F.R.C.P., D.P.H.
D.C.H.

Professor of Child Health, University of Sheffield;
Paediatrician, Children's Hospital, Sheffield

Considering that crying is universal among children, and that the crying of children occasions so much distress to adults, there is comparatively little in the literature on the subject. In this paper I have attempted to bring together data concerning crying from my own experience and from a wide variety of sources.

How soon does a Child Cry?

He may cry before birth. There have been numerous reports in the literature about infants crying *in utero*—the so-called vagitus uterinus. King and Bourgeois (1947) collected 25 cases from the literature from A.D. 1800. According to Parviainen (1949) vagitus uterinus was renowned in fable and legend. He wrote that there are stories of it in ancient Hindu, Babylonian, Assyrian, Greek, and Roman writings. St. Bartholomew and Mahomet were said to have cried *in utero*. One child was said to have cried 14 days before birth. McLane (1933) described a case which occurred in an operating theatre. The cry was heard by all present, and a superstitious nurse spent the rest of the time on her knees in prayer. Crotty and Kuehnle (1948), in reviewing the subject, wrote that for a cry to be heard the membranes must have ruptured and air must have entered the uterine cavity. The cry may result from some manipulative procedure, or merely from uterine contractions. In the past vagitus uterinus was associated with a high foetal mortality, but it is thought (Field, 1943) that this was merely due to panic at what was wrongly thought to be foetal distress, with consequent precipitate efforts to deliver the child. The cause of crying *in utero* is unknown.

How does he Cry?

Charles Darwin was greatly interested in the manifestations of emotion in man and animals (Darwin, 1889), and went to great trouble to find out how animals in countries abroad expressed pleasure and displeasure. He wrote a very accurate account of the facial changes when a person cries. More recently Collins (1932) reviewed the literature on the subject.

Crying is normally involuntary, though some actors, including an occasional politician in a foreign country, appear to be able to produce tears at will. When a small child cries out when put into his bed at night, the cry is often voluntary at first, and has been termed the "testing cry," implying that it represents an attempt to get the mother back into his room (Illingworth, 1951, 1953), but if he fails to get his own way the voluntary cry is apt to be followed by an involuntary cry, with the shedding of tears and sobbing. According to Weingrow (1933) the crying centre is in a cerebro-thalamo-lenticulo-rubro-ponto-cerebellar pathway, connected by association fibres and tracts with many parts of the brain and cord. Magoun and his co-workers (1937) wrote that co-ordinated facial and vocal activity, like that seen or heard in man during the expression

*Based on a lecture given to the Doncaster and Harrogate Medical Societies in April, 1954.

of unpleasant emotion, is caused by electrical stimulation of a localized area in the mid-brain and pons of the monkey and cat. It is of interest that whereas in a peripheral lesion, such as Bell's palsy, there is paralysis of both automatic and volitional facial movements, in cases with a central lesion, causing a hemiplegia, there may be paralysis of volitional facial activity with normal automatic facial movements, in the way of laughing and crying.

The first sign of crying is often the flushing of the face and the wrinkling of the forehead. Darwin described the vertical wrinkles in the forehead when a child begins to cry, due to the contraction of the corrugator supercilii ("grief muscles") drawing the inner end of the eyebrows downwards and nearer together. Not infrequently the first sign of crying in a child is the pouting of the lower lip. Darwin wrote that oranges, gorillas, and chimpanzees show a similar pouting of the lower lip when they are annoyed. Another early sign of crying is trembling of the lower lip or alae nasi.

The next stage in crying is the drawing downwards of the corners of the mouth, so that the nasolabial folds are exaggerated. The upper lip is raised, and the mouth opens, assuming a square shape. The tongue is slightly elevated from the floor of the mouth and hollowed out, so that it is concave. It often trembles. The eyes close, and tears may then appear.

Darwin was particularly interested in the closure of the eyes during weeping. He and his friends showed that the tension of the eyeball increases during weeping, in association with the flushing of the face and engorgement of the superficial veins, and suggested that the closure of the eyes represents nature's effort to compress the eye to protect it from congestion. It is true that if one forces the eyelids open at the start of crying there is no congestion of the scleral vessels, but the vessels rapidly become filled with blood, while after a period of crying the eye is "congested" and pink. The closure of the eyes in crying may be of similar origin to their closure in sneezing or coughing.

Tears are not usually produced on crying till a baby is 3 to 4 weeks of age, and they do not run down the face until a few weeks later. Darwin accidentally showed, however, that in one of his own children tears were produced when he caught the eye with his coat sleeve, though no tears appeared on crying for a further three weeks. The shedding of tears, except in actors, is involuntary.

Collins (1932) reviewed the literature about weeping in animals, and concluded that no animals, not even crocodiles, shed tears. Deer are said to "weep" when they shed their horns, and Hamlet exclaimed, when the King stopped the play which was designed to expose his crime, "Why, let the stricken deer go weep," but they do not produce tears.

The Australian koala bear is said to whimper and cry when chased, as is the ape and monkey, but they do not produce tears. Darwin quoted a story about an Indian elephant shedding tears when mortally wounded in a hunt, but the possibility of direct injury to the eye could not be excluded.

Associated with the facial changes are the altered respirations, consisting of sudden deep inspirations with prolonged expiration. The slow decrease of pressure in the chest is probably related to the congestion of the face and neck veins. When a small child has been left crying for a long time he is apt to "sob." Long after he has been soothed, and begun to smile and laugh, sudden jerky inspiratory movements due to some degree of glottic spasm continue at decreasing intervals, until eventually they stop. The longer a child is left crying the longer the "sobbing" continues. It does not usually pay to put a child back into his cot, having soothed him after a night terror, if these sudden inspiratory movements are still occurring (Illingworth and Illingworth, 1954), for the child is very likely to start crying again as soon as he is left. Sobbing does not occur in animals (Darwin, 1889).

In addition to facial and respiratory changes, the baby shows generalized mass activity when he is crying—moving his arms and legs up and down, and alternately bending and extending his back. As he grows older this generalized mass activity disappears, though adults are known to grind their teeth and stamp their feet in rage—a relic of this primitive mass activity.

Types of Cry

A clinician recognizes the hoarse gruff cry of a cretin, the hoarse cry of laryngitis, the shrill cry of hydrocephalus, meningitis, or cerebral irritability, the grunting cry of pneumonia, the feeble cry of amyotonia or of a severely debilitated infant, and the whimper of a seriously ill child.

Experienced mothers claim that they can often tell the reason for a child's crying by the nature of the cry. Sherman (1927) is frequently quoted in this respect. She subjected a group of babies, all under 12 days of age, to a variety of stimuli—hunger, sudden change of posture, restraint of the head, and needle pricks—and asked nurses, undergraduates, and graduates, in another room within hearing distance but out of sight, to name the nature of the stimulus in each case. They all failed. This has long been quoted as evidence that the nature of the cry does not depend on the type of stimulus causing it. An obvious criticism of her work, however, is that she did not state whether the graduates and others had children of their own, and, more important still, she did not include the mothers of the babies in the audience. The mothers might well have recognized the cause of crying in their own baby. I have often been told by mothers in a four-bedded ward in a maternity unit that they do not awaken when a baby other than their own cries, but they waken immediately when their own baby does.

It would seem to me to be obvious that the cry of hunger or of loneliness is quite different from the cry of pain: how much of that difference lies merely in the intensity of the crying is a matter of opinion.

Why does he Cry?

I do not propose to discuss here the classical work of Barcroft (1946) concerning foetal respirations, but I will quote some work of psychologists. Adler described the first cry as "an overwhelming sense of inferiority at thus suddenly being confronted by reality without ever having to deal with its problems." Rank (quoted by Ruja, 1948) wrote that birth represents "a loss of paradise. The pleasurable primal state is interrupted." It is not clear how Rank knew that the baby finds it pleasant *in utero*. Petö (1946) thought that the movements of crying represent originally an attempt of the body to remove foreign material. "We behave towards pain as though it were something removable from our bodies, and in order to bring about this removal we mobilize the whole body apparatus: we try to get rid of it, to project it into the outer world." Sperling (1949) wrote that crying out at night in night terrors is due to "the repression of intense sexual and aggressive impulses stemming from the oedipal complex. Another cause is sibling rivalry, with repressed hostility and resentment toward the mother and death wishes toward the sibling." Greenacre (1945) declared that there is a strong connexion between weeping and urination. Concerning the different attitude towards weeping in the two sexes, she wrote: "It seems probable that this difference in social custom came originally out of the fact that the male child's urination early assumes the significance of achievement of an aggressive activity to an extent much greater than that of the female child ever can. In consequence it is a greater outlet for his tension and a projectile weapon as well." She thought that much weeping in girls is due to subconscious penis envy. "They weep with a quiet resentful approximation of the stream which comes from above rather than from below."

The causes of crying in infants and children have been discussed in detail elsewhere (Illingworth and Illingworth, 1954). It was emphasized there that an important factor which governs the amount they cry is the personality. Some are placid easy babies who will accept almost anything. They will wait for a time for food when they feel hungry, and they are content to lie in a pram for hours without being picked up. Others are determined difficult babies who almost from the moment of birth do not hesitate to let their wants be known and to express their disapproval of what is being done or not being done for them. It is very easy to ascribe the constant cries of a baby to mismanagement, when in fact the wisest management in the world would not stifle much of his crying. It is quite untrue to say that every baby who cries a lot is naughty, "nervous," or spoiled. Critics who say this have either not possessed a child of their own, or have had an easy-going placid child who was very different from the one in question. Nevertheless a great deal of crying is due to wrong management.

The common causes of crying can be summarized as follows:

(a) The First Three Months

The chief cause is discomfort, of which hunger is the most likely source. Excessive or prolonged crying may be the result of keeping the baby waiting a long time for food when he is ready for it, owing to adopting a rigid feeding schedule in the mistaken idea that a baby will learn bad habits if he is fed more or less when he wants it. Prolonged crying at night in the first ten weeks is caused by the same totally unfounded fear of bad habit formation. He may be caused to cry from hunger even when there is enough breast milk, if he is not given long enough to obtain the milk. It is common to find that nurses and doctors have instructed mothers to feed babies exactly ten minutes on each breast—as if all breasts and nipples are alike in the ease with which milk may be obtained from them, and as if all babies are alike at all ages in the speed and efficiency with which they suck. Many babies are caused to cry from hunger because someone—the doctor, nurse or mother—is so obsessed by the fear of overfeeding that the baby is half starved. I have yet to see a baby who cries because of overfeeding.

Discomfort may arise from wind, but most crying which is ascribed to wind is in fact due to something else—hunger, the desire to be picked up, boredom, or other causes. Nevertheless, pain from wind does occur, and it causes high-pitched screams which can only be due to pain. Crying in the evenings of the first three months, mostly between 6 and 10 p.m., in a baby who is receiving adequate amount of food, and which continues even when he is picked up, is most likely to be due to the so-called "three months colic." It is probably caused by localized collections of wind in loops of intestine (Illingworth, 1954). Crying from discomfort may be due to his being too hot, too cold, or to having a wet or soiled napkin. Some babies cry when passing urine.

A most important cause of crying in this period is loneliness or a desire to be picked up. At least, it seems as if this is the cause of the crying, for the crying promptly stops when the baby is picked up and cuddled. It is remarkable how many mothers fail to realize that babies want and need cuddling, and so make the mistake of thinking that all the baby's crying is due to hunger. The basic feature which differentiates crying from hunger from that of loneliness is the fact that crying from hunger or any other cause of discomfort is not stopped by picking the baby up.

Less important causes of crying in this period are sudden noises, the shining of light into the eyes, sudden changes of posture, holding the baby's head or limbs, undressing or bathing the baby, or cleaning his nose. Even in the first three months babies cry when they are tired and about to go to sleep, or when they need sleep. The cause of the

excessive crying on the breast shown by so-called "irritable" babies in the first 10 days or so after birth is unknown. It may be related to their personality.

Aldrich and his co-workers (1945) made the interesting observation that the crying of a baby in a nursery is not infectious, in that it does not cause other babies to cry.

(b) The Older Baby

Discomfort due to hunger or other causes continues to cause crying, but to a lesser degree than in the younger baby, for tolerance increases with age.

A most important cause of crying in this period is boredom. Many babies are left to cry for hours in a pram outside, with nothing but a brick wall to see, and their mothers cannot understand what is wrong with them. All the babies want is to see what is going on and to have company. Many such babies are perfectly content in a pram in the kitchen, where they can see the mother working. Many older babies are left outside, crying and screaming, with nothing to see or do, when they should be indoors, with toys to play with and people to talk to them. Much crying from boredom is thought by mothers to be crying from wind or hunger.

Crying may be due to efforts to force a child to take food, especially in the weaning period, and to refusal to let him help to feed himself. It may be due to forcing him to sit on the "pottie" against his will. It may be due to an unaccustomed face or room, to departure of the mother from the baby's cot or from the place where he is playing. It may be due to his inability to reach a toy. It is caused by cleaning his nose at bedtime. Crying at night is basically due to the baby's desire for the company of the mother whom he loves. Crying may be due to the pain of an erupting tooth, but much crying ascribed to this is due to other causes, such as boredom and mismanagement. A most important cause of crying is fatigue. A baby may cry for long periods if not put to bed for his rest before he is too tired.

(c) The Older Child

Most crying is related to the child's developing ego and negativism, or to his need for love and security. Attempts to force a child to eat, sleep, or use the "pottie," or to learn good manners and good behaviour before he is ready for it, lead to refusal to comply and to crying. Between the age of 1 and 3 years or more children go through a stage of negativism, and crying is very common when they fail to get their own way and are thwarted. They need to be recognized as persons of importance, and readily cry if discouraged or ridiculed. Much crying is merely a device for seeking attention. When too much fuss is made of a child who has a minor fall or injury, crying is apt to be excessive.

The need for love and security leads to much crying between the ages of 1 and 5 or 6. Crying at night continues to be due basically to the child's love for his mother, even though an essential factor is mismanagement, in leading to bad habits. When a child succeeds in getting his mother to visit him 10 times in the night or succeeds in his desire to be taken into his parents' bed, his crying is due to a combination of his love for his parents and their mismanagement in acceding to his wishes. Some crying at night is due to fear of the dark or of shadows on the wall, and some is due to nightmares or night terrors. Crying on being awakened is characteristic of the 2½ to 3-year-old. It is a developmental feature, with no other apparent reason for it.

Insecurity from any cause, whether due to unhappiness at home or school, unkindness, impatience, excessive discipline or lack of discipline, jealousy, or overprotection, leads to excessive crying in the young child. The amount of crying is always increased by fatigue, boredom, or hunger.

Except in the case of gross neurological disorders, such as pseudo-bulbar palsy, there is always a cause for crying, but it is not always easy to find it. Children go through good and bad phases without any apparent reason, though it is satisfying to ascribe a child's excessive crying to teething or to his going through a bad phase, when in fact it is due to one's own intolerance and impatience. Phases of excessive crying do occur, however. They may follow periods of overstimulation, as at Christmas. More often they are merely related to stages in his development.

The list given above is not intended to be complete, but it does include the main causes. I set a question in an examination paper on the causes of excessive crying in a 3-months-old baby. One of the students wrote, "The baby may be crying excessively because he is being irritated by a wasp."

Treatment of Crying

Although it would seem obvious that, except when a bad habit is being broken, the cause of a child's crying should be sought and attended to, so that he is comforted and soothed, there is no unanimity about this. There are still some who teach that many babies should be fed strictly by the clock, however much they cry, that they should never be fed at night, and that they should never be picked up when they cry. Sackett (1953), for instance, advises mothers to fondle and cuddle their babies only when they are happy and never when they are crying. John Gibbens (1950) wrote: "Many mothers believe that a baby is too young to understand, but this is not so. Even the youngest baby is quick to learn that he is being a perfect nuisance with his grizzling, that you'll do nothing for him as long as he persists in this idiotic behaviour. Many babies will stop at once if you say firmly, 'Stop that horrible noise. I won't have it!' No one has ever spoken like that before, and they are so surprised that they often hush up at once." Would that it were so easy. Foxe (1941) wrote: "A mother who does not permit the child to cry by itself binds the child more closely to her. A child that cries by itself achieves a great degree of independence from personal attachment." He discussed in a sensible way the question of which is best for the child. It would seem obvious that the young child should be closely attached to the mother. Jahr (1944) warns against giving a baby too much attention. He says, with some reason, "Infants don't cry aimlessly. They cry because they want something, and it is up to the parents to decide in each case whether or not the need is justifiable."

It would seem that the points at issue are these. Does it do any harm to leave a child to cry for prolonged periods? Does it do any harm to pick a child up when he cries and attend to his needs? The answer to the first question is that it may do harm to leave a baby or small child to cry for prolonged periods. Firstly, he may make himself sick. Some small children vomit if left crying for more than 15 to 30 minutes. The mechanism is obscure, but it may be due to air-swallowing. Secondly, there is some evidence that prolonged crying in infancy, with separation from the mother, may cause psychological harm. We have all seen babies who fail to thrive in hospital until the mother is admitted to the hospital to look after the baby and feed it. Bakwin and Bakwin (1953) described defective weight gain, poor appetite, and low-grade fever in babies who were separated from their mothers in this way. I regularly see children from an institution in order to assess their eligibility for adoption, and I am always impressed by their subdued and cowed behaviour, which is not due to any unkindness but is presumably due to prolonged deprivation of mother-love.

Bowlby (1951) in his famous monograph has marshalled the evidence that separation of the child from his mother for the first three years may have a permanent effect on his character—rendering him aggressive, unable to give or receive affection, selfish, lacking

in regard for the rights of others, and bitter. It may well be that if complete separation from the mother is so harmful, prolonged crying in the home, with a refusal of the mother to pay heed to it, may render the child unhappy and insecure later, and lead to a variety of behaviour problems. It is certain that when babies are left to cry for prolonged periods in this way they do not quickly grow out of it. It is a matter of common observation that the crying may continue for week after week, and month after month, until eventually with increasing age they stop it. Aldrich and Aldrich (1938) wrote: "Most spoiled children are those who as babies never had essential gratifications owing to a mistaken attempt to fit them into a rigid regime. The spoiled child who has missed satisfaction as a baby adopts the efficient technique of whining and temper tantrums to get what he wants. The mechanism of spoiling is the neglect of needs rather than overindulgence. Twenty-five years' experience has taught me that responsive adults breed responsive babies, and that rigid disciplinarians of babies at this age breed spoiled, unhappy children with no confidence in themselves or their parents."

The idea held by some that crying may lead to convulsions is untrue. The so-called "crying convulsions" or "breath-holding convulsions" are due to holding the breath in expiration. They frequently follow a short cry, but they are not the result of it.

As for the second question, whether it does any harm to pick a baby up when he cries, it can be said with certainty that there is no evidence that it does harm. Some babies are a great deal more demanding than others, and experience has shown that when demanding babies are picked up as often as they reasonably can be when they ask for it they settle down and stop demanding so much attention after the first few weeks. They do not, in other words, develop a bad habit of constantly expecting to be picked up. In any case, if such a habit did develop, as a result, perhaps, of unnecessary picking up, it can be broken as soon as it is realized that the crying has become a habit. Crying out at night certainly does become a habit in the older baby, and it has to be dealt with firmly (Illingworth, 1953). The young baby should be picked up when he cries, certainly when by the nature of his cry it is obvious that if left he will continue to cry for a long time. He should not be picked up at the slightest whimper. He should not be picked up when he is crying from fatigue and about to go to sleep—unless he has been allowed to get so tired that he cannot go to sleep, when he may have to be rocked until he lapses into slumber. A baby who screams because of colic or because of pain from teething should certainly be picked up and soothed. No baby should ever be left crying for prolonged periods—except when one is breaking a habit produced by mismanagement.

A baby is spoiled by being constantly picked up when he is lying perfectly content in his pram, or by being constantly played with when he is quite happy in his play-pen or elsewhere. He is spoiled by being picked up at the slightest whimper, but there is nothing whatsoever to be said in support of those who advocate leaving a baby to cry for prolonged periods so that he will "learn good habits" or "learn that he cannot have all his own way." It should not be forgotten that babies are human beings, and all human beings want love. Why not give it to them?

AN AMIDO-NITROTHIAZOLE FOR TRICHOMONIASIS

BY

S. R. M. BUSHBY, M.Sc., Ph.D.

Wellcome Research Laboratories, Beckenham, Kent

R. D. CATTERALL, M.R.C.S., L.R.C.P.

AND

MARY WILLIAMSON, M.B., B.S.

Department of Venereal Diseases, London Hospital
(Whitechapel Clinic)

Some 16 different drugs have been recommended at various times for the treatment of vaginitis due to *Trichomonas vaginalis*, but methods of treating this infection are still unsatisfactory. Although acute vaginitis is much improved by treatment with some of the drugs, relapses are common and the evidence of infection often persists as a chronic leucorrhoea. The unsatisfactory results have been attributed either to reinfection or to incomplete eradication of the trichomonads. Whether the origin of the infection be primarily venereal, or due to accidental contamination from infected lavatory seats, towels, and other fomites, it seems probable that the prevention of reinfection will always be difficult in practice. Failure to eradicate the primary infection, however, can only be due to the use of insufficiently active drugs or to inaccessibility of some of the trichomonads. If failure is due to inaccessibility then no topical drug, however active, will be fully successful. If, however, the failure is due solely to low activity of the drug, then the solution to the problem should be relatively simple, for more active drugs than those generally used are available.

Up to the present nitrothiazoles have not been used for the treatment of human infections, but Waletzky *et al.* (1949) found 2-amino-5-nitrothiazole, "enheptin T," to be effective for the treatment of turkeys experimentally infected with *Histomonas meleagridis*, a flagellate related to the trichomonads; and Carmichael and Maclay (1952), McGreggor (1952), and Swales (1952) found it effective for the natural disease. Stabler and Mellentin (1953) have reported that it cures pigeons infected with *Trichomonas gallinae*, and they suggested that it should be tried for human infections. Enheptin T is, however, bright yellow and stains skin and clothing intensely, an undesirable property for a drug that is to be used as a vaginal pessary. Bushby and Copp (1955), who made an independent study of the activity *in vitro*

of nitrothiazoles for *T. vaginalis*, found that some of them which were only slightly coloured had about ten times the activity of enheptin T and more than a hundred times that of acetarsol.

In this investigation we have compared the activity *in vitro* of the most active of these compounds, 2-formamido-5-nitrothiazole (291 C 51), with 14 of the

antitrichomonal drugs which have been recommended during the last 10 years, and which are still readily available. We have also used it in the treatment of 96 women with trichomoniasis, comparing the results with those obtained in the 49 women treated with acetarsol.

The 14 drugs which were compared with the nitrothiazoles were: phenylmercuric dinaphthylmethane disulphonate ("penotran"), phenylmercuric acetate, 5-chloro-7-iodo-8-hydroxyquinoline ("vioform"), silver picrate, 5-nitro-2-furaldehyde semicarbazone (nitrofurazone), sodium perborate, mild silver protein ("argyrol"), chlortetracycline, 2-methoxy-6-chlor-9 (α -methyl-*o*-diethyl-aminobutyl)-aminoacridine dihydrochloride (mepacrine hydrochloride), 3-acetyl-amino-4-hydroxy-phenylarsonic acid (acetarsol), 5,7-di-iodo-8-hydroxy-quinoline ("diodoquin"), 4:4'-diamidino-diphenoxypropane di-(β -hydroxyethane sulphonate) (propamidin), 7-iodo-8-hydroxyquinoline-5-sulphonic acid (chiniofon), *p*-carbaminophenyl-arsonic acid (carbarsone).

Activity in vitro

Methods.—A recently isolated strain of *T. vaginalis* grown in serum-glucose-nutrient broth enriched with an extract of ox liver (pH 6.4) was used for comparing the trichomonastatic and trichomonacidal properties. The drugs were added to the medium usually at a concentration of 10,000 μ g. per ml., serially diluted 1 in 3, and then sterilized by heating for half an hour at 56° C. For the trichomonacidal tests 1 ml. of a suspension containing 400 trichomonads per c.mm. was added to 1 ml. of the dilutions and incubated at 37° C. Each tube was examined microscopically for motile organisms, and viability tests were made on those containing no motile organisms by subculturing into fresh medium free of the drug and incubating for 48 hours.

In the trichomonastatic tests the inoculum was 1/10 of that used in the trichomonacidal tests, and the tubes were examined for increases in the number of trichomonads after 48 hours' incubation.

Results.—The activity of the various drugs is shown in Table I.

Drug	References to Clinical Use*	Minimum Effective Concentration (μ g. ml.)			
		Trichomonacidal Activity			Trichomonastatic Activity
		1 Hr.	6 Hrs.	24 Hrs.	48 Hrs.
291 C 51	—	1,000	100	10	3

* See page 80.

Chemical Properties and Pharmacology

291 C 51 is a weak acid; a saturated aqueous solution (0.1% at 37° C.) has a pH of 4.5. The solid compound and the aqueous solutions are faintly yellow, and the colour increases slightly when the solutions are made alkaline. Animal experiments show that 291 C 51 has a low toxicity: 5 mg. produced no reaction when placed on the conjunctivae of rabbits once daily on three consecutive occasions; the insertion twice daily for 15 days of one of the 100-mg. pessaries used in the clinical trial (see below) into the vagina of each of two dogs caused no irritation; and the daily instillation of 30 ml. of 0.5% aqueous solution of the sodium salt into the bladders of two dogs for three weeks also caused no ill effects.

The oral and subcutaneous L.D.₅₀ single doses in mice are approximately 400 mg. per kg. Subcutaneous doses of 100 mg. per kg. twice daily for four days to mice and two daily oral doses of 200 mg. per kg. to rabbits were non-toxic. A daily oral dose of 100 mg. per kg. to a monkey for 44 days and a single oral dose of 600 mg. to man produced no toxic effects. After oral or parenteral administration the urine becomes a deep yellow colour and paper chromatographic analysis shows that the drug is not excreted in its original form. The urine and the serum of the rabbits, monkey, and man, collected during the toxicity experiments, one, two, and four hours after dosing, possessed no trichomonastatic activity when tested *in vitro*, showing that 291 C 51 is changed *in vivo* to an inactive form.

Clinical Trials

Material and Methods

The patients treated in this trial were attending the Whitechapel Clinic of the London Hospital. They were divided into three series: the first consisted of 10 whose treatment was restricted to seven days; the second, of 38 treated for 14 days; the third, of 98 treated for 14 days with 250-mg. pessaries of acetarsol or with 291 C 51, in alternate cases. Series I and II consisted of patients who had relapsed after treatment with acetarsol or some other antitrichomonal drug. The patients of series III had not been previously treated in this clinic. 291 C 51 was used as a foaming pessary* containing 100 mg. of the drug, and the procedure ordinarily followed in this clinic when using acetarsol was employed. The routine procedure was: two tablets were inserted high into the vagina nightly for 14 days except in the first 10 cases (series I) in which the treatment was for seven days only. After the initial insertion of the first two tablets by nursing staff, patients were instructed in the method of inserting the tablets "as high up as possible," and subsequent treatment was left to the patient.

Assessment of Results

These fell into three groups—cure, relapse, and defaulters. For the assessment of cure the following criteria had to be fulfilled: (1) After completion of the course there must be no symptoms or clinical evidence of vaginitis for at least three months. (2) Smears taken from the vagina must remain negative for trichomonads in a series of tests extending over three menstrual periods after completion of treatment. Relapses also included probable cases of reinfection because it was impossible to differentiate these. Defaulters were patients who failed to renew their appointments in spite of letters of reminder to each of them.

During treatment the signs and symptoms of vaginitis disappeared and no trichomonads could be seen in smears, but in each series the relapse rate was high. The results are given in Table II, and the ultimate effect of treatment is not significantly different with either drug. Seven days' treatment with 291 C 51 produced no cures and is presumably insufficient. The high proportion of defaulters is unfortunate, especially in the third series. The reason for patients not attending again are unknown and it is purpose-

*The trade name for these pessaries is "aroxine."

TABLE II

	Series I	Series II	Series III	
	291 C 51	291 C 51	291 C 51	Acetarsol
Duration of treatment	7 days	14 days	14 days	14 days
No. treated	10	38	49	49
Cures	0	3	5	6
Relapses:				
After 1 week	2	7	5	1
" 1 month	—	4	7	6
" 2 months	—	5	8	8
" 3	3	3	1	2
Defaulters	5	16	23	26

less to speculate on whether they considered themselves cured or decided that the treatment was useless. A high incidence of defaulters is the rule among these patients, however treated. In series III the defaulter rate is almost identical in the groups treated with 291 C 51 and with acetarsol. Whatever the causes, they appear to have operated equally in both groups.

None of the patients treated with 291 C 51 complained of toxic side-effects, except one who suffered from a reaction due to sensitization. This produced irritation and burning of the vulva with visible oedema early in the course of treatment. The condition quickly subsided when antihistamines were given and treatment with 291 C 51 was stopped. No evidence of hypersensitivity to 291 C 51 was obtained in this patient by intradermal testing with 0.1% solution or by patch testing with a crushed pessary on a scarified area of skin of the forearm. The patient denied using any additional drug during the course of treatment.

Discussion

The examination *in vitro* confirms the high antitrichomonal activity of this nitrothiazole. Of the drugs that have been previously recommended for the treatment of trichomonal vaginitis, only penotran and phenylmercuric acetate are somewhat more active than 291 C 51, and this applies especially to the rate at which they kill the organisms. Both of these drugs, however, have to be used in the relatively low concentration of 1:500 or less, whereas 291 C 51 is used with only slight dilution and so has the higher therapeutic index.

Compared with acetarsol, 291 C 51 has a very much higher activity *in vitro*, yet clinically it is no more effective. Both drugs are, however, very effective in suppressing the infection, and most of the patients who had relapsed after treatment with 291 C 51 had no symptoms of vaginitis, the relapse being judged solely on microscopical or physical examination.

The fact that a drug with about a hundred times the activity *in vitro* of acetarsol should prove no more effective *in vivo* suggests that the failure of local treatment to prevent relapses is not due to the lower activity of the drug. Whether systemic treatment would be more efficacious by reaching inaccessible organisms is unknown, for as yet there is no suitable drug available; 291 C 51 is too rapidly inactivated when taken orally or parenterally to be used systemically, and Bushby and Copp found it inactive when given orally or subcutaneously to mice infected intraperitoneally with *T. vaginalis*. Chlorotetracycline is a highly efficient systemic drug for bacterial infections, but its antitrichomonal activity is too low for it to be effective except when applied locally. The antibiotic trichomycin has antitrichomonal properties *in vivo* when given to mice with peritoneal infections (Hosoya *et al.*, 1953), but so far there are only reports of its use locally in women (Hosoya *et al.*, 1953; Magara *et al.*, 1954), and information about its systemic effects are awaited with interest. In the meantime if the resistant character of trichomonal vaginitis, due either to failure to eradicate the infection or to unavoidable reinfection, necessitates prolonged and suppressive treatment, 291 C 51 has the advantages of being non-arsenical and non-toxic, and in our experience it is as effective as any non-arsenical drug at present available.

Summary

2-Formamido-5-nitrothiazole has an antitrichomonal activity *in vitro* some 100 times greater than that of acetarsol. It has low toxicity.

Nevertheless in a clinical trial it proved no more effective than acetarsol in preventing relapses, which suggests that relapses are not necessarily due to low activity of the drug. This new antitrichomonal drug is a non-arsenical and therefore possibly more suitable than acetarsol as a suppressant.

Our thanks are due to Mr. A. J. King, senior physician at the Whitechapel Clinic, and to Professor Clifford Wilson, of the London Hospital, for encouragement and advice, and to Miss Joyce Peacock, A.I.M.L.T., of the Wellcome Research Laboratories, for technical assistance in the *in vitro* work.

Asking "What is a Virus?" Dr. K. M. SMITH, F.R.S., begins by outlining two theories (*Nature*, 1955, 175, 12). First, they may be parasitic organisms that have developed their parasitism to the highest possible degree. Alternatively, viruses, or at least some of them, may have no external origin; they may be derived from the cell proteins of one organism and become viruses only when introduced into the cells of another organism. Some support for this second theory may be obtained from a study of certain plant viruses. The potato King Edward, Dr. Smith points out, is invariably infected with a virus, yet the infection is entirely symptomless. The virus can be detected by transferring the sap to other plants, when they show signs of virus infection. Such a wholly latent virus, which causes no symptoms at all in its normal host, Dr. Smith compares with the partially latent virus of herpes simplex, which causes symptoms only when activated by some stimulus, emotional or infective, as during an attack of the common cold. Dr. Smith also discusses the use of viruses to exterminate insect pests, a method already used with some success in Canada and the U.S.A.

CONTROL OF CROSS-INFECTION BY MEANS OF AN ANTISEPTIC HAND CREAM

BY

JOHN MURRAY, M.D.

Director of Pathology

AND

ROY M. CALMAN, M.B.

Bacteriologist

(From the Bernhard Baron Memorial Research Laboratories,
Queen Charlotte's Maternity Hospital, London)

From the early days of antiseptics the problem of bacterial cross-infection has attracted increasing attention, first in maternity work, and more recently in burns, accident, and plastic surgery units.

Control of this cross-infection is concerned with the prevention of organisms reaching patients from their environment, which includes all persons attending them. Methods of control of infection due to droplet airborne particles, dust, ward utensils, linen, and contaminated dressings have been extensively investigated, and methods of prevention are well described (Medical Research Council, 1951). A recent appraisal of the use of dust-free air in special units has been made by Lowbury (1954).

The purpose of this paper is to describe attempts to reduce the incidence of cross-infection by treatment of the hands of persons attending patients.

The commonest and most important organisms encountered in cross-infection in maternity hospitals are pyogenic staphylococci and streptococci. Nowadays infection with the β haemolytic streptococcus is confined to relatively rare single cases and small outbreaks, and the measures for its control are well understood. *Staphylococcus aureus* produces a large variety of minor infections in a considerable percentage of babies, and a much smaller number of more serious infections in both mothers and babies.

Hospitals are then faced with the problem of a pool of pyogenic organisms which not only is circulating in the personnel but is spread throughout the buildings in the form of contaminated dust, fluff, bedding, towels, etc. At this hospital we have found that about 60% of nurses carry pyogenic staphylococci in their noses. This figure is similar to that reported by Barber *et al.* (1949) from another maternity unit, and contrasts with the lower incidence in the general population found by the same authors, and also by Rountree and Thomson (1949).

We are convinced that these nasal carriers provide a substantial reservoir for hospital infections, and that the main method of transfer of these organisms is by way of the nurse's or doctor's hand. This view is in agreement with the observations of Moss *et al.* (1948), who established that the nose was the predominant source of *Staph. aureus* on the hands.

In the course of our general investigation into modern antiseptics we became impressed by the possibility of utilizing the persistent antibacterial action of certain antiseptics applied to the skin, as suggested for the control of streptococci by Colebrook and Maxted (1933).

It became clear that these antiseptics might provide a method of interrupting the cycle of transfer of organisms. Amongst a group of antiseptics tested in an investigation to be described elsewhere, we were struck by the high antibacterial levels attainable in therapeutic concentrations, using a new compound (10,040) described by Davies *et al.* (1954) having the basic formula

the diacetate and dihydrochloride of which we have had the opportunity of testing.

As a result of satisfactory experience using an obstetric cream incorporating 1% of this substance, we persuaded the manufacturers to prepare a hand cream with the same comparatively high concentration. This cream ("hibitane") when spread thinly on the hands is capable of suppressing the majority of normal hand bacterial flora, and, as we shall show, renders the hands resistant to bacterial contamination for a considerable period.

Methods

Finger Sampling Technique.—Initial experiments showed that if sterile surgical gloves or fingerstalls were worn on "socially clean" hands for periods up to two hours the number of organisms which could be recovered from the interior varied according to the amount of sweating which occurred.

Thus, if dry gloves were worn for two hours, during which the subject sat still, and then the gloves were rinsed out with nutrient broth, very few colonies indeed were found on plate culture. Whereas if sterile gloves were moistened with broth before being put on, and worn for 30 minutes, very large numbers of organisms could be recovered on culturing the interior of the gloves. Based on these observations, a method of culturing the skin of fingers was therefore devised.

Sampling of Normal Untreated Fingers.—The hands were washed with soap and water, rinsed, and dried on clean towels. Sterile rubber fingerstalls moistened inside with 0.5 ml. of nutrient broth were slipped on and worn for 30 minutes. On removal, 1 ml. of broth was placed inside and shaken so as to rinse the interior thoroughly. Then 0.5 ml. of the broth rinse was withdrawn with a pipette and added to 9.5 ml. of 25% sterile serum water. A further tenfold dilution was then made, giving a final dilution of 1/200. From this last dilution 1 ml. was withdrawn and a poured plate prepared. Colonies were counted after 48 hours' incubation at 37° C.

Normal "Resident" Skin Bacteria.—Results of a typical experiment are shown in Table I, where it can be seen that the variation in the number of colonies recovered from adjacent fingers of the same hand is on the whole not very great.

TABLE I.—Normal "Resident" Finger Organisms

Subject	Control Test of Adjacent Untreated Fingers		
	Index	Middle	Ring
A	368	121	2,548
B	662	670	2,984
C	696	1,292	1,088

Colonies counted on plate (1:200 dilution).

Sampling of Treated Fingers.—Fingers treated with antiseptic creams were sampled in a similar manner, starting at various times from immediately after application, up to two hours afterward. In each experiment untreated fingers of the same hand were used as controls.

Quantity of Antiseptic Creams Used.—The weight of antiseptic cream used was limited to the amount which could be

rubbed into the skin so that no excess cream remained. Quantities of 0.1 to 0.25 g. were tried for each finger, and ultimately 0.15 to 0.2 g. was used in most of the experiments. The results obtained with varying amounts of cream were remarkably similar.

Preliminary Tests

To exclude the possibility of the fingerstall tests being vitiated by the carry-over of antiseptic into the culture plates, blank tests were done.

For these 0.1 and 0.2 g. quantities of cream were emulsified in tubes containing 1.5 ml. of nutrient broth. From each of these tubes 0.5 ml. was transferred to 9.5 ml. of 25% serum peptone water and was allowed to stand for ten minutes as in the tests proper.

A final dilution to 1/200 was made and a poured plate prepared containing 1 ml. of this dilution and seeded with a weak suspension of an overnight culture of *Staph. pyogenes*. At the same time control plates were poured containing the same inoculum of bacteria but no dilution of cream.

The precise dilution of inoculum of *Staph. pyogenes* necessary to give countable colonies on the control plates was first determined, and at a culture dilution of 1 in 1,000,000 the control plate gave 62 colonies. With the use of the same inoculum, plates containing the dilutions from 0.1 and 0.2 g. of antiseptic cream gave 55 and 60 colonies respectively. It is therefore clear that no antiseptic activity could be carried over on to the test plates with this technique.

Results

In these experiments the tests were carried out simultaneously on the same finger of three subjects—A, B, and C.

Suppression of "Resident" Skin Bacteria

The reduction of recoverable bacterial flora is demonstrated well by Tables II and III, in which control and test

TABLE II.—Suppression of "Resident" Organisms by Antiseptic Cream (0.1 g. of 10,040 Diacetate Cream was Rubbed Into Each Test Finger)

Subject	Fingerstalls on for			
	30 Minutes		60 Minutes	
	Test (Index Finger)	Control (Middle Finger)	Test (Index Finger)	Control (Middle Finger)
A	8	1,336	32	204
B	3	58	12	53
C	0	233	305	610

Colonies counted on plate (1/200 dilution).

TABLE III.—Suppression of "Resident" Organisms by Antiseptic Cream (0.2 g. of 10,040 Dihydrochloride Cream Rubbed Into Each Test Finger)

Subject	Fingerstalls Worn for 30 Minutes	
	Test (Middle Finger)	Control (Index Finger)
A	1	333
B	5	324
C	2	1,330

Colonies counted on plate (1/200 dilution).

ingers are compared. It can be seen that similar results are obtained with either the diacetate or the dihydrochloride of 10,040 as the antiseptic in the cream.

A similar experiment to that shown in Table II was made, using 0.25 g. of antiseptic cream, and the results may be seen in Table IV, where the figures for both controls and tests are very low in the two-hour experiment. The most probable reason was that all the fingers used had had 0.2 g. of antiseptic cream applied five hours previously for a different experiment. The hands had, however, been washed several times and used for normal laboratory duties in the interval.

TABLE IV.—Suppression of "Resident" Organisms by Antiseptic Cream (0.25 g. of 10,040 Diacetate Cream Rubbed Into Each Test Finger)

Subject	Fingerstalls on for			
	1 Hour		2 Hours	
	Test (Index Finger)	Control (Middle Finger)	Test (Index Finger)	Control (Middle Finger)
A	3	4,000	1	20
B	17	387	1	59
C	3	1,450	0	18

Colonies counted on plate (1/200 dilution).

Finger-tip Contamination Technique

For the contamination tests a strain of *Bact. coli* was chosen, because these organisms are more resistant to contact with antiseptics than staphylococci.

Test fingers were treated with 0.2 g. of 10,040 cream, which was rubbed in completely, leaving no surplus to be seen on the surface. Contact was then made after periods of 30 minutes and one hour by pressing the fingers for 30 seconds on to filter paper moistened with a culture of *Bact. coli*. For this purpose to sterile 5-cm. filter papers in Petri dishes were added 1-ml. quantities of a 1/100 dilution of an 18-hour culture of *Bact. coli*. This dilution contained approximately 25,000,000 organisms per ml.

The fingers were allowed to dry in the air for one minute and then pressed on to horse-blood-agar plates for 30 seconds. These plates were examined at 24 and 48 hours, and the colonies in the fingerprints were counted.

A remarkable reduction was found in the number of bacteria which could be transferred by "creamed" fingers as compared with control untreated fingers. Table V shows the results of an experiment using the finger-tip contamination technique.

TABLE V.—Finger-tip Contamination

Subject	Test Fingers (0.2 g. of 10,040 Cream Rubbed into Each Test Finger)			Control
	Index Finger		Middle Finger	Ring Finger
	30 Minutes	Recontaminated after further 30 Minutes	Contaminated after 1 Hour	Not Creamed
A	1	1	6	65
B	1	4	7	64
C	0	0	0	42

The figures represent number of colonies counted in each fingerprint on blood-agar plate.

Included in the second column of Table V are the results of contaminating the same finger twice—first, 30 minutes after application of antiseptic cream, and, secondly, after a further 30 minutes—and they indicate the excellent persistent qualities of the antiseptic.

Clinical Use in the Hospital

When the laboratory investigations were completed it was decided to try the effect of 10,040 hand cream throughout the hospital.

For this purpose tubes of the antiseptic cream were placed beside each wash-basin in wards and nurseries. The nursing and medical staffs were encouraged to rub about 1.5 to 2 g. of the cream on to their hands after washing. While the concentration of antiseptic cream was maintained at 1%, the formulation of the base was altered from time to time in order to find a compatible formulation which was cosmetically attractive and which therefore would be freely used by the staff. The preparation of acceptable emollient hand creams is made difficult by the fact that many of the modern antiseptics are inhibited by the presence of some of the bases of the popular commercial creams.

The 10,040 cream has been in use in the hospital for more than 18 months, and has proved successful. The antiseptic incorporated in the cream was originally used in

the form of the diacetate of 10,040, and latterly in the form of the dihydrochloride, laboratory tests having shown no difference between these two salts. Throughout the 18 months that the cream has been in use, no cases of idiosyncrasy to the antiseptic have occurred.

During the period of this clinical trial not only have the number of clinical cases been reduced, but there have been no patients with serious staphylococcal infections in the hospital: but possibly of greater significance is the observation that those staphylococcal infections which did occur no longer appeared as groups in particular wards, but were scattered sporadically throughout the hospital. It may well be that other factors played a part in the remarkable results achieved and that the use of the antiseptic hand cream was not alone responsible. Nevertheless, the improvement was very real.

Discussion

In a maternity hospital staphylococcal lesions of the newborn are by far the commonest forms of cross-infection, although minor infections of mothers are by no means rare. We have stressed our view of the importance of the hands as a vehicle for transfer of organisms. Our experimental results show beyond doubt the ability of a suitable hand cream to provide a bactericidal layer of prolonged activity against this type of organism, and they have also shown that hands so treated will not readily transfer even more resistant organisms, such as coliform bacilli, from heavily contaminated material.

A possible fallacy of the fingerstall technique was the carry-over of antiseptic into the final poured plates. It was calculated that in the unlikely event of all the antiseptic becoming dissolved in the broth with which the fingerstalls were lubricated the quantity reaching the final dilution would be too small to have any inhibitory action. As an additional precaution, however, 25% serum peptone water was used in the first dilution. The preliminary blank tests amply confirmed the absence of carry-over to the final plates.

While our work has been carried out largely with 10,040 cream, we have no doubt that other antiseptics might be used in the same way, and that a variety of formulations could be employed for application of the antiseptic to the hands. For example, the particular preparation which we have tried most extensively throughout the hospital is in the form of an emollient hand cream for use after washing, in order not only to render the hands antiseptic but also to assist in the prevention of "chapped" hands. This formulation would not be satisfactory for application before putting on surgical gloves. For such purposes powders or quick-drying lotions might be more suitable.

We have had the opportunity of trying a number of hand preparations of different antiseptics, and, while some are active, in others a base was employed by makers which inactivated the original antiseptic. For example, one of the creams had so little antibacterial activity that staphylococci could be recovered abundantly from cream inoculated and incubated for 48 hours. There were others again which, although very active against skin bacteria, were unsatisfactory from the point of view of repeated application to the hands.

It is not our intention to specify these unacceptable preparations, as they were in most cases specially prepared by the manufacturers for our experimental work, and are not at present available for general use.

Our experience with antiseptic hand creams in the laboratory and in practical hospital use leads us to conclude that a considerable contribution to the control of cross-infection can be achieved by the wide use of such creams. We therefore recommend that in departments where cross-infection is likely to occur each wash-basin should be provided with a "dispenser" or tube of antiseptic cream, and that the nursing and medical staff should be encouraged to use the hand cream as often as possible after washing between cases.

Summary

The incidence of staphylococcal infection in babies born in a maternity hospital is shown to be related to the prevalence of carriers of the staphylococcus among nurses, the organism often being conveyed by the hands. The use of an antiseptic hand cream would to a large extent prevent this transfer of bacteria from nurse to baby.

A new antiseptic compound—1:6-di-4'-chlorophenyl-di-guanidohexane 10,040—was incorporated in a cream ("hibitane") and its effectiveness in keeping the skin free from bacteria tested in the laboratory, two new methods being used. Both methods showed that this cream was capable of greatly reducing the bacterial count of the skin.

Use of the cream in the wards led to a marked decrease in the number of clinical cases of staphylococcal infection: during the period of trial no groups of infection were seen in any ward or nursery.

Recommendations for the regular use of antiseptic hand cream are made.

We would like to thank our obstetric colleagues and the nursing staff of the hospital for their co-operation in the clinical trials, and we are glad to thank Mr. E. Clark for technical assistance. We are grateful to Imperial Chemical (Pharmaceuticals) Limited for generous supplies of materials, and in particular to Dr. K. G. Green, without whose continued interest and help the investigation would have been impossible.

RUPTURE OF A COLD ABSCESS INTO THE BRONCHUS

BY

ZVONKO FASTNER, M.D.

(From the Medical Department, School of Medicine, University of Zagreb, Yugoslavia)

According to Cleveland (1940) a cold abscess is the most common complication of tuberculous spondylitis and occurs in 68–86% of cases. Ruptures of these abscesses to the body surface, with fistula formation, are less common, while rupture of cold abscesses into the pleural cavity or into the bronchopulmonary system or oesophagus is rare.

Review of Literature

Loeffler (1922) cites Ideler, who by 1911 had seen six cases of cold abscess communicating with a bronchus or pleural cavity. He does not state how many cases were pleural, and how many were bronchial, or a combination of the two. Nor does he say anything about the outcome of these cases.

Cameron (1925) reported a case of long-standing tuberculous spondylitis in which a cold abscess developed in the inguinal region. During an iodoform injection into the abscess the patient tasted iodoform in his mouth, and after several minutes expectorated iodoform. Coughing lasted for several days, then gradually lessened and stopped completely after six weeks. Evidently an old bronchial fistula

must have opened as a result of the injected liquid. Presumably this bronchial fistula was normally symptom-free, because the pus from the abscess followed the line of least resistance and drained by gravitation through the inguinal sinus.

Mayet and G  n  vier (1928) reported two cases of cold abscess rupturing into a bronchus; both remained latent, however, and were discovered only when iodoform was therapeutically injected into a skin fistula. Strasser (1938) reported two similar cases with skin fistulae coexistent with a bronchial and tracheal fistula respectively. He proved the fistulous communications by radiography.

Imbach (1938) described a case of combined cutaneo-bronchial fistula. Here again the diagnosis was demonstrated after a therapeutic injection of lipiodol was expectorated by the patient; otherwise there were no other symptoms of bronchial fistula. Imbach mentioned that he had ten case reports of rupture of a cold abscess into the bronchial system.

Brooks (1942) described six cases of rupture—two into the lung, three into the pleural cavity, and a combined one. In five cases the abscess was of tuberculous aetiology, and one was due to actinomycosis. All the ruptures into the lung caused fatal results from bronchopneumonia, pulmonary abscess, or amyloidosis, but it is significant that none of them caused disseminated tuberculosis.

Morgan and Bosworth (1946) reported a case of rupture of a cold abscess through the pleural cavity into the bronchus. This was the first case to be treated with antibiotics. The patient began to recover with streptomycin, but the eventual outcome is not recorded. Finally, Heuck (1949) described a case with a coexisting fistula to the inguinal region and to the bronchus in which there were no troublesome bronchial symptoms.

The following is a report of a case with a fistula between a cold abscess and the bronchus without fistulous communication with any other part of the body.

Case Report

A farmer aged 38 had perfect health until 1942, when, after a gunshot wound, he had his left leg amputated below the knee. In June, 1951, he started coughing, and this increased in spite of treatment by his family physician. He expectorated abundant sputum, sometimes malodorous but never blood-stained. He lost 25 lb. (11.3 kg.) in weight and observed that the left side of his body sweated profusely. The family history was without significance. The patient was admitted to hospital in November.

On examination he was seen to be tall, slim, and pale. His thorax was symmetrical and without impairment of respiratory movements. Normal resonance was found on percussion, except paravertebrally on the right side, where there was an area of dullness corresponding to the spinal processes of D 2-4. Air entry was slightly diminished on the right side, where rales were also present. The blood picture showed: red cells 3,650,000; white cells, 10,300, with 76% segmentary neutrophils. The sedimentation rate was 43 mm. Westergren in the first hour and 81 mm. in the second. *Streptococcus haemolyticus*, *Str. viridans*, *Str. non-haemolyticus*, *Bact. coli*, and *Bacillus fusiformis* were present in the sputum. The results of other investigations were within normal limits.

By the time of admission the patient was expectorating about 300-350 ml. daily. No elastic fibres could be shown in the sputum. Bronchoscopy showed massive purulent secretion into the left main bronchus, stemming mainly from the upper left bronchus. No pathological processes were to be seen in the lumen of the bronchus. X-ray examination of the chest showed abnormal hilar shadows on both sides. A tomogram of the mediastinum revealed a sharply limited shadow as large as an apricot in the posterior part. An x-ray film of the thoracic vertebrae showed destruction of the lower part of the body of D 7 and the upper part of D 8, together with a partial fusion of the vertebral bodies in their anterior

parts with some angulation. The presence of *Mycobacterium tuberculosis* in the sputum was demonstrated microscopically and by culture. From these findings it was evident that the cold abscess had ruptured into the bronchus.

A left paravertebral puncture of the abscess was performed under x-ray control with the idea of proving the communication of the abscess with the bronchopulmonary system. A 1% solution of Congo red was injected and was immediately expectorated by the patient. A further puncture was made a few days later—this time on the right side—but the injected solution was expectorated only after half an hour. The prompt expectoration of the Congo red solution when injected into the left side of the abscess proved that the cavity communicated with the left bronchus and confirmed the bronchoscopy finding that pus came only from the left bronchus, although the actual site of the fistula was not visible.

Daily injections of 200,000 I.U. of penicillin for ten days into the abscess to control the secondary infection thinned the sputum but did not lessen the amount. The dose of penicillin was therefore increased to 600,000 I.U. each day, given intramuscularly. The quantity of sputum then fell to 50 ml. a day.

By the end of January, 1952, the daily sputum amounted to only 10 ml., and streptomycin was substituted for penicillin. Leucocytes, which rose to 14,400 during the treatment, now fell to 11,600. The patient had obviously improved and his weight had increased from 115 to 132 lb. (52 to 60 kg.).

The Mantoux reaction, which was negative at the beginning of the treatment in dilutions of 1:100,000 and 1:1,000,000, became positive by the end of January in the same dilutions.

With streptomycin alone the quantity of sputum increased to 60 ml. a day, and in February penicillin was given in combination with streptomycin. The sputum again lessened. The erythrocyte sedimentation rate was 16 mm. in the first, and 30 mm. in the second hour. From the beginning of January the patient was constantly afebrile. On February 25 streptomycin was stopped, after a total of 68 g. had been given, but penicillin was continued. On March 31 treatment with nitrogen mustard was started. This treatment is based upon the experiences of Aleksandrowicz (1948), who stated that nitrogen mustard has a favourable effect upon tuberculous cold abscess. The patient was given four doses each of 7 mg. There were no troublesome reactions.

On April 8, after the treatment with nitrogen mustard was finished, a control tomogram showed that the abscess cavity had not diminished. On April 11 his erythrocyte sedimentation rate was 11-45 and the blood picture showed: erythrocytes, 4,040,000; haemoglobin, 80%; leucocytes, 3,600 (eosinophils 4%, non-segmented 4%, segmented 73%, lymphocytes 5%, monocytes 15%). The fall in the leucocyte count was due to the effect of nitrogen mustard, not to the lessening of the inflammatory process. The patient's weight was 141 lb. (64 kg.). Unfortunately he discharged himself from hospital on April 22 after having received 54,600,000 I.U. of penicillin, 68 g. of streptomycin, and 28 mg. of nitrogen mustard.

According to subsequent information the patient felt well at home for two months, but then expectoration increased, and by August it was as abundant as before treatment. Thereafter he went steadily downhill, and died on October 30, 1952.

Discussion

This case is worth recording because of its rareness and because, according to the literature, it is the second of its kind to be treated with antibiotics. But there is a difference between the two cases. The first one (Morgan and Bosworth, 1946) was treated with streptomycin immediately after a sudden rupture of an abscess in which secondary infection had not developed, while the present case had predominant

symptoms of established secondary infection. That explains the beneficial effect of the penicillin when streptomycin was ineffectual. Nitrogen mustard was also ineffective.

The course of the disease in this case is also interesting in comparison with others reported. The latter had a chronic, nearly always benign, clinical course on every occasion when, in addition to the bronchial fistula, there was a skin fistula through which most of the pus drained. But in those cases, like my own case, in which a fistula into a bronchus or lung was the only clinical finding (Brooks, 1942), the patient died quickly of bronchopneumonia or pulmonary abscess when the abscess ruptured. However, my patient had a relatively favourable course before he came to hospital, in spite of the abundant suppuration and the fact that it was two months before he had treatment.

The interruption of the treatment, with the return of secondary infection and abundant sputum, was obviously fatal. The final decline was probably due to a progressive anaemia and amyloidosis.

Summary

A case of tuberculous spondylitis of the thoracic spine with a cold abscess which ruptured into a bronchus is described. The abscess was later contaminated with pyogenic micro-organisms, and in the clinical picture abundant expectoration predominated. An abscess of the mediastinum and caries of the seventh and eighth thoracic vertebrae were demonstrated radiologically. The communication between abscess and bronchus was proved by the injection of Congo red into the abscess. The dye was immediately expectorated. The patient was treated with penicillin and streptomycin, and with nitrogen mustard. While under treatment with antibiotics a significant amelioration of the clinical picture was achieved, but the nitrogen mustard was ineffectual. The patient voluntarily refused further treatment and left hospital; he gradually deteriorated and died of cachexia.

On the subject of the notification of infectious diseases, the Medical Officer of Health for Barnsley, Dr. G. A. W. NEILL, writes as follows in his annual report: "Notification by general practitioners of infectious disease has improved somewhat, but is still far below the standard required by law. It is appreciated that many practitioners consider that notification of certain diseases is of little value. In neglecting to notify they overlook the fact that they are still required by statute to carry out the procedure of notification and that by their omission they commit an offence. This causes a very great deal of difficulty for everyone concerned and could well give rise to great unpleasantness and friction. It would seem that a better way would be for doctors who hold this view to attempt to alter the law constitutionally by representation through the appropriate professional body than by persistent breach of it. No notifications on the statutory forms were received in respect of some 99 cases of infectious disease seen by general practitioners and admitted to hospital. On this account it should be emphasized that a telephone call to the medical officer of an isolation hospital to arrange admission does not constitute notification in the manner required by the Public Health Act, 1936, s.144."

TRAUMATIC RUPTURE OF A MAIN BRONCHUS

BY

A. W. FOWLER, F.R.C.S.

Assistant Traumatic and Orthopaedic Surgeon, Bridgend General Hospital

Rupture of a main bronchus is a rare complication of closed injuries to the chest. In the following case of complete rupture of the left main bronchus the patient died after 55 hours. It is recorded because it illustrates some important diagnostic problems. Had these been understood at the time the patient might have survived.

Case Report

A healthy girl aged 18 was run over by a bus at 7 p.m. on December 27, 1953. On admission to hospital she was distressed and dyspnoeic, and complained of severe pain in the back and left shoulder. Examination of the chest revealed an area of paradoxical respiration beneath the right scapula and a left-sided pneumothorax. The maximal cardiac impulse was felt just to the left of the sternum. A radiograph of the chest (Fig. 1) showed fractures of the posterior angles of the sixth and seventh ribs on the left, and fractures of the necks of the sixth, seventh, and eighth ribs on the right. There was a left pneumothorax with partial collapse of the lung and displacement of the trachea and mediastinum to the right. Following an injection of morphine, 1 gr. (16 mg.), the patient settled down to sleep. In the absence of cyanosis and with a respiration rate of 30 a minute no treatment of the pneumothorax was thought necessary. The next day she seemed a little better; respirations were steady at 32 a minute and the colour remained good.

At 1 p.m. on the third day, however, she collapsed with extreme dyspnoea and cyanosis. A radiograph (Fig. 2) now showed complete collapse of the left lung and a small pneumothorax on the right. Within a few minutes a needle was inserted in the left pleural cavity and connected to an under-water seal. A small negative pressure developed with each inspiration and air bubbled out with each expiration. The expected improvement in the patient's condition did not occur. An exhaust pump was then connected to the outlet of the bottle so that air was drawn off the chest continuously. There was still no improvement, and it was noted that when the air was drawn off rapidly there was an increase of respiratory distress. A bronchial fistula was then diagnosed, and after inserting an intercostal catheter an attempt was made to re-expand the left lung by a combination of vigorous pleural suction and bronchoscopic aspiration. Several ounces of fluid was drawn off through the bronchoscope, but the lung remained completely collapsed. By this time the patient was *in extremis* and no further treatment was possible. She died at 2 a.m. on December 30.

Necropsy revealed a small quantity of blood-stained fluid in the left pleural cavity. There was a small tear in the pleura over the root of the left lung which exposed a completely divided main bronchus. The ends of the divided bronchus were widely separated. None of the other hilar structures was damaged. The left lung was completely collapsed but undamaged. The right pleural cavity contained about 10 oz. (284 ml.) of blood. The right lung was partly collapsed and contained extensive haemorrhages. A probe was passed down the trachea and left main bronchus before disturbing the thoracic contents; this went straight into the pleural cavity, thus demonstrating the source of the fluid obtained by bronchoscopic suction. Many more rib fractures were found than were visible on the radiographs; 14 were recognized with certainty. The effect of

must have opened as a result of the injected liquid. Presumably this bronchial fistula was normally symptom-free, because the pus from the abscess followed the line of least resistance and drained by gravitation through the inguinal sinus.

Mayet and G  n  vri  r (1928) reported two cases of cold abscess rupturing into a bronchus; both remained latent, however, and were discovered only when iodoform was therapeutically injected into a skin fistula. Strasser (1938) reported two similar cases with skin fistulae coexistent with a bronchial and tracheal fistula respectively. He proved the fistulous communications by radiography.

Imbach (1938) described a case of combined cutaneo-bronchial fistula. Here again the diagnosis was demonstrated after a therapeutic injection of lipiodol was expectorated by the patient; otherwise there were no other symptoms of bronchial fistula. Imbach mentioned that he had ten case reports of rupture of a cold abscess into the bronchial system.

Brooks (1942) described six cases of rupture—two into the lung, three into the pleural cavity, and a combined one. In five cases the abscess was of tuberculous aetiology, and one was due to actinomycosis. All the ruptures into the lung caused fatal results from bronchopneumonia, pulmonary abscess, or amyloidosis, but it is significant that none of them caused disseminated tuberculosis.

Morgan and Bosworth (1946) reported a case of rupture of a cold abscess through the pleural cavity into the bronchus. This was the first case to be treated with antibiotics. The patient began to recover with streptomycin, but the eventual outcome is not recorded. Finally, Heuck (1949) described a case with a coexisting fistula to the inguinal region and to the bronchus in which there were no troublesome bronchial symptoms.

The following is a report of a case with a fistula between a cold abscess and the bronchus without fistulous communication with any other part of the body.

Case Report

A farmer aged 38 had perfect health until 1942, when, after a gunshot wound, he had his left leg amputated below the knee. In June, 1951, he started coughing, and this increased in spite of treatment by his family physician. He expectorated abundant sputum, sometimes malodorous but never blood-stained. He lost 25 lb. (11.3 kg.) in weight and observed that the left side of his body sweated profusely. The family history was without significance. The patient was admitted to hospital in November.

On examination he was seen to be tall, slim, and pale. His thorax was symmetrical and without impairment of respiratory movements. Normal resonance was found on percussion, except paravertebrally on the right side, where there was an area of dullness corresponding to the spinal processes of D 2-4. Air entry was slightly diminished on the right side, where rales were also present. The blood picture showed: red cells 3,650,000; white cells, 10,300, with 76% segmentary neutrophils. The sedimentation rate was 43 mm. Westergren in the first hour and 81 mm. in the second. *Streptococcus haemolyticus*, *Str. viridans*, *Str. non-haemolyticus*, *Bact. coli*, and *Bacillus fusiformis* were present in the sputum. The results of other investigations were within normal limits.

By the time of admission the patient was expectorating about 300-350 ml. daily. No elastic fibres could be shown in the sputum. Bronchoscopy showed massive purulent secretion into the left main bronchus, stemming mainly from the upper left bronchus. No pathological processes were to be seen in the lumen of the bronchus. X-ray examination of the chest showed abnormal hilar shadows on both sides. A tomogram of the mediastinum revealed a sharply limited shadow as large as an apricot in the posterior part. An x-ray film of the thoracic vertebrae showed destruction of the lower part of the body of D 7 and the upper part of D 8, together with a partial fusion of the vertebral bodies in their anterior

parts with some angulation. The presence of *Mycobacterium tuberculosis* in the sputum was demonstrated microscopically and by culture. From these findings it was evident that the cold abscess had ruptured into the bronchus.

A left paravertebral puncture of the abscess was performed under x-ray control with the idea of proving the communication of the abscess with the bronchopulmonary system. A 1% solution of Congo red was injected and was immediately expectorated by the patient. A further puncture was made a few days later—this time on the right side—but the injected solution was expectorated only after half an hour. The prompt expectoration of the Congo red solution when injected into the left side of the abscess proved that the cavity communicated with the left bronchus and confirmed the bronchoscopy finding that pus came only from the left bronchus, although the actual site of the fistula was not visible.

Daily injections of 200,000 I.U. of penicillin for ten days into the abscess to control the secondary infection thinned the sputum but did not lessen the amount. The dose of penicillin was therefore increased to 600,000 I.U. each day, given intramuscularly. The quantity of sputum then fell to 50 ml. a day.

By the end of January, 1952, the daily sputum amounted to only 10 ml., and streptomycin was substituted for penicillin. Leucocytes, which rose to 14,400 during the treatment, now fell to 11,600. The patient had obviously improved and his weight had increased from 115 to 132 lb. (52 to 60 kg.).

The Mantoux reaction, which was negative at the beginning of the treatment in dilutions of 1:100,000 and 1:1,000,000, became positive by the end of January in the same dilutions.

With streptomycin alone the quantity of sputum increased to 60 ml. a day, and in February penicillin was given in combination with streptomycin. The sputum again lessened. The erythrocyte sedimentation rate was 16 mm. in the first, and 30 mm. in the second hour. From the beginning of January the patient was constantly afebrile. On February 25 streptomycin was stopped, after a total of 68 g. had been given, but penicillin was continued. On March 31 treatment with nitrogen mustard was started. This treatment is based upon the experiences of Aleksandrowicz (1948), who stated that nitrogen mustard has a favourable effect upon tuberculous cold abscess. The patient was given four doses each of 7 mg. There were no troublesome reactions.

On April 8, after the treatment with nitrogen mustard was finished, a control tomogram showed that the abscess cavity had not diminished. On April 11 his erythrocyte sedimentation rate was 11-45 and the blood picture showed: erythrocytes, 4,040,000; haemoglobin, 80%; leucocytes, 3,600 (eosinophils 4%, non-segmented 4%, segmented 73%, lymphocytes 5%, monocytes 15%). The fall in the leucocyte count was due to the effect of nitrogen mustard, not to the lessening of the inflammatory process. The patient's weight was 141 lb. (64 kg.). Unfortunately he discharged himself from hospital on April 22 after having received 54,600,000 I.U. of penicillin, 68 g. of streptomycin, and 28 mg. of nitrogen mustard.

According to subsequent information the patient felt well at home for two months, but then expectoration increased, and by August it was as abundant as before treatment. Thereafter he went steadily downhill, and died on October 30, 1952.

Discussion

This case is worth recording because of its rareness and because, according to the literature, it is the second of its kind to be treated with antibiotics. But there is a difference between the two cases. The first one (Morgan and Bosworth, 1946) was treated with streptomycin immediately after a sudden rupture of an abscess in which secondary infection had not developed, while the present case had predominant

symptoms of established secondary infection. That explains the beneficial effect of the penicillin when streptomycin was ineffectual. Nitrogen mustard was also ineffective.

The course of the disease in this case is also interesting in comparison with others reported. The latter had a chronic, nearly always benign, clinical course on every occasion when, in addition to the bronchial fistula, there was a skin fistula through which most of the pus drained. But in those cases, like my own case, in which a fistula into a bronchus or lung was the only clinical finding (Brooks, 1942), the patient died quickly of bronchopneumonia or pulmonary abscess when the abscess ruptured. However, my patient had a relatively favourable course before he came to hospital, in spite of the abundant suppuration and the fact that it was two months before he had treatment.

The interruption of the treatment, with the return of secondary infection and abundant sputum, was obviously fatal. The final decline was probably due to a progressive anaemia and amyloidosis.

Summary

A case of tuberculous spondylitis of the thoracic spine with a cold abscess which ruptured into a bronchus is described. The abscess was later contaminated with pyogenic micro-organisms, and in the clinical picture abundant expectoration predominated. An abscess of the mediastinum and caries of the seventh and eighth thoracic vertebrae were demonstrated radiologically. The communication between abscess and bronchus was proved by the injection of Congo red into the abscess. The dye was immediately expectorated. The patient was treated with penicillin and streptomycin, and with nitrogen mustard. While under treatment with antibiotics a significant amelioration of the clinical picture was achieved, but the nitrogen mustard was ineffectual. The patient voluntarily refused further treatment and left hospital; he gradually deteriorated and died of cachexia.

On the subject of the notification of infectious diseases, the Medical Officer of Health for Barnsley, Dr. G. A. W. NEILL, writes as follows in his annual report: "Notification by general practitioners of infectious disease has improved somewhat, but is still far below the standard required by law. It is appreciated that many practitioners consider that notification of certain diseases is of little value. In neglecting to notify they overlook the fact that they are still required by statute to carry out the procedure of notification and that by their omission they commit an offence. This causes a very great deal of difficulty for everyone concerned and could well give rise to great unpleasantness and friction. It would seem that a better way would be for doctors who hold this view to attempt to alter the law constitutionally by representation through the appropriate professional body than by persistent breach of it. No notifications on the statutory forms were received in respect of some 99 cases of infectious disease seen by general practitioners and admitted to hospital. On this account it should be emphasized that a telephone call to the medical officer of an isolation hospital to arrange admission does not constitute notification in the manner required by the Public Health Act, 1936, s.144."

TRAUMATIC RUPTURE OF A MAIN BRONCHUS

BY

A. W. FOWLER, F.R.C.S.

Assistant Traumatic and Orthopaedic Surgeon, Bridgend General Hospital

Rupture of a main bronchus is a rare complication of closed injuries to the chest. In the following case of complete rupture of the left main bronchus the patient died after 55 hours. It is recorded because it illustrates some important diagnostic problems. Had these been understood at the time the patient might have survived.

Case Report

A healthy girl aged 18 was run over by a bus at 7 p.m. on December 27, 1953. On admission to hospital she was distressed and dyspnoeic, and complained of severe pain in the back and left shoulder. Examination of the chest revealed an area of paradoxical respiration beneath the right scapula and a left-sided pneumothorax. The maximal cardiac impulse was felt just to the left of the sternum. A radiograph of the chest (Fig. 1) showed fractures of the posterior angles of the sixth and seventh ribs on the left, and fractures of the necks of the sixth, seventh, and eighth ribs on the right. There was a left pneumothorax with partial collapse of the lung and displacement of the trachea and mediastinum to the right. Following an injection of morphine,    gr. (16 mg.), the patient settled down to sleep. In the absence of cyanosis and with a respiration rate of 30 a minute no treatment of the pneumothorax was thought necessary. The next day she seemed a little better; respirations were steady at 32 a minute and the colour remained good.

At 1 p.m. on the third day, however, she collapsed with extreme dyspnoea and cyanosis. A radiograph (Fig. 2) now showed complete collapse of the left lung and a small pneumothorax on the right. Within a few minutes a needle was inserted in the left pleural cavity and connected to an under-water seal. A small negative pressure developed with each inspiration and air bubbled out with each expiration. The expected improvement in the patient's condition did not occur. An exhaust pump was then connected to the outlet of the bottle so that air was drawn off the chest continuously. There was still no improvement, and it was noted that when the air was drawn off rapidly there was an increase of respiratory distress. A bronchial fistula was then diagnosed, and after inserting an intercostal catheter an attempt was made to re-expand the left lung by a combination of vigorous pleural suction and bronchoscopic aspiration. Several ounces of fluid was drawn off through the bronchoscope, but the lung remained completely collapsed. By this time the patient was *in extremis* and no further treatment was possible. She died at 2 a.m. on December 30.

Necropsy revealed a small quantity of blood-stained fluid in the left pleural cavity. There was a small tear in the pleura over the root of the left lung which exposed a completely divided main bronchus. The ends of the divided bronchus were widely separated. None of the other hilar structures was damaged. The left lung was completely collapsed but undamaged. The right pleural cavity contained about 10 oz. (284 ml.) of blood. The right lung was partly collapsed and contained extensive haemorrhages. A probe was passed down the trachea and left main bronchus before disturbing the thoracic contents: this went straight into the pleural cavity, thus demonstrating the source of the fluid obtained by bronchoscopic suction. Many more rib fractures were found than were visible on the radiographs; 14 were recognized with certainty. The effect of

pressure on the thoracic cage after death convinced me that the bronchus had been severed by being nipped between the anterior chest wall and the vertebral column.

Review of the Literature

Comprehensive reviews of the literature by Vaccarezza and Raimondi (1943) and Kinsella and Johnsrud (1947) provide clinical details of 38 cases of rupture of a main bronchus recorded between 1848 and 1942. Twenty other cases have been described since 1942, giving a total of 58 cases for analysis. Of the 55 cases in which the cause of

life is to be saved. Such a case was the one encountered by me, and the challenge was not met because of the delay in diagnosis. If the bronchial rupture had been diagnosed before function in the opposite lung had become impaired by oedema and collapse then surgical treatment would have been possible and might have been successful.

A traumatic pneumothorax usually indicates a perforation of the lung. In most cases this quickly seals off and absorption of the air takes place. Occasionally an opening in the lung or bronchus acts like a valve and tension develops, necessitating urgent decompression. However, it is evident that a complete rupture of the bronchus which results in free communication between the trachea and pleural cavity will not give rise to a tension pneumothorax. In our patient there was never any evidence of intrapleural tension; when the pneumothorax was first connected to the underwater seal, air bubbled out only on expiration. When continuous suction was applied the pneumothorax remained stationary, but vigorous suction increased the dyspnoea by drawing off from the trachea a large volume of the tidal air. It is often stated that the presence of a pneumothorax does not demand treatment unless it is of the tension variety. In the vast majority of cases this is true, but where there is a bronchial rupture an expectant policy can be disastrous. It is suggested, therefore, that a diagnostic needling should be done in all cases of pneumothorax due to crushing injury whether there is tension or not. (A simple and readily available apparatus for this procedure can be made by changing around the tubes entering the bung of an empty blood-transfusion bottle to which a small quantity of sterile water is added.) If, in spite of continuous aspiration of air, the lung does

not re-expand, then a large broncho-pleural fistula must be present. In this event thoracotomy should be seriously considered, and should not be delayed if there is evidence of damage to the opposite lung.

Only two emergency thoracotomies for the treatment of ruptured bronchus in a closed chest injury have been recorded. Kirkpatrick (1950) did a pneumonectomy on a boy of 13 who had a complete division of the right main bronchus, and Scannell (1951) sutured a hole in the right main bronchus in a boy of 10. Both these operations were successful, and it is significant that both were done within four hours of the accident. No one has yet recorded a primary suture of a completely ruptured main bronchus, but there are three reports of successful suture of a main bronchus divided accidentally during the course of a lobectomy. The clean division of the bronchus in our patient seemed to indicate that suture would have been technically possible.

Summary

A case of complete division of the left main bronchus in a run-over accident is described. The patient died after 55 hours, but might have survived if diagnosis had been early and thoracotomy had been done. It is suggested that all severe crushing injuries to the chest complicated by pneumothorax should be immediately investigated with the possibility of bronchial rupture in mind.

I wish to thank Mr. Dilwyn Thomas for help in the preparation of this paper.

Medical Memoranda

A Case of Human Anthrax

Anthrax is a comparatively rare disease in this country, although its true incidence is difficult to arrive at in view of the fact that it is not a notifiable disease unless contracted at work. The following case is of general interest in view of this comparative rarity and also because of the possibility of an unusual mode of infection.

CASE REPORT

The patient, aged 49, is manager of a hardware store in a South London suburb which sells the usual articles, including brushes, brooms, and dehydrated animal manure. On December 2, 1953, while pruning a tree in his garden at Farnborough, Kent, he felt what he thought to be an insect on his neck and brushed it off. Next day he noticed a pimple on his neck where the insect had been. The following day he felt ill, having nausea and anorexia. The pimple was larger but not painful. On December 5 he saw his doctor, who gave him an injection of penicillin for a "boil." Next day he felt much worse, having anorexia, nausea, and abdominal pain. His doctor was called, and he was given another injection of penicillin. On December 7 he was extremely ill and was delirious. He was sent into Farnborough Hospital, a diagnosis of anthrax having been made by his own doctor.

On admission five days after he felt the insect on his neck the patient was very toxic and obviously had to concentrate hard to understand questions. He complained of continuous severe headache and spots before his eyes, also of anorexia and nausea. He vomited several times, and had a feeling of tightness across his chest and epigastrium, with colicky abdominal pain. His temperature was 101° F. (38.3° C.); pulse 84, and respirations 20. On the right side of his neck over the lower third of the sterno-mastoid was an oval ulcer 1 by 1½ in. (2.5 by 3.8 cm.); it had a raised edge consisting of many small vesicles surrounding a blackish central slough. There were large tender cervical glands deep to the ulcer and above it. The whole of his right side from the ear to below the nipple was red and the site of a brawny oedema.

He was admitted to a side room under full precautions. A swab was taken, and after an initial dose of soluble penicillin he was kept on "distaquine" 300,000 units four times a day for seven days. Under this treatment he improved rapidly. The oedema of his neck and chest disappeared by December 13, and on that date also he was afebrile. He had a slight recurrence of abdominal pain on the 14th. The local lesion remained relatively unchanged, although the vesicles were a little smaller. He was discharged on the 16th on his own insistence, although the ulcer was still present. A swab from the ulcer was negative at this time. He was seen in the casualty department daily for dry dressings. On January 3, 1954, the scab was off, the lesion was healed, and he was symptom-free. He had been quite well during the period as an out-patient, but had had periodic slight episodes of abdominal pain.

The following investigations were undertaken: (1) A swab from the ulcer yielded a growth of an organism which on culture and biochemically resembled *Bacillus anthracis*. A guinea-pig was inoculated for virulence and died within 24 hours. A virulent *B. anthracis* was found in the animal's spleen. (2) The E.S.R. was 12 mm. in the first hour, and the white blood count was 8,000 per c.mm. on December 12. (3) X-ray examination of his chest with a portable apparatus on December 11 gave normal results. We are at a loss to explain the abdominal pain, but feel that it may have been due to an associated mesenteric adenitis.

The public health department was notified, and the hardware shop and its contents, including samples of brushes, were inspected. Nothing suspicious was found. His home was examined for a possible source of infection and speci-

mens of clothing were taken. Nothing helpful was found. The only new garment he had bought that year was a shirt, and this was examined and found blameless. He had not bought a new shaving-brush and his old one was cultured, with a negative result. Although we realize the possibility of the dehydrated animal manure being a very likely cause in this case, he does not carry it on his shoulder and it is kept in carefully wrapped packets.

We feel that there is quite a likelihood of an insect being the vector in this case, but this possibility is not mentioned in any of the standard textbooks of medicine or surgery to which we have referred. It is, however, discussed by Topley and Wilson (1946).

Added interest is given to this case in view of a similar one in the same London suburb (Baker, 1953). In this case a woman was infected, and an insect seems to have been a very likely cause. We have been in touch with this patient and with her medical adviser, and she has never at any time entered our patient's store. We have been unable to confirm any cases of animal anthrax in the district in the last six months.

Two main points make this case worth reporting. Firstly, the possibility of an insect vector in spite of no animal cases being reported in the neighbourhood; and, secondly, the rapid and complete recovery, on penicillin, from a relatively rare and serious condition.

We wish to thank Mr. C. C. Cookson for permission to publish this case, Dr. L. Griffiths for bacteriological help, and Dr. J. J. P. Ferguson, the general practitioner; we wish also to thank Dr. G. P. Baker, of the Mayday Hospital, for information about his case.

Sudden Death in Labour Following an Injection of Penicillin

This is an unusual case of sudden death occurring in labour in an apparently healthy patient following an injection of penicillin. It was concluded that death was due to anaphylaxis.

CASE REPORT

The patient, aged 42, was a 10-para, with one stillbirth, five normal deliveries, and three miscarriages. She had been given crystalline penicillin following a miscarriage in 1949 with no ill effect. She had had rheumatic fever at the age of 16. There was a history of syphilis, for which she had had treatment, but details were not known. She had also had chronic bronchitis.

History of Present Pregnancy.—L.M.P., September 12, 1952; E.D.D., June 19, 1953. On her first attendance at the antenatal clinic, examination of the chest showed nothing abnormal. The Kahn test was "weakly positive" and the Wassermann reaction was negative. Her blood group was O Rh positive. She attended the clinic at irregular intervals. She showed no symptoms of toxæmia at any time.

She was admitted to the Hull Maternity Hospital, supposedly in labour, at 10.30 a.m. on June 30. The membranes had ruptured and she was having very vague pains. On admission her blood pressure was 130/80 and temperature 98° F. (36.7° C.); the urine was normal and there was no oedema of ankles or sacrum. She was examined at 11.30 p.m. on the same day, and was found to be in early labour. Morphine, ½ gr. (16 mg.), was given. In the evening of July 1 she developed a temperature of 101° F. (38.3° C.), and was given 400,000 units of "distaquine" penicillin intramuscularly at 6.30 p.m. Other patients had received injections from the same batch without ill effect. At about 7.30 p.m. the patient vomited; after this she was quite normal and felt all right. A few minutes later she

FIG. 1

FIG. 2

Fig. 1.—Radiograph taken shortly after admission. Note the partial aeration of the left lung. Fig. 2.—Radiograph taken on the third day. The left lung is totally collapsed and there is a partial pneumothorax on the right.

the injury was stated all were due to being crushed. Forty-eight were caused by road vehicles, and in many of these the wheel of the vehicle passed over the chest.

The cases fall into three groups according to the mode of presentation. Twelve victims (20%) died instantly or within an hour of the accident from associated injuries. The bronchial rupture in most of these cases was no more than a post-mortem finding.

Twenty-three patients (40%) presented with serious intra-thoracic injuries. Twelve of these died, some under conditions similar to those described in our case. Of the 11 patients who survived 9 recovered from the acute illness without the aid of surgery, but they subsequently developed bronchial stricture. The two operative cases are discussed later.

Twenty-three patients (40%) were referred to the authors as cases of established pulmonary collapse due to bronchial stricture. They gave a history of chest injury weeks, months, or years before which had been treated elsewhere. Some of these patients were said to have been very ill at the time of the accident, but nearly all had recovered without the true nature of the injury being suspected. Probably most of these were cases of partial rupture of the bronchus without interruption of the continuity of the lumen. Where there had been no history of pneumothorax or emphysema the injury has been more correctly described as a bronchial fracture (Griffith, 1949).

Discussion

From this brief summary of recorded cases of rupture of a main bronchus it is apparent that many survive the emergency in the absence of surgical treatment. Aspiration of air may well be all that is necessary to tide the patient over the acute injury, and the inevitable bronchial stenosis can be treated later. But among the acute injuries there are a few which present a challenge to the surgeon. These demand early diagnosis and urgent operative treatment if

had a contraction and at the height of it she suddenly called out and collapsed. She was unconscious and her breathing was stertorous. The nurse administered oxygen and sent for medical aid. The patient was found to be dead. The face was cyanosed, there was no breathing or heart beats. An attempt was made at resuscitation by artificial respiration with oxygen and an airway, but without success.

A post-mortem report by Dr. Mackenzie, senior registrar pathologist, was as follows: "Chest.—The heart was normal in size and showed no disease of the valves or of the coronary arteries. The blood in the heart and great vessels was quite fluid, no P.M. clots being present. Over the surface of the lungs were many petechial haemorrhages. The lungs showed a mild emphysema only. The trachea and bronchi were normal . . . otherwise there was nothing of note."

The pathologist decided that death was due to anaphylaxis caused by the penicillin injection to which she had been previously sensitized.

COMMENT

This case appears to have a certain resemblance to the case described by Thompson (1952). There were the same symptoms: vomiting, cyanosis becoming very intense, stertorous breathing, protruding tongue. The main difference is in the matter of time: in Thompson's case the reaction occurred about ten minutes after the injection, and in our case it did not occur until approximately one hour ten minutes after the injection. The other, more startling, difference is that in Thompson's case, and also in that of Waldbott (1949), there was a warning non-fatal reaction. Our patient had none.

A further case of death by anaphylaxis caused by penicillin has been described by Mayer *et al.* (1953). This was referred to by the *Lancet* (1953), when various other references were given.

My thanks are due to Mr. D. Hyslop, consultant obstetrician, Hull (A) Group Hospital Management Committee, for permission to publish this case.

Spontaneous Adrenal Haemorrhage in Ulcerative Colitis

As the Friderichsen-Waterhouse syndrome, bilateral adrenal haemorrhage is a well-recognized complication of acute infections by meningococci and, more rarely, by other organisms. Adrenal haemorrhage has also been reported in cases of pregnancy and in single cases in a heterogeneous group of miscellaneous morbid conditions. These include such diverse conditions as burns, hypertension, hydatid infection of the liver, leukaemia, and carcinoma of the lung (Altschule, 1939; Godfrey, 1947; Lauckner and Hebbert, 1947; Dewhurst, 1951). The present report is concerned with a case of acute ulcerative colitis which terminated in a massive bilateral adrenal haemorrhage.

CASE REPORT

The illness began when the patient, a farmer aged 47, previously very fit, had an acute attack of diarrhoea accompanied by abdominal colic, and also, a few days after the onset, by fever. Examination of the stools failed to demonstrate any pathogens. For the first fortnight the general condition remained very good, but in the third week of the illness some deterioration became apparent. The patient was passing, on an average, 12 offensive fluid stools a day, but blood and mucus were not present. At the end of the fourth week he was admitted to hospital, having been given at home an intensive course of chloramphenicol without any improvement.

On the day of admission blood and mucus appeared in the stools, and the patient was pyrexial; there was obvious loss of weight. No other significant findings were elicited on clinical examination. Stools contained many pus and red cells, but no pathogens. There was polymorph leucocytosis. Agglutination tests and blood culture were negative. The next event, three days after admission, was the sudden and quite unexpected collapse of the patient. The pulse became imperceptible, and after a steadily deepening coma of a few hours' duration death occurred.

Necropsy revealed an extensive ulcerative colitis extending from the caecum to the rectum. The cause of death was a massive bilateral adrenal haemorrhage. The adrenals were converted into sacs of blood, a thin rind of cortical tissue being all that remained of the parenchyma. Haemorrhage was not found in other organs, the only other abnormality noted being coronary atheroma.

DISCUSSION

We have been able to find accounts of two cases in which adrenal haemorrhage has been associated with ulcerative colitis. Wilson and Roth (1953) reported a case in which a massive bilateral adrenal haemorrhage occurred in a woman aged 51 who was receiving corticotropin treatment for an exacerbation of ulcerative colitis. The aetiological relationship in this case between the colitis and the adrenal haemorrhage is not quite clear. An acute upper respiratory tract infection was present, and Wilson and Roth thought that corticotropin treatment or the infection may have been the determining factors of the haemorrhage. In a survey of the complications observed in a series of 129 cases of ulcerative colitis admitted during eleven years to the Radcliffe Infirmary, Oxford, Rice-Oxley and Truelove (1950) encountered one case in which there was adrenal haemorrhage. The patient died within one month of the onset of a severe ulcerative colitis. Necropsy revealed multiple small areas of haemorrhage in both adrenals. The authors thought that adrenal failure might be a factor contributing to the extremely rapid loss of weight and dehydration often seen in fulminating types of ulcerative colitis.

In the case reports referred to in the opening paragraph various theories have been advanced to account for the occurrence of adrenal haemorrhage. Haemorrhage has been ascribed to the operation of vascular damage, allergy, toxæmia, and a general tendency to bleed. Because ulcerative colitis has been included in the list of adaptation diseases we have been interested by the views of Selye (1950). The adrenal stimulated by the anterior pituitary plays an important part in the general adaptation response to stress, and Selye believes the Friderichsen-Waterhouse syndrome may be the result of cell damage following exhaustive overstimulation of the gland. (If this is true the part played by the corticotropin treatment in Wilson and Roth's case can readily be understood.) If adrenal haemorrhage in ulcerative colitis is to be ascribed to the operation of a stress factor it would not be surprising if the complications of this disease included other recognized manifestations of the diseased adaptation response. It is of interest, therefore, that Rice-Oxley and Truelove found a relatively high proportion of skin and joint lesions of an allergic type in their survey of the complications of ulcerative colitis.

Our thanks are due to Dr. A. W. Hansell for notes on the patient's condition before admission to hospital.

Reviews

COLLECTED LECTURES

An Autumn Gleaning. By Sir Henry Hallett Dale, O.M., G.B.E., F.R.S., M.D., F.R.C.P. (Pp. 226+x. 21s.) London: Pergamon Press Ltd. 1954.

This book contains lectures on a variety of subjects given by Sir Henry Dale between 1935 and 1953. They are mostly medical, though in addition there are extracts from five presidential addresses to the Royal Society, a Pilgrim Trust lecture on the freedom of science, given in Philadelphia, and one on personal memories of Lord Rutherford. All are illuminated by the author's close personal knowledge of his subject and by his admirable historical presentation. The account of the discovery of insulin by Banting and Best is perhaps one of the most interesting chapters of the book, describing as it does how Banting had begun to practise medicine in London, Ontario, in 1920, and had accepted part-time duty as a demonstrator of physiology in the University of Western Ontario. In the course of preparing a lecture on diabetes he was seized with the idea that the previous failures to find insulin in the gland were due to its destruction by trypsin. He then sold his practice and his house and furniture and went off to Toronto to find an opportunity of putting his idea to the test of experiment. The whole of this story from the beginning makes fascinating reading and gives much material for reflection on the general question of medical research as an aim in life, to which a later chapter is devoted.

In selecting other subjects the treatment of which seems to deserve special mention, that of Thomas Addison as a pioneer of endocrinology must be of interest to all physiologists, and that of the mechanism of anaphylaxis must be of interest to all pathologists and physiologists. The presentation of this latter subject brings out many points which are usually misunderstood. It is interesting to learn that Isaac Newton nearly failed to write the *Principia*.

RAMÓN Y CAJAL

Don Quixote of the Microscope. An interpretation of the Spanish savant Santiago Ramón y Cajal (1852-1934). By Harley Williams. (Pp. 255; 3 illustrations. 15s.) London: Jonathan Cape. 1954.

The life of Ramón y Cajal exerts a fascination on all who become acquainted with its many facets. Whether it be the simplicity of his character as opposed to the richness of his thought, of the fact that, brought up as he was in a poor rural district of Spain, he yet succeeded in breaking down the obscurity of man's most complicated physiological process; or, yet again, whether it be the fact that from a wild and uncouth childhood he developed into a manipulator of the first rank and a philosopher in whom his countrymen universally recognized their champion in the great world of science—each one will himself decide. From whatever angle it is regarded, his life is indeed an epic.

Cajal was born in a small town among the mountains of north-eastern Spain. As a boy he fought his way to eminence among his fellows. His father, a doctor, intended him to follow his own profession, but Ramón was stubborn and he had artistic instincts. From the long battle between these two developed Cajal's respect for his father's wishes and his determination in pursuing to their end those problems to which he later devoted his life. No sooner was he qualified in medicine than he joined the army and had a taste of guerrilla warfare in Cuba. Malaria and dysentery led to his discharge, and for a time his sturdy physique seemed broken. A few years later he developed tuberculosis, and he seems to have cured himself by strenuous walking in the mountains. While an assistant professor of anatomy at the University of Saragossa, and still only 25 years of age, he acquired a microscope and a microtome. It was possibly

the first modern microscope in the university. He plunged at once into the study of histology, and soon had a number of papers to his credit. When he died he had written nearly 300 papers and 15 books. The bulk of his researches dealt with the minute structure of the brain and arose from his adaptation of Golgi's process of staining with silver. Golgi had himself found the process difficult and unpredictable, but Cajal made it the key which unlocked for him the structure of the nerve cell and its fibres. One of the first foreign honours which Cajal received was the invitation to deliver the Croonian Lecture to the Royal Society. There was a fund of incident in his first brief and memorable visit to London.

Cajal wrote a long autobiography in which he described his life in considerable detail, and others have in their various ways attempted to place before the reader a picture of the man as seen through other eyes. Dr. Harley Williams has in this little book written a very charming biography. His sympathy with his subject is evident throughout, and his simple explanations of what Cajal's various researches really achieved will be much appreciated by the non-professional reader. The author has obviously spared no pains to augment his material from independent sources. The addition of an index would have enhanced the value of the book.

E. ASHWORTH UNDERWOOD.

MUSCULAR CONTRACTION

Muscular Contraction. By M. Dubuisson, Ph.D. (Pp. 243 +ix; illustrated, 47s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954.

Dr. Dubuisson is the Director of the Laboratory of General Biology at Liège. In this volume he has rewritten some lectures given in America. It falls naturally into three parts: the chemical composition of the muscle cell, the location of the constituents in the muscle fibre, and the physicochemical aspects of muscular contraction. The first part presents a very thorough discussion of proteins of the muscle fibre, giving the history of their discovery and their role in considerable detail. Of great value is the threefold approach to the question: the enzymatic properties, the solubility, and the electrokinetic properties of the proteins. In the second part are summarized the results obtained with the electron microscope, and in the final part is an excellent account of recent biophysical work of the school and followers of A. V. Hill.

This monograph is entirely at the honours-school and postgraduate level of physiology and biochemistry. It is not to be recommended to the clinician unless he is interested in the scientific background of this field of medicine. It is reasonably critical, particularly in those fields where Dr. Dubuisson and his colleagues have been working. It has arrived at a timely moment, since a synthesis of the varied lines of approach (biochemical and biophysical) has long been needed. The author feels it is at the moment immature to sketch a general view of the mechanism of muscular contraction, since there is as yet a gap between the physicochemical aspects of contraction and properties of the muscular constituents when in the cell and in close relation with each other. The illustrations, references, index, binding, and printing are excellent.

A. ST. G. HUGGETT.

BRONCHOVASCULAR ANATOMY

Anatomy of the Bronchovascular System: Its Application to Surgery. By George L. Birnbaum, M.D. Foreword by Everts A. Graham, M.D. (Pp. 300+xv; illustrated. \$15 or £5 12s.) Chicago: Year Book Publishers Inc. London: Interscience Publishers Ltd. 1954.

The title of this volume is a good indication of its contents, since the author has taken certain facets of thoracic work in detailed consideration and has not attempted to produce a balanced survey of thoracic surgery as a whole. He starts with an orthodox embryological study of the tracheo-bronchial tree and pulmonary blood vessels, illustrating a

number of the common anomalies; he then proceeds to the anatomy of the bronchial tree, using the classification of Jackson and Huber. This is perhaps a little unfortunate in view of the recent introduction of the standard international nomenclature. Short sections on bronchial blood vessels, lymphatics, and innervation make useful but not outstanding reading. Then follows a well-illustrated section on congenital heart disease depicting the type of case which can be treated successfully by surgery. The section on abnormal pulmonary vessels gives nearly all the variations that have been encountered and affords a useful reference to any surgeon who may come across one of these unusual cases; there is also a short account of experimental surgery of the pulmonary vessels. Turning again to the bronchial tree, the author gives a good description of excision and grafting of the trachea and bronchi and of the various operations that have been used with limited success in asthma. The final chapters are concerned with pulmonary resection and give a detailed catalogue of the various methods commonly employed.

Dr. Birnbaum at the outset admits that he was aiming to produce an atlas of pulmonary vessels, and he has included an illustrated appendix giving the anatomy of the vessels based on a study of fifty adult lungs. The book, however, exceeded this boundary, and as a series of descriptive essays on individual subjects it makes interesting reading and affords a valuable source of reference.

T. HOLMES SELLORS.

OPERATIVE GYNAECOLOGY

Die Gynäkologischen Operationen, und Ihre Topographisch-anatomischen Grundlagen. By Heinrich Martius. Seventh edition. (Pp. 434+xvi; 450 illustrations. D.M. 87.) Stuttgart: Georg Thieme. 1954.

Martius's handbook continues to flourish as the hardest of perennials. It has been the vade-mecum of German gynaecologists for a generation, and with little alteration from the first edition this seventh issue looks like maintaining its original popularity. And rightly so, for in format the book is excellent. It is concisely written and beautifully illustrated, the copious drawings being closely integrated with the text. There are, of course, many variations from English and American practice, for German gynaecology has not yet recovered from its wartime isolation. For example, no fewer than twenty-three pages are occupied with operations for retroversion; implantation of the ovary into the uterus, a generally discarded procedure, is described minutely, but the use of plastic tubing in salpingostomy, a notable advance, is not mentioned. On the other hand, British surgeons might profitably study the chapters on the Pfannenstiel incision and colpotomy, two valuable approaches much neglected in this country.

The print is spoiled by poor spacing and the writing marred by the archaic use of composite words. Some of these are the etymologist's delight, such as "die Bulbo-kavernosusfettlappenzusatzplastik" and "der Scheiden-dammbeckenbodenschnitt." But on the whole the presentation is first-class, and, though the book cannot compare with the larger classics of Bonney, Peham, or Wilfred Shaw, its size is more convenient and its contents more than adequate for graduate use.

A. DAVIS.

SYMBOLISM OF THE SELF

The Self in Psychotic Process: Its Symbolization in Schizophrenia. By John Wier Perry, M.D. Foreword by C. G. Jung. (Pp. 184; illustrated. 37s. 6d.) Berkeley and Los Angeles: University of California Press. London: Cambridge University Press. 1953.

The word "self" has a special significance in analytical psychology: it implies a wholeness of personality embracing the conscious and the unconscious components. The notion of the self implies a new centre of gravity comprising ego and non-ego. This centre is believed to contain the

power through which the individual life attains or may attain fullness. Dr. Perry gives an account of a schizophrenic patient in whom the process of achieving wholeness was observed and noted, particularly in a series of drawings made by the patient. This development was not due to something new, but to the release of latent power striving for expression.

The book is in two parts. The first is a description of the process of recovery and reorientation. The author claims that this occurred spontaneously. The patient had no analysis, and from this it is apparently inferred that development towards recovery was unaffected by the therapist. In other words, the healing process is said to come from the psyche itself as a spontaneous effort of the unconscious towards wholeness and health. The validity of this argument—at all events in this instance—may be doubted. While the therapist said little he was nevertheless present, though we are given no information about the frequency or the nature of the interviews. He did, however, "promote a general attitude towards the symbol," and certainly the patient paid close attention to his observations. Furthermore, there was "a strongly toned transference." Dr. Perry is modest in his claims, but it would seem that he is over-impressed by the clinical material and disposed to interpret it according to his own expectations.

The second part of the book deals with the mandala and other symbols of the self as found in the East and in the West. There is nothing original in this section, but it is well done and provides an excellent introduction to the study of symbolism. This second part is an admirable addition to an interesting clinical study. The index is full and accurate, so that the book can be used for reference purposes.

E. A. BENNET.

BIOMATHEMATICS

Biomathematics: The Principles of Mathematics for Students of Biological Science. By Cedric A. B. Smith, M.A., Ph.D. Third edition and rewritten version of the work by the late W. M. Feldman, M.D. (Pp. 712+xv. 80s.) London: Charles Griffin and Co., Ltd. 1954.

This is a new version of the well-known book of the same name by W. M. Feldman first published in 1923 and revised in 1935. Dr. Smith has kept some of Feldman's material, particularly the physiological examples, but he has completely rewritten the exposition. The new book is more comprehensive than its predecessor; it includes an introduction to matrix algebra, and there is an up-to-date account of statistical methods which were inadequately treated in the older book.

The reader of a new popular book on mathematics will be interested as much in the style of exposition as in the choice of subject-matter. Such books frequently adopt a simplified approach which sometimes fails to reach the heart of the problem. *Biomathematics*, although not a formal textbook, has the flavour of real mathematics about it. This means that the reader who wants to benefit most from it will often have to work hard to absorb the argument. His reward will be an insight into mathematical procedures which is not usually achieved. Regarded as a work of reference, this book contains more than one would have thought possible to include in a single volume.

It is always possible to criticize mildly an author's choice of material in this sort of book. Many readers will regard some of the diversions (such as a chapter on a reform of arithmetical notation) as dispensable luxuries; others will welcome them as light relief. I should have liked a fuller treatment of chemical kinetics introducing the logistic function. The Poisson distribution, which has wide applications in biology, is scarcely mentioned. There is a rather startling treatment of logarithms, which, although theoretically neat, may not succeed as well as the familiar approach.

Biomathematics is a refreshingly original book, and should be widely used by students and research workers.

SATURDAY JANUARY 8 1955

SMOKING AND CORONARY THROMBOSIS

The steadily accumulating evidence to show that smoking greatly increases the risk of developing lung cancer has reawakened interest in the physiological and medical effects of an almost universal habit. Five years ago Bülbring, Burn, and Walker¹ showed how smoking can affect the coronary blood flow: they found in dogs that nicotine caused an initial increase in flow followed by a prolonged reduction, and that the reduction was similar in rate of onset and duration to that produced by an extract of the posterior lobe of the pituitary. Moreover, the amount of pituitary extract required was equivalent in amount (taking into consideration the difference in the volume of circulating blood) to the amount released in man by the smoking of one to two cigarettes. To extend laboratory investigations to observations on large numbers of human beings is seldom easy, but fortunately individual variability is such that men have created the conditions of a vast experiment. Not everyone smokes, and those who are smokers do not all smoke the same amount. Moreover, there is a tendency for a person who has once begun to smoke to remain within the same broad category of light or heavy smoker—unless he gives up smoking altogether. All that is necessary, therefore, to obtain evidence of a relationship between smoking and disease in man is to record the smoking habits of a large enough group of persons and to wait till the passage of time reveals the nature of the illnesses from which they subsequently suffer.

An extensive investigation of this type has been undertaken in the U.S.A. by the American Cancer Society, and the first findings have been reported by Hammond and Horn.² The basic data were collected with the co-operation of over 22,000 volunteer helpers, scattered throughout 394 counties and covering farming districts as well as large cities and small towns. The helpers were organized in groups of 5 to 15 persons, each of whom was invited to collect data on a standardized questionnaire from approximately 10 white men aged between 50 and 69—a condition which was imposed because the investigation was primarily

concerned with the study of lung cancer. By this means smoking histories were obtained from 190,134 men between January 1 and May 31, 1952. Subsequently on each November 1 the original helpers have been asked to return a simple form stating whether the men they had originally interviewed were alive or dead; and the State health departments have then been asked to supply an abstract of the death certificate for each man reported as having died. Follow-up data after eighteen months have been obtained for 187,766 men (99.8% of the total), of whom 4,854 (2.6%) were found to have died. Details of the certified cause of death have been obtained for 4,710. The most striking finding is that the general death rate from all causes was appreciably higher, within each quinquennial age group, for regular cigarette smokers than for non-smokers, and—in all save the oldest age group—became progressively higher as the amount smoked daily increased. On the other hand, among smokers of pipes or of cigars who had never at any time regularly smoked cigarettes the death rate was little or not at all higher than the rates suffered by the non-smokers. The number of deaths among men who had at some time regularly smoked cigarettes was 53% higher than it would have been if the death rates had been the same as they were among non-smokers, and 75% higher among those who were currently smoking more than twenty a day. So great an increase cannot be explained by an increased risk of lung cancer alone—which accounted for 167 deaths (3.5% of the total)—and it was found that there was also a clear-cut relationship between cigarette smoking and the death rate from disease of the coronary arteries. Owing in part to the method of collection of the data (by which men who were already seriously ill were unlikely to have been interviewed), the deaths in the first eighteen months included a particularly high proportion due to acute illnesses; consequently nearly half the total deaths were attributable to coronary disease. Between the ages of 50 and 64 the death rates for coronary disease were 95% higher among men who had ever regularly smoked cigarettes than among non-smokers and 120% higher among those who were currently smoking more than twenty a day. At ages 65–69 the differences were much less, being about 15%. Among cigar and pipe smokers there was no increased mortality at all.

The strength of the association is less than that observed with lung cancer, but owing to the large number of cases recorded there is no doubt about its statistical significance. The results are similar to those which have been reported in this country by Doll and Hill³ and on which we have previously commented.⁴ In the British study of the mortality of doctors, 230

³ *British Medical Journal*, 1954, 1, 1451.

⁴ *Ibid.*, 1954, 1, 1480.

⁵ Morris, J. N., Heady, J. A., Raffle, P. A. B., Roberts, C. G., and Parks, J., *Lancet*, 1953, 2, 1053 and 1111.

⁶ *New York Times*, October 23, 1954.

deaths were attributed to coronary disease and the death rate was found to rise steadily from 3.9 per 1,000 among non-smokers aged 35 and above to 5.2 per 1,000 among smokers of 25 or more grammes of tobacco a day; whether the increase was limited to cigarette smokers could not be determined because of the relative paucity of smokers of tobacco in other forms. The agreement between these two investigations—the one large-scale, the other smaller but based on a more homogeneous population—makes it difficult to believe that the association is not real. Whether it is causal can, in the long run, be most effectively proved by seeing whether abstention from cigarettes brings about a reduction in the mortality from the disease. Some will doubtless prefer to believe that the habit of smoking and death from coronary disease are related only in that both are the product of a third and common cause. Occupation requiring only light physical work, which has been shown to be associated with coronary thrombosis,⁵ might, for example, provide greater opportunities for heavy cigarette smoking. The association would, however, need to be very strong to account for the results, and it is difficult to believe that it could in any way account for those obtained among doctors. At all events the American Cancer Society—whose vice-president said not long ago that the problems raised by the effects of smoking on the heart and arteries were even more pressing than were the more publicized findings linking smoking and lung cancer⁶—has decided that the time has come to call a conference of Federal and voluntary agencies to discuss the whole subject as a public health problem.

MAINTAINING A PATIENT

The hospital costing returns published by the Ministry of Health have been criticized often enough by the experts; but they have now appeared again, in more detail than before, for the financial year 1953-4 with summarized comparisons going back to 1950-1.¹ What is the purpose of them? They purport to show the cost, or rather the average cost, of maintaining an in-patient in each of the 2,500 hospitals of England and Wales. The cost is calculated from the expenditure under the various subject headings—food, drugs, wages and salaries, fuel and power, and so on—from which the hospitals' budgets are estimated. This method, however, has some serious drawbacks. A hospital with a large out-patient department will have a larger expenditure on staff—and consequently food—than another hospital with the same number of beds but with few out-patients. The result, so far as the first hospital is

concerned, will be an inflation of the cost of maintaining an in-patient. It is true that the returns try to get round this obstacle by eliminating out-patient costs on the basis that five out-patient attendances equal one in-patient day. But no one pretends that this assumption is anything but arbitrary. It is generally recognized that a true costing system would allocate to each medical or surgical unit, or even each ward, its proper share of the hospital's total bills. Overheads, such as administration, would then be reflected in a unit's costs, but not the cost of the medical and nursing staff of other units. By this method the distorting effect of out-patient expenditure would be properly eliminated, and the cost of running the gynaecological unit could be compared with that of the orthopaedic unit and so on.

Over two years ago both the Nuffield Provincial Hospitals Trust and King Edward's Hospital Fund for London published reports on the feasibility of a system of unit costing in hospitals, and the Ministry of Health has set up a working party to devise a scheme for introducing such a system. Until then we have to make do with the present returns, which provoke some interesting speculation—even if allowance is made for the arbitrary assumption behind them. The published summary of the figures for the different types of hospitals put out by the Ministry is misleading in that it does not give the adjustment, made in the returns themselves, for staffed but unoccupied beds. The adjustment may be arbitrary, but at least it explains the apparent high cost of maintaining a patient in an isolation hospital. This is given as £19 9s. 2d. a week, compared with an average for the general hospitals of £15 15s. 5d. and of £19 2s. 9d. and £25 4s. 2d. respectively for the provincial and London teaching hospitals. But when adjusted for the "vacant bed factor"—isolation hospitals are naturally very under-occupied over the year as a whole—the cost of isolation beds falls to under £11 a week. Over and over again, when the costs of two hospitals of comparable size are examined closely, it will be found that it is a high occupancy rate in one that reduces its maintenance costs by comparison with the other's. The low cost of mental hospitals (£4 12s. 6d. per patient a week) can also be partly explained by their very high occupancy rate, which is another way of saying that they are overcrowded. But it is also due to the small proportion of staff to patients—the cost of medical salaries per patient a week is only 11s. 3d., compared with £1 9s. in large general hospitals, and of nursing salaries £1 8s. 9d., compared with £3 2s. 5d. When

¹ National Health Service Hospital Costing Returns, Year Ended March 31, 1954, H.M.S.O., 17s. 6d.

costs are divided among 2,000 patients, instead of, say, 500, they are bound to shrink significantly. The expenditure on drugs varies too: in a large general hospital it amounts on the average to 12s. 8d. a patient a week, and in a "chronic hospital" to 2s. 2d. The average for the mental hospitals is only 11d., and even though a mental hospital is now spending, say, £1,000 a year on chlorpromazine, this sum divided among 2,000 patients barely affects the weekly maintenance costs.

It is when two comparable hospitals are examined, with roughly the same occupancy rates for their beds, and large discrepancies are found in their costs, that official explanations may be called for. Of two London undergraduate teaching hospitals, for instance, with a difference of only 15 in the number of their beds and in each case with an occupancy rate of 89%, the one has a maintenance cost per patient about £3 a week higher than the other. Does this indicate more extravagant staffing?—it is noteworthy that nursing and ward orderly costs combined are over £1 a week more. Or does it merely reflect the arbitrary assumption behind the elimination of out-patient costs, for the one had many more out-patient attendances than the other? Perhaps questions such as these cannot be answered until unit costing has been introduced. The present returns merely provoke the questions, they cannot provide the answers.

SPECIFIC TREATMENT FOR MENTAL DEFECT

The total number of mental defectives under statutory care in England and Wales in 1953 was 118,963,¹ and there is evidence to suggest that more than half of them are above imbecile level.² In this high-grade group social factors are more important than lack of cognitive ability when it comes to living and working among normal people.³ With idiots and imbeciles, however, it is the gross inadequacy of cerebral function which is important. Crome has shown that almost all low-grade mental defectives have obvious structural alterations in the brain, and, if this is so, it seems that specific therapy designed to achieve a radical cure of mental defect has little chance of success. The best that can be done is, by suitable training, to enable the maximum use to be made of such potentialities as are located in a shrunken, scarred, or deformed brain. From time to time enthusiastic claims are made, and often widely disseminated in the lay press, for some new drug as a general treatment for the miscellany of clinical conditions included under

the heads of "idiocy" and "imbecility." More critical trials—such as those carried out on glutamic acid^{4,5}—have not usually given grounds for optimism.

A minority of children with severe mental defect are in an exceptional position because their condition is due essentially to metabolic disorder. If these children are treated early, when the structural defect is minimal, it would seem theoretically possible to restore the function of the brain to normal by correcting the metabolic error. The great value of specific treatment was first seen in cretinism, though optimism based on physical improvement was sometimes modified by less satisfactory response in the mental state. At the present time, however, cretinism makes only a small contribution to the total of mental defectives. In the Fountain Hospital for mentally defective children there are at present no diagnosed cretins in a population of some 800. Phenylketonuria is another comparatively rare disorder which has come under investigation more recently.⁶ The nature of the metabolic block in this condition, which is invariably associated with mental backwardness, is not clear. On the assumption that it was due to a deficiency in tyrosine synthesis Cowie⁷ fed this substance to patients at the Fountain Hospital, where 26 cases have been seen during the past five years. No appreciable benefit resulted, and the patients excreted more phenylpyruvic acid in the urine. Meantime other workers, taking the view that the symptoms are due to an excess of toxic metabolites rather than to a deficiency, have been trying out a diet low in phenylalanine, which may be compared to a pre-insulin diabetic diet.⁸ Bickel⁹ has published the findings in one case so treated, and in the opening pages of this issue Dr. L. I. Woolf, Dr. Ruth Griffiths, and Professor Alan Moncrieff give a more complete account of three cases treated at the Hospital for Sick Children. The results are encouraging, though the clinical improvement described is more convincing than the intelligence-quotient changes, which are notoriously subject to variation, especially in young mental defectives. The outlook for the treated children seems much brighter than it might have been, but psychologists must be even more cautious than biochemists about projecting their curves into the future, especially when no controls are studied. None the less, this is an important piece of work, and more early cases should be collected for study under carefully controlled conditions. It is to be hoped that this first glimpse of success will encourage further work on metabolic diseases causing brain damage.

THE BABY'S CRY

"Infants," wrote Walter Harris in 1689, "give no light into the knowledge of their diseases other than what we are able to discover from their uneasy cries." The subject perhaps deserves deeper study than it has received, and in a lecture which appears at page 75 of the *Journal* this week Professor R. S. Illingworth makes an instructive contribution to it. Crying (with the shedding of tears) is peculiar to human infants, and indeed it is their most potent means of asking for nourishment, summoning assistance and protection, and acting aggressively.

It is all the more important to them because, compared with other mammals, human babies are so helpless and immobile. Small wonder, then, that this immensely strong force for survival sometimes goes awry, driving mothers to distraction and fathers from their homes.

There is some uncertainty whether the cause of the crying can be discerned by listening alone, but even if there is no qualitative variation between the cry of hunger and that of pain the difference in intensity is sufficient to allow mothers usually to make the correct diagnosis. Most paediatricians believe that they can recognize pathological cries, such as the high-pitched one indicative of some intracranial disorder. The meaning and purpose of the first cry after birth is variously interpreted by different workers. To the physiologist it is simply a neat mechanism for ensuring deep respirations, but to the psychoanalyst it is a vigorous protest against an uncomfortable ejection from the peace and security of the womb. Many far-fetched theories to account for crying in older children have been propounded, but we are on firmer ground in thinking that some infants show a constitutional predisposition to cry at the slightest provocation whereas others are placid and easy from birth.

All normal babies cry from time to time, and the common causes change with age. In the first three months persistent crying is usually due to hunger. Unfortunately the easy remedy is often not applied for fear of overfeeding or because the symptoms are mistakenly attributed to wind. However, not all crying can be cured in this way: "three-months colic" is a clinically recognizable syndrome which is apt to run in families and may be linked with a particular kind of temperament, though some believe that it is due to gas trapped in a loop of bowel. Loneliness and frustration are other common causes of crying in infancy, which, unlike hunger and colic, are relieved by picking the baby up. In older infants and young children the picture becomes more complicated. In children with an irritable temperament and a determined negativism lie the foundations for this kind of difficulty, and contributory causes in the environment may be lack of love or security, over-stimulation, jealousy, over-protection (producing the "cry-baby"), and parents' demanding a too high standard. The happy child in the good home will occasionally go through bad phases which may be unaccountable, or these may follow a period of excitement, as in the aftermath of Christmas.

The treatment, as with other medical problems, must depend upon the cause. Difficulties arise when the crying has, or seems liable to, become a purely attention-seeking device. Violent crying indicates a need which most mothers know they should satisfy, but on the other hand some mothers artificially engender a need in order to satisfy their own wish to be wanted, with the result that the baby becomes spoiled and a vicious circle is begun. Striking the happy medium may be easy to the observer but hard to the parents or guardians. In general, paediatricians now favour gratifying the infant's needs, because they believe that a sense of comfort and security

then is the soundest foundation for future emotional stability. In short, this means plenty of mother-love and a fully adequate diet. Professor Illingworth, in his otherwise admirably comprehensive study, makes one curious omission from the treatment—namely, the use of the dummy. Mothers have used this device for centuries as a solace to infants, and, in spite of the active disapproval of doctors, dentists, and nurses, many babies are pacified with one. The recent Newcastle study¹ of a thousand families revealed that over 50% of the satisfactory mothers used them, and there was no evidence that they predisposed to infantile infection. M. A. Wessel *et al.* have also reported² that mothers in a series they studied found no difficulty in discontinuing them later on. When all is said and done, the mother must remain the best judge of what calms a crying baby most effectively. When sick infants are admitted to hospital they are deprived of their mother, and very often their dummy too, at a time when they need both most. We are trying to reduce the former deprivation so far as practicable, but objections are still raised to allowing dummies in the children's ward. Perhaps some of these objections are unreasonable.

RAYNAUD'S PHENOMENON AND OCCUPATION

Recognition that Raynaud's phenomenon is sometimes due to occupational causes dates from 1911. Alice Hamilton,¹ and other workers between the two world wars, found that working with pneumatic hammers was a predisposing cause, and pounders-up in the boot and shoe trade were also known to be affected. Since 1945, with the papers by Telford *et al.*² and Agate *et al.*³ describing outbreaks in other trades, has come the realization that there may be several occupations potentially harmful to workers' hands because of vibration. Agate⁴ has described the incidence and course of the disease in a large outbreak, raising questions of disability, and has made a study of harmful vibrations. Raynaud's phenomenon of occupational origin does not differ materially from that due to other causes. Attacks are intermittent, consisting of discoloration and numbness of the fingers in response to cold. It is usually difficult to distinguish from the constitutional disorder sometimes called "hereditary cold fingers" which Lewis and Pickering⁵ found to affect at least 25% of young adults. The occupational variety tends to affect first those fingers most subjected to vibration, but this is by no means the rule, and as the condition progresses its pattern becomes indistinguishable from the phenomenon arising from other causes. So close is the clinical resemblance that an abnormally high incidence of vascular disorder in a given group of workers has to be proved before the blame can fairly be laid on some occupational factor. The real existence of an

occupational form of Raynaud's phenomenon cannot, however, be doubted, for in some industrial processes the disorder has been found to affect 85–90% of the workers. In nearly all the occupational cases the disability is slight: often the attacks come on out of doors or only in a man's leisure time. The disease does not progress to trophic skin changes or gangrene, and where these are seen some other causal factor is to be suspected: only rarely have patients been seen with aching pain and cramps giving rise to real hardship.

In the last decade, with the increasing mechanization of manual tasks, more and more cases of the phenomenon have been coming to light in various industries. Some claims of disability were made and some cases reached the courts, and the question had to be considered whether Raynaud's phenomenon should be prescribed under the National Insurance (Industrial Injuries) Act of 1946. A report⁶ has now been submitted to the Minister by the Industrial Injuries Advisory Council, to which he had referred the question in March, 1950, and which in turn referred it to its Industrial Diseases Subcommittee. The delay of almost five years is an indication of the complexity of the matter. The obstacles to the prescription of this disorder have been squarely faced. First is the difficulty of distinguishing occupational from non-occupational cases of Raynaud's phenomenon. The subcommittee, in a majority report, considers that the distinction would usually be possible, but clinicians may doubt this (and it is they who would have to deal with cases under any new regulation). Physical examination is often unhelpful, and may at the time show no evidence of any disease. A successful claim would depend on establishing that symptoms appeared for the first time after exposure to significant vibration of the right type. Too often the only evidence would be the claimant's word, and realists will agree that bias, however unintentional, cannot be excluded where money is at stake. Yet to allow only those claims where objective signs of disease were present and accepting them as *post hoc* would be to exclude many that were genuine. The majority report considers limiting the "cover" to those specific trades in which the hazard is well recognized. But the chances of exposure to some kind of vibration are so many and varied that the inevitable disputes could be settled only by a succession of protracted surveys of incidence trade by trade. Particular difficulty is to be expected in assessing disability, for it is often negligible, and complete days are not lost from work. The report suggests that even in those few cases where basic disablement benefit would be payable the assessment would be of the order of 3%, and very few men indeed would qualify for special hardship allowance. The possibility of a special form of prescription to cover disablement of not less than a certain figure was considered—and, in fact, recommended in a dissenting note to the subcommittee's report by Dr. L. G. Norman—but found impracticable and unlikely to have its intended effect of reducing the number of trivial claims made.

In adopting the majority report of its subcommittee and advising the Minister against prescription, the Indus-

trial Injuries Advisory Council has taken a realistic course. The technical and clinical difficulties in putting the contrary decision into practice would be very great. Regulations likely to lead to thousands of claims—many based only on the claimant's own statements and not often succeeding—would probably fall into disrepute. The fairness with which the facts were considered will be apparent even to those who will disagree with the majority report. The subcommittee's minority report, by Mr. C. R. Dale, subscribed to by four other members of the council, eloquently and with some logic advises prescription for the sake of the few. But the fact remains that it has yet to be proved beyond a doubt that there are a significant number of men seriously incapacitated by this occupational disease.

THE OXFORD MEDICAL SCHOOL

It was announced last week that extensive building will take place at the Radcliffe Infirmary for the academic clinical departments of the Oxford Medical School. There will be new departments for the next Regius Professor of Medicine (if a clinician) and for the newly appointed Nuffield Professor of Surgery, and much larger facilities than at present for the Nuffield Professors of Clinical Medicine and of Anaesthetics, in addition to improved accommodation for biochemistry and pathology. Although a few students had previously carried through their clinical training at the Radcliffe Infirmary, no complete clinical school existed at Oxford until 1940. Then, under the stress of war, an undergraduate clinical school was hastily created on the basis of the post-graduate research units set up from 1936 onwards as a result of Lord Nuffield's benefaction, and many students began to receive their whole medical course at Oxford. By 1943 the University had decided that it wished to have a permanent undergraduate clinical school, but that it should be small and of a special type in which emphasis would be laid on the scientific aspects of clinical medicine. On the strength of this expressed intention of the University the Goodenough Committee recommended that public funds be allotted for a clinical school at Oxford and that the University itself be left free to decide what form the school should take. The University Grants Committee acted on this recommendation, and the clinical school has remained. Since the end of the war about one-third of Oxford preclinical students have stayed on for their clinical training, and some students have come from other universities.

By 1952 the University had gained enough experience to review the progress and future of the clinical school. After careful deliberation a letter was sent to the Minister of Health in March, 1954, setting out what is needed in the teaching hospital for the success of a clinical school of the special type to which the University is committed. In brief, the University asked for a more effective voice in the management of the hospital, with special reference to clinical facilities (beds and laboratories) and the appointment of consultants. The approval by the Board of Governors of the United Oxford Hospitals and by

the Minister of Health of the £400,000 building programme (to which the University is contributing nearly half) is the first tangible sign that the University's plan is to be put into effect. The Board of Governors has been hesitant about offering full facilities to the University, perhaps for a reason which is peculiar to Oxford—namely, that the teaching hospital is the only general hospital in Oxford and consequently must provide a complete hospital service for the city. Some members of the Board may have been uneasy lest further development of teaching and research might conflict with this duty. But Oxford is unique in possessing a new clinical school and a clear mandate to teach clinical medicine as a science, and the recent outcome of the efforts to achieve a fuller co-operation between the University and the Board are greatly to be welcomed. The further development of the medical school should only enhance the medical care available to the citizens of Oxford.

ERRORS IN CLINICAL JUDGMENT

Since medicine is still chiefly practised at the bedside it is important to understand the value and limitations of time-honoured clinical methods. Although for "exam" purposes clinical signs are apt to be treated as infallible, in practice the deductions based purely on clinical observation are found often to be unreliable and sometimes false. Fletcher¹ showed that expert physicians varied greatly in their interpretation of the physical signs in patients with emphysema, and he concluded that emphysema, in its early stages, could not be diagnosed with confidence by clinical examination alone. Even the answers to simple questions put to a patient about his symptoms may vary according to how the question is asked. In a study of the symptoms of coalminers with chest disease Cochrane and his colleagues² found that the interpretation of symptoms was markedly influenced by the bias of the questioning doctor. At page 65 of this issue of the *Journal* Drs. R. S. F. Schilling and J. P. W. Hughes and Mr. I. Dingwall-Fordyce report their investigations into the diagnosis and clinical features of byssinosis in Lancashire cotton workers. Byssinosis, unlike pneumoconiosis, produces no radiological changes in the lungs, so that the disability must be assessed purely on clinical observations. Two investigators made an independent assessment of the history, symptoms, and signs in 187 mill workers exposed to cotton dust and in 88 other workers not so exposed. The results showed that one observer consistently found more evidence of disease among the cotton workers than did the other. Thus one or both of the investigators, though fully aware of the possibility, showed bias for or against finding abnormal signs. Where objective measurements could be made, as in blood-pressure recordings, there was very little bias. As might be expected, divergence of opinion between the two observers was greatest in assessing those signs lacking a clear definition.

One of the salutary lessons to be learned from this investigation is that epidemiological studies carried out by a single observer might inadvertently lead to false

deductions and unwarranted claims. It also serves as a reminder that physical signs are not necessarily reliable because they are traditional. No doubt the individual clinician becomes more discerning about physical signs as he gains experience; he comes to know on which physical signs he can rely, and he rarely makes a diagnosis on an isolated clinical finding. Nevertheless, a more general appreciation of the limitations of clinical signs will lead to more critical standards of medical practice.

INDUSTRIAL HEALTH

On the whole the report of the Chief Inspector of Factories for 1953 is one of progress and improvement both in accident prevention and in the maintenance of health of the industrial population.¹ The one source of dissatisfaction arises from the figures for accidents to young persons, which show that the rate per 1,000 for girls is higher than at any time since 1949 and for boys equal to the 1952 level. Repeating his last year's remarks, the Chief Inspector points out that "young persons constitute industry's most precious material, and employers would do well to ask themselves if they are watching over it with all the care it needs." Management is not, however, always to blame; "sky-larking," not entirely confined to boys, disobedience to and misunderstanding of instructions, and lack of concentration have been responsible for a number of accidents. The establishment of good traditions by the example of older workers is recommended as a most valuable factor in the prevention of much unnecessary and regrettable disablement in the young worker.

A general improvement in the design of new machinery in the form of metal guards and interlocks has taken place, and special consideration has been given to hydro-extractors and centrifugal machines, which may become very dangerous if metal decay leads to bursting of the baskets. The mechanization of steel rolling mill processes has eliminated the danger of burns from hot metal, and accidents to the hands of cold-rolling mill operators have been greatly reduced, though one serious casualty occurred during the absence of a guard. In spite of these and other improvements there was an accident increase of 2.33% over the figures for 1952, but the number of fatal accidents decreased from 796 to 744. There is always some difficulty in persuading workers to make use of protective equipment of any kind, as shown in two cases of aniline poisoning, which were due to failure to change clothes and wash thoroughly after contamination with aniline. Goggles are especially disliked, but the rewards of such eye protection are sometimes dramatically obvious, as when two men, whose spectacles and goggles became encrusted with molten aluminium suddenly ejected into their faces, were undoubtedly saved from blindness by the protection afforded. Gassing cases showed a slight decrease in the total number notified, but the proportion of fatalities was high—9%. Carbon monoxide, with 121 cases, 19 fatal, and blast furnace gas, with 33 cases,

11 fatal, both showed a slight increase, and chlorine, with 36 cases, showed the highest number since 1945.

The general health of the working community, as affected by the factory environment, is difficult to assess accurately in the absence of satisfactory records of sickness absenteeism in the majority of factories, particularly the smaller ones, which represent a greater proportion of industry as a whole than the larger firms, with a high standard of working conditions. The standard of amenities for personal hygiene has certainly improved enormously since 1939, when washing facilities were first made compulsory in all factories, while the provision of canteens and the fulfilment of requirements of adequate ventilation, heating, and lighting have undoubtedly contributed greatly to the raising of the level of industrial health. First-aid and ambulance facilities have shown a special development in the growth of joint schemes, by which one factory provides a central clinic shared by a group of others on an estate. Among cases of notifiable industrial disease, lead poisoning occurs chiefly in ship-breaking, electric accumulator works, and with contact with molten lead, but for the fourth year in succession no fatal case was reported. Benzol, or benzene, one of the most potentially hazardous substances used in industry, was relatively innocuous in 1953. Only four cases of acute poisoning, or "gassing," were reported, and, though blood examinations of a large number of benzol workers showed some abnormalities consistent with benzene absorption, no cases of severe chronic benzene poisoning, with its characteristic irreversible depression of the bone marrow, occurred. The use of x rays and radioactive materials, though recognized as a grave potential hazard, appears to be well controlled. X-ray installations conform in general with the recommendations of the British X-ray and Radium Protection Committee; even where mobile sets are used the cabins are amply shielded. The majority of sets used for fluoroscopic examination of packed confectionery, tinned foods, sparking-plugs, etc., are generally also well protected, but need constant inspection to detect leaks and misuse by workers. There has been a great extension of the application of radioactive isotopes, in both strength and variety. Personal dosimeters are a valuable means of assessing the risk to operatives and of keeping the dosage to a minimum; the estimated dosage per operative per week in one of the major steel factories averaged only one-fiftieth of the minimum recommended dose. "Luminizing," the application of radioactive compounds to watch and instrument dials, has decreased considerably since the end of the war, only 144 luminizers now being employed in the whole of Great Britain. Their general health, and that of former luminizers followed up after some years' cessation of work, is good, and their blood picture, while suggesting, as in previous years, a transitory overstimulation of the reticulo-endothelial system, shows no evidence of bone-marrow depression. Records of radiation dosage, estimated by film badges supplied by the National Physical Laboratory, showed in most cases satisfactory low levels; a few reached or nearly approached the recommended tolerance level of 0.3 r per week.

Two codes of special regulations were issued during the year—the Mule Spinning (Health) Special Regulations, specifying the type of oil used with a view to the prevention of mule spinners' cancer, and the Iron and Steel Foundries Regulations for promoting safer and healthier conditions in iron and steel foundries.

NEW YEAR HONOURS

The full list of medical men in the New Year Honours List appears at p. 101. Medical representation in the House of Lords will be much strengthened by the barony conferred on Dr. E. D. Adrian, O.M., P.R.S. As a physiologist Dr. Adrian achieved an international reputation at an age when many medical men are completing their training. In 1932 he was awarded, jointly with Sherrington, the Nobel Prize in medicine and physiology "for their discoveries regarding the function of the neurons." Ten years later he was awarded the Order of Merit. His great distinction of character and mind has been universally recognized, not least, perhaps, by his appointment as Master of Trinity College, Cambridge, in 1951. As honour has succeeded upon honour through a life of achievement and service Dr. Adrian has remained imperturbably modest, and by his example and grace of speech, whether as President of the Royal Society or of the British Association, or as lecturer at Cambridge on the physiology of the nervous system, has put the undergraduate and the learned world deeply in his debt. Sir John Stopford, who has so conspicuously combined the careers of science and administration at Manchester University, becomes a K.B.E. Elected to the chair of anatomy in 1919 (in succession to the late Sir Grafton Elliot Smith) and a Fellow of the Royal Society in 1927, Stopford early won distinction for his neurological researches, particularly into the components of sensation. In 1935 he was appointed vice-chancellor of the university, and has rendered signal service not only to his university but to university education in general. The science of anatomy is also fittingly recognized in the knighthood bestowed on Professor W. E. Le Gros Clark, F.R.S., of Oxford. An authority on the primates and fossil remains of human ancestors, and on the anatomy of the brain, he has been a powerful influence in the teaching of his subject in this country. Professor L. S. P. Davidson, President of the Royal College of Physicians of Edinburgh, is also made a knight: he has written original contributions on a variety of subjects and been a great influence as a teacher and contributor to textbooks. Knighthoods have also been bestowed on Mr. A. A. Gemmell and Professor R. R. Macintosh. Mr. Gemmell is President of the Royal College of Obstetricians and Gynaecologists and was for many years its treasurer. Professor Macintosh holds the Nuffield chair of anaesthetics at Oxford and has contributed much to the development of this specialty. The many friends of Dr. A. J. Collins, of Sydney, both in Britain and in Australia will join in congratulating him on his knighthood. As teacher and consultant, and in the affairs of the B.M.A., Dr. Collins has been a beneficent influence in the medical world of Australia, where he is now President of the Federal Council of the B.M.A.

EMERGENCIES IN GENERAL PRACTICE

RESPIRATORY INSUFFICIENCY IN POLIOMYELITIS AND OTHER DISEASES

BY

W. RITCHIE RUSSELL, C.B.E., M.D., F.R.C.P., F.R.C.P.Ed.

Clinical Lecturer in Neurology, University of Oxford

The term "bulbar paralysis," or "bulbar involvement," in diseases such as poliomyelitis is correctly used only when the disease in question is affecting brain-stem nuclei in the pons or medulla, especially the nuclei of the motor cranial nerves. Of these latter, the nuclei which cause special anxiety are those which protect the airways from inhaling foreign substances—namely, those which innervate the throat and larynx. The term bulbar paralysis should not therefore be used when the chief disability depends on paralysis of the muscles of respiration—the intercostals and diaphragm—without any difficulty in swallowing.

It should, of course, be appreciated that either paralysis of the throat or paralysis of the muscles of respiration may lead to a very similar picture of respiratory insufficiency; and yet they must be distinguished from each other, as the appropriate treatments for the two conditions are quite different one from the other. There is, moreover, a third type of respiratory difficulty which may develop either from direct involvement of the respiratory centre by disease or, if respiratory insufficiency is not quickly treated, from the effects of anoxia on the respiratory centre. Finally, there may develop any combination of these various causes of respiratory insufficiency, so that the assessment of a complicated case may present great difficulties.

Presenting Symptoms and Signs

The patient (child or adult) developing bulbar poliomyelitis soon becomes obviously ill and fevered, with head pain and neck stiffness. Drowsiness may alarm the relatives quickly, but often the patient remains fully conscious. Various visible palsies of cranial nerve muscles may develop, such as those concerned with eye movements, the face or jaw, the palate, pharynx, larynx, or neck. The most dangerous by far are those which affect the throat and interfere with swallowing. There may be a history of choking and subsequent refusal of food or regurgitation of fluid through the nose.

This state of affairs requires careful treatment by the general practitioner if dangerous complications are to be prevented. His task is to recognize the various paralytic and pulmonary complications which may occur, to provide first aid for these, and to supervise the safe transfer to a hospital where the necessary apparatus and skilled personnel are available. Generally that is all he should do, and no attempt need be made to diagnose in greater detail at this stage. It will, of course, be appreciated that cases of bulbar poliomyelitis can only be cared for successfully by nurses and doctors experienced in this difficult condition, and the general practitioner's efforts will be unavailing if the care of the patient after reaching hospital is left in the hands of inexperienced personnel.

Clinical Signs and Treatment

The patient is usually found lying in bed on his back (supine), with one or more pillows, and a most essential part of the examination is simply to listen carefully to the breathing before disturbing him in any way. When there is paralysis of the swallowing mechanism the air for each breath often bubbles through a pool of secretions in the

pharynx. This closely resembles the well-known "death-rattle," in which the deep unconsciousness of approaching death leads to a similar state of affairs. The death-rattle of pharyngeal paralysis is, however, modified by the patient's conscious effort to avoid inhaling secretions, but when, as in some cases of bulbar poliomyelitis, the patient is also stuporous, then the development of a death-rattle may cause the doctor great anxiety if the true state of affairs is not promptly recognized. When collapse of a lung has already occurred the condition may closely resemble primary pneumonia.

When this rattle in the throat develops in bulbar poliomyelitis or in some other condition, its recognition calls for immediate action, and for this the principles of postural drainage of the airways require to be understood, as their prompt application will save many lives, not only of patients with poliomyelitis but also of those with poisoning, in drowning, with concussion, and with other neurological diseases which cause either dysphagia or deep coma.

Postural Drainage of the Air Passages

As soon as the doctor recognizes that there is a pool of mucus in the pharynx, he must remove all pillows from the bed and turn the patient on his face (prone), with the head to one side (Fig. 1) as for first aid in drowning or

FIG. 1

FIG. 2

after throat operations. This simple manoeuvre in itself will often save life in cases of pharyngeal paralysis, and these patients must be prevented from turning on their back into the supine position except under supervision, until the ability to swallow returns.

If, as often happens, secretions have already been inhaled by the time the patient is seen, the foot of the bed should in addition be raised at least 18 in. (45 cm.)—the height

of the average wooden chair (see Fig. 2)—and the chest squeezed manually during expiration to assist the expulsion of inhaled secretions.

The improvement in the patient's condition which follows these simple manoeuvres is often most gratifying. Large quantities of secretions may flow from the patient's mouth, so that a towel under the head and plenty of swabs are helpful. Some physicians attempt to establish adequate postural drainage with the patient lying on his back, but this is much less satisfactory than with the patient in the prone or semi-prone postures, and very steep angles of tilting are required to maintain adequate postural drainage in the supine position. The prone position not only allows fluid in the pharynx to flow safely out of the mouth and nose, but also assists drainage of the trachea, as the trachea is placed more anteriorly in the neck than in the chest. The prone or semi-prone posture should therefore be insisted on, but frequent changes of posture under supervision to right and left semi-prone, and to right and left lateral are helpful. The lowest placed lung may accumulate secretions, therefore the foot of the bed should be well raised for a short time before and after changes of posture to ensure that dislodged secretions flow safely out of the lungs, and not into healthy lung tissue.

Paralysis of Respiration

The airways having thus been cleared, it is now possible to observe whether the strength of spontaneous respiration is sufficient or whether there is also a developing paralysis of the respiratory muscles. The strength of the respiratory excursions may be judged by inspecting the movements of the chest and abdomen, and by listening with a stethoscope over the trachea. In most cases of bulbar poliomyelitis with paralysis of swallowing sufficient strength of respiration is maintained provided that the airways are clear and the lungs are healthy. If, however, pulmonary atelectasis or other lung complications have been allowed to develop, even a slight degree of respiratory weakness may lead quickly to a critical state of affairs in which artificial respiration as well as postural drainage is required to save life. Bronchoscopy may also be necessary.

Death in poliomyelitis is usually due to respiratory complications, and is only rarely due to the direct effects of the virus on the brain-stem centres—brain-stem lesions are common but will recover sufficiently if life is preserved by protecting the lungs.

Even the healthy individual can choke owing to a failure of the physiological mechanisms which separate what is intended for the oesophagus from what is intended for the trachea and lungs. This separating mechanism is at the best a delicate affair, and when disordered by disease may lead to a very dangerous situation in which secretions, blood, or vomit may be inhaled into the lungs. Of these, vomit is the most dangerous, as the inhalation of acid gastric secretions on a single occasion leads rapidly to necrosis of lung tissue, which is likely to cause circulatory collapse and death a few hours after inhalation has occurred. More commonly, however, the inhalation of secretions leads to collapse of one or more lobes of the lungs. It is thus obvious that the inhalation of vomit and secretions must be carefully prevented by recognizing when this danger exists, and instituting prophylactic treatment before serious damage occurs.

Other Conditions Requiring Similar Care.—All severe brain disease, such as meningitis, brain abscess, or head injury, may develop accumulations of secretions in the pharynx which require postural drainage just as urgently as in bulbar poliomyelitis. Paralytic conditions which lead to similar dangers include acute infective polyneuritis (Guillain-Barré syndrome), myasthenia gravis, and botulism.

Transfer to Hospital

The transfer to hospital of a patient with bulbar poliomyelitis often requires careful planning. In the first place he must be made fit for transfer by full drainage of the throat and trachea by means of postural drainage as

described above. Vomiting is likely to occur in the ambulance, so the prone or semi-prone posture without pillows must be maintained on the stretcher. A doctor should accompany the patient in the ambulance, and should be prepared to raise the foot of the stretcher to improve postural drainage and to introduce some form of artificial respiration should it be necessary.

Artificial Respiration

As has already been emphasized, the major problem in most cases of bulbar poliomyelitis is concerned with the associated paralysis of the pharynx and larynx. However, the development of paralysis of the muscles of respiration or of the respiratory centre may greatly complicate the patient's handling and transfer.

In many of these difficult cases the services of an experienced anaesthetist are required, and the local poliomyelitis centre may be able to send an anaesthetist to accompany a difficult case during transfer. Modern methods of anaesthesia cause both unconsciousness and muscular paralysis, and thus reproduce closely the types of disorder seen in poliomyelitis. The anaesthetist should be prepared to suck out the trachea, and if necessary to pass an endotracheal tube and to maintain positive-pressure breathing during transfer to hospital.* Mechanical suckers are of great value but are no substitute for postural drainage. Even a simple type of manually assisted respiration during transfer to hospital will greatly relieve the patient who is developing respiratory paralysis.

The Unconscious Patient

When the patient is unconscious there may be great difficulty in distinguishing between a disease affecting the brain-stem centres and the effects of cerebral anoxia. These are difficult cases to care for, but it is important to know that patients with bulbar poliomyelitis who become stuporous often make an excellent recovery if life can be preserved for the period of the acute illness. Every effort must therefore be made to tide these alarmingly ill patients over the early days of the acute disease, and such a patient should never be left without an experienced nurse or doctor at the bedside. It may be necessary for some days to listen to every breath. It is better to avoid attempting to reduce throat secretions with drugs such as atropine, as profuse watery secretions flow out freely and cause less harm than sticky mucus, which may soon become dangerous, and for the same reason humidification of the air may be desirable. Children with bulbar poliomyelitis are often very restless, and their clinical condition demands sedation. The use of sedatives, however, may in such cases precipitate failure of the respiratory centre, and so should not be given until mechanical methods of artificial respiration are available under experienced supervision. In such cases restlessness is often a symptom of respiratory insufficiency.

Finally, it should be pointed out that every region requires a nucleus of experts to deal with cases of threatening respiratory insufficiency, and their skill should not be dissipated on the 80% of patients with poliomyelitis whose lives are never in danger.

THE ASSESSMENT OF INTELLIGENCE

RECENT TRENDS IN MENTAL MEASUREMENT

The last of a series of lectures on "Psychology and Education," given recently at the University of London Institute of Education, was by Professor P. E. VERNON, who holds the chair of educational psychology in the University.

Professor Vernon gave three interpretations of the term "intelligence." What he called intelligence A was the underlying inborn potentiality, some quality of the central nervous system, determined ultimately by the genes. Intelligence B was the all-round ability or mental efficiency displayed in adult life, and very largely acquired. Intelligence C was the I.Q. or mental age or other score obtained from standard tests. This last might or might not correspond very closely with intelligence B, and, like intelligence B, it was very largely the product of environment, though limited by the innate potentiality or intelligence A.

Intelligence B, neurologically, corresponded to the amount of cerebral activity of which the individual was capable. In the absence of adequate environmental stimulation at the appropriate age many patterns of discharge in the association areas of the brain might not be properly formed, so that the intelligence was impaired. A dog brought up in the restricted environment of a cage was less intelligent and less capable of problem-solving than a dog brought up as a pet, with the free run of a rich environment; and so with humans. Intelligence could not properly be distinguished from acquired information and education, but a relative distinction might be useful. On the one hand, there were concepts which depended largely on knowledge specifically taught in school or in books, whose absorption and retention was also governed by the person's interest in the subject and by his industry. On the other hand, there were more general qualities of comprehension, judgment, and reasoning which could be manifested through responses to verbal stimuli or through practical skills that had been picked up in the course of everyday living without much specific instruction.

What do Intelligence Tests Measure?

Mental tests were often seriously misunderstood. They were looked on as a psychologist's magic for finding out things that could not be revealed in any other way. The tests were simply well-chosen samples of people's thinking and behaviour. If intelligence testers could collect a sufficiently broad sample of everything that the layman recognized as intelligence then the I.Q. (or intelligence C) would be identical with all-round ability (or intelligence B), but the latter covered the whole of the mental life whereas intelligence tests covered only rather narrow and partial samples. Legitimate deductions about intelligence B might be made from a study of intelligence tests, but the tests were apt to be too restricted and unrepresentative.

The extent of variations in I.Q. on retesting had been underestimated. Over the primary and secondary school period and early adulthood the average person did stay within the same band or region of I.Q. But he might vary on retesting by 7 points either way, or 10 points if frequently retested, and a small number of persons might gain or lose 30 or even 40 points.

These facts, however, must be set against the still greater unreliability of any other form of assessment such as school examinations and teachers' ratings. An individual intelligence test at age 5 or 6 provided a useful indication of general educability in infant and junior school; a well-constructed group test at age 10 or 11 yielded as a whole slightly better predictions of secondary school success than almost any other single instrument; and tests around age 15, although they seldom correlated highly with success in any specific job, gave strong indications of the intellectual level of employment for which the individual was suited and his likelihood of benefiting from more advanced education. But

fluctuations in intelligence and education were such that few psychologists were happy about any rigid scheme of segregation or streaming by ability, though big fluctuations in ability were the exception rather than the rule.

Environmental Effects on Intelligence

After discussing the several reasons for the imperfect reliability of intelligence tests, Professor Vernon turned to the evidence of the effect of environment on intelligence, and quoted work of Freeman and Newman to suggest that the differences between good and poor upbringing could produce differences of only 10 or at most 20 points in I.Q. The statement (which was accepted by a large number, though not a majority, of teachers in a questionnaire), that differences between the average I.Q. of children from different social classes arose simply because better-off parents could provide better opportunities for developing the abilities measured by the tests, was definitely false, because there was some correlation between the I.Q. of orphans and the social class of their true parents, who had not brought them up. At the same time there was also an appreciable correlation with the social class of the foster parents, showing that environment as well as heredity did contribute. Another strong argument was the big differences in I.Q. between children in the same family or orphans in the same institution, which could hardly be attributed purely to differences in upbringing.

Some critics had said that if intelligence tests were affected by environment there was no justification for using them for educational screening, since they were supposed to show inborn potentiality for acquiring further education. The answer was that what intelligence tests showed was the joint product of the genetic potentiality and the upbringing. The tests worked all the better because they were impure. If it ever did become possible to measure intelligence A (inborn potentiality) completely it would not be possible to give anything like as good predictions of future educational and vocational success. Potentiality for acquiring further education was not entirely inborn.

Future Developments in Mental Measurement

In the United States there was a definite trend away from talk about intelligence tests, and American psychologists preferred to develop batteries of differential aptitude tests, or sets of tests designed to elicit the individual's group factors or abilities along a number of different lines. The pattern or profile of such scores was likely to be much more revealing for educational or vocational guidance than the single, vague global I.Q. Professor Vernon suggested that a good deal of controversy would be avoided if at 11+ something like academic aptitude were substituted for intelligence tests and the types of items for such tests were chosen, not because somebody thought they measured inborn intelligence, but because they effectively predicted subsequent grammar school success and added appreciably to predictions based on attainments tests or examinations alone. He considered that it would be a real advance to give up putting together a hotchpotch of items and calling it an intelligence test, and, instead, choose a series of important aspects of general ability appropriate to a limited age range, measure these by homogeneous scales or subtests, and finally combine the results of the subtests in a rational manner designed to give the most effective predictions of whatever it was desired to predict.

In conclusion Professor Vernon suggested that no one should bother too much about improvements in selection techniques. A well-known statistician had said that if it went much further there would be no need to have any general certificate examination, because they would all know at age 11 who would pass, and in what subjects. This remark brought home the futility of expecting to segregate with absolute accuracy by age, ability, and aptitude. Of course children developed and changed between age 11 and 16 or

18. Instead of laying all the blame for mistakes on the psychologists' intelligence and attainments tests it would be better to modify the system which forced them to be used in an artificial competitive atmosphere. In that way better diagnostic instruments for use in educational and vocational guidance might be developed.

MEDICAL NEW YEAR HONOURS

The names of the following members of the medical profession were included in the New Year Honours List published in the *London Gazette* on January 1.

EDGAR DOUGLAS ADRIAN, O.M., M.B., F.R.C.P., President of the Royal Society; President of the British Association for the Advancement of Science; and Master of Trinity College, Cambridge.

K.B.E. (Civil Division)

SIR JOHN SEBASTIAN BACH STOPFORD, M.D., F.R.C.P., F.R.S. Vice-Chancellor and Professor of Experimental Neurology in the University of Manchester.

Knighthood

WILFRID EDWARD LE GROS CLARK, M.D., D.Sc., F.R.C.S., F.R.S. Dr. Lee's Professor of Anatomy in the University of Oxford.

ARCHIBALD JOHN COLLINS, D.S.O., M.C., M.B., Ch.M., F.R.A.C.P. President of the Federal Council of the British Medical Association in Australia. Honorary Consulting Physician, Royal Prince Alfred Hospital, Sydney, New South Wales.

LEYBOURNE STANLEY PATRICK DAVIDSON, M.D., F.R.C.P., F.R.C.P.Ed., F.R.S.Ed. Professor of Medicine in the University of Edinburgh and President of the Royal College of Physicians of Edinburgh.

ARTHUR ALEXANDER GEMMELL, M.C., T.D., M.D., F.R.C.S.Ed. President of the Royal College of Obstetricians and Gynaecologists.

ROBERT REYNOLDS MACINTOSH, D.M., F.R.C.S.Ed., F.F.A.R.C.S. Nuffield Professor of Anaesthetics in the University of Oxford.

C.B. (Military Division)

CHARLES WILLIAM GREENWAY, C.B.E., M.R.C.S., L.R.C.P. Major-General, late R.A.M.C., Honorary Surgeon to the Queen.

JAMES HAMILTON, C.B.E., M.B., Ch.B. Surgeon Rear-Admiral.

C.B. (Civil Division)

The Hon. WALTER SYMINGTON MACLAY, O.B.E., M.D., F.R.C.P., D.P.M., D.T.M.&H. Senior Medical Commissioner, Board of Control.

C.M.G.

CYRIL FRANCIS FERNANDO, O.B.E., M.D., M.R.C.P. Medical Officer and Physician, General Hospital, Colombo.

RAYMOND LEWTHWAITE, O.B.E., D.M., F.R.C.P. Director of Colonial Medical Research, Colonial Office.

C.V.O.

JOSEPH GRAEME HUMBLE, M.R.C.S., L.R.C.P. Honorary Consulting Haematologist, Westminster Hospital, and Senior Lecturer in Haematology, Westminster Hospital Medical School.

C.B.E. (Military Division)

JOHN HENRY BREUELL CROSBIE, M.B., B.Ch. Surgeon Captain, R.N. (ret.).

FREDERICK CAVENDISH HILTON-SERGEANT, M.B., Ch.B., D.P.H. Major-General, late R.A.M.C. Honorary Physician to the Queen.

C.B.E. (Civil Division)

ARTHUR FREDERIC ALFORD, M.B., Ch.B. Senior Medical Officer, Ministry of Education.

WILLIAM EDWARD LODGEWYK HAMILTON CROWTHER, D.S.O., V.D., M.B., B.S., F.R.A.C.P. A prominent physician in the State of Tasmania.

MAURICE WALTER GOLDBLATT, M.D., Ph.D., D.I.H. Director, Industrial Hygiene Research Laboratories, Imperial Chemical Industries Ltd.

JOSEPH HAROLD SHELDON, M.D., F.R.C.P. Director of Medicine and Senior Physician, Royal Hospital, Wolverhampton.

DENIS JOHN WILLIAMS, M.D., D.Sc., F.R.C.P. Civilian Consultant in Neurology and Electroencephalography to the Royal Air Force.

O.B.E. (Military Division)

THOMAS WILSON FROGGATT, M.B., Ch.B. Surgeon Commander, R.N.

JOHN IRVINE, M.B., Ch.B. Lieutenant-Colonel, R.A.M.C. In recognition of services in Korea during the period February 1 to July 31, 1954.

THOMAS MCGREGOR MCNIE, M.B., Ch.B., M.R.C.O.G., D.Obst.R.C.O.G. Lieutenant-Colonel, R.A.M.C.

JOHN HOPE POOL, M.D. Acting Wing Commander, Royal Auxiliary Air Force Reserve of Officers.

O.B.E. (Civil Division)

BASIL WILLIAM ARMSTRONG, M.C., M.B., B.S. Lately Medical Superintendent, Royal Sea-bathing Hospital, Margate.

DAVID ALEXANDER BAIRD, M.B., Ch.B. Director of Medical Services, Somaliland.

ARTHUR BEAUCHAMP, M.R.C.S., L.R.C.P. General Practitioner, Birmingham, and Deputy Chairman of the Representative Body of the British Medical Association. For services to the Ministry of Health.

ELIOT CECIL CURWEN, M.B., B.Chir. Honorary Physician to the Police Convalescent Seaside Home, Hove.

WELIWATTAGE LIVERIS PERERA DASSANAYAKE, L.R.C.P.&S.Ed., D.P.H., D.T.M.&H. Superintendent, Filariasis Campaign, Ceylon Government Medical Service.

WILLIAM MARSDEN FORD-ROBERTSON, M.D. Medical Director of the Lebanon Hospital for Mental and Nervous Disorders, Beirut.

THASSOS CHARIDIMOU GIRCOTIS, M.D. For medical services in Cyprus.

GEORGE RAJANAYAGAM HANDY, M.D., M.R.C.P. Visiting Physician, General Hospital, Colombo.

WILLIAM EDWARD HUTCHINSON, E.D., M.D., D.P.H., J.P. Assistant Director of Medical Services (Civil Defence), Singapore.

EDWARD NORMAN JAMIESON, F.R.C.S.Ed. Surgeon, Lewis Hospital, Stornoway.

JAMES HUTCHINSON KENNEDY, B.M., B.Ch., D.T.M. Government Medical Officer at Ndanga, Southern Rhodesia.

ARTHUR GENTRY PITTS, F.R.C.S., F.R.A.C.S. A medical practitioner at Waimate, New Zealand. For services to the community.

JOHN HERBERT OWEN ROBERTS, M.D., D.P.M., J.P. Medical Superintendent, North Wales Hospital for Nervous and Mental Disorders, Denbigh.

LORIS ROHAN SHARPLES, M.B., Ch.B. For public services in British Guiana.

WALTER ANSLEY YOUNG, M.R.C.S., L.R.C.P., J.P. For public services in the Federation of Malaya.

M.B.E. (Military Division)

ALEXANDER JOSEPH ZOSIMUS NAVARATNE, Captain, Ceylon Army Medical Corps.

ERNEST SIDNEY ODBERT, M.B., B.Ch. Squadron Leader, R.A.F.

LESLIE FRANK RICHMOND, T.D., M.D. Major, R.A.M.C., T.A.

M.B.E. (Civil Division)

MOYA KATHLEEN BAILEY, M.B., B.S., D.Obst.R.C.O.G. (Dr. Blackall). A prominent medical practitioner in the Australian Capital Territory.

FRANK HOWARD BUDDEN, M.B., B.S., D.T.M.&H., D.O. Medical Officer (Ophthalmology), Northern Region, Nigeria.

MARIA LEONORA DU TOIT, M.B., Ch.B. For medical services in the Tiv Division, Northern Region, Nigeria.

LUCIFERN ARNOLD GUNESKERA, Medical Practitioner, Colombo.

JAMES DONALD HOLMES, M.B., C.M. Admiralty Surgeon and Agent, Finchley and District, London.

THOMAS AFFLECK MORRISON, M.B., Ch.B. Chairman, Brighton Executive Council, National Health Service.

CHARLES VINCENT MTAWALI, African Assistant Medical Officer, Tanganyika.

IDA MIRRIE LEES SEYMOUR, L.R.C.P.&S.Ed. Lately Medical Officer, Department of Health for Scotland.

CARDIOVASCULAR DISORDERS AND MORTALITY RATES IN AMPUTEES

Two years ago a medical committee under the chairmanship of Sir Ernest Rock Carling presented a final report to the Ministry of Pensions on the results of an investigation into the longevity and liability to cardiovascular disease of Service amputees from the First World War (see *British Medical Journal*, 1953, 1, 717). The investigation suggested that those who had had severe wounds and amputations experienced later a higher mortality rate, that in those with leg amputations cardiovascular disorders were a commoner cause of death than would be expected, and that a history of "serious sepsis" following wounding was somehow related to these findings. The committee has now reviewed the evidence, and has written to the Chief Medical Officer of the Ministry of Pensions and National Insurance in the following terms:

"In our 'Final Report' on 'Cardio-vascular Disorders and Mortality Rates in Amputees' we stated that although the conclusions affirmed earlier in the Interim Report were not materially altered by our subsequent deliberations we nevertheless found upon analysis some variation in particular groups and we indicated that specialized pathological and clinical research might contribute advantageously to our knowledge. Accordingly the Ministry of Pensions made arrangements for the medical examination of some 4,500 amputees with 1,000 non-amputee pensioners as 'controls.' It is regrettable that the figures obtained by the examination of living amputees failed to provide statistically significant evidence largely because of the failure of a considerable number of those, in what was intended to be a representative sample, to attend for examination. So far as it goes the evidence obtained discloses no excess of high blood pressure among amputees and no material excess of cardiovascular disease.

"Having now reviewed the whole of the evidence from all sources, we find that:

"Out of every 1,000 amputees alive in 1930 there was a mean annual mortality of 12.6 in the years 1930 to 1950. Out of every 1,000 of the general population of comparable sex and age alive in 1930 there was a corresponding mean annual mortality of 11.4. The mean annual mortality rate of amputees was therefore just over one per thousand in excess of that of the corresponding general population. Expressed differently this means that, starting, say, with 100 amputees alive in 1930, 25 had died by 1950 compared with 23 of the corresponding general population.

"Out of every 1,000 who had suffered wounds not leading to amputation there was a mean annual mortality of 13.15 in the years 1930 to 1950. Out of every 1,000 of the general population of comparable sex and age alive in 1930 there was a corresponding mean annual mortality of 11.9. The mean annual mortality rate of the wounded was therefore just over one per thousand in excess of that of the corresponding general population. Expressed differently this means that, starting with, say, 100 wounded pensioners alive in 1930, 26 had died by 1950 compared with 24 of the corresponding general population.

"With so small a difference of total mortality the actual distribution among the certified causes of death assumes very little importance. Some members of the Committee think that within the limitations of the statistical material available there is evidence of some slight excess of cardiovascular disease as compared with the normal population, with a consequential deficiency of deaths from other causes. The Committee as a whole, however, are still of the opinion indicated in the Interim Report that cardio-vascular diseases have not been experienced more frequently to an extent of any significance amongst the causes of death in limb amputees as compared with those with serious leg wounds without amputation.

"Some amputees, especially those with a high thigh amputation, necessitating a tilting-table, with excessive obesity or with severe stump pain find the wearing of a prosthesis an increasing burden as age advances. These may deserve individual reconsideration though other classes of pensioner will also find their disabilities more burdensome with the passage of time. Neither as regards their mortality nor

their morbidity do amputees form a class apart. They have neither a higher mortality rate nor a higher cardio-vascular rate than other classes of seriously wounded.

"The committee have reconsidered the evidence as to sepsis as a factor and feel that they over-emphasized its importance in the last report.

"In conclusion the committee now advise on the terms of reference as follows:

"Limb amputations, and the subsequent wearing of a prosthesis, do not, in time, produce effects on the body as a whole which may initiate, or aggravate, cardio-vascular disorders to any significant extent.

"There is no material difference between the mortality rates of amputees, by reason of amputation, and that of the corresponding rates for pensioners who have suffered wounds not leading to amputation. Such excess as there is in both classes over that in the general population is quite small."

Correspondence

Brain Injury in Boxing

SIR.—I would like to congratulate you on the very able leader on boxing (*Journal*, December 25, p. 1535), as well as your decision to publish the pragmatic article by experienced experts (Drs. J. L. Blonstein and E. Clarke, *Journal*, December 25, p. 1523). I fear, however, that the latter article might be interpreted as indicating that all was well with amateur boxing, in regard to the incidence and severity of harmful sequelae, in so far as useful recommendations had already been made and some prudent practices adopted. I venture to doubt whether such a conclusion would be valid.

The sorbo-rubber floor (or the American equivalent) should not only be recommended but should be made compulsory. The matching of age and weight is not enough. Experience, competence, and adequate training are much more important, and no match should be allowed to take place in which one boxer is unskilled and unable to put up a reasonable defence. This not infrequently happens in inter-hospital boxing, where a novice is persuaded to enter on the chance of scoring a point, even without a win. It is true that referees do, nowadays, make better use of their right (and duty) to stop a bout where one opponent is obviously outclassed or has received a severe blow that renders him incapable of effective defence for a period of uncertain duration; but the possibility of the "loser" turning the tables by a lucky blow, or an unexpected recovery, often makes a referee unwilling to face the criticism of alleged untimely or premature intervention. Education of boxers and onlookers in this regard is still needed. Apart from physical injury, there is also the adverse psychological effect of taking one or more severe hidings from tougher and more experienced opponents.

Nevertheless, and in spite of the ominous stress your annotator felt bound to make on the fact that an aim of a boxer was to knock his opponent out (concussion), I still feel from the experience of some ten years of active participation, and many more years of interest, that boxing is sufficiently worth while as a virile character sport to justify our taking every precaution to ensure its continuation under conditions of reasonable prudence. Trials of skill, endurance, and courage will still remain in very full measure for those who enter the ring in combat.—I am, etc.,

London, W.1.

S. LEONARD SIMPSON.

The Handicapped Adolescent

SIR.—In your leading article (*Journal*, December 25, 1954, p. 1536) under this heading you say, "There may in fact be some medical neglect of the problems of the adolescent," and you suggest that appropriate "attention is not always paid by our medical services to the late teenagers." One illustration of the truth of your statement concerns school-

children with pulmonary tuberculosis. Few of these call for prolonged institutional treatment, but those that necessitate such a regime should be sent only to sanatoria fully equipped to deal with both their therapeutic and educational needs. Unfortunately this is not always the case. Not infrequently children are admitted to my sanatorium who have undergone previous residential treatment in conditions quite unsuited to their youth and their educational needs. The following are typical examples:

Girl, 14 years of age, admitted after undergoing many months' residential treatment with adults. She had received no education for one year. Girl, 12 years of age, previous residential treatment intermittently for past two years. Approximately one year spent in convalescent home where one teacher for about 100 children ages 2-14. "Boys had teacher one week and girls the next." Girl, 13 years of age, admitted after 15 months' residential treatment among adults; no schooling.

These scanty facts have come to light whilst taking the children's own histories. No effort has been made to confirm them. There may be some inaccuracies, but it is clear that there are instances where education is allowed to drift seriously whilst treatment for tuberculosis is undertaken. There can be little doubt that inquiry would bring many similar cases to light. Neglect of this sort is inconsistent with national standards of child welfare.

It should be axiomatic that institutional treatment for children with pulmonary tuberculosis cannot be efficiently conducted without adequate concurrent education. The organization of such facilities can only be undertaken economically if the area to be served covers a very numerous population. It is doubtful whether even the regional boundaries are large enough for this purpose. Probably the whole country could best be served by about half a dozen national centres. Such centres should be prepared to admit boys and girls up to 16 years of age, and, in addition, to accept a small number of tuberculous adolescents over this age if still receiving education. Parents will not always accept treatment for their children which precludes frequent visiting because of long distance, but experience proves that most parents prefer efficient treatment at a distance to doubtful facilities near by. If parents were encouraged to look upon such centres as residential sanatorium schools few would raise any objection. It is realized, however, that there would always be a residuum of children who could not be accommodated in these special centres. These might still have to be dealt with in small groups or as individual cases in circumstances where medical and educational facilities could not be up to the standard required. There would be much advantage in such cases being known to the medical staff of the special centre, who could visit or advise as required.

Tuberculosis in childhood has too long been dominated by ideas and practice arising out of a knowledge of the disease in adults. But the disease in young people has its own pattern and calls for different management. It is high time it became generally realized that special arrangements are required.—I am, etc.,

Brentwood, Essex.

F. J. BENTLEY.

Treatment of Bronchial Obstruction

SIR.—The paper on the treatment of bronchial obstruction by Dr. G. S. Kilpatrick and Mr. P. D. Oldham (*Journal*, December 11, 1954, p. 1388) disturbs me. My scientific friends will be aware that I have been very diligent in pressing for the use of statistical methods in experimental medicine; but when a deduction from a statistical analysis conflicts with common sense I suspect some inadequacy in the analysis. And the conclusion that the authors arrive at that their observations cannot be taken to show that treatment with calcium chloride is worse than that with adrenaline seems to me to be not sense. Eight patients chosen substantially at random each show no important change with calcium chloride, and all give a positive response to adrenaline. The decision to adopt a sequential scheme apparently prevents me saying that the odds are 2⁸ to 1 that calcium

chloride is worse than adrenaline; but, whatever the odds, in my view there is sufficient evidence to be reasonably confident that calcium chloride is no good. Perhaps some statistician will help me out of what must appear to be a lapse into heresy.—I am, etc.,

London, S.E.25.

J. W. TREVAN.

Trilene in Domiciliary Midwifery

SIR.—The report of the M.R.C. Committee¹ and the action of the Central Midwives Board (*Journal*, December 18, 1954, p. 1470) will be generally welcomed, and it is to be hoped that a considerable increase in the use of "trilene" will follow, both in domiciliary work and in maternity units. However, the patients for the trial were selected "solely on the basis of the expectation that the confinement would be normal." Therefore neither the report nor your leading article deals with a possible complication.

A proportion of the labours where the mother receives trilene will for various reasons end in operative delivery. Such patients will still be excreting trilene from the lungs, so that if general anaesthesia is used the closed circuit method must be avoided. Toxic products may be produced when even small amounts of trilene come into contact with soda-lime. These toxic products can cause cranial nerve palsies and even death. In view of this danger, anaesthetists called to obstetric emergencies must pay more attention than in the past to the exact nature of the analgesia previously employed.—I am, etc.,

Bromley, Kent.

H. A. CONDON.

REFERENCE

Cheyne-Stokes Respiration

SIR.—Our experience with ear oximetry in Cheyne-Stokes respiration in heart disease is the same as that of Drs. H. R. Gilmore and H. Kopelman (*Journal*, December 18, 1954, p. 1439) and of Matthes²—namely, that the lowest arterial saturation occurs at the peak of the hyperpnoea. We agree that these cases have both a prolonged lung-head circulation time and some abnormality of the respiratory centre, but we hold that dynamic sensitivity of the centre is increased rather than depressed. The sequence, hyperventilation → decreased stimulus → hypoventilation → increased stimulus → hyperventilation, will be self-perpetuating if the second hyperventilation is as great as the first; and for this to be so, the response of the centre to changes in the stimulus (to be understood as comprising both $p\text{CO}_2$ and hypoxia) must be sufficiently great. Only the dynamic sensitivity, change of ventilation produced by change of stimulus, is important here, and this can vary independently of the response to a given steady stimulus.

Figures 4 and 5 of Gilmore and Kopelman's paper, illustrating the effects of oxygen and carbon dioxide inhalation, support this analysis. The first effect of oxygen is to moderate the hyperpnoea—that is, to lessen the response to the high $p\text{CO}_2$ produced by the preceding apnoea. The oxygen evidently does not equally depress the response at low levels of $p\text{CO}_2$, or apnoea would still follow the moderated hyperpnoea. Carbon dioxide also decreases the dynamic sensitivity by maintaining ventilation where there was previously apnoea, without adding equally to the hyperpnoea, which was already virtually maximal. The relation between this type of periodic breathing and that occurring at high altitudes or with cerebral injury is still uncertain. In animal experiments it has been demonstrated that cerebral injury may produce periodic respiratory movements even when the blood gases are maintained constant by artificial ventilation.³ The topic is thus more complex than might appear.—We are, etc.,

London, S.E.1.

Carcinogens in Cigarette Smoke

SIR.—Most smokers are fastidious about preventing cigarette smoke from reaching their nostrils and eyes, and except in comparatively rare types—ex-pipe smokers who retain the cigarette between their lips throughout the smoke (and, incidentally, spill the ash over their persons) and ex-cigar smokers who chew the cigarette-end—I have not observed staining of the lips or eyebrows of heavy cigarette smokers, and would consequently not expect an increase in epithelioma of these parts as a result of cigarette smoking. The skin of the fingers is so tough—by comparison with the epithelium of the bronchi—that carcinoma of the fingers would be most unlikely unless the amount of carcinogen in tobacco smoke were extremely high.

It is probable that the frequent mopping of the lips, tongue, and buccal cavity by salivation, eating, and drinking wipes away carcinogens before these have time to act and that this accounts for the absence of an increase in carcinoma of these parts in smokers. But this does not apply in the larynx and I am unable satisfactorily to account for the situation there. It may be significant that severe degrees of laryngitis are much less common among heavy cigarette smokers than similar degrees of bronchitis. Perhaps the vocal cords are so well tucked away during smoking that they escape heavy exposure to tobacco smoke.

For almost a decade I have heard nothing of the plausible untruth, at one time widely current, that the amount of nicotine absorbed in smoking is infinitesimal, and I may have helped to dispose of it.¹ Professor R. D. Passey's attempt (*Journal*, December 18, 1945, p. 1485) to show that the amount of carcinogen in tobacco smoke is, in effect, infinitesimal, so far as carcinoma of lung is concerned, is strikingly reminiscent of this old untruth.—I am, etc.,

¹ *Lancet*, 1942, 2, 742.**Talc Pneumoconiosis**

SIR.—I read with interest the account by Drs. Bertram Mann and J. B. Deasy (*Journal*, December 18, 1954, p. 1460) of miliary lung opacities in a worker exposed to talc. In view of the non-specificity of radiological miliary mottling, it will be interesting to learn whether the future brings confirmation of their opinion. In 1950 I reported similar findings in a printing works employee.¹ This man operated a guillotine for trimming book edges, and the cheap paper used gave off a large quantity of dust. Analysis of the dust by Professor King at Hammersmith Hospital showed it to contain 5.8% of silica (from talc used as "filler"). However, histological examination after his death three years later failed to demonstrate any fibrous silicate in the lungs. The changes were considered to be accounted for by the repeated attacks of bronchopneumonia from which he suffered and which eventually caused his death.—I am, etc.,

¹ *Proc. roy. Soc. Med.*, 1950, 43, 906.**Changes in the Mental Health Services**

SIR.—Scotland has had another injustice thrust upon her. Dr. John Marshall (*Journal*, December 18, 1954, p. 1484) has made the fatal mistake of not verifying his facts before adding his enthusiastic support to the establishment of mental observation wards. After reading his letter I applied to the secretary of the General Board of Control for Scotland for detailed information on this subject. In their annual report for 1906 the Board expresses its sympathy with a movement set on foot in 1901 to establish wards in public infirmaries for the study and treatment for short periods (up to six weeks) of cases of incipient or unconfirmed mental disorder. Even in 1890 such accommoda-

tion existed in the Glasgow area, and so great was the benefit that in 1904 Dr. John Garswell became responsible for the care and treatment of a group of 50 patients (25 of each sex) in Duke Street Hospital, Glasgow. Dr. Garswell was succeeded by Dr. Ivy McKenzie, whose work is so well known. In more recent years excellent observation wards were developed at Stobhill Hospital, Glasgow.

In Edinburgh since the beginning of the century one of the wards of the Royal Infirmary has served the beneficent purpose of caring for cases of delirium, attempted suicide, and other acute episodic nervous and mental states. Furthermore, during the 1914-18 war the late Professor G. M. Robertson started his campaign to "de-asylumize asylums." He established nursing-homes which care for 70 patients and, in addition, inaugurated a psychiatric clinic known as Jordanburn Hospital which accommodates 50 patients. No formality whatsoever governs the admission and treatment of patients to any of the above-mentioned establishments. Dr. Marshall's statement, therefore, to the effect that if a person "is unable or unwilling to sign voluntary papers there is no alternative in Scotland but to certify him" is entirely contrary to the actual facts. The vast majority of all toxic and episodic states are successfully dealt with in the Glasgow and Edinburgh areas, at least, without recourse either to voluntary or certification forms. There is much to be said in favour of mental observation wards, but the reasons given for their establishment should be accurate.—I am, etc.,

Edinburgh, 3.

DAVID K. HENDERSON.

SIR.—Dr. J. B. S. Lewis (*Journal*, December 4, 1954, p. 1354) attacks the mental observation wards on the basis of his L.C.C. experience, which must be before 1948, a time when the wards had not recovered from war conditions. Dr. J. Gibson (*Journal*, December 18, p. 1485), in supporting him, freely admits, "I have not myself seen one." Dr. R. Asher (*Journal*, January 1, p. 44), however, goes too far in wanting these wards run by general physicians; he would not take kindly to psychiatrists running general wards because so many illnesses are psychosomatic. I agree that the strength of the observation ward lies in its being part of a general hospital, not only by providing rapid and effective treatment for the organic confusions and psychoses, but by integrating more closely psychiatry with general medicine, thus overcoming the fear and ignorance implied in the attitude "they are only lunatics"—an attitude not confined to administrative staff, but found too often among doctors without psychiatric understanding.

Dr. Lewis opposes the upgrading of observation wards to "first-class treatment centres." I have recently completed one year's work in an observation ward attached to a London teaching hospital, where over one-third of admissions are discharged directly home (in 1953, 567 patients were discharged out of 1,445 admissions); therefore the unit is, in fact, an acute treatment centre, with a gratifying percentage of recoveries in the 14-day observation period. If there is close integration with the psychiatric out-patient department, surely the work is satisfying enough to attract the best type of doctor and nurse. In our unit there is no overcrowding, the number of beds is laid down by the Board of Control, and further admissions can be, and are, refused. Effective separation is achieved by the use of two floors, side rooms, small side wards, and adequate partitions. Dr. Lewis's alternative, direct admission to mental hospital, fails through lack of beds (recently an important regional hospital had a waiting-list of six weeks for voluntary patients and three weeks for certified patients). Even if accommodation were found, staff could not be. Our unit has, full-time, two psychiatric registrars and a psychiatric consultant for 76 beds. In the average mental hospital a medical officer usually has up to 200 beds.

Much irrational fear of mental hospitals still exists, and many patients are more willing to enter an observation ward than go direct to mental hospital. Relatives are more likely to agree to certification if they feel that the patient has been under continuous observation before a decision is made, and if their trust and co-operation are built up during the daily visiting, which is encouraged. Moreover, one-third of our

transfers to mental hospitals are voluntary patients. If one bears in mind that most admissions are of acutely disturbed patients who could not wait to go as voluntary patients in the normal way, this result debunks the horror stories so naively accepted by some of your previous correspondents (are not similar stories told of general wards?). I feel that these functions of the observation ward are not provided elsewhere, and these units play an irreplaceable part not only in the mental health services but in the Health Service as a whole. They need support, extension, and improvement—not suppression.—I am, etc.,

London, W.1.

I. S. KREEGER.

The Corneal Grafting Act (1952)

SIR.—The increasing numbers of inquiries which are received from doctors, solicitors, and the general public indicate that the provisions of the Corneal Grafting Act (1952) need further elucidation, especially with reference to the bequest of donor eyes. Briefly, the Act enables a person to make a verbal or written bequest of his or her eyes for therapeutic purposes, but the bequest can be nullified by the objection of surviving spouse or nearest relative. The collection of donor eyes is the responsibility of those who require them, subject to the provisions of the Act, and collection entails a certain amount of organization and effort: in practice death is usually notified to the hospital by the doctor in attendance or by a relation. The duty team then proceeds to collect the material, taking sterilized enucleation equipment, which is always maintained in readiness: eyes have to be removed within 10 hours of death to be suitable for optical grafts. In our experience these melancholy occasions are invariably treated with a sense of dignity and respect by the bereaved relatives, who derive consolation from the fact that the last wishes of the deceased are carried out. The only occasion on which umbrage has occurred was when it was not possible to comply with a bequest because notification of death did not reach the surgeon in time, and the relatives felt that they had not kept faith.

For administration purposes and to arrange the orderly admission of patients for corneal grafting to hospital the preservation of donor eyes has become an essential part of this method of treatment. At the present time the most suitable method of preservation, beyond a few hours, is to bank the eyes in sterile antibiotic-liquid-paraffin solutions at 4° C. in a refrigerator: such material is suitable for subsequent grafting up to 14 days after removal, provided it is sterile. The sterility of cadaver donor eyes has become a matter of great importance, as it has been found that about one-third of such eyes have initial contamination by pathogenic organisms and have to be discarded. This wastage can be checked by antibiotic preventive measures at the time of excision or before preservation. The eyes or corneas are well irrigated with penicillin solution before removal and are immersed in penicillin-streptomycin solution before being placed in the eye bank. Control cultures are taken at various stages of preparation and preservation: a positive culture excludes the use of the eye for donor material.

At East Grinstead the supply of donor eyes has been more than doubled since the Corneal Grafting Act became law, but it is still far from adequate for all purposes. The indications of corneal graft surgery continue to expand, and the selection of material and cases becomes more and more critical. As a result of these measures, and the use of improved material, the standards of visual success are steadily rising, and about three-quarters of those cases on whom a corneal graft operation is performed may expect improvement of vision in varying degrees to normality. A recent valuable adjunct to the final success of corneal graft surgery is the use of the contact glass.

It is hoped that this summary may help to answer some of the many inquiries which are received, and it is stressed that the collection of this valuable material has been much facilitated by the co-operation of the general practitioner, house-surgeon, relations, and ophthalmic surgeon.—I am, etc.,

London, W.1.

B. W. RYCROFT.

Tuberculin Testing

SIR.—In a letter from Dr. W. H. Tattersall (*Journal*, November 6, 1954, p. 1105) a plea was made that the "Heaf gun" be evaluated speedily as an alternative to the jelly test to provide a standard tuberculin test. When a physician is attempting to exclude tuberculosis as the possible cause of a patient's illness, it is unlikely that he will be satisfied with the single test and will probably wish to use ascending concentrations of tuberculin as in the Mantoux test. But for the purpose of conducting epidemiological surveys, of testing contacts of cases of tuberculosis, and of selecting and retesting subjects for B.C.G. vaccination, it would be of great value if there were available a single test, simple to execute and to interpret. For such a purpose it is probably important that not only the jelly and Heaf tests should be examined but also the von Pirquet and Mantoux tests, using varying strengths of old tuberculin and of P.P.D.

It may interest those of your readers who are concerned with this problem to learn that the Research Committee of the British Tuberculosis Association is planning such an inquiry. The task is by no means a simple one and it may well take time to reach conclusions of value.—We are, etc.,

JOHN CROFTON,

Acting Chairman.

G. MAHER-LOUGHNAN,
Hon. Secretary.

London, N.W.9

Low Backache

SIR.—I must support Dr. L. S. Calvert's statements in his letter on low backache (*Journal*, December 18, 1954, p. 1488). For the past two years I have been using the method of diagnosis and treatment advocated by Dr. Cyriax at St. Thomas's Hospital with most gratifying results. Prior to learning of Dr. Cyriax's methods, I too, like the orthopaedic panel, had no answer to the problem of low backache with, or without, sciatica. Now, using the manipulative technique and methods of traction described in Dr. Cyriax's textbook,¹ backache due to disk lesions is no longer a major problem. There are still a number that fail to respond to these methods, but the large majority are completely relieved in a very few treatments.

I feel sure that one answer to the problem is the training of more interested general practitioners in the technique of manipulation and also ensuring that all physiotherapists are able to apply these methods as well. Dr. Cyriax has proved beyond any shadow of doubt that his methods are effective and free from danger.—I am, etc.,

Southampton.

DAVID B. RAMSAY.

REFERENCE

¹ *Textbook of Orthopaedic Medicine*, 1950, London.**Fluoridation of Public Water Supplies**

SIR.—I share the perturbation of many who live in North Wales at the published intention of the Anglesey County Council, acting on the invitation of the Government, which has actually gone to the length of offering indemnity against possible legal costs and damages in the matter, to conduct a controlled experiment in the fluoridation of the public water supply in a part of Anglesey. Despite some verbal quibbling about it, this undoubtedly amounts to compulsory medical treatment with a toxic substance intended to produce a physiological change in the body, to be administered indiscriminately by medically unqualified persons, and in amounts varying widely with the consumption of water and the concentration of salts in it by boiling.

The public is being assured that the medical profession is virtually unanimous in its approval of this project both in its ethical aspect and in its positive certainty of the complete innocuousness of fluorides at the proposed low concentration, even for daily consumption for an indefinite period. Indeed, the writer, a non-medical biologist, has been challenged to produce any medical opinion in this country which is critical of fluoridation, and so far has failed to do so. If this unanimity really exists, or is allowed, as at present, to pass by default, then the profession must

be prepared to bear the brunt, for the Government, of the inevitable public opposition to mass-dosing without consent, as well as the responsibility for any damage, physical or psychological, which may result from it. However, inquiries among my own medical acquaintance seem to show that, whereas any professional meeting can be relied upon to pass a resolution favouring fluoridation, no individual doctor can be discovered who claims to know much about its effects, or to be able to diagnose slow chronic fluoride poisoning if it should occur. If this is the situation the "experiment" could do widespread damage without anyone's being the wiser, and the value of statistics "proving" the absence of fluoride poisoning at the proposed concentrations would be nil. I should very much like to see this important matter discussed in your columns.—I am, etc.,

Bangor.

C. G. DOBBS.

Dyspareunia Clinic

SIR,—Owing to the fact that for some years I have been particularly interested in the problem of infertility, I have become increasingly aware of the large part which dyspareunia plays in the causation of this complaint. It is sometimes the only bar to conception, but it is one of the most difficult to overcome because it is frequently a condition not capable of easy remedy either by surgery or medicine. A patient often seeks her doctor's help on the grounds of infertility, whereas her real complaint is her inability to adjust herself to participate in a normal married life.

The cure of such a condition nearly always entails the expenditure of more time than the busy practitioner has to give, and even if the patient is referred to a gynaecologist the latter can do little to help in the course of one consultation or in the pressure of his out-patients clinic. I am writing, therefore, to bring to the notice of your readers the fact that a clinic for the exclusive purpose of treating such cases has been opened under the auspices of the Family Planning Association—namely, the Marriage Welfare Centre at 12, Telford Road, Ladbroke Grove, London, W.10. The aim of this clinic is to provide expert guidance to such patients, giving to them the time and patience which it is a practical impossibility to give in clinics which are run for the purpose of investigating infertile marriages or in a doctor's busy surgery. Sessions are run on Mondays from 6 to 8 p.m. and patients are seen by appointment.—I am, etc.,

London, W.1.

R. CHRISTIE BROWN.

Placental Globulin in the Prevention of Measles

SIR,—A recent paper by Drs. H. Ganguli and S. N. Mukherjee (*Journal*, December 11, 1954, p. 1395) reported a follow-up on the use of placental gamma globulin for measles prophylaxis in 32 cases in a Calcutta hospital ward. From the investigation it was concluded that the low incidence of measles obtained was due partly to prompt isolation of the patients and partly to the injection of gamma globulin. From observations made during a large-scale follow-up on gamma globulin distributed in Scotland by the Scottish National Blood Transfusion Association it seems probable that under hospital conditions, without special isolation precautions, a low rate of infection (under 25%) may be expected even when no prophylactic injections are given. Some physicians maintain that with strict nursing procedures cross-infections in the open ward may be eliminated almost completely. If special isolation measures are taken, as in the above investigation in Calcutta, it is possible that the low incidence of measles obtained could be due solely to the quarantine precautions. This would make it difficult to draw any conclusion regarding the efficacy of the placental gamma globulin under trial.

At a recent symposium on gamma globulin organized by the International Children's Centre in Paris (December 2 to 4, 1954) mention was made of the fact that certain placental preparations which had been distributed in Europe contained a considerable amount of protein other than gamma globulin. In a follow-up designed to check the

potency of such materials the following are desirable: (a) the use of intimate contacts as test subjects—for example, house contacts—in preference to hospital contacts; (b) a control group, not receiving injections, or, if this is not practicable, a valid estimate of the expected incidence; (c) numbers of cases sufficient to give statistically significant results; and (d) accurate records of the dosage given on a body-weight basis. In the paper quoted, particulars were not given of the source of the placental gamma globulin, of the concentration, nor of the electrophoretic composition. Assuming the highest probable figure of 16.5% for the concentration, it appears that "protective" doses—15 mg. per pound (0.45 kg.)—were given to only a few of the patients.—I am, etc.,

Edinburgh, 3.

DRUMMOND ELLIS.

Tendo Achillis Bursitis

SIR,—The condition called tendo achillis bursitis (winter heel), described by Professor N. W. Nisbet (*Journal*, December 11, 1954, p. 1394), is seen not infrequently in Army personnel. It develops during the first week or two of basic training and would appear to be caused, as Professor Nisbet writes, by the rubbing of the boot against the back of the heel. There is severe pain over the tendo Achillis, radiating into the calf, and all cases exhibit crepitus, identical with that seen in tenosynovitis of the wrist. This crepitus extends from the insertion of tendo Achillis for one to two inches (2.5–5 cm.) upwards—that is, reaching as high as, but no further than, the back of the boot. Most cases are unilateral, but I have seen some men with the condition affecting both tendons.

In this regiment at least one case is seen weekly, often more. Serving in an all-male regiment, I have only seen it in men, and there appears to be no seasonal change. All cases are treated with "elastoplast" strapping and are ordered to wear loosely tied light shoes; a few of the more resistant cases are further aided with chiropody felt beneath the elastoplast, over tendo Achillis. Under this treatment the pain and swelling disappear in most cases in about four to seven days, but I can record one case which persisted for over three weeks. No case has been severe enough to merit reference to hospital for operative treatment. All the men had been wearing new boots, and the condition rarely returns when the men recommence wearing their boots. It would be interesting to record the frequency of this condition in the basic training units of the women's Services.—I am, etc.,

Catterick, Yorks.

B. W. LAITHWAITE.

A Rational Approach to Prostatectomy

SIR,—I was very interested in the comments of Mr. T. L. Chapman (*Journal*, December 11, 1954, p. 1418) on my recent paper (*Journal*, November 20, p. 1201). With regard to the bad-risk patients, if these are "tided" over by a Riches catheter inserted suprapubically it is often possible to deal with the prostate at a later date. For example, I have dealt with many patients in whom acute prostatic obstruction has supervened on congestive cardiac failure, hemiplegia, etc., and in a matter of several weeks have been able to carry out a perurethral prostatectomy when the general condition had improved. In a recent case it proved to be worth while performing a cold-punch prostatectomy in a man who had had a resection for carcinoma of the lung; as a result of the prostatectomy the patient was able to micturate normally for the last nine months of his life and was considerably more comfortable as a direct result.

I have always been a great admirer of Mr. Chapman's work, and his great skill with the Gershom Thomson cold-punch resectoscope is well known. It must, however, be remembered that when a large obstruction is removed by the perurethral method this is a tedious and lengthy procedure and necessitates the presence of the resectoscope in the urethra for the whole of that period. The constant friction of the resectoscope must thus be taken into account.

and it is for this and other reasons that I have suggested that the suprapubic approach is better for the large adenomatous obstruction in the great majority of cases. Finally, I agree entirely with Mr. Chapman when he says that it is only by a careful and prolonged follow-up of results that a final decision can be made.—I am, etc.,

Liverpool, 1.

J. COSBIE ROSS.

Torsion of Normal Fallopian Tube

SIR,—I read with interest the letter of Drs. D. Mayiakos and Alex Romanos (*Journal*, September 25, 1954, p. 754). As this condition seems to be very rare, I would like to publish the following case.

My patient had her second child on September 9, 1953, a normal confinement. She came to my consulting-room on October 28, 1953, seven weeks after her confinement, complaining of an intermittent pain which had started two days before in her waist, low down, on her left side. She was nursing at the time. The pain passed gradually round to the front on the same side, still intermittent, and she now felt it as far down as her left knee. The pain came on sharply, lasting for about a minute, then disappearing altogether. She was passing urine more frequently than usual, but the pains had no connexion with micturition. The urine was cloudy, there was a trace of albumin, with both red and white corpuscles under the microscope. The uterus was small and anteverted. Behind the uterus and to the left side there was a round, very tender swelling, slightly movable. She complained of feeling faint. Pulse and temperature were normal, and the abdomen generally soft and supple. A provisional diagnosis was made of an intermittent twisting of an ovarian cyst. She was sent home. Seen 24 hours afterwards, she had passed a bad night and the pain was now constant and very severe. Per vaginam the swelling was larger and acutely sensitive. She felt very faint, but no vomiting. Pulse and temperature were normal. A diagnosis of a twisted ovarian cyst was made and an immediate operation was advised. A round, smooth, haemorrhagic swelling was found, somewhat larger than a tangerine orange. The left ovary was normal. After removal the tumour consisted entirely of the left Fallopian tube, which had four complete twists in it. Convalescence was normal. Early this year she started her third pregnancy, and she had a normal confinement on November 9, 1954.

What is the cause of torsion of a normal Fallopian tube? —I am, etc.,

Valparaiso, Chile.

STANLEY M. WELLS.

Uveitis with Deafness

SIR,—The case report by Dr. P. K. Robinson (*Journal*, October 2, p. 792) has attracted my attention because, having carried out an extremely thorough series of investigations, he has omitted (or failed to record) the investigation which I should have placed first on the list. The patient, a male stoker aged 41 years, had a clean medical history apart from an attack of urethritis of uncertain cause seven years before. Most urologists would, I think, agree that the man, seven years after his attack, would very probably still harbour a chronic low-grade infection involving perhaps the posterior urethra, prostate, or seminal vesicles. For this is often the trend in such cases, and total eradication of the infection is a prolonged and difficult matter. Then, three months before admission to hospital, the patient noted what was apparently a swollen left inguinal lymph node, and in a matter of a few weeks the insidious illness affecting the eyes and ears began its morbid course. I would suggest the possibility that this inguinal node was a visible manifestation of an extension of the infection from the posterior urethra and neighbouring areas to the anterior urethra. In other words, an old chronic dormant infection had temporarily flared up and extended beyond its customary limits.

To any believer in the theory of chronic local infection as a cause of irido-cyclitis, the above chain of circumstances would appear to be exactly right as a precipitating factor in such an eye condition. And if the ocular tissues are capable of responding in a certain pathological fashion to such an exciting cause, why not also the delicate cells of the meninges, and the cochlear and vestibular apparatus? The investigations carried out in this case were extensive, but one wonders

why prostatic massage with meticulous analysis of the expressed fluid was not done. This could conceivably have produced the clue to the solution of a difficult case. At the least, I think this investigation would have been as relevant and desirable as, for example, the tests for brucellosis and toxoplasmosis. Again, it is noted that x-ray examination was made of the skull, chest, hands, and feet, but no mention is made of the teeth. Even in an edentulous patient I would advocate dental x-rays in this type of case (for infected dental roots).

The omission of these two investigations leads one to the conclusion that the investigators concerned hold no brief for local sepsis as a cause of irido-cyclitis of the type encountered here. But if this be so, are they justified in such a view? My purpose in writing this letter is to direct the spotlight back on to the small, chronic, low-grade, walled-off, apparently harmless local lesion as being the guilty party in the causation of many cases of irido-cyclitis. I also express the hope that further research will be done on this important problem.—I am, etc.,

Brisbane, Australia.

FERGUS M. YEATES.

Foreign Currency for Patients

SIR,—Since the war it has been necessary to restrict the use of British currency abroad, and seven years ago the Exchange Control Medical Advisory Committee was set up to deal with applications by patients advised to seek medical treatment overseas. No one, in the Government or otherwise, liked the idea of restricting facilities used for health, and the responsibility of allocating foreign exchange on medical grounds was entrusted to a medical committee, with the duty to safeguard the interests of the patient as well as conserve, so far as possible, our limited foreign exchange.

It is the Government's policy to simplify exchange control procedure, and in future the patient's bank will be authorized to grant foreign currency solely on the strength of a doctor's recommendation that it is required "on medical grounds." Banks will provide a printed form, but the doctor may write his own certificate, provided similar wording is used. When currency is required for the United States of America or Canada the patient's doctor will be asked to certify that the dollars are required "for medical or surgical treatment" which cannot be obtained elsewhere.

The Exchange Control Medical Advisory Committee would like to take this opportunity of thanking their medical colleagues all over the country for their patience and forbearance. The doctor has generally had the delicate responsibility of deciding whether he ought to support a patient's desire to go overseas, or whether treatment at home would be equally satisfactory. Judging applications has not been easy, but the Committee is happy to think that, even in the most stringent financial period, over 75% of applications were granted, and during most of the Committee's existence more than 85%. Few, if any, sick people in genuine need of treatment which could not be obtained in this country or the sterling area have been unable to obtain it.—I am, etc.,

London, W.C.1.

HARLEY WILLIAMS.

POINTS FROM LETTERS

Intramuscular Iron

Dr. CONN LUCEY (Galway) writes: "Imferon" and "ferri-venin" are put up in identical ampoules. It is impossible to distinguish one from the other except by close scrutiny of a legend which is easily erased from the ampoule by slight friction. Since imferon may be given intravenously as well as intramuscularly, might it not be as well to abandon the use of ferri-venin and use one preparation only—that is, imferon—for both intravenous and intramuscular therapy?

Advertisements by Post

Dr. DOROTHY G. E. POTTER (Cleve, near Bristol) writes: We suffer a daily bombardment of postal advertisements. Now Father Christmas has been enlisted into the service of prescribing asthmatic relief. I feel that the Christmas card has reached its lowest stage of debasement by caricaturing Father Christmas.

Obituary

C. JENNINGS MARSHALL, M.D., M.S., F.R.C.S.

Mr. C. Jennings Marshall, senior surgeon to Charing Cross Hospital at the time of his sudden death on December 29, 1954, was within a few months of retirement from the staff of the hospital which he entered as a university scholar in 1909. He was 64 years of age.

Born at Cardiff on June 6, 1890, Charles Jennings Marshall received his early education and preclinical medical training in that city before he enrolled at the Charing Cross Hospital Medical School. He was an exceptionally brilliant student who showed early promise by being awarded honours in three subjects and a gold medal when he graduated M.B., B.S. at London University in 1912. After holding house appointments in several departments of the hospital he proceeded to the M.D. in 1914 and was awarded the Murchison Scholarship of the Royal College of Physicians in the same year. While surgical registrar at Charing Cross he gained the F.R.C.S. in 1915 and another gold medal at the M.S. examination in 1916.

In company with his old chief, Sir Herbert Waterhouse, he went to Petrograd (now Leningrad) during the first world war to act as assistant surgeon at the Anglo-Russian Hospital which had been established there as a good-will gesture to our allies. He was part author of an article which appeared in this *Journal* in 1917 under the title of "Notes from the Anglo-Russian Hospitals." Upon his return from Russia he joined the R.A.M.C. and served on the Salonika front. Shortly after the end of the war he was appointed assistant surgeon and junior orthopaedist at King's College Hospital and he also began his long association with the Victoria Hospital for Children, Tite Street. A few years later, however, he returned to his mother hospital as assistant surgeon and thus became one of the small number who have been on the staff of two teaching hospitals in London. At the time of his death he was a member of the board of governors of the hospital. He was, in addition, consulting surgeon to the Bromley Hospital, to the L.C.C. at St. Charles's Hospital, and to the Surrey County Council. During the last war he was director of the surgical section at Sutton Emergency Hospital. From 1919 to 1932 he served as a Ministry of Pensions consultant. He returned to his birthplace in 1953 to be a vice-president of the Section of Surgery at the Annual Meeting of the British Medical Association. As became a general surgeon, Jennings Marshall's professional interests were catholic, with perhaps a special emphasis on genito-urinary work, and as a result of a wide experience his diagnostic powers were of a very high order. In the theatre he was a rapid and clean operator whom it was a delight to watch, and he was responsible for many valuable innovations of technique, details of which he did not trouble to publish but which his students will well remember to their advantage. He was a good teacher who impressed upon everyone the value of clinical examination and who could be scathingly opposed to a too precipitate resort to the laboratory for help. His knowledge of surgical history was extensive, and it was a commonplace to hear him comment on some claim to a new operation, "Oh, but that was advocated and practised by so-and-so fifty years ago."

During the course of his career he produced three textbooks—*Surgical Pathology* (with A. Piney), *Surgical*

Anatomy and Physiology (with Norman C. Lake), and *Chronic Diseases of the Abdomen*—and a small volume entitled *The Surgeon* in a series on careers. His writings all displayed a precise turn of phrase and a detailed attention to the exact meaning of words which made the books characteristic. He had also been examiner in surgery for the universities of London and Manchester.

Jennings Marshall had many interests outside medicine. In the early days of wireless broadcasting he experimented with many receiving sets which his knowledge of the subject enabled him to construct well in advance of current commercial practice. He was also interested in music and the arts, and was for many years an active member of the Savage Club, to whose Saturday dinners it was his delight to invite his friends. His personality and teaching will long be remembered at Charing Cross, and there must be a large number of his students, house-surgeons, and registrars who have reason to be grateful for all they have learned from him, and a now reduced number of his contemporaries and colleagues who are equally grateful for his friendship and help. He is survived by his widow, formerly Miss Hope Embleton-Smith, whom he married in 1945.

Dr. R. H. YOLLAND writes: I first knew Mr. C. Jennings Marshall in 1920 when he was assistant orthopaedic surgeon at King's College Hospital and I was casualty officer there. He was a wonderful teacher, and I still remember to this day how interesting he made his surgical anatomy classes, which were always packed out by students. He was also a very fine hockey player, receiving a trial cap for Wales. He played hockey for King's in 1921–2 and was a great inspiration to the side, as he was always so keen and before the cup-ties always spent hours coaching the team, of which I had the honour to be a member. He was a very fine surgeon and it was a joy to watch him doing a partial gastrectomy. He was appointed surgeon to Bromley Hospital many years ago and I often saw him there. He was a fine diagnostician and will be greatly missed.

ELIZABETH CASSON, O.B.E., M.D., D.P.M.

E. M. M. writes: A wide circle of associates and friends will have heard of the death of Dr. Elizabeth Casson, the pioneer in the organized training for occupational therapy in this country, with profound sorrow and a feeling of personal loss, a loss shared with her family, to whom she was particularly devoted. The details of her career were recorded in the obituary notice published last week (p. 48). Dr. Casson, having first engaged in house property management under Octavia Hill, and having taken up medicine only in her thirties, may be said to have had a number of irons in the fire, but it was all the same fire, burning to bring personal consideration into the treatment of people, particularly of sick people. "Re-ablement" was the keyword to all her work.

Dr. Casson's name is perhaps most often associated with Dorset House, the nursing-home opened in 1929 at Bristol for the treatment of psychoneurotic and early psychotic patients. In 1930 the training school of occupational therapy was added to it, the training of students being run always in the closest association with treatment of patients. In 1938 the venture extended to the opening, near Dorset House, of a workshop for the treatment of physical cases by occupational therapy. Here, in addition to light occupations, heavy work was introduced. But no hours set apart for occupational therapy were, in Dr. Casson's view, the time basis of the treatment: the whole of the daily programme and the future establishment of the patient had to be considered, and this was a matter for the entire staff. Many patients, while still linked with the rehabilitation centres, were placed experimentally in suitable work and were helped to progress to permanent employment.

Linked with this background of treatment and enterprise at Bristol was another nursing-home at Clevedon. When,

owing to blitzes, Bristol became untenable, there followed the dispersal, but not the disintegration, of the various sections of Dr. Casson's work. The original building, Dorset House, was requisitioned. Another house was taken at Clevedon, where the nursing-homes made their centre. The school was moved to temporary quarters in the Midlands. At the end of the war the former Dorset House was not de-requisitioned immediately. Therefore, in order to make it more accessible, the school was moved to Oxford. Throughout these and succeeding years the link between the two centres has been maintained by the regular visits of Dr. Casson and exchange visits of staff and students. Both groups, working somewhat separately, and each now with its own responsible and separate management, jointly mourn the loss of their founder.

To have worked in association with Dr. Casson was an inspiration and an adventure. To quote an old student: "She was one of those rare people, entirely herself. . . . I can, at any moment, conjure up a picture of her extraordinary vividness." It was a vividness of undeterred determination, kindled by, in her own terms, "motives of organized activities," directed always to the fulfilment of her aims. She showed an intense sense of the practical, but those who knew her best could not have failed to discover her very real dedication, her capacities for affection, and her generosity. Throughout the whole of her work she, in the terms of Andrew Boorde, the sixteenth-century physician, deemed it important that "the physician and the cook must consult together" lest "a wearish dish . . . the which the sick cannot take" be the result. Those who were privileged to work with and for her were aware of this partnership, and can only hope that they will be enabled to continue with something of her wisdom and inspiration.

Dr. G. DE M. RUDOLF writes: May I add to the obituary notice of Dr. Elizabeth Casson something about her philanthropy? Having seen the plight of patients who were unable to afford the full fees of private psychiatric hospitals and yet were able to pay smaller amounts, Dr. Casson founded, in 1929, a residential clinic for them at Bristol. By good management she was able to make a small profit, of which she used up to £1,000 a year for financing the occupational therapy school in the same buildings. She continued this help for many years. By the beginning of the war in 1939 the residential clinics, which then also included Mount Pleasant at Clevedon, had grown to hold 100 patients. Owing to enemy action Dr. Casson moved the Dorset House home to Clevedon, where she continued the principle of low fees. Dr. Casson spent little on herself, using her income to benefit her patients. Often she made no charge, or asked a sum less than the usual small fees.

Dr. WILLIAM MCALISTER, who retired from the post of physician superintendent of Bangour Hospital, West Lothian, in May last year, died at his home at Dunbar, Berwickshire, on October 5, 1954. He was 66 years of age. William McAlister was born at Campbeltown, Argyllshire, on May 15, 1888. He graduated M.A. at Edinburgh University in 1910, and before taking up the study of medicine was for two years a teacher in George Watson's College in Edinburgh. He graduated in medicine at Edinburgh in 1918, having served for a period of his medical course as a surgeon probationer in the Royal Navy in the first world war. In the same year he began his career in psychiatry as an assistant physician at the Royal Edinburgh Hospital for Mental and Nervous Disorders. His ability was quickly recognized by the physician superintendent, Professor George Robertson, and he was soon promoted to the post of deputy physician superintendent, holding the post until he was appointed physician superintendent of Bangour Mental Hospital in 1931. In 1926 he obtained the Diploma in Psychiatry of Edinburgh University and became a Member of the Royal College of Physicians of Edinburgh. Three years later he was elected a Fellow of the College. He was a lecturer in psychiatry in Edinburgh University and an examiner for the Royal College of Physicians of Edinburgh. When the British Medical Association

held its Annual Meeting at Edinburgh in 1927 he served as one of the honorary secretaries of the Section of Mental Diseases. During the second world war he acted as psychiatric consultant to the Scottish Command. He was the secretary of the Scottish Division of the Royal Medico-Psychological Association from 1935 to 1943 and chairman of the Division in 1945–6. He was also a member of the National Health Services Council and of the South-eastern Regional Hospital Board (Scotland). He is survived by his widow and one daughter.

We are indebted to Dr. ANGUS MACNIVEN for the following appreciation: William McAlister possessed qualities which would have earned him distinction in any profession. He had a first-class mind. He had a remarkable memory and was a quick, effortless thinker, his ready grasp of the essentials of any problem placed before him being both impressive and enviable. He was a fluent speaker—his debating powers were formidable—and he was a most successful lecturer and teacher. His admirable qualities as an administrator were strongly tested at the outbreak of the second world war when Bangour, while continuing as a mental hospital, became an emergency hospital of about 800 beds for medical and surgical cases. The heavy additional burden of administrative work which he had to discharge during the war years was carried with outstanding success and apparently without effort. His valuable work during that period was recognized by his appointment as O.B.E. in 1945. William McAlister was a modest, unassuming man who inspired confidence and affection in all who knew him. He was tolerant and considerate of other people's views, but firm in his own convictions. He was a humane man who had a keen sense of justice and great sympathy for those oppressed and in trouble, and he was inflexible in his determination to do what he felt was right. Many are indebted to him for acts of kindness known only to himself and the recipient. When in 1950 he developed a serious illness from which he never fully recovered he continued until his retirement to carry out his duties and his responsibilities to the full with quiet, uncomplaining fortitude.

Lieutenant-Colonel R. S. ASPINALL, I.M.S. (ret.), died in a London hospital on December 25, 1954, at the age of 59. Robert Stivala Aspinall was born on February 5, 1895, and on the outbreak of war in 1914 left his medical studies at Guy's Hospital to serve for a time in the ranks. He returned to England to take the London conjoint diploma in 1916, and immediately after qualification took a commission in the R.A.M.C. He was wounded in action in 1917 while serving as a regimental medical officer in France. In 1922 he joined the Indian Medical Service, and after only two years in the military division was selected for employment in the Foreign and Political Department, in which he spent the rest of his service. The Foreign and Political Department, working as it did mainly in Indian States and frontier tracts, required the services of officers of high all-round professional ability with special gifts for tactful dealing with princely personalities and with delicate diplomatic problems. "Robbie" Aspinall, as he was affectionately known throughout the areas in which he served, was well equipped by nature and study to deal with any professional or social emergency. For some years he was the chief official practitioner (civil surgeon) in the winter and summer capitals of India (Delhi and Simla) and was a notable success in both appointments. In 1929 he became a Fellow of the Royal College of Surgeons of Edinburgh. He was appointed C.I.E. in the New Year Honours List in 1936, while still a major, and was promoted lieutenant-colonel later in the same year. During the greater part of the second world war he was residency surgeon in Mysore State and was stationed at Bangalore, the headquarters of the Southern Army. The enormous increase in the population of Bangalore, both civil and military, threw a great strain on the residency surgeon in both his clinical and his administrative capacities, but Aspinall coped with both aspects of his work with great skill. He was selected for promotion to the post of inspector-general of civil hospitals in the Punjab just

before the transfer of power in 1947. Two years later he retired from the I.M.S. He had but recently remarried and settled in practice in the West End of London when his fatal illness supervened. A clubbable man with a host of friends in London and all over India, Robbie Aspinall will be much missed. To his widow and his two sons by a former marriage we extend our sympathy.

Dr. G. A. VAN SOMEREN died on December 4, 1954, after a short illness, at the age of 43. Gerald Antony van Someren was born on January 6, 1911, and was educated at Epsom College and at the Middlesex Hospital, qualifying M.R.C.S., L.R.C.P. in 1936. His interest in psychiatry was aroused early in his student days, and, after holding several house appointments at Acton Hospital, he went to Carlton Hayes Mental Hospital, Leicester, in 1938 as assistant medical officer. In the second world war he served with the R.A.F. from 1940 to 1945, being graded psychiatrist in 1944. After demobilization he took his D.P.M. in 1946, and in the following year became senior physician at Runwell Mental Hospital, holding the post until 1950, when he was appointed consulting psychiatrist to the City General Hospital, Stoke-on-Trent, where he organized and built up the psychiatric department. He was also part-time psychiatrist to other hospitals in the area.

Dr. PETER STOCK writes: Dr. G. A. van Someren's extraordinary success and personal popularity were due not only to his great skill as a psychiatrist but also to his outstanding qualities as a man. Anyone who came in contact with Tony van Someren recognized in him a man of the highest intellectual and moral integrity, which he combined with a ready and understanding sympathy for human suffering or weakness. No limit was set to the trouble he would take over a case when he felt his help was needed. He even on one occasion took a patient with him on holiday when he felt that interruption of treatment would be detrimental. His clarity of thought and expression always made his reports about patients a pleasure to read, whether they were intended for professional colleagues or for laymen. He was an accomplished musician and had a wide variety of social interests, but his unsparing devotion to his work left him little time for relaxation. To those who were privileged to see him during his last illness, the courage and tranquillity with which he faced death were as much an inspiration as had been the honest integrity and human kindness which formed the keystones of his professional life. Much sympathy will be extended to his widow, who had been his unfailing support and help throughout his professional career, and to his three children.

A. T. writes: May I offer a little tribute to the memory of Dr. G. A. van Someren from those of us who went to his Highland dancing evenings? There will be no more Petronellas on September evenings at "Mount St. George," nor eightsome reels in the courtyard on Midsummer night, but what a store of happy memories we have.

Medico-Legal

LEGAL AID STATISTICS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The annual report of the council of the Law Society contains statistics of the working of the legal aid scheme which are of some interest in view of the fact that most actions for negligence against doctors are now brought by plaintiffs who receive help under the Legal Aid and Advice Act, 1949. During the period April 1, 1953, to March 31, 1954, in the whole of England and Wales, but Scotland excluded, civil aid certificates for actions in the Queen's Bench Division numbering in all 5,468 were accepted by applicants. It is in the Queen's Bench Division that actions against doctors are brought. A substantial number of applicants do not accept civil aid certificates because they will not pay the

amount of the assessed contribution, but no figures for the number of refusals are included in the report. During the same period a total of 3,581 actions in the Queen's Bench Division involving assisted persons and 22 actions started under the old "Poor Persons" procedure and continued under the 1949 Act were disposed of. Of these, 1,346 and all 22 of the former Poor Persons procedure actions were won by the assisted person: 462 were lost by the assisted person; and 1,773 were compromised. There is no separate figure for actions abandoned by plaintiffs. Depending upon the procedure followed, such cases were compromised in the 462 lost or the 1,773 compromised, if they have been disposed of at all. If they have simply been allowed to go to sleep they are not included in the statistics.

Dr. Cochrane Shanks, president of the Medical Defence Union, has given¹ the following figures for actions for negligence against doctors referred by the M.D.U. to its solicitors in the period 1947 to 1953. The plaintiffs won one-third of the cases actually tried and lost two-thirds of such cases. Of all cases brought, one-third were either won by the plaintiff or settled by the M.D.U.; two-thirds were lost or abandoned by the plaintiff.

Apart from the 22 old Poor Persons procedure actions, all of which were won, the general Queen's Bench Division figures for the year to March 31, 1954, expressed in percentages, were: won, 37.6%; lost, 12.9%; settled, 49.5%.

It would be of considerable interest to know what the equivalent figures were for actions against doctors in which the defence societies were involved and which were disposed of during the same period. A comparative analysis on these lines year by year since the legal aid scheme started would furnish some sort of objective evidence on whether the scheme has resulted in any hardship on doctors which is not shared by all who are involved in litigation against assisted persons.

INJECTION THAT WENT WRONG

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On May 28, 1950, Mrs. Ellen Thomas, then aged 30, was admitted to Sharoe Green Hospital, Fulwood, Preston, where a child was born to her later in the day. On June 3 the baby died, and in order to arrest her lactation Mrs. Thomas was given the usual treatment in such circumstances of hexoestrol dipropionate injections. A first injection was given by a staff sister into Mrs. Thomas's left thigh, and later injections were given into the left and right buttocks. A few days later the first injection became painful, the area in which it had been made became discoloured, and an abscess developed which caused Mrs. Thomas much trouble and pain over a period of many months. On June 10 a specimen of pus from the abscess was submitted to the pathological laboratory, and on culture it produced a heavy growth of a haemolytic streptococcus belonging to Lancefield's Group A, *Streptococcus pyogenes*.

There was no clinical evidence to show the origin of the organism. The staff sister had no sore throat or cold at the time the injection was given. Mrs. Thomas was noted as suffering from an irritant cough on June 6, but was not shown to be carrying the organism in her nose and throat. Bacteriological examination of the bowel content of the dead baby produced no trace of staphylococcus or streptococcus. Dr. A. A. Miller, consultant pathologist to the Manchester Regional Hospital Board and Group Pathologist to the Preston and Chorley Hospital Management Committee, thought it possible that, although Mrs. Thomas showed no signs of puerperal infection, she might have been suffering from a latent infection which was activated by the irritation of the tissues caused by the hexoestrol dipropionate injection.

In due course Mrs. Thomas brought an action for damages against the Preston and Chorley Hospital Management Committee, in which she alleged that the infection was caused by negligence on the part of the staff sister in giving the injection. The action was tried before Mr. Justice Sellars,

¹ The Times, October 25, 1954.

who was satisfied by the staff sister's evidence that the proper routine for sterilizing the equipment used and the proper aseptic precautions in administering the injection were carried out. Mr. Justice Sellars held that the probable cause of the trouble was that Mrs. Thomas's nose or throat was infected, that in those few days after the birth the infection got into the blood stream and attacked the tissues damaged by the injection. That would arise with no negligence on the part of the defendants whatsoever. Judgment was accordingly given for the defendants, the hospital management committee.

Universities and Colleges

UNIVERSITY OF OXFORD

Leave of absence and dispensation from statutory duties has been granted to R. R. Macintosh, D.M., Fellow of Pembroke College, Nuffield Professor of Anaesthetics, for three months from January 1, 1955, in order that he may visit Africa under the Nuffield Scheme for Dominion Demonstratorships and Clinical Assistantships.

In Congregation on November 20, 1954, the following degree was conferred:

D.M.—C. B. Wynn-Parry

UNIVERSITY OF CAMBRIDGE

In Congregation on November 27, 1954, the following degrees were conferred:

M.A.—A. D. Dickson, M.B., B.Ch., University Demonstrator in Anatomy; Christopher Parish, F.R.C.S., Associate Lecturer in Thoracic Surgery; L. M. Rouillard, F.R.C.S.Ed., Associate Lecturer in Plastic Surgery.
M.D.—G. Hildick-Smith, P. J. Wormald, H. G. Mather, P. F. D. Naylor
M.B., B.Chir.—R. J. Vince
M.B.—R. K. Gilbert, R. N. Galloway, F. L. Johnstone, M. R. K. Plaxton, R. G. D. Small

*By proxy.

UNIVERSITY OF ABERDEEN

At a Graduation Ceremonial on December 15, 1954, the following degrees were conferred:

M.D.—W. H. R. Auld (with honours), L. A. Wilson (with honours), I. W. Caldwell, J. K. W. Morrice, J. H. S. Whyte.
M.B., Ch.B.—Helen C. Brown, T. G. Hamilton, A. N. Hepburn, J. Hepburn, G. B. Knox, K. J. Mackay, W. J. Macrae, R. Muir, I. M. Munn, D. R. Pratt, R. MacD. Rowland, M. A. Shields, A. N. B. Stott, Catherine H. Tullett (formerly Park).

UNIVERSITY OF EDINBURGH

At a Graduation Ceremonial on December 17, 1954, the following degrees and diplomas were conferred:

M.D.—G. S. Kilpatrick, I. W. Lusk (in absentia), G. M. Maxwell (highly commended for thesis).
Ph.D.—In the Faculty of Medicine: S. M. Ghosh, M.B., B.S.
M.B., Ch.B.—A. J. Bennett, A. A. H. Brown, J. A. Brown, C. F. M. Caird, P. G. Colley, R. W. Davidson, H. P. Davis, G. F. Davis, P. G. Drummond-Smith, W. D. Fanner, A. Ford-Hunter, D. A. K. Geldenhuys, H. C. R. Henwood, P. Y. Kyle, M. H. Lea, Kian Poon Lim, A. G. Mackinnon, D. G. Macfie, D. Moore, Sheila M. L. Moore (in absentia), D. R. Oliver, W. E. Parrott, Shirley A. Peacock, W. H. Rabie, J. L. Smith, A. T. Thomson, R. A. P. Whitelaw, J. Wood, I. F. Young.
DIPLOMA IN PUBLIC HEALTH—D. F. Baxter
DIPLOMA IN MEDICAL RADIOLOGY—W. N. Boyd, R. F. Cant, J. H. Greig, A. H. Morris, A. A. Wild.
DIPLOMA IN PSYCHIATRY—J. G. Henderson, P. J. Zeck.

The following fellowship, scholarship, bursaries, and prizes were awarded in the Faculty of Medicine: *George Guthrie Research Fellowship in Child Health*, J. F. L. Collins. *Hastlow Research Scholarship in Rheumatism*, W. R. M. Alexander. *Andrew Graham Ritchie Bursaries*, Rosemary McCredie, A. W. McKenzie, A. Ramsay. *Mackie Bursaries*, J. C. Macintosh, J. G. Westerman. *E. B. Jamieson Prizes in Anatomy*, H. A. Crispin, J. S. Munro, D. O. Oliver.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following degrees were conferred on December 2, 1954:

M.D.—R. S. Crone, W. G. Keane, T. J. C. Warriner.
M.Ch.—D. F. V. Lane.
M.A.O.—H. McVey.
M.B., B.Ch., B.A.O.—D. A. Akintunde, W. Bottomley, T. P. Cairns, R. Chesney, A. G. P. Cotter, W. S. Crawford, Dorothea H. M. Dalling, R. I. Dankyi, G. P. O. Fenton, V. Gouws, S. W. D. Hall, M. M. Haniff, A. N. Henry, D. N. Johnstone, Anne J. Kevany, E. L. Kostick, J. G.

Leather, W. McGuinness, O. A. Ojo, W. McN. Orr, J. L. Parker, P. J. P. Pillar, Danuta E. Pollard (formerly Kolodziejka), J. W. Redmond, A. A. Skuce.
L.Med., L.Ch., and L.A.O.—T. J. Stack.

The following candidates have been approved at the examinations indicated:

FINAL M.B., B.Ch., P. R. D. Black, Jean R. Ellis, Marie M. Johnston, M.D., K. Campbell.
FINAL M.B., B.Ch., D. L. Kelly.
FINAL B.Ch.—A. C. A. Hempel (with second-class honours), Margaret H. S. Clements.
FINAL B.A.O.—G. A. Weaver, I. B. Sangmaah.

UNIVERSITY OF DURHAM

In Congregation on December 18, 1954, the following degrees were conferred:

M.B., B.S.—A. L. Brown, P. J. Burnett, Mary Campbell, J. R. Clark, J. L. Colville, G. S. Coxon, Joan A. Davidson, I. Dunlop, E. E. Egan, J. F. Fenby, A. L. Ferguson, W. G. Gerner, C. B. Hackett, Susan I. A. Hart, N. C. Haswell, C. A. Nott, B. J. O'Neil, A. W. O'Sullivan, J. P. P. F. W. Rowell, Joan C. Russell, Elizabeth J. Stodart, E. Thompson, B. R. Tindie, S. V. J. Watson, Pamela White, and Frank Kwee Chuan (in absentia).

UNIVERSITY OF LONDON

The following degrees were awarded by the Senate on November 17, 1954:

M.D.—C. I. Levene
M.S.—B. A. Ward

The following candidates have been approved at the examinations indicated:

THIRD M.B., B.S.—D. N. Cons, J. R. C. O. Erichsen, J. W. W. Holland, Mary P. Meerman, Kathleen C. Martin, Freda Newman, P. J. Taylor, Joan M. Adams, R. L. W. Adson, S. J. P. Adcock, A. M. O. Akintunde, M. R. Alderson, A. B. Allen, A. Allibone, D. A. Ampolo, G. H. Anderson, D. A. Andrewes, F. M. Andrews, I. S. Andri, B. S. Baker, Elizabeth S. M. Barnes, A. A. Barton, A. E. Bashford, Norma A. Beardwell, R. W. R. Beasley, Felicity M. Bedford, D. L. Bee, N. L. Beisly, J. G. Benfield, D. A. Bennett, G. Berks, R. V. Baily, H. R. Bisson-Dath, A. A. Black, M. W. Black, J. Blake, R. S. Blewett, P. Bliss, M. Bloom, Diana Boyd, Patricia M. Boyd, P. S. Boyne, M. G. Bridger, L. R. Bromwich, W. E. Brooks, D. K. Brown, J. P. Brumby, A. L. Bruce, A. M. Brown, D. P. Brown, M. Brown, P. H. Brown, A. L. Bruce, Patricia Burne, M. F. Campton, B. R. J. Carroll, A. P. Carter, R. H. Castle, W. B. Castle, J. F. Catchpool, N. F. B. A. Chav, A. R. Chiswick, R. Chynoweth, K. A. Clare, Margaret A. Clark, J. G. Cochran, Sheila E. Cozins, J. A. Collins-Wells, B. B. Collins, R. A. Cooper, P. S. V. Cox, Anne S. Crabtree, D. F. Croxall, Caroline J. Crumlin, Anne M. Davies, Dilys K. Davies, J. L. Davis, C. F. Day, J. M. de Mowbray, P. J. Denvir, L. J. A. Dodds, I. Downes, P. Drummond, A. H. Dunkley, R. G. Dunning, M. O'N. East, W. M. Easther, Maria S. Edwards, B. Ekins, M. Entwistle, F. A. Fairweather, H. P. L. Fala, I. V. Farman, C. D. Farrer, C. L. Finn, Lorna O. A. Fletcher, H. Forbes, Y. N. P. Forget, Julia M. Fourman, Patricia J. Fowler, R. M. Franklin, Patricia E. Frisby, P. C. Fulford, Celeste U. Furlong, Beatrix L. Gampell, A. B. Gardner, A. H. M. Gaze, S. A. A. George, D. A. Gill, Pauline M. Gilling, J. S. Goodall, G. C. L. Goss, G. Gower, M. A. H. Graham, S. T. Guest, P. M. Gurrin, Elizabeth W. Hall, G. S. Hall, I. Hall, J. Harrison, D. R. W. Hartley, R. J. Hawkins, G. A. Heasman, I. Heller, W. T. Henry, G. H. Herd, Margaret Hooper, P. J. Hornblow, Margaret W. Hughes, A. B. Hugo, R. J. Hunter, H. Inceman, P. B. C. B. Ivory, D. C. O. James, K. S. Jap, Marjorie L. Jones, I. W. Jordan, A. N. Katta, H. Keen, A. E. M. Kirk, J. L. H. Lacey, R. Lacey, P. Lallan, N. Landau, Patricia A. Laslett, Diana E. Lathbury, R. H. U. Laurence, J. L. Leaney, W. M. Lennox, Pamela A. Liddstone, D. C. Linch, Marion D. Lindsay, Ann H. List, J. R. Lockwood, C. Lawson, A. H. Macdonald, J. McKenna, Agnes M. Maclean, L. R. MacLean, Margaret L. Macpherson, A. R. Manwaring, R. E. W. Manton, B. H. Markham, K. D. F. Martin, Richmond M. Martin, Pamela Matheson, C. D. May, G. W. E. Meers, A. P. Mcgrath, R. J. J. Meyrick, Joan M. Montague, C. E. G. F. Morris, R. N. Morris, Patricia E. Muir, Margaret Muller, W. A. Murphy, Rachel F. Need, V. A. Neuf, D. W. Norrie, P. L. I. Nwabakozu, D. B. A. Odomata, M. I. M. Osadebe, P. O'Gorman, R. A. Onofade, R. O. Ormerod, R. A. Osborn, M. J. Ostme, D. C. Ower, R. T. Perkins, Catherine Parry, Pamela B. Passmore, M. B. Pepper, M. V. Perkins, J. O. Peskett, K. D. Phillips, D. S. Pickup, G. K. Padesley, J. A. Pollock, D. S. Porter, Marjorie E. Postons, R. E. Price, W. L. G. Quinlan, J. K. Radnor, G. D. Ramsden, A. G. Ratcliffe, G. S. Rawson, P. B. Read, Pamela A. M. Rendell, E. G. Revnard, P. C. G. A. Reynolds, C. J. Rhodes, A. R. Rirk, D. J. C. Roberts, J. G. Robertson, L. Robertson, M. S. Robertson, T. J. F. Rockey, P. S. Rolland, I. C. Rose, G. Ross, S. M. Ross, B. C. Roughton, C. A. Rushmer, Patricia M. Russell, S. Sackwood, G. J. Wyrer.

¹With honours. ²Distinguished in pathology. ³Distinguished in medicine. ⁴Distinguished in applied pharmacology and therapeutics. ⁵Distinguished in obstetrics and gynaecology.

The degree of M.S. was awarded to G. J. Hadfield on October 20.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—N. M. Bailey, J. T. Birless, M. A. Bloomfield, Margaret A. E. Boyce, J. D. Bradshaw, J. J. Burke, R. A. Butler, Alison M. Carrie, D. F. G. Clegg, Jean C. M. Collins, K. M. Dickinson, H. E. Godfrey, H. L. Green, S. F. Greenwood, G. E. B. Grove, Jane Hargreaves, I. S. Ingleby, Gwneith M. Jones, J. D. Knight, P. Lomax, J. Potter, Margaret J. Pybus, I. Ramage, E. Roditi, R. Schofield, Betty West, G. A. Wilcock, D. B. Wooldridge.

UNIVERSITY OF BIRMINGHAM

In Congregation on December 17, 1954, the following degrees were conferred:

M.B., Ch.B.—Y. Asirifi, P. H. Astill, Joyce E. Bailey, Patricia A. Bramley, J. Bullock, E. P. C. Hadley, Olga R. Harbron, Ella E. L. Holt, J. W. P. Jarrams, D. Learmont, A. P. Mayne, E. T. Melley, W. K. Merfield, K. Middleton, J. D. Nicholas, P. A. North, L. J. T. Pearson, A. Sutherland, Elizabeth M. Tilsen, D. Wright, R. A. Yeomans.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—E. F. B. Cadman, B. R. Frisby, S. Gillis, G. Hughes, D. E. Paterson, G. W. Storey, E. H. Wilson.
M.Ch. (Orth)—B. S. Jones, M. A. Vail.
M.B., Ch.B.—J. D. Aarow, J. A. Barlow, I. K. Brown, B. J. Chatlick, G. O. Dubourg, T. R. Evans, Patricia O. Grundy, P. A. Harrison, T. R. T. Hughes, R. A. Johnson, J. L. Mason, W. V. N. Pugh, Mary E. Shepherd, D. Taylor-Robinson, R. A. Yorke.

DIPLOMA IN RADIOLOGY (RADIOTHERAPY).—Part II: P. K. Ganruli.
DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—B. A. Chaudhary, J. Ghosh, June H. Green, B. A. Johnson, A. J. Jones, G. P. Lowther (recommended for the Milne Medal in Tropical Medicine), M. L. Marotta, A. M. Maiden, B. C. Onyiah, D. J. Patel, B. Prasad, C. I. Somaya, J. K. N. Yearley.

DIPLOMA IN PUBLIC HEALTH.—Part I: Jessie I. Anderson, S. M. Bieber, Sheila C. Blackburn, Barbara Briges, R. D. Choudhury, Diana Daniel, Phyllis J. Disley, O. L. Evans, R. G. Hendry, Irene Lynch, C. A. McKeagney, R. S. Male, T. O'Shea, F. Seymour, J. M. Sword, J. C. Taylor, A. H. Wilde.

UNIVERSITY OF LEEDS

Mr. C. R. Berkin has been appointed Senior Registrar and Tutor in Orthopaedic Surgery from a date to be arranged for the period ending December 31, 1955, in the first instance.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council on November 19, 1954, Dr. C. E. Davies was appointed part-time Lecturer and Clinical Teacher in Medicine and Dr. Isabella G. Monypenny part-time Instructor in Anaesthetics.

Dr. Margaret M. Platts was appointed to the J. G. Graves Medical Research Fellowship and Dr. R. Kilpatrick to the James Morrison Research Fellowship.

The following full-time appointments are announced: Mr. O. Daniel, Senior Lecturer in Surgery; Dr. D. Balducci, Research Assistant in Bacteriology and Virus Diseases.

Mr. P. A. King, Tutor in Surgery, has resigned his appointment.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting of the College held on December 2, 1954, Professor L. S. P. Davidson was re-elected President, Dr. A. Rae Gilchrist was elected Vice-President, and the following were elected Members of Council: Dr. E. R. C. Walker, Dr. W. Lindsay Lamb, Dr. I. Simson Hall, Dr. J. G. M. Hamilton, and Dr. Thomas Anderson.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on December 15, 1954, with Professor Walter Mercer, President, in the chair, the following were admitted Fellows after having passed the requisite examinations:

W. A. Baker, G. T. F. Braddock, G. K. Chaudhuri, J. N. de Klerk, C. J. Dewhurst, J. B. Doss, J. M. du Toit, M. M. El Fiki, H. Fine, W. D. Graham, J. J. Ironside, A. J. A. McCormick, G. T. Mair, K. P. P. B. Menon, M. J. Meter, D. P. Misra, G. F. Murnaghan, B. V. Nabar, J. S. Pathak, J. Pigot, N. B. Reddy, W. C. Robinson, R. S. Krishna, P. K. Sethi, G. Singh, R. G. D. Taylor.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following candidates were admitted to the Licence of Medicine and Midwifery of the College on December 3, 1954:

P. Barnes, I. D. Bosman, P. J. Browne, I. W. Browne, P. J. Campbell, D. Elloff, A. A. Endelman, V. B. Gautama, J. W. D. Hand, R. J. Hayes, D. P. McCarthy, W. F. McCourt, B. G. Nanji, Anne T. Nolan, B. M. Nolan, M. C. O'neley, D. E. Page, L. G. K. Quarcoo, G. I. Roberts, S. K. Roy, A. P. Ryan, W. T. Salmon, T. A. Scully, S. Sugarman, N. H. Webb.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on November 27, 1954, with the President, Mr. Arthur A. Gemmell, in the chair it was reported that a further gift of £5,000 from Mrs. Margaret Black to the Sims-Black Travelling Professorship Fund has been received.

The following awards were made for 1955: *Leverhulme Research Scholarships*, Professor I. Donald, Dr. J. Gardiner, Dr. F. H. Leckie, and Dr. M. L. Paterson. *Bernhard Baron Travelling Scholarship*, Professor S. L. Townsend (Melbourne). *Green-Armistage Short-term Travelling Scholarship*, Dr. J. W. F. Scrimgeour.

The Council acknowledged a further grant for research from the British Empire Cancer Campaign.

The following candidates were admitted to the Membership: R. K. Banerjee, K. Das Gupta, W. G. McBride, and L. H. Wilson.

The following candidates have been awarded the Diploma in Obstetrics:

Mavis J. Affarson, Barbara D. Allen, D. L. Archer, R. Armistage, W. M. Baird, C. E. Ballance, A. P. Barter, S. G. A. Bartlett, D. A. V. Bearblock, W. M. Bealey, F. X. Bencini, B. R. A. Binnewald, Ethel A. L. Blake, R. A. T. Boland, J. M. Bolton, G. M. P. Boyes, D. S. N. Brierley, R. C. Brookes, T. Brown, Jennifer Browne, J. C. Bryce, D. Budge, A. R. Burnett, Margaret H. Butler, A. P. Camilleri, Kathleen M. Carruthers, D. Cavanagh, A. F. Champion, J. Chapman, B. Charterjee, H. D. Chomse, T. K. Chong, Agnes Clark, J. M. Clark, A. G. Clow, Winifred J. Coates, Sheila M. Cochrane, R. L. K. Colville, E. Cooper, K. Coventry, W. H. A. C. Cox, A. V. Craig, D. O. Craig, D. S. Craig, A. A. Craigen, D. J. Cross, L. Crouch, S. H. Dallas, D. D. Davies, R. Davis, G. R. C. Deacon, P. A. De Raeye, R. F. Dingley, Marjorie J. Duckworth, Sheila G. F. Duncan, I. M. Dunhie, A. E. Elliott, Cathleen M. Elliott, Mary A. Eldale, L. A. J. Evans, Noreen M. H. Evans, F. H. Evans, P. G. Fildes, A. G. Findlay, Anna L. Frenkiel, C. J. Friend hip, Margaret P. Gardiner, N. S. C. Gent, A. K. Ghosh, J. G. O. Gill, R. M. H. Gompertz, C. J. Goosen, A. C. Gow, Dorothy M. Gratton, June H. Green, P. J. Guly, Frances M. W. Hamilton, J. N. Harkness, N. B. Harris, J. D. Harrie, Charlotte Harstein, Kathleen F. Hastings, D. B. Hawkins, W. P. Hayne, J. B. Heard, K. R. Heber, E. R. Herst, J. McL. Hill, Barbara M. Hitch, K. S. Holmes, E. T. R. Holt, Helena E. Hughes, K. R. Hughes, Muriel M. Hughes, H. A. Hurwood, Jane C. Iles, A. Ingram, Doreen L. Ireland, E. P. James, G. Jayaswal, D. S. Jeffery, A. H. John, M. Johnstone, R. S. Johnstone, D. R. Jones, E. W. P. Jones, I. S. Jones, R. D. Jones, Catharina J. Joubert, P. J. Joubert, Victoria K. Kelly, D. M. Kirkwood, Ethel E. D. Knowles, K. K. Lazarus, W. E. Lewis, W. G. Lewis, J. F. Lowe, S. J. H. Lowry, I. B. Lyon, I. S. Macdonald, Jean M. Mackay, Frances E. A. McVey, Doreen M. Gratton, June H. Jeffery, A. H. John, M. Johnstone, R. S. Johnstone, D. R. Jones, E. W. P. Jones, I.

London 55 (Hackney 19, Islington 9); Norfolk 39 (Norwich C.B. 31); Yorkshire West Riding 38 (Sheffield C.B. 27); Lincolnshire 21 (Scunthorpe M.B. 20).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 18 (No. 50) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1954					1953				
	Eng. & Wales	Lond.	Scot.	N. Ire.	Eire	Eng. & Wales	Lond.	Scot.	N. Ire.	Eire

STILLBIRTHS	210	21	29			199	25	19		

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Swedish National Health Insurance Scheme.—At the New Year Sweden started compulsory health insurance in place of voluntary schemes run by State aided benefit societies. According to a report in the *Manchester Guardian* every wage-earner of 16 and over must join the scheme. Benefits include free hospital treatment, cheap medicines, reduced doctor's bills, and sick pay during absence from work.

The Common Cold.—The Common Cold Research Unit is again appealing for healthy volunteers between the ages of 18 and 45 years. The Unit wants 500 this year. Prospective volunteers should be advised to write to the Medical Officer, Harvard Hospital, Salisbury, who will gladly provide full details. Last year a new strain of common cold virus, which resulted in a high proportion of colds in the volunteers, was studied. The common cold virus can be cultured on human embryonic lung.

Atomic Power.—According to the science correspondent of *The Times* the problem of the disposal of atomic waste is not nearly so formidable as once was thought. There is no great difficulty with radioactive elements of short half-life (of less than a year), as their activity diminishes rapidly on storage; nor, rather surprisingly, with those with a very long half-life: the amount of radiation they produce is small compared to their bulk; but it is the intermediate group, consisting of radioactive strontium with a half-life of about 20 years, and radioactive caesium with a half-life of 33 years, that is likely to prove troublesome. However, methods of separating these isotopes of strontium and caesium from other radioactive products have already been worked out on the laboratory scale. Practical steps to use atomic power for generating electricity in Britain are now being taken. Near Thurso, in the north of Scotland, the Atomic Energy Authority has taken over a former naval air station and will soon be starting work on the installation of a nuclear reactor for generating electricity, according to reports. The reactor will make steam which in turn will operate conventional electricity generating plant. On the international scale, plans for the peaceful use of atomic energy are now making headway. The United Nations Assembly resolved last month to hold an international conference not later than August, 1955, on the development of atomic power and problems such as radiation protection and the role of atomic energy in medicine and biology. With this in view Dr. M. G. CANDAU, Director-General of W.H.O., has been conferring with experts in this field, including Dr. J. F. LOUIT, of Harwell.

Medical Visitors to Canada and the United States.—The Ciba Foundation, in conjunction with the Horse Shoe Club of Great Britain, is collecting the names of British doctors now visiting or intending to visit Canada or the United States for a period of three months or more. These doctors will be sent a letter containing information which, it is hoped, will be of use to them during their stay abroad. Further information may be obtained from Dr. GORDON WOLSTENHOLME, of the Ciba Foundation, 41, Portland Place, London, W.1.

Nuffield Dental Fellowships.—Details of the Nuffield Foundation's dental fellowships and scholarships are given in our advertisement columns this week at page 47. One of the purposes of these fellowships is to enable selected graduates in medicine and science to receive training that will qualify them to undertake teaching and fundamental research on dental health and disease.

Eli Lilly Medical Research Fellowship (South Africa).—Applications may now be made by medical practitioners registered in South Africa for the 1955 Eli Lilly Medical Research Fellowship. It is valued at 250 dollars a month

for 12 months plus return travelling expenses to the point of study in the United States. Further details from Dr. H. A. SHAPIRO, P.O. Box 7605, Johannesburg.

Colouring Matter in Food.—The use of colouring matter in food is the subject of a report, published this week, based on the work of the Preservatives Subcommittee of the Food Standards Committee of the Ministry of Food. Under the Public Health (Preservatives, etc., in Food) Regulations, 1925-53, the addition of any colouring matters to articles of food is permitted, with a few specific exceptions. The main recommendation of the present report, which examines the situation in the light of modern knowledge, is that the regulations should be amended so as to permit the use in food of specified colours only; and in an appendix to the report there is a list of 13 natural colours and 32 synthetic colours which the subcommittee suggests should be permitted. The report states: "The introduction of a list of permitted colours adjudged to be suitable for use in food would afford greater protection both to the consumer and food manufacturer, since merely to prohibit use of colours known to be harmful would still leave in use a very large number for which there is little or no biological information."

Anaesthetic Appointment at Glasgow.—The University of Glasgow in conjunction with the Western Regional Hospital Board has created a senior lectureship in anaesthetics within the St. Mungo Department of Surgery at Glasgow University and Glasgow Royal Infirmary. This appointment carries the clinical ranking of consultant. Dr. ALFRED C. FORRESTER, consultant anaesthetist at Glasgow Royal Infirmary, has been appointed to the lectureship. Dr. Forrester is chairman of the Anaesthetic Services Subcommittee of the Central Consultants and Specialists Committee (Scotland), and is the Scottish representative on the B.M.A. Anaesthetists Group Committee. Dr. R. C. O. SALMONS has been appointed assistant to the post.

Fellowship to North America.—The International College of Surgeons offers a Fellowship of 3,000 dollars to a young medical graduate from Europe or South America. The award is to enable the holder to spend a year working at one of the teaching centres in the United States or Canada. Before the Fellowship can be confirmed, the candidate must secure a year's appointment as a resident or fellow at the teaching centre of his choice. The scholarship has been provided for by the generosity of the Woman's Auxiliary of the United States and Canadian Sections of the College. British applications should be made to Dr. J. F. BRILSFORD, 20, Highfield Road, Edgbaston, Birmingham, 15.

Prizes in Laryngology and Otology.—The Royal Society of Medicine announces the award of the W. J. Harrison Prize in Laryngology to Mr. C. P. WILSON, senior surgeon in the E.N.T. Department, Middlesex Hospital; the W. J. Harrison Prize in Otology to Miss M. R. DIX, of the Otological Research Unit at the National Hospital for Nervous Diseases; and the Norman Gamble Prize to Mr. J. C. SEYMOUR.

News in Brief.—Dr. ALBERT SCHWEITZER will be 80 on Friday, January 14. There will be a short tribute to him on the Television Service at 10 p.m. on that day.

In South Africa, where a severe outbreak of poliomyelitis is proceeding, the South African poliomyelitis research foundation proposes to vaccinate 2½ million children against the disease later in the year.

The Eugenics Society is starting an investigation of the family backgrounds of bright pupils nominated by their teachers. The society is looking for Britain's "promising families."

Prostitution under State supervision has been legalized in the Argentine after a twenty years' ban.

British Tuberculosis Association has changed its address to 59, Portland Place, London, W.1. (Tel.: Museum 3810.)

COMING EVENTS

Hunterian Festival Dinner at the Royal College of Surgeons.—The Hunterian Festival Dinner will be held this year on Monday, February 14. Normally admission is by invitation, but this year, as the dinner will be held for the first time in the new Great Hall of the College, it will be possible to admit, on payment, up to 100 Fellows and Members. Will any Fellow or Member of the College who wishes to attend please write immediately to Mr. W. F. Davis, Deputy Secretary, Royal College of Surgeons, Lincoln's Inn Fields, W.C.2 (HOL: 3474), enclosing a cheque for £2 15s. to cover the inclusive cost of the dinner. Evening dress and decorations will be worn.

Chronic Rheumatic Diseases.—Concentrated week-end course at the Rheumatism Unit, St. Stephen's Hospital, Chelsea, S.W.10, on March 19 and 20. Details from the secretary, Fellowship of Postgraduate Medicine, 1, Wimpole Street, London, W.1.

Royal Institute of Public Administration.—The Edinburgh and East of Scotland Regional Group is holding a conference on "Health Services" at Peebles on March 31 and April 1 and 2. The general theme is "Working Together—Progress and Prospects." Fee one guinea. Details from hon. sec., 245 High Street, Edinburgh, 1.

Congress on Urinary Lithiasis.—At Evian, France, from September 2 to 4, under the presidency of Professor L. DE GENNES and Professor J. CIBERT. Details from Professor C. LAROCHE, 16, rue Christophe-Colomb, Paris, 8.

NEW ISSUES

British Heart Journal.—The new issue (Volume 17, No. 1) will be available in a week's time. The contents include:

VECTOCARDIOGRAMS OF NORMAL AND PREMATURE BEATS IN DIFFERENT LEAD SYSTEMS. W. Den Boer, H. C. Burger, and J. B. Van Milaan.
MYOCARDIAL CHANGES OCCURRING IN POTASSIUM DEFICIENCY. P. M. McAllen.

THE DISTINCTIVE ELECTROCARDIOGRAM OF CORONARY ARTERIOSPASM. William Evans.
SECONDARY R WAVES IN RIGHT CHEST LEADS. Fulvio Camerini and L. G. Davies.

RADIOLOGY OF THE LUNG IN SEVERE MITRAL STENOSIS. D. S. Shoff.
A NEW METHOD OF DETERMINING THE DEGREE OR ABSENCE OF MITRAL OBSTRUCTION. S. G. Owen and Paul Wood.

AORTIC STENOSIS. A POST-MORTEM CINERADIOGRAPHIC STUDY OF VALVE ACTION. I. K. R. McMillan.

PALPABLE VENOUS PULSATIONS IN A CASE OF TRANSPOSITION OF BOTH ARTERIAL TRUNKS AND COMPLETE HEART BLOCK. J. D. Archison, R. J. Duthie, and J. S. Young.

THE MECHANISM AND SIGNIFICANCE OF THE AURICULAR SOUND. David Weizman.

UNILATERAL MEMBRANOUS PULMONARY VENOUS OCCLUSION, PULMONARY HYPERTENSION AND PATENT DUCTUS ARTERIOSUS. D. Emslie-Smith, I. G. W. Hill, and K. G. Lowe.

PATENT DUCTUS ARTERIOSUS WITH PULMONARY HYPERTENSION. Peter Harris.

LONG SURVIVAL WITH INFERIOR VENA CAVA DRAINING INTO LEFT ATRIUM. D. L. Gardner and Leslie Cole.

REDISTRIBUTION OF SYSTEMIC BLOOD FLOW IN PULMONARY STENOSIS. R. J. Shephard.

CONTINUOUS VENOUS HUM IN A CASE OF PORTAL CIRRHOSIS. A. I. S. Macpherson and E. V. B. Morton.

EBSTEIN'S ANOMALY: REPORT OF A CASE DIAGNOSED DURING LIFE. A. J. Kerwin.

PULMONARY ARTERY THROMBOSIS FOLLOWING CARDIAC CATHETERIZATION. J. A. Nighthale and B. L. Williams.

ABSTRACTS OF CARDIOLOGY.

Published quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, January 8
E.E.G. SOCIETY.—At National Hospital, Queen Square, W.C., 10.30 a.m., scientific papers.

Monday, January 10
ASSOCIATION OF CLINICAL BIOCHEMISTS (SOUTHERN REGION).—At University College Hospital, 3.15 p.m., annual general meeting. 4.30 p.m., scientific papers.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration.

Tuesday, January 11
BRITISH DENTAL ASSOCIATION: WOLVERHAMPTON AND DISTRICT SECTION.—At Star and Garter Hotel, Wolverhampton, 6.30 for 7 p.m., informal meal; at Royal Hospital, Wolverhampton, 8 p.m., Professor J. M. Webster: Forensic Aspects of the Teeth and Lower Jaw. Members of South Staffs Division, B.M.A., are invited.

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, Thurlow Place, S.W., 8.30 p.m., discussion to be opened by Sir Charles Peirce and Mr. E. D. O'Brien: Some Problems of Modern Diplomacy.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. G. Cochrane: Leprosy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Watson Smith Lecture by Dr. G. B. Dowling: Scleroderma and Dermatomyositis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Imperial Cancer Research Fund Lecture by Dr. J. Bamforth: Early Beginnings of Carcinoma.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. P. L. Mollison: The Rhesus Factor.

Wednesday, January 12

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. D. Fergusson: Prostatic Cancer.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 154, Great Charles Street, 8.15 p.m., Dr. Robert Forbes: Recent Developments in Medical Litigation.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—8.30 p.m., Sir Charles Dodds, F.R.S.: Influence of Chemistry on Medical Practice.

ROYAL STATISTICAL SOCIETY.—STUDY SECTION.—At E.L.M.A. Lighting Service Bureau, 2, Savoy Hill, London, W.C., 6 p.m., joint meeting with Study Circle on Medical Statistics. Dr. R. H. Thouless: Statistics in Parapsychology.

Thursday, January 13

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. A. A. Mason: Use of Hypnosis in Skin Disorders.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., discussion to be opened by Dr. R. P. Kemp and Dr. I. Harvey Flack: Medical Education in Patient and Public.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Major L. C. Hollister: Internal Splinting of Fractures.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Mr. C. P. Wilson: Lateral Cysts and Fistulae of the Neck of Developmental Origin.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. T. Cecil Gray: Anaesthesia in the Age of Stress.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At St. Ebba's Hospital, Epsom, 7.30 p.m., clinical meeting.

Friday, January 14

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. G. Cochrane: Leprosy.

INSTITUTE OF LARYNGOLOGY AND OTITIS.—3.30 p.m., Mr. S. A. Beards: Headaches of Nasal and Sinus Origin.

●ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Mr. Arthur H. Jacobs: Surgical Approach in Surgical Pathology of the Kidney.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Mr. A. W. McKenzie: Addison's Disease.

Saturday, January 15

BIOCHEMICAL SOCIETY.—At King's College, Strand, W.C., 2 p.m., scientific papers.

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—10.30 a.m., Symposium: Dermatology.

APPOINTMENTS

BETTS, J. WOODROW, M.B., B.S., F.R.C.S., Consultant Surgeon to Lincoln County Hospital, John Coupland Hospital, Gainsborough, and the Grace Swan Memorial Hospital, Spilsby, under the Sheffield Regional Hospital Board.

BRITISH RAILWAYS (LONDON MIDLAND REGION)—J. F. Kelly, M.B., B.Ch., D.P.H., and J. Havdn Williams, M.B., B.S., Assistant Medical Officers.

DOYLE, WILLIAM J., M.B., B.Ch., B.Sc. (Public Health), D.P.H., County Medical Officer of Health for Devon, following the retirement of Dr. L. Meredith Davies in May, 1955.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—E. J. Delaney, M.B., B.Ch., B.A.O., L.M. Anaesthetic Registrar, United Norwich Hospitals; M. W. Partington, M.B., B.S., Ph.D., Medical Registrar, United Norwich Hospitals; A. K. Ghosh, M.B., D.G.O., D Obst R C O G., Registrar in Obstetrics and Gynaecology, Peterborough Memorial Hospital.

BIRTHS, MARRIAGES, AND DEATHS

MARRIAGES

Mulcahy—Hanton.—On December 30, 1954, at the Church of the Immaculate Conception, Wexford, Risteárd Mulcahy, M.D., M.R.C.P., to Aileen Hanton.

DEATHS

Dicks.—On December 20, 1954, at Lapin, Warren Edge Road, Southbourne, Bournemouth, Hants, Eustace James Carey Dicks, M.B.E., M.D., late of Ealing, London, W.

Eland.—On December 14, 1954, Arthur John Charles Eland, M.D., of Filkins, Lechlade, Glos.

FitzGerald.—On December 21, 1954, at his home, Penharbour, Greystones, Co. Wicklow, Eire, FitzGerald Gabbett FitzGerald, C.B., D.S.O., L.R.C.P.S.I., Major-General, late R.A.M.C., retired, aged 76.

Hardwick.—On December 16, 1954, at Island House, Newquay, Cornwall, Arthur Geoffrey Patte-on Hardwick, M.C., M.R.C.S., L.R.C.P.

Henderson.—On December 18, 1954, George Henderson, M.B., C.M., of Haddenley, Foley Road, Claygate, Surrey, aged 83.

Lomas.—On December 17, 1954, at 1069, Manchester Road, Castleton, Rochdale, Lancs, Alfred Lomas, M.B., Ch.B., aged 80.

Morris.—On December 21, 1954, at Royal Infirmary, Edinburgh, John Rutherford Morris, L.R.C.P.S. Ed., late of Sedburgh, Yorks.

Mullally.—On December 19, 1954, the result of an accident, Joseph Gerard Pius Mullally, M.B., B.Ch., of St. Anne's, Ridge Way, High Wycombe, Bucks.

Rao.—On December 21, 1954, at Wanstead Hospital, Bantwal Narasinga Rao, M.B., B.S., of 5, Hermon Hill, Wanstead, London, E., aged 60.

Rosa.—On December 21, 1954, at 4, Bellevue Crescent, Edinburgh, Albert Frederick Rosa, M.D.

Sellar.—On December 20, 1954, at The Bield, Juniper Green, Edinburgh, Thomas McCall Sellar, M.C., M.B., Ch.B.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Oral Penicillin in Children

Q.—Since the advent of benzathine penicillin we have been treating mild infections—especially in children—with one dose of crystalline penicillin followed by benzathine penicillin suspension, two drachms (7 ml.) six hourly for the first 24 hours and then one drachm six hourly. A recent publication suggests that this is unduly extravagant and that an oral tablet is as effective; previously we had used the oral tablets only in children under six months. Is there any difference in the oral tablets on the market?

A.—It is true that, in comparisons which have been made between the absorption of benzathine penicillin suspensions and that of procaine or soluble penicillin when given by the mouth, the blood concentrations attained with the latter have generally been higher. The precise form of soluble penicillin used in these tests was not always the same, but in view of the consistency of the results it does not appear that the differences—e.g., between tablets and solutions, and the presence or absence of a buffering agent—are of much consequence. Wright *et al.*¹ found absorption to be rather better from a buffered than an unbuffered tablet of penicillin G: the B.P. tablet of penicillin is required to contain penicillin G and may also contain up to 5% of sodium citrate, the usual buffering agent employed. Either the official preparation or other tablets manufactured in this country, some containing more sodium citrate than this and some none, may be used with the expectation of a satisfactory effect in any conditions suitable for oral treatment.

Leucotomy in Schizophrenia

Q.—Has leucotomy proved successful in the treatment of schizophrenia?

A.—While schizophrenia is usually a chronic progressive illness it is often characterized by spontaneous remissions in its early stages, and permanent recovery initiated by treatment with insulin or with electrical convulsant treatment is also quite common. It is thus very difficult to assess the value of any form of treatment in arresting the disease. The possibility that leucotomy might itself produce full arrest is not now considered likely, and its function is thought to be one of eliminating or compensating for certain of the symptoms. It is thus able to relieve distress or may allow the patient to adapt himself to life in the community instead of living in a mental hospital. For this reason, and because the operation is destructive and its effects irreversible, it is no longer recommended in early schizophrenia, and other physical methods which leave no permanent deficit are normally given full trial before it is used. A possible exception to this is the schizophrenic illness in which distressing obsessions are a prominent feature in the early stages.

The effects of the classical operation, which is carried out through burr-holes without exposure of the cortex, have been shown by post-mortem studies to be very variable in their location, and many neurosurgeons now favour one of the more exact and limited sections, including the lower medial cut, which appears in favourable cases to lessen mental tension with a minimum of adverse side-effects. In

addition the extent to which the frontal-deficit syndrome appears after the operation must depend on individual differences of structure, just as the extent to which the deficit disables the patient will depend on the previous personality. Broadly speaking, apathetic patients are not helped, but those who suffer from morbid thoughts and from hallucinations or whose behaviour is unpredictable and impulsive are improved, as are those with depressive features, especially when the onset is later in life. The operation cannot be regarded as a full treatment in itself and can only be considered as a preliminary to the rehabilitation procedures by which the patient is retrained to live a normal life in the months following the operation. Patients can be made worse by the operation—by losing the capacity to inhibit morbid impulses, or by losing all spontaneity and leading a vegetative existence, or by developing epilepsy. Relapse is not uncommon but second operations are quite often successful. The operation may thus be indicated in the schizophrenic the chronic and severe character of whose illness is proved, and who either is distressed by his symptoms or causes distress to others by his behaviour. The selection of patients must always be based on a detailed study of each individual in the light of the known effects of the operation and the environment to which the patient will return if he recovers. Even so, it is very rash to predict its effects in detail. It is hardly justifiable, in view of the fact that the patient can be made worse, to carry out the operation for negative reasons—that is, because all other treatment has failed.

Like convulsive therapy, leucotomy was originally introduced as a treatment for schizophrenia, but it has been shown to give its best results in other psychological disorders.

Climate and Osteoarthritis

Q.—What climatic conditions are contraindicated for a sufferer from osteoarthritis? He is going to live abroad.

A.—Patients with osteoarthritis usually feel best in warm equable climates and appear to suffer most during periods of rapid climatic change. Conditions such as obtain in South Africa have proved satisfactory in individual cases.

Sneezing in the Surgery

Q.—What measures can a general practitioner adopt to prevent the patient with a streaming head cold from passing the infection to (a) other patients in the waiting-room, (b) the practitioner himself? At this time of year the number of people attending the surgery with severe colds greatly increases. The waiting-room is full of sneezing and spluttering, and as I look through the haze of cigarette smoke and droplet infection it is disheartening to see the regular attenders—the chronic bronchitics, the asthmatics, and the early heart failures—subjected to this potentially lethal atmosphere. It is also depressing to reflect that in due course I myself shall become infected. Colleagues adopt various remedies: notices in waiting-rooms, gauze face-masks, an occasional sniff at a sample of nasal inhalant, a brandy and soda after the surgery, sucking hexylresorcinol lozenges, installation of expensive ultra-violet lighting, etc. There has been little success.

A.—The protection of people from infection with the common cold is difficult to achieve. An effective gauze mask worn by the sufferer should in theory prevent the dispersal of virus, but of course a person with a heavy cold would find it very unpleasant or perhaps impossible to wear such a mask. It cannot be hoped that spread would be controlled by the use of nasal inhalations, brandy and soda, lozenges, or ultra-violet light. There should be less concern about exposure of the doctor, as he must inevitably have constant exposure in the course of his daily work, and the risk in his surgery will not be disproportionately great. It is likely that the development or otherwise of colds depends not only on exposure to virus but on other factors at present difficult to define precisely.

Visceroptosis

Q.—Is visceroptosis still accepted as a cause of abdominal symptoms?

A.—The answer to this question must certainly be "Yes." The diagnosis of visceroptosis is probably more accurately made now than 30 years ago; the disease is a quite definite entity. The crux of the situation would seem to be a mobile caecum rather than a displaced caecum. It is possible to have both a very high and a very low caecum entirely without symptoms. But, if the caecum is mobile, gravitational stasis occurs in the ascending colon, and as a result the mesentery becomes a supporting structure. This leads to secondary circulatory changes (in duodenum, intestine, etc.), so that a state of chronic ileus is established leading to the well-known symptoms of distension, discomfort, constipation, flatulence, and toxic manifestations. If these symptoms are relieved by lying down—particularly after the ingestion of food—the diagnosis of visceroptosis is probably quite genuine.

This answer is taken from the third book of *Any Questions?* Copies of both the second and third books of *Any Questions?*, each containing some 200 expert answers, are available from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any book-seller, price 7s. 6d. a copy (postage 6d.). The third book contains a cumulative index.

Drugs and Fertility

Q.—Are any drugs, given in therapeutic doses, known to affect fertility, temporarily or permanently?

A.—There have been few, if any, systematic studies of the effect of drugs on fertility, and consequently knowledge on this subject is scanty. However, there seems good evidence that the sulphonamides in therapeutic doses may suppress temporarily the development of spermatozoa within the testis and so lead to impaired fertility. Testosterone in sufficient doses is well known as a depressant of spermatogenesis, and it has been claimed that on cessation of treatment the recovery of spermatogenesis may be followed by a rebound in which sperm production becomes better than it was before treatment. Such a rebound often does not occur, and occasionally the suppression of spermatogenesis appears to be permanent. Evidence has been produced that over-indulgence in tobacco (for example, 30 or 40 cigarettes a day) may lead to marked oligospermia which improves on giving up smoking. Many other chemical agents such as alcohol, benzene, mercury, phosphorus, lead, etc., have been thought to produce impairment of fertility, which, in some cases at least, would appear to be permanent.

Little is known about the effect of drugs on ovulation in women, apart from the fact that oestrogens in sufficient doses will inhibit ovulation—temporarily. The evidence for the efficacy of various anti-fertility factors, such as lithospermum and *metaxylohydroquinone* (the alleged active principle of pea oil), has not yet reached the stage of acceptability.

Urticaria and Malaria

Q.—Is giant urticaria recognized as a presenting symptom in malaria? If so, what is the relationship of the two conditions—could the urticaria be due to a definite allergy to the malaria parasite?

A.—From time to time cases have been reported in which urticaria has accompanied the malarial paroxysm and has disappeared following the administration of antimalarial drugs. It has been suggested that this is an allergic phenomenon due to infestation with malaria parasites, analogous to that which occurs in hydatid disease. Thomas and Ridout¹ described a case of vivax malaria in which the initial paroxysm was accompanied by giant urticarial weals covering the whole body and extremities and considerable oedema of the glottis. The symptoms cleared up following the administration of quinine, but reappeared on the third day, when a second paroxysm occurred, with a temperature of 106° F. (41.1° C.), a pulse rate of 160, and severe

dyspnoea. Adrenaline was then administered; there was a rapid response and no further anaphylactic symptoms were observed.

Treatment of Amyotrophic Lateral Sclerosis

Q.—Is there any effective treatment for amyotrophic lateral sclerosis?

A.—Amyotrophic lateral sclerosis is part of the wider picture of motor neurone disease or progressive muscular atrophy. The aetiology of this condition is completely obscure, and there is no proof that any form of treatment has the slightest effect on the inexorable progress of the disease. At different times claims have been made for the value of vitamins, endocrine preparations, and vital dyes, given by various routes, but there is no shred of evidence that they have any effect. In most examples it is essential to examine the spinal fluid, because occasionally the disease can be closely mimicked by neurosyphilis, in which case both prognosis and treatment become quite different. Although in its florid form the diagnosis is one of the easiest in neurology, it would perhaps be true to say that more mistakes are made over this diagnosis than any other in the neurological field. Common mistakes are to attribute wasting of small hand-muscles to ulnar palsy or cervical spondylosis. When the disease presents with purely pyramidal signs a diagnosis of disseminated sclerosis or cerebral tumour may be made. In the past therapeutic claims have no doubt frequently been based on inaccurate diagnosis.

Cracking One's Fingers

Q.—I have a patient of 29 who is a teleprinter operator. Before taking up this occupation he had a habit of pulling his fingers to make them crack. He found that he was unable to operate the teleprinter easily until he had cracked his fingers. What happens when one cracks fingers? Is it harmful when done habitually?

A.—This appears to be an example of the condition termed "vacuum click." This click occurs in the metacarpophalangeal joint, and the most likely explanation of its occurrence is that given by Wiles (*Essentials of Orthopaedics*, 1949, p. 210, London)—namely, that slight separation of the joint surfaces increases the potential capacity of the joint and thus creates a vacuum into which the capsule is sucked with an audible snap. It is impossible to explain why cracking the fingers appears to improve their performance on a teleprinter, but the exercise certainly does no harm, and can safely be done to the patient's heart's content.

NOTES AND COMMENTS

Cold in Bed.—Dr. A. W. B. LONDON (Peterston-super-Ely, Glam.) writes: I wonder if the 60-year-old woman has enough bedding underneath her, as well as above ("Any Questions?" December 18, 1954, p. 1497). Every camper knows that you can pile on bedclothes "ad smotheram" and hot-water bottles, but if you do not have enough underneath you will still feel cold. I suggest this as I do not see it mentioned in the answer to the question.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JANUARY 15 1955

THE CIRCLE OF WILLIS*

BY

Sir CHARLES SYMONDS, K.B.E., C.B., D.M., F.R.C.P.

Physician for Nervous Diseases, Guy's Hospital; Physician, National Hospital, Queen Square

My first task is to thank you, Mr. President, Fellows and Members of the College, for appointing me to make this Oration according to Harvey's instructions, wherein he designed the pattern for a tradition now almost three centuries old. Whoever is charged with the duty must feel at this moment proud of the honour and humbled by the greatness of the occasion.

Of the directions given to the Orator two are simple—to commemorate the benefactors of the College, and to bid you continue in mutual love and affection among yourselves. The other is the exhortation to the Fellows and Members to search and study out the secrets of Nature by way of experiment. In this connexion we must remember that Harvey was what to-day would be called a physiologist. It is true that he practised medicine, but not very much, nor, according to one of his biographers, very well (Anon., 1830). His great discoveries, including that of the circulation of the blood, were based mainly on observations upon animals. It was natural, therefore, that he should direct the Orator to appeal for recruits to this branch of learning, and that the appeal should be addressed to the Fellows and Members of the College, for it was only physicians who were then qualified for this work. Since then the scene has changed. There is specialization of function such as Harvey could not imagine. The physiologist and physician are different persons.

The Urge to Discover

Moreover, the science of medicine, which had hardly begun in Harvey's day, now has values of its own which he would doubtless have found satisfying. He would not, I am sure, have wished you all to turn physiologists. He would none the less have urged you to prosecute research. This, I believe, is what most of us want to do when we enter the practice of consulting medicine, and for many of us the urge to discover something new is one of the motives that directs our choice of career. We start with enthusiasm, but the later results are on the whole disappointing. For this there are many reasons, of which the first and most obvious is that to want to do a thing well is not the same thing as having an aptitude for it, but I do not think this is so widely applicable as is sometimes supposed. Another reason often given is that research in medicine is a full-time employment, with the implication that a man must choose between research and practice. This idea has been fostered by the growth of units whose senior members give the whole of their time to clinical re-

search and are not engaged in the ordinary practice of medicine.

It is true that the whole-time clinical research worker has great advantages, from which he has not been slow to profit. Witness the volume and quality of the work published from these units during the past thirty years. The practising physician also has some advantages, which are not so apparent and deserve mention. One lies in what I may call the range and intensity of his exposure to stimulus. He goes to his out-patient clinic, his wards, or his consulting-room not knowing in the morning what the day will bring to him of the phenomena of disease. No sooner has he focused his attention on one problem than it is switched to another. At the end of the day his mind carries a load of unanswered questions. This you may say is distracting and an impediment to thought, but the variety of experience has a value.

There is much darkness in the world of medicine, and light may come from an unexpected quarter, so that the man who is compelled to shift his gaze from one point of the compass to another may be better off than he who is always looking in one direction. It may happen to those wholly engaged in clinical research that they miss the opportunity of seeing in matters outside their scope something of fundamental importance to their inquiries, while to the practitioner chance may offer a new concept of disease from the observation in the same week of two cases which are clearly alike but like nothing else that has ever been seen. For the practising physician also the unanswered questions are perhaps more often invested with a sense of urgency than is the case with his whole-time research colleagues. The practitioner cannot thrust problems aside merely because they are insoluble. He cannot discard speculation because it is not susceptible to experiment. Every case he sees of motor neurone disease or disseminated sclerosis must become for the moment a personal issue wherein he has to acknowledge defeat. He is very often made to feel very uncomfortable.

Practitioners' Handicaps

In so far, then, as the impetus to research may be derived from external stimuli, the practising physician has no handicap, but he has others. First, he lacks time for quiet thought. This was what Sir Thomas Browne (1646) felt when he wrote that his work had been composed by snatches of time from his practice, envying those whose "quiet doors and unmolested hours afford no such distractions." The right man, you

*The Harveian Oration delivered at the Royal College of Physicians of London on October 18, 1954.

may say, will make time, but in the press of sessions, practice, and committees this is difficult, and is made no easier by the social conditions of our present days. I believe it right that time should be given to the consulting physician for thought, and that under present conditions it should be given by the State in the sense that some of the time he spends at his hospitals should be allowed for study and research. Provision for this has been made under the National Health Service, and it is to be hoped that the boards and committees of hospitals will make full use of their opportunity in this direction. Looking back myself, I can see how much I might have gained from an hour or two spent each week at hospital making notes of particular cases, for my own use. There is need also for a place for study, and I hope that in the building plans of our new hospitals rooms will be provided adjacent to the wards for the use of the physicians.

The second handicap carried by the practising physician is lack of training in methods of laboratory investigation. Time was when no more was necessary for research than the use of the five senses. Thomas Willis discovered diabetes mellitus from the observation that among those who had frequency of micturition, or what was then called the "Pissing Evil," there was a group who wasted and died, and that in them all the urine was wonderfully sweet to the taste. Discoveries of fundamental importance may still be made without recourse to the laboratory. In our own time one of the most remarkable has been the proof that what we knew as sciatica is almost invariably caused by intervertebral disk disease. It is, however, generally true that a man who would do research in these days must augment the scope of his senses by using an ever-increasing number of technical devices, the mastery of which itself consumes the months. There is no adequate provision for such training in our plan for the education of the consulting physician, but it would surely not be impossible to include a year for the senior registrar in a laboratory where he could learn the rudiments of at least one technical method of investigation, and if such experience came to be generally regarded as of advantage to the candidate for staff appointment the best men would naturally be attracted.

On the other side I would suggest that some at least of the senior appointments in full-time clinical research should be given to men who have been engaged in consulting practice. If a man had before going into practice worked long enough in a laboratory to have learned its methods he would return to it with a mind enlarged and refreshed and, what is perhaps more to the point, with enough unanswered questions to keep him busy for a long time. I believe that among those engaged in consulting practice there would be some who at the end of five years would turn with enthusiasm to whole-time research employment. Some interchange of the kind suggested seems needed to bridge the gap between practitioner and clinical research worker which now exists, to the detriment, I believe, of both parties.

Thomas Willis

Thomas Willis, born forty-three years after Harvey, was a physician who managed to combine research with a busy private practice. Willis was elected a Fellow of the College in 1664 at the age of 43. He had had an unusual career. Born at Great Bedwyn, Wiltshire, he became at the age of 15 a batler to a Canon of Christ Church, Oxford, and subsequently took his B.A. On the death of his father and at

the outbreak of the Civil War he went to his home at North Hinksey, but we are told by his brother-in-law, John Fell (Willis, 1684b) that, being "harassed by the incursions of the Rebels, who were possessed of a Garrison strong enough Five miles from thence, and every where Plundering, he betook himself again to Oxford, being the Tents of the King as well as the Muses; where listing himself a souldier in the University Legions, he received Pay for some years, until the Cause of the Best Prince being overcome, Cromwell's tyranny afforded to this wretched nation a peace more cruel than any war." Soon after the end of the war Willis took his Bachelor of Medicine degree, and we are informed by his contemporary, Anthony Wood (1813-20), that he then "fell to the practice of it and every Monday kept Abingdon market." Thenceforward he became a busy practitioner and remained so until the end of his life, though for six years he combined with this the office of Sedleian Professor of Natural Philosophy at Oxford before moving to London in 1666. And there, Wood tells us, "in very short time after he became so noted, and so infinitely resorted to, for his practice, that never any physician before went beyond him or got more money yearly than he." He died of pneumonia in his house in St. Martin's Lane in November, 1675, and was buried in Westminster Abbey.

During the early years of his practice in Oxford Willis was one of a dozen learned men, four of them physicians, who met regularly for discussion. This was an offshoot of the invisible college, a name given by Robert Boyle to a group who before the war used to meet weekly for philosophic discourse at a London tavern. When the war broke out they split, those remaining in London meeting as before, and those at Oxford in rooms at Wadham. Some time before 1659 the meetings ceased in Oxford and were continued in London, and out of this association was born the Royal Society, of which Willis was one of the original Fellows.

Interesting Conclusions

Willis is, of course, best known for his studies of cerebral anatomy, but, besides being the first person to recognize diabetes mellitus, he was led by his reasoning from clinical observation to certain other interesting conclusions. He was, I believe, the first to envisage a hormone, arguing that "about the time of ripe age as the blood pours forth something through the Spermatic Arteries to the Genitals so also it receives a certain ferment from those parts through the veins: to wit, certain particles imbued with a seminal tincture are carried back into the blood which make it vigorous and inspire into it a new and lively virtue. Wherefore at that time . . . hairs break out, the voice becomes greater, the courses of women flow," and so on. He wrote much on epilepsy and introduced the idea of an explosion in the brain as the cause of seizures, using the analogy of gunpowder. He opposed the current view that the origin of what we call focal seizures lay in the part in which the spasm or sensation appeared, and declared his opinion that the primary cause was always in the brain, "to wit that the spirits inhabiting it being disposed to explosions, and there being exploded, bring on or cause every Falling Evil"; though he thought a peripheral stimulus might excite the explosion.

He wrote well of migraine and gives us an excellent description of this malady in the case of Lady Conway, whose letters (Nicolson, 1930) leave no doubt that she found in him a better doctor than Harvey, who had previously attended her.

In his dissertation "Of the Palsie" he describes clearly the disease we now know as myasthenia gravis, observing it to be distinct from all other kinds of paralysis on account of the variability of its occurrence and the effects of fatigue. Patients with this affliction, he says, may appear well in the morning, "able to walk firmly, to fling about their arms hither and thither, or to take up any heavy thing; before noon . . . they are scarce able to move Hand or Foot." And he goes on to quote the case of a patient under his care, "a prudent and honest woman, who for many years

hath been afflicted by this sort of spurious palsy, not only in her members but in her tongue: she for some time can speak freely and readily enough, but after she hath spoken long, or hastily or eagerly, she is not able to speak a word but becomes mute as a Fish, nor can she recover the use of her voice under an hour or two."

Of his methods he wrote thus: "After I had not found in Books what might satisfy a mind desirous of Truth, I resolved with myself to reach into living and breathing examples: and therefore sitting oftentimes by the Sick, I was wont carefully to search out their cases, to weigh all the symptoms, and to put them, with exact Diaries of the Diseases, into writing; then diligently to meditate on these; and then began to adapt general Notions from particular events. . . . He was first and foremost a clinician, but he was also a fine anatomist, who made great and lasting contributions to the advance of knowledge, especially of the structure of the brain and lungs, their value being enhanced by the beautiful drawings of Christopher Wren.

Association with Lower

In his work on the brain Willis was ably assisted by Richard Lower, who was later to earn fame for his work on the heart and the first blood transfusion. Lower was a younger man than Willis, and afterwards succeeded him in his practice. Wood, in his biographical sketches of the two men, suggests that Lower received too little credit for his contributions to the success of his senior. Willis, for example, was credited with the discovery of a spa, doubtless to the benefit of his practice. But Wood (1813-20) writes that in April, 1664, Lower in his travels with Dr. Willis "made a discovery of the medicinal water at East Throp . . . in Northamptonshire, the doctor being then, as usually, asleep or in a sleepy condition on horseback." Afterwards he says Lower imparted his discovery to the doctor, who claimed it for his own. Whatever may be the truth about East Throp, Willis (Franklin, 1931), in his introduction to *Cerebri Anatome*, pays handsome tribute to Lower, "a doctor," he says, "of outstanding learning and an anatomist of supreme skill. The sharpness of his scalpel and of his intellect, I readily acknowledge, enabled me to investigate better both the structure and the function of bodies, whose secrets were previously concealed." And later he writes: "When we were entering upon a much more difficult task, the dissection of the nerves, the really wonderful dexterity of this worker and his untiring perseverance were conspicuous in the extreme and no obstacle could withstand his effort."

Wood, however, could not let this pass, and, writing of Lower, tells us that after taking his degree at Christ Church he "entered upon the physic line, and practised that faculty under Dr. Tho. Willis, whom he helped, or rather instructed, in some parts of anatomy, especially when he was meditating his book *Cerebri Anatome*," and in his list of Willis's published works (Wood, 1813-20) adds under *Cerebri Anatome* this sentence, "Whatsoever is anatomical in that book, the glory thereof belongs to the said R. Lower, whose indefatigable industry at Oxon produced that elaborate piece." Lower himself does not appear ever to have complained that he was not given his due, and his first published work was a spirited defence of Willis's treatise on fevers against the critics, which, as Fulton (1935) has observed, is testimony of the harmonious relations between the two men. Why, then, did Wood write as he did?

Biased Opinions

Anthony Wood, who would have liked to earn fame as a historian, lived in Oxford from 1632 to 1695. His most notable work was the publication, under the title *Athenae Oxonienses* (Wood, 1813-20), of short biographies of distinguished Oxford graduates up to his time. In these his love for gossip so far outran his discretion that a copy of the second volume of the *Athenae* was burned in public by order of the Vice-Chancellor, and the author was expelled

from the University. The book, however, was well received in Cambridge. Wood also kept voluminous diaries (Wood, 1891-1900), which give an entertaining account of his life and times and reveal him as a prejudiced and quarrelsome man. John Fell, the great Dean of Christ Church and later Vice-Chancellor and Bishop of Oxford, who has already been mentioned as the brother-in-law of Willis, was at the same time Wood's benefactor and one of the targets for his abuse. Fell paid for the printing of some of his books, and claimed the right to edit them. Wood could not accept criticism, grumbled, and quarrelled with him.

Richard Lower appears from the diaries to have been one of Wood's intimate friends. During the years 1658 to 1662 Lower's name appears frequently as a companion in the taverns of Oxford. The entries begin with the mention of Mr. Lower, who later becomes Mr. Richard Lower until July 28, 1660, when the entry reads "Spent on Dick Lower at the Mermaid Tavern one shilling." Of Thomas Willis there is no mention in the diaries until 1664, when there is a note of the discovery—by Lower—of the healing well at East Throp. The omission is curious, for Willis was not a negligible person, and it is hardly to be supposed that in a city the size of Oxford the two men never met. That they must in fact have been known to one another is proved by a passage in a letter written in 1725 by Browne Willis, Thomas's grandson, to Bishop Kennett, and preserved in the Bishop's copy of the *Athenae*.

Browne Willis was a scholar and antiquarian of repute, and the purpose of his letter was to refute the statement made by Wood in the *Athenae* that Thomas Willis's grandfather was a tailor. This letter begins, "I most readily obey your lordship's commands in communicating something of my good grandfather Dr. Willis. A. Wood, who was his next neighbour in St. John Baptist's parish Oxon. and had a disagreement with the family, says several things untrue of his descent." From these observations it seems likely that Wood had a prejudice against Willis and a favourable inclination towards Lower, and it is certain that as a historian he would have been influenced by whatever prejudices he may have had.

There is, moreover, evidence that Wood's account of the relative contributions of Willis and Lower to *Cerebri Anatome* was derived from a source already biased. Henry Stubbe, philosopher and physician, published (Stubbe, 1670) a series of papers the sole object of which was to discredit the Fellows of the Royal Society (whom he called contemptuously the Virtuosi), and he attacked Willis among others. He alleges that Willis could not have spared the time from his great practice to compose *Cerebri Anatome*, and writes, "Whatsoever there is in that Piece, which is Anatomical, the glory thereof belongs to Dr. Lower, whose indefatigable industry produced that elaborate Treatise" (p. 95). We know from Wood's diary that he had purchased Stubbe's book, and his comment in the *Athenae*, published many years later, is an almost exact transcription of the sentence I have just quoted; but what he ignored, or perhaps had never read, was a postscript. This is to be found out of its context at the end of Stubbe's little volume. It begins "I think myself obliged to adde one thing more where I speak as if Dr. Willis had had little to do in the discoveries of Dr. Lower about anatomy," and goes on to say that, although Lower did the dissections, Willis's was the master mind which inspired and directed the work. The last sentence of this recantation is revealing: "Thus much I thought fitting to annex, lest the Virtuosi should censure me as partial to my old School-fellow, Dr. Lower, or swayed by any regard then that of Truth" (p. 178).

It is due to Willis that this story should be told in full, for some of those who have written about him have followed Wood, including Michael Foster (1901), who tells us that Lower was "the henchman of the fashionable Willis whose false fame in large measure rested on Lower's careful, unacknowledged work." In this I scent something of the odour in which the physiologist held the successful practitioner 50 years ago.

Willis's "Cerebri Anatome"

Cerebri Anatome was published in 1664 and is chiefly distinguished for the description of the cranial nerves, but better known for the dissertation upon the arteries at the base of the brain. Wren's drawing shows the anterior cerebral arteries joining where the anterior communicating artery should be and bifurcating a little further forward, but, apart from this, there is no fault. Willis, however, saw that there was a circle and that it must have some physiological significance. In discussing this he first suggests that the function of the circle is to mix the blood before its distribution to the brain, but on a later page adds:

"But there is another reason far greater than this of these manifold ingraftings of the Vessels, to wit, that there may be a manifold way, and that more certain, for the blood about to go into divers Regions of the Brain, laid open for each; so that if by chance one or two should be stopt, there might easily be found another passage instead of them: as for example, if the Carotid of one side should be obstructed, then the Vessels of the other side might provide for either Province. . . . Further, if both the Carotids should be stopt, the offices of each might be supplied through the Vertebrals" (Willis, 1684a)

He goes on to say:

"It is not long since we dissected the dead body of a certain man, whom a great Scirrhus or hard Swelling within the Mesentery, growing at last ulcerous, had killed. When his Skull was opened, we beheld those things belonging to the Head, and found the right Carotid, rising within the Skull plainly bony or rather stony, its cavity being almost wholly shut up; so that the influx of the blood being denied by this passage, it seemed wonderful, wherefore this sick person had not dyed before of an Apoplexy: which indeed he was so far from, that he enjoyed to the last moment of his life, the free exercise of his mind and animal function. . . . This Gentleman, about the beginning of his sickness, was tormented with a cruel pain of the Head towards the left side. The cause whereof I know not how better to explain, than that the blood excluded from the right Carotid Artery, when at first it rushed more impetuously in the left, had distended the Membrane" (Willis, 1684a).

Dissertations on the Circle

It is perhaps remarkable that Willis nearly three hundred years ago asked himself why this man did not have a hemiplegia, and perceived from his dissections of the circle that anatomy might supply the answer, but it is even more to his credit that he should have remembered the episode of headache and found what was probably the correct explanation for it. Willis was an indefatigable student of symptoms. This is apparent in the case histories illustrating his clinical writings, and when he was at his dissections he was ever thinking not only of the function of the structures he laid bare but of the disorder of function that might result from their disease. This, you may say, is the way any liberal-minded anatomist thinks, but Willis was a busy practitioner, able to draw upon his own experience of symptoms unexplained. We may be sure that he would have been interested in what we now think about the functions of his circle, and the symptoms that occur when one of the internal carotid arteries is occluded. His observation that this may happen without hemiplegia has, of course, been amply confirmed, and also the appearance of headache as a symptom of the event. That it may be the only symptom we know from an example in which headache in a young woman without other symptoms was investigated by arteriography and internal carotid occlusion demonstrated; and in patients with hemiplegia headache as a preliminary symptom is not uncommon. The explanation we believe to be correct is that which occurred to Willis—distension of other vessels—for we know that when the wall of an artery of the head is stretched beyond physiological limits headache results.

Recent Experimental Work

As to what happens in the circle after occlusion we can only speculate, but our speculations may be guided by methods of observation and experimental records which

were not available to Willis. The experiments in which he would have delighted most are those in which a dye or other visible substance is injected into one of the afferent arteries of the circle, for such experiments he performed himself in the cadaver. Cerebral arteriography has now enabled us to see in man the course of radio-opaque solutions injected into the internal carotid and vertebral arteries, both in the normal state of the circulation and when one or both internal carotids are occluded. What we see in the arteriograms cannot be an accurate picture, for the opaque solution is injected under pressure, but arteriography has taught us a great deal. Provided that the anterior communicating artery is of fair calibre, fluid injected into one internal carotid artery, when the other is occluded by digital compression, flows into both hemispheres, and if there is bilateral carotid occlusion proximal to the circle a vertebral injection enters the branches of the internal carotid arteries by way of the posterior communicating branches, as Willis imagined.

A way of learning what happens in the normal circle is to watch the flow of injected dye in a living animal, the brain being exposed by operation. This had been done before, but not with the essential precaution of introducing the solution of dye into a vertebral or carotid artery without disturbing the normal pressure. McDonald and Potter (1951), observing this precaution, have shown that the dye entering a vertebral artery flows into the basilar and posterior cerebral arteries and forward into each posterior communicating artery up to a point about midway along its length. Conversely, dye injected into a carotid artery passes into the anterior and middle cerebral arteries of that side and the anterior cerebral artery, and backwards into the posterior communicating artery up to a point halfway along its length. At this point injection into either the vertebral or the carotid artery results in an interface of blood and dye, a dead point, at which the pressure of the two opposing streams is balanced. There is in fact no flow of blood through the posterior communicating arteries at all.

In the rabbit, which was used for these experiments, there is a single anterior cerebral artery and therefore no anterior communicating artery, but, having regard to the observation that in man a radio-opaque solution injected into one internal carotid ordinarily fills only the anterior cerebral of the same side, it is probable that in the normal circle of Willis there is another dead point at the mid-point of the anterior communicating artery. Thus there are virtually three separate streams of arterial blood supplying the brain, one from the basilar and one from each internal carotid artery, separated from one another not by any physical barrier, but by the dead points in the posterior and anterior communicating arteries, the position of each of these dead points depending upon the balance of pressure in the opposing streams.

Internal Carotid Occlusion

The most frequent cause of internal carotid occlusion is atherosclerosis, and the site is usually in the neck within a centimetre of the origin of the artery. Before the advent of total obstruction there must be a gradual narrowing of the lumen, which favours the establishment of collateral circulation. We may compare this with what happens when there is atherosclerosis of a coronary artery, for in the heart as in the brain occlusion may occur without infarction if the process of narrowing is slow and there is time for a good collateral circulation to develop. In the brain there is opportunity for widening of anastomotic channels between the superficial branches of the posterior and middle cerebral arteries, and, as we know from arteriography, the communication in the orbit between branches of the external carotid and the ophthalmic branch of the internal carotid can short-circuit the obstruction in the neck. The direction of flow in the ophthalmic artery being then reversed, it receives blood from the external carotid which, entering the lumen of the internal carotid above the obstruction, fills the middle cerebral artery. But the circle of Willis must

provide the most important source of compensatory flow. When pressure falls on the obstructed side there must be a shift of the dead point in the anterior communicating artery and a flow of blood from the unobstructed side to fill the anterior and probably the middle cerebral arteries on the obstructed side. Both hemispheres must then obtain their main blood supply from the unobstructed internal carotid, which, being in a part of its course enclosed within a bony canal, cannot be capable of any great dilatation, though even a small increase in its diameter would be an important contribution, since the volume of fluid passing through a tube varies with the fourth power of its radius. It is probable that under these conditions the maintenance of cerebral blood flow in patients who do not develop hemiplegia as an immediate effect of carotid occlusion depends mainly upon a rise of mean arterial blood pressure, for this has been observed as an effect of carotid ligation.

The equitable distribution of blood to the two hemispheres after occlusion of one internal carotid artery requires an anterior communicating artery of adequate diameter, but it seems probable that alterations of calibre in the peripheral vessels of the two hemispheres must play a part. The local effect of cerebral ischaemia is vasodilatation from the accumulation of CO₂. The hemisphere on the obstructed side, therefore, at any rate for a time, may claim more than an equal share of blood with a corresponding vasoconstriction in the hemisphere on the unobstructed side. This surmise finds support in the observation immediately after common carotid ligation of abnormal waves in the electroencephalogram in both hemispheres and occasionally only in that supplied by the unobstructed artery (P. Schurr, personal communication). If after internal carotid occlusion by disease, the total cerebral blood flow is at times less than normal and the hemisphere on the obstructed side simultaneously demands more than its fair share, this might explain the occurrence of transient loss of function in the limbs on the ipsilateral or obstructed side of the body in certain cases.

Compensatory Mechanisms

When cerebral function remains intact after internal carotid occlusion we may assume that the various compensatory mechanisms have come into action, but the situation must still be precarious. The haemodynamic crisis that has occurred is not a transient affair. There is a perpetual struggle both for the maintenance of the total cerebral blood flow and for its equitable distribution; and loss of blood volume, a fall of blood pressure, or a temporary upset of the balance between vasoconstriction and vasodilatation may cause local ischaemia or infarction with reversible or irreversible loss of function. An irreversible hemiplegia is the commonest ending, and is indeed often the first event, but it is the preliminary symptoms occurring in certain cases which invite explanation. Headache, as Willis first observed, may be one. Hemiplegia may be preceded by episodes of weakness or numbness over a period which may extend from a few hours to several years. The loss of function in these episodes may be severe, with rapid and complete recovery, and this may recur so often that occlusion of peripheral branches, by extension of clot from the site of the original obstruction, or by detached emboli, can hardly explain them. I suggest that this episodic loss of function, which must be ischaemic, is not due to any fresh vascular obstruction, but to a temporary failure of the compensatory mechanisms.

I shall venture, following the example of Willis, to relate some particulars of a patient in whom the brain was finally inspected.

This patient was a woman aged 53, known to have had mitral stenosis with auricular fibrillation for several years. The first symptom of cerebral disorder was headache, which had begun to trouble her three years previously. Its first onset was sudden, and thereafter it occurred almost daily for several hours and continued thus for six months, after which it became much less frequent and severe. Eighteen months before I saw her she had transient loss of vision in the right eye, shortly followed by

numbness and weakness of the right limbs with recovery in 24 hours. A month later there was another episode of transient right hemiparesis. A few days after she had recovered from this she had a left hemiparesis, from which recovery was complete in 48 hours. From this time onwards she had frequent attacks of a similar nature in which sometimes the right limbs were affected, sometimes the left. On the last occasion, six weeks before I saw her, she suddenly found her left hand weak and tremulous and then her right leg. This was accompanied by right-sided headache. Recovery occurred as usual in 24 hours. These episodes had been attributed to cerebral emboli, but when she came to see me in my consulting-room she was active and well, apart from the complaint of general tiredness, and on examination showed no trace of weakness or loss of sensation nor any abnormality of the reflexes apart from a relative briskness of the left arm jerks. She was admitted to hospital a few days later and died from the effects of an embolus in her left internal carotid artery. At the post-mortem inspection the findings relevant to this story were an old organized embolic occlusion in the right internal carotid artery just proximal to the circle of Willis, and two small areas of infarction of old standing, one in each hemisphere in the neighbourhood of the internal capsule.

I suggest that the occlusion of the right internal carotid artery was responsible for the phase of headache, which became less as anastomosis improved. At some time thereafter she had a small embolic infarction in each hemisphere. Each of these lesions could have caused a transient hemiparesis but could not have accounted for the very frequent attacks that have been related. Each, however, may well have resulted in a special local demand for compensatory circulation, and so have added to the effect of temporary failure of the compensatory mechanism as a whole in determining transient weakness and numbness of the limbs.

Only in one other patient have I encountered the story of transient loss of function in the limbs on the same side as the carotid obstruction, a woman who finally developed a left hemiplegia with arteriographic proof of occlusion of the right internal carotid artery in the neck. She had first attended hospital six years previously for attacks which were then regarded as hysterical. They continued up to the time of the hemiplegia. They never occurred except during menstruation, and then quite often. The onset was rapid, with a feeling she described as that of going under ether, and this feeling persisted throughout the attack. The next sensation was that of weakness and numbness experienced in those parts of her body which were in use—the arm or leg on one side of the body, never on both sides, but as often on the right as the left. If she were talking at the onset of an attack indistinct speech would be the first evidence of weakness. The whole episode lasted about five minutes, and with it she would have a bursting sensation in the neck. She had very occasionally lost her senses briefly at the height of the attack. There may be in this case some anomaly of the circle of Willis. I mention it as an example of symptoms which seem to depend upon some recurrent haemodynamic crisis following internal carotid occlusion, for I suppose this existed from the first and that the hemiplegia was the final result of a complete failure of compensation.

A Well-recognized Symptom

Transient blindness on the same side as the obstructed internal carotid is now a well-recognized symptom, though by no means common. These attacks, usually occurring at irregular intervals of days or weeks, are of a fairly constant pattern, of sudden onset and lasting from one to five minutes. As a rule they precede hemiplegia, often by many months, and frequently cease before that event. There is no doubt that the blindness is due to transient retinal ischaemia, for the retinal arteries have been observed in an attack and are bloodless. I suspect this is an example of what may be happening elsewhere in the cerebral circulation, but here with a more impressive clinical effect, for the reason that the retinal arteries have no anastomosis. The cessation of these attacks of blindness some time after internal carotid occlusion may be due to an increase of the flow from the external carotid side as anastomotic channels widen.

Conclusion

I imagine it may have been the lot of more than one Harveian Orator, as he comes to the end of his discourse, to fear that he has disappointed expectation and fallen short in the performance of an honourable duty. I have taken the name of Thomas Willis for commemoration as one of the Benefactors of the College. He gave well of the fruits of his labours preserved in those many pages which even Anthony Wood (1813-20) praised for the "natural smoothness, pure elegance, [and] delightful, unaffected neatness" of their Latin style. I have occupied some part of your time with speculation about the cause of symptoms resulting from occlusion of the internal carotid artery. If there be anything in this of the least value let me exhort you, as I have the right, to search and study out these secrets of nature by way of experiment. Willis would have approved this exhortation and perhaps have thought us laggards. He foresaw great works. The ancients, he said, bound to false suppositions, might be excused the faulty structure of their reasoning, but "those who come after should take care for the Re-edifying of the Building even from the ground, on which our most famous Harvey hath laid the Circulation of the Blood as a new Foundation in Medicine."

PANCREATITIS FOLLOWING PREGNANCY

BY

R. A. JOSKE,* M.D., M.R.A.C.P.

From the Clinical Research Unit of the Walter and Eliza Hall Institute of Medical Research and the Royal Melbourne Hospital, Victoria, Australia

The relation between pregnancy and pancreatitis is little discussed in the literature, although many reports of pregnancy complicated by pancreatitis have been published (Kingsley, 1934; Cassel and Malewitz, 1950; Burger, 1952) since the cases of Schmitt (1818) and of Lawrence (1831) early last century. Langmade and Edmondson (1951) collected 53 cases from the literature and reported nine more of their own.

The earliest report of pancreatitis occurring in the post-partum period seems to be that of Haidlen (1884). Watts (1918) and Fallis and Plain (1939) have each reported two cases, and others have been described or mentioned by Deaver (1918), Paxton and Payne (1948), Roberts *et al.* (1950), Rose (1951), and Comfort and Steinberg (1952). McWhorter (1932) reported 64 cases of pancreatitis in two of which "the onset of pancreatitis occurred shortly after childbirth." Langmade and Edmondson (1951) noted that, in pancreatitis compli-

cating pregnancy, liability to an exacerbation during the puerperium was an outstanding characteristic.

Nevertheless, most recent writers do not stress pregnancy as an aetiological factor in pancreatitis (Paxton and Payne, 1948; Warren, 1948; Macnab, 1949; Fallis, 1951; Saint and Weiden, 1953). There is, however, increasing evidence to support the idea of Whipple (1907) that "acute" and "chronic" pancreatitis are differing phases of the same disease process (Comfort *et al.*, 1946), while Saint has rightly emphasized that "pancreatitis" is a general term covering several diseases which have in common only the feature of localization to the pancreas (Saint and Weiden, 1953).

This paper reports six patients with pancreatitis, in all of whom the disease was first manifest a few weeks or months after completion of pregnancy, in whom the clinical and laboratory findings were similar, and none of whom presented any evidence of the known causes of pancreatitis. It is suggested that these patients may be representative of one type of pancreatitis which forms a distinctive syndrome, to be separated from the large group of patients with "pancreatitis of unknown aetiology." For convenience, some of the features of these cases are given in Table I.

Case 1

A woman aged 20 was admitted on May 29, 1954. One year before admission she had been delivered of a stillborn child. Six weeks after this she developed flatulent dyspepsia and intermittent epigastric distress, later followed by severe constant epigastric pain radiating through to the back on the left side. She vomited occasionally. The pain was worse after fatty foods. Two weeks before admission she had more severe pain than previously, and this was followed by persistent vomiting and then jaundice with dark urine and pale stools.

On examination she was jaundiced. Her temperature was 99.8° F. (37.7° C.), pulse 80, blood pressure 120/90 mm. Hg. There was rigidity and guarding over her abdomen, but she was more tender in the epigastrium. The liver and gall-bladder were palpable. The diagnosis of obstructive jaundice due to pancreatitis was made. The urinary diastase level was 400 units.

Laparotomy was performed on June 1. The gall-bladder was normal and contained no calculi, while the pancreas was irregularly enlarged and thickened. The common bile duct was drained and a pancreatic biopsy was performed: this showed pancreatitis (Fig. 1).

FIG. 1.—Pancreatic specimen taken for biopsy at operation in Case 1. At this stage the patient was still jaundiced and the urinary diastase elevated. The specimen shows increased fibrous tissue and cellular infiltration without necrosis of the parenchymal cells; the pancreatic ducts are slightly dilated. (Van Gieson, x144.)

TABLE I.—Some Clinical Features of Six Patients with Post-partum Pancreatitis

Case No.	Family History	Parity	Pregnancy	Child	Time of Onset of Symptoms after Pregnancy	Time of Onset of Acute Pancreatitis	Abdominal Pain	Vomiting	Jaundice	Gall-stones	Result
1	Aunt had cholelithiasis	1	Normal	Stillborn	6 weeks	12 months	+	+	+	0	Well
2	Nil	1	"	Living	3 months	3 "	+	+	+	+	Recurrent pain two years later
3	"	1	Hypertension, induction of labour	"	2 weeks	6 weeks	+	+	+	+	Well. Again pregnant
4	"	1	Normal	"	9 months	11 months	+	+	0	+	Well
5	"	1	Some flatulence and vomiting	"	A few days post partum	2 years	+	+	Slight	+	Well
6	Father had cholelithiasis	2	Normal	"	11 weeks	14 weeks	+	+	0	?	?

Her convalescence was uneventful. A cholangiogram through the tube in the common bile duct on June 28 showed the anatomy of the biliary tree to be normal, and the contrast medium entered the duodenum freely (Fig. 4). The tube was removed on June 30. She has remained well since.

Case 2

This patient, aged 23, was first admitted on February 3, 1954. Three months before admission she had a normal delivery after a normal pregnancy. Two days before admission she had a sudden onset of severe colicky pain in the epigastrium radiating through to the back and associated with nausea and persistent vomiting. This was followed next day by jaundice with dark urine and pale faeces.

On examination she was icteric. Her temperature was 99° F. (37.2° C.), pulse 100, blood pressure 125/80 mm. Hg. There was tenderness in the epigastrium. The diagnosis of pancreatitis and cholelithiasis was made, although no urinary diastase estimation was done at this stage. She responded to conservative treatment with pethidine and antibiotics.

A cholecystogram on March 1 showed multiple non-opaque calculi in the gall-bladder. At laparotomy on March 5 the pancreas was enlarged, firm, and nodular. The common bile duct was normal. The gall-bladder was not thickened, but it contained small stones. Cholecystectomy was performed uneventfully. The patient has since remained well.

Case 3

A young woman, aged 19, was first admitted on December 31, 1951. Eight weeks previously she had been successfully delivered of her first child after a pregnancy complicated by hypertension and terminated by medical induction of labour. Two weeks later she had developed sudden severe pain in the back, followed by two milder attacks. Four days before admission she had a fourth attack, more severe than the earlier ones, felt both in the back and in the epigastrium and associated with vomiting. Her urine was dark and her faeces were pale.

On examination she was icteric; temperature 99° F. (37.2° C.), pulse 96, blood pressure 140/80 mm. Hg. She was thought to have cholelithiasis, and a cholecystogram on January 14, 1952, showed multiple radiolucent calculi. At operation on January 17 the gall-bladder was thickened and contained calculi. Cholecystectomy was performed. The pancreas was not examined. Convalescence was delayed by a wound infection producing erythema nodosum and necessitating secondary suture. She was discharged on March 1.

When seen again on January 28, 1954, she complained of flatulent dyspepsia and recurrent severe abdominal pain radiating through to the back and with occasional vomiting. The attacks had occurred every two or three weeks for some months. She had noted no jaundice. The clinical diagnosis of relapsing pancreatitis was confirmed by a urinary diastase of 160 units on January 28. She has been treated with a low-fat diet and atropine and ephedrine orally, with decrease in the frequency and severity of her pain.

Case 4

A woman aged 22 was admitted on March 22, 1954. Two months before admission, and nine months after a normal pregnancy, she developed flatulent dyspepsia and recurrent epigastric pain radiating through to the back, associated with vomiting and a dark coloration of her urine. Three days before admission she had severe persistent pain in the left upper quadrant of her abdomen radiating to the back, and frequent vomiting.

On examination she was not jaundiced. Her temperature was 101° F. (38.3° C.), pulse 100, blood pressure 140/90 mm. Hg. There was tenderness and rigidity in the upper abdomen, more marked on the left side. A clinical diagnosis of pancreatitis was confirmed by a urinary diastase estimation of over 2,000 units. She responded to conservative treatment with gastric aspiration, intravenous fluid replacement, pethidine, and antibiotics.

Oral cholecystography on April 7 failed to outline the gall-bladder, but an intravenous cholelithogram on May 20 showed a large gall-bladder containing multiple stones up to 1 cm. in diameter.

Laparotomy was performed on June 4. An operative cholangiogram showed the dye medium to enter the duodenum freely. There was no evidence of residual pancreatitis. The common bile duct was normal. The gall-bladder contained multiple stones and was removed, and a pancreatic biopsy was done (see below). The patient has remained well since operation, although she is again pregnant.

Case 5

A woman aged 26 was first admitted on March 22, 1949. Two years previously, a few days after childbirth, she developed epigastric pain and flatulence lasting a few days and recurring thereafter at intervals of weeks. Six days before admission she had sudden severe epigastric pain radiating through to the back and associated with nausea and vomiting.

On examination she was acutely ill and slightly icteric. Her temperature was 100.6° F. (38.1° C.), pulse 120, blood pressure 150/100 mm. Hg. Epigastric tenderness and rigidity were present. The diagnosis of acute pancreatitis was confirmed by a urinary diastase level of over 1,000 units. She was treated conservatively with morphine and antibiotics, and gradually improved over the following week.

A cholecystogram on April 8 showed multiple small calculi in the gall-bladder, and laparotomy was performed on May 4. There was fat necrosis in the omentum and mesocolon; the pancreas was thickened and irregular; the gall-bladder was thickened and contained calculi, but the common bile duct was normal. Cholecystectomy was performed uneventfully.

When last seen twelve months after operation she was well and free of pain and dyspepsia.

*Working with the aid of a grant from the National Health and Medical Research Council of Australia.

Case 6

A woman aged 22 was admitted on March 17, 1954. Fourteen weeks previously she had completed a normal pregnancy. Three weeks before admission she had a mild attack of epigastric pain lasting two days. Two days before admission she had sudden onset of severe constant epigastric pain radiating to both flanks, with nausea and vomiting.

On examination she appeared flushed and drawn, but was not jaundiced. Her temperature was 100.6° F. (38.1° C.), pulse 136, blood pressure 130/90 mm. Hg. Her abdomen was slightly distended, with generalized tenderness, and there was guarding in the epigastrium.

A urinary diastase estimation of 2,000 units confirmed the clinical diagnosis of pancreatitis. Conservative treatment with intravenous therapy, pethidine, and antibiotics resulted in rapid improvement in her condition, and she was discharged on March 31. No follow-up studies have yet been possible on this patient.

Laboratory Investigations

The laboratory investigations in all patients followed a similar pattern, and may conveniently be considered together (Tables II and III).

TABLE II.—Salient Laboratory Findings in Six Cases of Post-partum Pancreatitis. In Cases 2 and 3 the Urinary Diastase Estimations were Made After recovery from the Acute Stage of the Disease

Case No.	Urine				Blood		Total Serum Lipides (mg. 100 ml.)	Serum Cholesterol (mg. 100 ml.)
	Proteinuria	Glucosuria	Bile	Diastase	Hb (g.%)	Leucocytes (per c.mm.)		
1	+	+	+	400	13.3	6,000	480	160
2	0	0	+	30	12.1	7,000	520	210
3	0	0	+	160	11.3	11,200	500	195
4	0	+	+	2,000	9.9	16,000	—	—
5	+	0	+	1,000	14.0	28,800	—	—
6	0	0	+	2,000	7.8	15,000	—	—

TABLE III.—Liver-function Tests in Six Cases of Post-partum Pancreatitis. The Significant Abnormalities are slight Elevation of the Serum Bilirubin and Alkaline Phosphatase in Cases 1, 3, 4, and 5

Case No.	Serum Bilirubin (mg. 100 ml.)	Cephalin Flocculation	Serum Albumin (g.%)	Serum Globulin (g.%)	Serum Gamma Globulin (g.%)	Serum Alkaline Phosphatase (K-A Units)
1	4.0	Weak positive	4.7	2.0	0.8	23
2	0.2	Negative	4.5	2.3	0.9	7
3	0.2	"	5.6	2.1	1.3	29
4	2.5	Weak positive	4.3	1.9	0.9	12
5	6.0	Negative	4.8	2.3	—	25
6	0.5	Weak positive	3.7	2.0	—	—

Urine Examination.—Two patients (Cases 1 and 5) showed transient proteinuria, two (Cases 1 and 4) transient glucosuria, and all cases had bile in the urine during the acute stage of the disease (Table II). In all cases examination of the urine was normal on discharge from hospital.

Urinary Diastase.—In four patients estimations of the urinary diastase level on admission to hospital with severe symptoms revealed diagnostic levels confirming the clinical diagnosis of pancreatitis (Table II). In Case 3 a less marked elevation to 160 units was recorded when the patient presented with post-cholecystectomy dyspepsia three years after the attack of "acute cholecystitis." This reading is regarded as diagnostic in this laboratory. In Case 2 no significant elevation of the urinary diastase was found, but it was not possible to examine the urine during an exacerbation of symptoms. In this patient the diagnosis of pancreatitis was confirmed at laparotomy. Serum amylase levels were not investigated.

Blood Examination.—The results of blood examinations were variable. Two patients had a moderate hypochromic anaemia. Acute exacerbations were accompanied by a polymorphonuclear leucocytosis, which in Case 5 reached 28,800 per c.mm. (Table II).

Liver-function Tests.—The results of liver-function tests are detailed in Table III. They show slight elevation of the serum bilirubin and alkaline phosphatase, without change in plasma protein levels. When symptoms were severe a weakly positive cephalin flocculation was sometimes noted. The findings suggest that jaundice in these patients is obstructive in type, although slight hepatocellular damage may accompany peritoneal irritation in exacerbations of the disease. None of these patients was subjected to liver biopsy.

Gastric Investigations.—Because of the frequency with which the patients complained of flatulent dyspepsia, a histamine test-meal examination was made in five cases (Cases 1, 2, 3, 4, and 5), and in all it revealed a normal gastric acidity. Gastric biopsy in Cases 1 and 4 by the method of Wood *et al.* (1949) showed normal mucosa in both.

Glucose-tolerance Tests.—Oral glucose-tolerance tests after 50 g. of glucose were performed on three patients (Cases 1, 2, and 4), and none had hyperglycaemia or a diabetic type of curve.

Serum Lipide and Cholesterol Levels.—There was no elevation of the total serum lipides measured by the turbidimetric method of Kunkel *et al.* (1948) or of the serum cholesterol in those cases in which they were measured (Table II). In Cases 2, 3, and 4 fat-tolerance curves after ingestion of 50 g. of butter were performed after recovery from the acute stage. In all three cases these suggested poor absorption, consistent with impaired pancreatic function (Fig. 2).

Other Investigations.—The intravenous secretin test was not used in this study, as in our hands it has produced results too variable to be of great diagnostic value. Similar variations have been reported from other centres (Dornberger *et al.*, 1948; Heffernon and Gunter, 1951). In all patients the Wassermann reaction was negative. The erythrocyte sedimentation rate was raised during exacerbations of symptoms.

Radiological Studies

Plain x-ray films of the abdomen and chest were normal in all cases.

Oral cholecystography was performed in Cases 2 to 5 after recovery from the initial "acute pancreatitis," an interval of about three weeks. In Cases 2, 3, and 5 this revealed multiple small non-opaque calculi in the gall-bladder. However, in Case 4 there was no radiological demonstration of the gall-bladder, and an intravenous choledochogram was done six weeks later, eight weeks after initial admission to hospital. This showed the gall-bladder to be enlarged and to contain multiple calculi; the bile ducts were not outlined.

A cholangiogram was performed at operation in Case 4 (Hughes and Kernutt, 1954b). There was good filling of the biliary tree. The contrast medium flowed freely into the duodenum, and there was no demonstrable abnormality at the lower end of the common bile duct. In one film the medium had entered the main pancreatic duct by retrograde flow, and no obstruction to this was noted (Fig. 3).

In Case 1 a cholangiogram was performed four weeks after operation before removal of the T-tube from the common bile duct. The medium entered the duodenum freely and the common bile duct was normal, with the usual anatomical tapering at the lower end (Hughes and Kernutt, 1954a). No evidence of cholelithiasis was obtained (Fig. 4).

Pancreatic Biopsies

Biopsy of a specimen from the body of the pancreas was obtained at operation in Cases 1 and 4. There were no adverse sequelae from these procedures.

In Case 1 the biopsy was carried out a year after completion of pregnancy and three weeks after the onset of jaundice, at a time when the urinary diastase was still slightly raised. This biopsy showed slight increase in fibrous tissue, distorting the normal pancreatic architecture. There was some infiltration by fibroblasts, lymphocytes, and polymorphs. The acini were slightly irregular but without areas of necrosis of the parenchymal cells (Fig. 1).

The biopsy in Case 4 was carried out twelve months after the birth of her child and five months after she first developed dyspepsia. At the time of operation she had been free of symptoms for two months. The biopsy showed normal pancreatic tissue, without evidence of the preceding inflammation and with no residual fibrosis or fatty infiltration.

Discussion

These patients, and those reported by other authors, have many features in common. All were young women who developed flatulence and recurrent bouts of abdominal pain and vomiting within a few days or weeks of pregnancy, culminating in an attack of "acute pancreatitis." In all of them the clinical and laboratory findings were closely similar.

The aetiology of the pancreatitis is of the greatest interest. None of the six patients presented clinical or epidemiological evidence of infection with mumps or the other viruses known occasionally to cause pancreatitis. All had excellent dietetic histories, with no suggestion of alcoholism or malnutrition. In only two of the six was there a family history of cholelithiasis; none had a family history of cardiovascular disease, xanthomatosis, diabetes mellitus, or pan-

FIG. 2.—Fat-tolerance curves in Cases 2, 3, and 4. In all there is a low fasting lipide level and a rise of less than 100 mg. per 100 ml. after 50 g. of butter orally.

FIG. 3.—Operative cholangiogram in pancreatitis following pregnancy (Case 4). There is no biliary obstruction and the anatomy of the bile ducts appears normal. There has been some filling of the main pancreatic duct.

FIG. 4.—Post-operative cholangiogram in post-partum pancreatitis (Case 1). The arrangement and calibre of the bile ducts are normal, and the contrast medium enters the duodenum freely. There has been some retrograde filling of the main pancreatic duct.

creatitis, and in four cases estimations of serum lipide and cholesterol levels revealed normal values (Table II; Fig. 2). One patient (Case 2) has a binovular twin who has borne two children without evidence of pancreatic disease. These facts render unlikely the hereditary type of pancreatitis recently described and associated frequently with hyperlipaemia (Holt *et al.*, 1939; Collett and Kennedy, 1948; Comfort and Steinberg, 1952; Klatskin and Gordon, 1952). It should nevertheless be noted that one patient (No. 11) in the family reported by Comfort and Steinberg (1952) first developed symptoms a month after the birth of her first child.

The relation between the pancreatic lesions and cholelithiasis must also be considered. Cholelithiasis was present in four of the five cases in which full radiological studies and laparotomy were performed, but in none were stones found in the common bile duct, and in none was any abnormality of the sphincter of Oddi demonstrated. In Cases 1 and 4 cholangiography showed the duct of Wirsung to be freely patent (Figs. 2 and 3). Langmade and Edmondson (1951) in their survey of 53 reported cases of pancreatitis complicating pregnancy found 34 in which the gall-bladder was examined at operation or after death, but calculi were noted in only 12 of these. They stated that "there was no particular difference between those with and those without [gall-stones] as far as the onset and course of their pancreatitis was concerned." There is also statistical evidence to suggest that there is little direct relation between pregnancy and cholelithiasis (Gross, 1929; Joske *et al.*, 1954). For these reasons it is thought improbable that cholelithiasis in these patients has any aetiological significance, but rather that biliary stasis due to pancreatitis may be responsible for the development of cholelithiasis, or that both cholelithiasis and pancreatitis are sequelae of the lipaemia of pregnancy.

Reflux filling of the main pancreatic duct was shown radiologically in two patients (Cases 1 and 4). The work

of Hicken and McAllister (1952) suggests strongly that reflux into the main pancreatic duct is a frequent and normal finding in man, and of no pathological significance. They found also that this reflux may occur whether or not there is a common entry of the common bile and pancreatic ducts into the duodenum. Experience with cholangiography in this hospital agrees with this (Hughes and Kernutt, 1954b), and the relation of biliary reflux to pancreatitis in man is thought to be slight.

It is therefore postulated that these patients were in fact suffering from a type of chronic relapsing pancreatitis which is in some way related to pregnancy, and that this may represent an entity within the large group of diseases considered together as "pancreatitis."

The abnormality in pregnancy causing pancreatitis remains unknown. Liver-function tests and biopsies on pregnant women show no suggestive pattern in this regard (Ingerslev and Teilum, 1945; Day and Hellestrand, 1947; Dieckmann *et al.*, 1951). Boyd (1934) has shown that neutral fat, phospholipids, and cholesterol are all increased in the plasma during pregnancy, while Potter (1936) states that the gall-bladder is distended and that there is hypercholesterolaemia at term in most women.

The management of this disorder is poorly understood. Treatment has been conservative, surgery being indicated only in the presence of cholelithiasis, for the relief of obstructive jaundice, and for drainage of residual abscesses after an acute exacerbation. Internal biliary drainage by sphincterotomy does not seem to be indicated, because of the apparently normal state of the ducts and sphincters found in these patients, and the recent anatomical studies of Hughes and Kernutt (1954a) and of Sterling (1954).

Where symptoms of flatulence and pain have persisted the patient has been placed on a high-protein, low-fat diet and given atropine and ephedrine by mouth. It is not yet possible to speak of the efficacy of this regime or of the possible effects of further pregnancies in these patients. The recurrence of symptoms in Case 3 after cholecystectomy suggests that this syndrome may be one cause of the "post-cholecystectomy syndrome," although the normal biopsy finding in Case 4 two months after cessation of symptoms indicates that resolution may be complete.

Summary

Six cases are reported of young women who developed pancreatitis shortly after pregnancy. In all of them the clinical and laboratory findings were similar.

The aetiology of the pancreatitis is considered to be related to the preceding pregnancy, although the mechanism of this is unknown.

It is suggested that these patients, and others in the literature, form a distinct subgroup within the general group of patients with pancreatitis.

Until the aetiological factors are better understood, it is suggested that the term "post-partum pancreatitis" be applied to this subgroup.

My thanks are due to Dr. Ian Wood, head of the Clinical Research Unit, and Mr. E. S. R. Hughes for their interest and help in this work; to my colleagues in the clinical research unit for the many investigations performed on these patients; and to the physicians and surgeons who referred these cases. The photographs were prepared by Dr. J. D. Hicks and Mr. Roy Ingles, of the Royal Melbourne Hospital.

TUBERCULOUS MESENTERIC ADENITIS IN CHILDREN*

BY

HUGH R. E. WALLIS, M.D., M.R.C.P., D.C.H.

Consultant Paediatrician, Bath Clinical Area; Medical
Officer, Kingswood School, Bath

The purpose of this essay is to draw attention to a cause of minor illness in children which is usually overlooked in this country. It is intended to show that tuberculous mesenteric glands may sometimes cause symptoms and continue to do so even after they have become calcified.

The condition is well recognized on the Continent. Klein in 1927 reported cases from Poland and commented: "Beaucoup de médecins, en présence de cette maladie, ne croient pas à la possibilité de son existence." In Sweden, Strömbeck (1932) made a thorough review of the published work on the subject. Alexandre (1949), in France, gave another excellent account.

The symptoms described are colicky central abdominal pain, nausea, vomiting, sweating, meteorism, diarrhoea, constipation, pallor, lassitude, and loss of weight. The physical signs are palpable tumours in the abdomen, local tenderness, fever (especially in the evenings), and calcification visible in the x-ray film.

Most physicians, when confronted with calcified glands, assume that calcification signifies a healed lesion and that they must look elsewhere to account for the symptoms. If this assumption be true then we must assume also that the calcification appears suddenly and instantaneously, and that at that moment

*Condensed from the Nathaniel Bishop Harman Prize essay, 1954.

all symptoms cease. It would be better if we were to say, with the prisoner of Chillon (he was referring to his hair):

Nor grew it white
In a single night.

Strömbeck (1932) has shown the progress of calcification over a long period while symptoms continued, and in the cases here reported the same phenomenon has been demonstrated.

In this country the condition has received more attention from surgeons than from physicians (Carson, 1918; Struthers, 1921; Braithwaite, 1926). Rendle Short (1928) pointed out that an evening temperature rising to 100-101° F. (37.8-38.3° C.) may persist for months or even years.

More recently the condition appears to have been overlooked. This is probably because medical teaching centres are situated in large cities where the milk supplied to children is free from tubercle bacilli. Conway (1951) analysed the history and diagnoses of 250 children in London who complained of abdominal pain. Not one case of tuberculous mesenteric adenitis was discovered.

The following are some of the cases met with during a period of two years in consulting paediatric practice. They have been selected to show the different ways in which the disease may present itself. All the children were tuberculin-positive. All of them had had their chests x-rayed, and no tuberculous lesions were found. None of them had been in contact with infectious tuberculosis.

Case 1. Abdominal Pain

A boy who lived in the country and who had consumed raw milk from the age of 1½ years began to have attacks of pain in the left hypochondrium at the age of 8 years. This pain had no relation to meals, and occasionally woke him up. It was sharp and doubled him up, and was sometimes severe enough for him to be sent home from school. When it occurred he felt sick and turned pale. There were no abnormal physical signs. He was admitted to hospital with a tentative diagnosis of hiatus hernia or renal abnormality. His temperature, blood counts, urine, blood urea, x-ray films of the chest and sinuses, barium meal, and intravenous pyelogram were normal. An x-ray film of the abdomen showed calcified glands over the fourth and fifth lumbar vertebrae.

Progress.—He was treated with 20,000 units of calciferol daily for one month. A year later he had gained 4½ lb. (2 kg.) in weight. He still complained of pain occasionally, but it was not as severe as before. X-ray examination of his abdomen showed condensation of the calcium in the affected glands and a new area of calcification opposite the second lumbar vertebra.

Case 7. Incident Mimicking Acute Appendicitis

A Ukrainian girl who in early childhood had lived in Germany and had drunk raw milk there was admitted to hospital at the age of 11 as a case of acute appendicitis. She had then had intermittent pain in the right iliac fossa for six months. Her temperature was 100° F. (37.8° C.), pulse 92, and respirations 22. A blood count showed 8,200 white cells per c.mm. (72% polymorphs). Next day her temperature fell to normal and remained between 98 and 99° F. (36.7 and 37.2° C.) for five days. Her pulse rate remained below 100. Nevertheless on the seventh day her appendix was removed. The operation notes state that it was "inflammatory." She made an uninterrupted recovery.

Two and a half years later she was referred to the outpatient department complaining of abdominal pain in the left side. This was worse when she ran, but also occurred

at rest. On examination there was some tenderness on deep pressure at the umbilicus. She was admitted for investigation, but no abnormality was found in the chest, heart, urinary system, or gastro-intestinal tract. X-ray examination of the abdomen showed some calcified glands in front of the fourth and fifth lumbar and the second and third sacral vertebrae.

Progress.—She was treated by a course of ultra-violet light and 20,000 units of calciferol twice daily for six weeks. Six months later she was well, and said that she had more energy. She had occasional pain, but it occurred less often. The glands were palpable just below the umbilicus. X-ray examination showed an increase in the calcification of those in the pelvis, whilst the others were unchanged. Three months after this she had no pain at all.

Case 5. Abdominal Pain and Vomiting. Primary Infection Observed

A girl who lived in the country and had raw milk began to complain at the age of 4 of left-sided abdominal pain at intervals. She was usually constipated, and occasionally had frequency of micturition and pain on passing water. In one of these attacks she vomited once and was admitted to hospital in another part of the country. The summary of her notes states: "On examination, a rather pale unwell-looking child, E.N.T. normal. Chest clear. Abdomen slightly resistant to palpation, especially in the left renal angle. Physical examination otherwise showed no abnormalities. Progress and investigations: urine x 6 normal; Hb 89%; W.B.C. 10,000; Mantoux 1 in 1,000 positive; x-ray film of chest, no lesion seen; E.S.R. 10 mm. in one hour. She was allowed up before discharge, during which time she appeared well and made no complaints. Discharge note: the period of ill-health during the last 18 months was possibly due to a primary tuberculous complex. There is no evidence of activity now."

During the next two and a half years she had repeated attacks of abdominal pain lasting for periods varying up to a week. In one attack she began to vomit, and her general practitioner referred her to hospital with the following note of his findings and opinion.

"Pale and looks ill. Temperature 100.5° F. (38° C.), pulse 90. There is a tender knobby mass in the left iliac fossa. Per rectum, very tender anteriorly. I feel sure the diagnosis is tuberculous adenitis, but I cannot exclude a low-grade appendix or other pathology." The patient was admitted and the findings were confirmed. Investigations showed a normal blood count. E.S.R. 15 mm. in one hour (Westergren). Several examinations of urine for tubercle bacilli were negative. X-ray film of the abdomen showed several large calcified glands to the left of the fourth and fifth lumbar vertebrae and one small gland to the right of the third lumbar vertebra. An intravenous pyelogram showed no abnormality, and the calcified opacities were seen to be separate from the renal tract.

Progress.—The patient was treated with 20,000 units of calciferol twice daily for one month and a course of ultra-violet light. Her temperature subsided rapidly. Five weeks later she had gained 9 lb. 12 oz. (4.4 kg.) and had less pain. A year later she was very well, had gained 16 lb. (7.3 kg.) since admission, and had no pains or sickness.

Case 17. Pyrexia of Unknown Origin. Tuberculous Rheumatism

A boy who lived in the country and had drunk raw milk regularly complained of pain in the left knee and groin at the age of 7½ years. He was admitted to hospital with a diagnosis of synovitis of the left hip. This was considered to be a simple synovitis, not tuberculous, and he was transferred to an orthopaedic hospital. His temperature was normal. The E.S.R. was 2 mm. in one hour (Westergren). A blood count and his urine were normal. A chest x-ray film was normal. The condition was treated by simple traction, and six weeks later it had improved considerably. The boy's temperature, however, was raised to 99.4° F.

(37.4° C.), or even 100° F. (37.8° C.) in the evenings, and the orthopaedic surgeon in charge could not explain this. The E.S.R. had risen to 38 mm., and his weight was stationary. A second x-ray film of the chest was normal. The urine contained no pus cells or tubercle bacilli. X-ray examination of the abdomen showed calcified glands on the right side of the fourth lumbar vertebra. It was considered that the cause of the temperature was the mesenteric adenitis, and that the synovitis of the hip was a manifestation of tuberculous rheumatism.

Progress.—He was treated by rest in bed, ultra-violet light, and 20,000 units of calciferol daily for a month. At the end of this time his temperature had settled, his E.S.R. was 11 mm. and he was discharged home. Two months later he had gained 4 lb. (1.8 kg.) and was very well. His mother stated that he had an enormous appetite. A year later he was very well and had no symptoms. X-ray examination showed no change in the glands.

Case 19. Coeliac Syndrome

This boy, who lived in the country and drank raw milk, suffered from phlyctenular conjunctivitis at the age of 2 years. Two years later he complained of anorexia and vomiting, and upper abdominal pain. His abdomen appeared to be "blown out with wind." His stools were loose and offensive. He was admitted to hospital, where his weight was found to be 30 lb. (13.6 kg.). The stools were typical of the coeliac syndrome. A fat-balance test showed only 66% absorption of fat. Trypsin was present in several specimens of stool. One physician who saw him commented, "On clinical grounds I do not think that this can possibly be coeliac disease because he is so happy and cheerful, and there has never at any time been any wasting of his muscles." He suffered from a microcytic type of anaemia. X-ray examination of the abdomen showed calcified glands to the left of the second lumbar vertebra.

Progress.—He was given iron for the anaemia, but had no special treatment for the coeliac syndrome. He did very well, and when seen 13 months later had gained 6 lb. (2.7 kg.) and grown 2 in. (5 cm.). He had no pain or diarrhoea. X-ray examination showed the glands to be more firmly calcified.

Summary of Cases

Altogether 20 children were seen in whom tuberculous mesenteric glands were considered to be causing symptoms. Of these, 14 had pain as the main complaint, one had pain and pyrexia, four pyrexia alone, one showed the coeliac syndrome, and one was a case of primary infection. Details of these cases are given in the Table. There were 15 boys and five girls.

Details of Cases

Case No.	Sex	Age at Onset (Years)	Length of History	Nature of Case	Site of Glands (Quadrant of Abdomen)
1	M	8	4 weeks	Abdominal pain	Left upper, central
2	M	5	1 year	" "	Right lower
3	M	9	4 months	" "	Left upper, right lower
4	M	7	3 "	Abdominal pain, tuberculous rheumatism	Left lower
5	F	4	2½ years	Abdominal pain	" "
6	F	6	2½ "	" "	Right "
7	F	13	6 months	" "	Central, pelvic
8	M	9	1 month	" "	Right lower
9	F	8	2 years	" "	Pelvic
10	M	3	3½ "	" "	" "
11	M	6	1 year	" "	Right lower
12	M	3	9 months	" "	" "
13	M	2	7 years	" "	" "
14	M	5	7 months	" "	Left "
15	M	10	1 week	Abdominal pain, pyrexia	Right "
16	M	6	1 month	Pyrexia	Pelvic
17	M	7	Found in hospital	Pyrexia, tuberculous rheumatism	Right lower
18	F	9	" "	Pyrexia	" "
19	M	4	8 months	Coeliac syndrome	Left " upper
20	M	2	Nil	Primary infection	" "

The age of onset was fairly evenly spaced throughout the third to eleventh years of life. The duration of symptoms before the first contact with a paediatrician varied from one week to seven years. Most cases were seen during the first year, and a small group at two to four years. The average length of history was one year four months.

All the patients except one lived in the country. The exception was a boy living in Bath who had previously lived in the country.

The glands demonstrated by x-ray examination were most often seen in the area of the ileo-caecal junction, but there were nearly as many along the line of attachment of the mesentery of the small intestine. In four cases the glands appeared to be in the pelvis. In two cases in which the infection took place at an early age the glands were demonstrated high up to the left (Cases 19 and 20). It may be that early or overwhelming infection occurs high up in the small intestine in an area which drains into glands on the left of the midline, whereas later and milder infections take place lower down the gut, where the mesentery is attached to the right side of the abdomen. In the infants at Lübeck the majority of the glands were found on the left.

In four of the cases it was possible, on looking back, to disclose illnesses which might have been due to primary infection (Cases 4, 5, 6, and 7). In one case the primary infection was observed in hospital and the glands were discovered by chance when the patient returned later with a different illness (Case 20).

Differential Diagnosis

The condition must be differentiated from non-tuberculous causes of pain, pyrexia, or vomiting, and these are legion. During the two-year investigation described below the following diagnoses were made in children who complained of abdominal pain; acute nephritis, dietary indiscretion, empyema, hernia of the linea alba, idiopathic epilepsy, idiopathic thrombocytopenic purpura, inadequate dentition, non-specific mesenteric adenitis, pneumonia, psychological disturbance, pyelitis, recurrent neutropenia, and salmonella food-poisoning. The causes of pyrexia are too numerous to mention.

If the tuberculin test is positive it is important to make sure that there is no active tuberculous lesion in any other organ. Pulmonary tuberculosis, especially when accompanied by pleurisy, may cause abdominal pain; and tuberculous peritonitis and inflammation of the spine must also be considered. Affection of the renal tract must be excluded by repeated examination of complete morning specimens of urine for pus cells and tubercle bacilli.

The radiological appearance of tuberculous glands is usually unmistakable. They are round or oval; the shadows are not homogeneous, but mottled, and appear like a mulberry or an archipelago as seen on a map. They may lie anywhere in the abdomen, but are usually seen along the line of attachment of the mesentery of the small intestine. In the lateral view they are often in front of the spine.

During the two-year survey other causes of shadows in the abdomen found were: stones in the gall-bladder, calcified phleboliths in a girl with multiple angiomas, calcification in an adrenal neuroblastoma, and various pills and tablets. No renal stones were seen.

The Lübeck Catastrophe

At Lübeck in 1930 virulent tubercle bacilli were administered inadvertently by mouth to 251 infants (Schürmann and Kleinschmidt (1935). Seventy-two died from tuberculosis within a year. Practically all the children who developed primary lung lesions died, while the majority who had primary alimentary lesions survived. In many cases the abdominal infection produced no symptoms or very vague ones. Calcification of the abdominal glands was seen at the earliest 18 months after the infection; and after

three years it had reached its final stage. Late results such as obstruction and the coeliac syndrome were not observed.

X-ray films were taken of 173 children at 4 years of age, and 126 of them had calcification in the abdominal glands. This was rather more common on the left side, suggesting that the site of infection was usually high up in the small intestine.

One most important point is the benign course of the disease in the abdomen compared with the serious outcome when the lungs were affected.

Treatment

In the majority of cases the disease proceeds to heal spontaneously, and it may be that there is no need to interfere with this natural process. Previous workers have usually approached the problem from the surgical angle. Arguments have been put forward for and against removal of the affected glands. It has been pointed out that sometimes when the diagnosis is in doubt it is imperative to operate rather than run the risk of neglecting to remove an acutely inflamed appendix. It has also been noted that after an exploratory laparotomy tuberculous mesenteric adenitis may improve in a spectacular manner, even though the glands are not removed, just as tuberculous peritonitis may.

Wallace (1946) and Gauvain (1948) have reported favourably on the calciferol treatment of tuberculous glands in the neck. Macrae (1947) has studied the effect in tuberculous peritonitis. Gauvain stated: "Calciferol causes an early flare-up of activity, followed generally by rapid healing, which is of such a sound degree that the glands can be immediately and, so far as we can tell at this early stage, safely excised with little risk of recurrence."

The dose of calciferol used by Gauvain was 100,000 units daily for several months. Macrae used even larger doses. He reported some alarming reactions. One of his patients died from haemoptysis from a very small cavity, the presence of which had been unsuspected. None of the patients consuming large doses of vitamin D felt fit, and all of them lost weight.

Results of Treatment.—It seemed that it might be dangerous to produce a flare-up in the abdominal glands, and that the ideal to aim at would be to produce a more gradual healing, imitating the natural process, but gently expediting it. It was therefore decided to give the children only 40,000 units of calciferol daily and to support this with a course of ultra-violet irradiation when this could be conveniently arranged. The treatment was continued for six weeks. Results are difficult to assess in a condition which usually proceeds to spontaneous cure. The numbers available are not sufficient for definite conclusions to be drawn, but on the whole the impression was that treatment gave considerable benefit. In most children the pains abated, the appetite improved, the weight increased, and after three to six months there were no more symptoms.

Flare-up.—Two of the treated children (Cases 8 and 16) demonstrated phenomena which might be considered to be due to mild exacerbations or flaring up of the disease. Neither was seriously inconvenienced and both were eventually regarded as cured.

Case 16.—A boy aged 6 years who lived in the country and consumed raw milk complained of pain in the legs and had fever of 99 to 100° F. (37.2 to 37.8° C.) for a month. He was admitted to hospital and found to have a positive tuberculin reaction. Calcified glands in the presacral region were seen on the x-ray film. Other investigations were negative. He was treated with calciferol and ultra-violet irradiation. Two months later he stated that he had had two attacks of abdominal pain lasting for two days. The pain was colicky and was felt at the umbilicus. He had lost 1½ lb. (0.7 kg.) in weight in the first month, but had regained it. Three months after this he had had no pain or pyrexia. He had gained over 5 lb. (2.3 kg.). X-ray examination showed firmer calcification.

Recommendations

When active tuberculous mesenteric adenitis has been diagnosed as the cause of symptoms it seems reasonable to recommend that the child should be given the benefit of treatment with calciferol. A convenient dose is 50,000 units daily, as tablets are made in this strength. This treatment is not expensive: the retail price of 50 tablets is 2s. 9d. and 500 cost 19s. 6d. Treatment should be continued for six weeks. In this dosage no fear need be entertained about toxic symptoms, but if headache, anorexia, or vomiting occurs the situation should be reviewed, especially with regard to raised blood pressure and protein in the urine.

In the acute case in which the possibility of appendicitis has to be considered a count of the white blood cells may be of value. If this is low or normal and an x-ray film of the abdomen shows calcified glands a policy of watching in hospital is probably justified. If there is any serious doubt it is better to proceed with a laparotomy.

There is no justification for treating this mild disease with streptomycin, para-aminosalicylic acid, or isoniazid.

Incidence in Consulting Practice

The Bath clinical area consists of a city of some 90,000 inhabitants and a large surrounding rural region with a total population of approximately 200,000. For medical purposes the area is covered by two consultant paediatricians. An analysis was made of all patients seen by one of these paediatricians during a period of two years (from October 1, 1951, to September 30, 1953, inclusive).

The total number of children seen for the first time either in the out-patient department or in the wards was 825. In 58 (7.03%) of these the main complaint was abdominal pain. Eight of the 58 had pyrexia also. Twenty-two other children were referred for pyrexia alone (2.73%).

Of the 58 children with pain 8 had tuberculous abdominal glands (13.79%). Of the 22 with pyrexia 1 (4.55%) had infected glands. Of the 80 who had either pain or pyrexia nine had infected glands (11.25%).

Relation to the Tuberculin Test.—Of the 58 cases with pain, 13 were tuberculin-positive. Eight of these had active tuberculous glands. Of the other five, one had a tuberculous infection of the lung, one a hernia of the linea alba, and in the remaining three cases a diagnosis could not be made. It may be that some of these children were undergoing a tuberculous process in the abdomen in which calcification had not yet appeared, or would never appear. Follow-up has so far revealed no such calcification.

Comparison With Tuberculosis of Other Systems.—During the two-year period, in addition to the nine cases of tuberculous mesenteric adenitis, one case of tuberculous peritonitis was encountered. There were 10 cases of tuberculosis of the lungs, two cases of tuberculous meningitis (both with primary lesions in the lung), one case of phlyctenular conjunctivitis, and one of tuberculous cervical adenitis. The total number of cases of active tuberculosis was 24. In 10 of them the abdomen was principally affected, and in 14 it was not. It may be inferred that in this clinical area abdominal tuberculosis is very nearly as important as the pulmonary variety.

In passing, three children were found to have healed calcified lesions in the lung, and two had healed inactive glands in the abdomen.

Incidence in a Group of Schoolboys

This is not a satisfactory control series. It is made up of boys only, of a social status not comparable to that of the population at risk. However, it consists of observations on healthy normal children who were not selected by reason of any medical symptom, and the results obtained were so startling as to be worthy of publication.

The boys were boarders aged 11 to 16 entering a public school in two successive years. They came from all parts of the country. A large number of them were the sons

of parsons; the rest were mainly sons of other professional men. Of the 128 boys seen and tested with tuberculin jelly, 25 reacted positively. These 25 boys were subjected to x-ray examination, and 18 (72%) of them were found to have calcified abdominal glands. One had calcified glands in the neck as well. Four (16%) had healed lesions in the lung, and the remaining three (12%) had no demonstrable tuberculous lesion.

The parents of the 18 boys with abdominal glands were asked for details of any unexplained pain, pyrexia, or obscure prolonged illness in the past. Seven reported unexplained pain and pyrexia, one pain and vomiting, one pain and anorexia, and one pyrexia alone. Only eight could recollect no symptoms at all. That the illnesses were not minor is shown by the following extracts (verbatim) from the replies.

Case 21.—"From the age of 4 years his health history has been one of recurring attacks of headache, raised temperatures, vague tummy-aches, intermittent diarrhoea, and marked lethargy. . . . He saw a number of doctors in each place where we lived, but none could find a reason for the symptoms, and I was assured 'He would probably grow out of it.' He was x-rayed in — about two years ago; three doctors failed to agree on the diagnosis. The tuberculosis specialist said there was nothing 'in his department'; but our doctor was not so happy about it, and, acting on his advice, I put the boy to bed for six months' complete rest. Since then he has seemed better."

Case 22.—"When he was 2 years old he first complained of a pain in his abdomen, but it did not trouble him very much. When he was 2½ he suddenly ran a temperature. We called in a doctor, who seemed unable to diagnose. When he was almost 5 he again ran a temperature, and very shortly afterwards our doctor suggested we called in a specialist. He examined him thoroughly, but could find nothing abnormal. After a further slight recurrence at about 7 years I arranged for Professor — to examine him, and he too could not find anything wrong. Since then he has had occasional spasms of pain which were relieved by resting for a short while."

Case 24.—"He certainly has had stomach pains, in which case we have always called our doctor in, but he has never been able to find anything wrong with him. Incidentally, he has for a period of a week run abnormally high temperatures, for no apparent reason, not once but many times. Secondly, he was always complaining of feeling very tired. I used to think he was lazy, when the doctor assured me at all times that he was a very healthy boy."

Case 26 (son of a medical man).—"He had repeated attacks of tonsillitis, and occasional attacks of abdominal pain when he was younger. I made the diagnosis at that time of tuberculous ileo-caecal glands, and x-ray examination of the abdomen at the age of 8 revealed what you have found—a calcified mass in the right iliac fossa."

Case 28 (from the family doctor).—"Six years ago he had symptoms of appendicitis, and a laparotomy was done. The appendix was mildly inflamed and there were definite tuberculous glands in the right iliac fossa."

Milk Supply

Abdominal tuberculosis is usually thought to be contracted by drinking infected milk. There are occasions when it may be traced to contact with open cases of pulmonary tuberculosis, but they are rare. Toddlers put most small objects in their mouths, and may thereby ingest some dried sputum from dust on the floor or road. Ashby (1923) reported cases of abdominal tuberculosis from Manchester in which no unboiled milk had been drunk. Strömbeck (1932) refers to cases occurring in Japan in 1904, when cow's milk was unknown as a food there.

Pasteurized and tuberculin-tested milks are usually considered to be safe. Pasteurized milk has been proved to be satisfactory and a stringent check is kept on its production. Tuberculin-tested milk, however, may occasionally contain

tubercle bacilli. The intervals between inspections are fairly long and tuberculous cows are occasionally found in the herds. The danger arising from this is made worse by the practice of bulking milk in 1,000-gallon (4,500-litre) containers for transport. Accredited and non-designated milks cannot be regarded as free from infection.

In the cases described above it was usual to obtain a history of drinking raw milk for prolonged periods, though the parents of some of the children would admit to no such exposure.

Wilson *et al.* (1952), writing on infection with bovine tubercle bacilli, state: "Many of the records suggested that the consumption of raw milk must have been only slight or occasional, pointing to the danger of drinking raw milk at any time or in any form."

It is possible that one draught of raw milk is enough to start a primary infection; and there must be few country children who have not at some time had a glass. However careful their parents may be, children are bound to go out for meals or snacks sometimes and to drink milk of unknown quality. Perhaps boys will do so more than girls, and this may be the explanation of the preponderance of boys in the series.

Of the milk supplied by retailers in Bath in 1953 85% was heat-treated, 14% tuberculin-tested, and only 1% raw. In Wiltshire, however, in the same year, 12.16% was heat-treated, 50.72% tuberculin-tested, and 37.12% raw. Some of the raw milk was transported out of the county and pasteurized elsewhere (mainly in London), but the situation is nevertheless alarming.

Figures for morbidity and mortality of non-pulmonary tuberculosis show the result of this. The morbidity rate for non-pulmonary tuberculosis in Wiltshire in 1952 was 0.1673 per thousand, compared with 0.1200 for Bath and 0.1410 for England and Wales. The death rates for 1952 were: Wiltshire, 0.0309, Bath, 0.0000, England and Wales 0.0280.

It would be fair to comment that a number of deaths occurred in the county from a disease which could and should be prevented. At some future date the county will become a "designated area" under the Milk (Special Designations) (Specified Areas) Order, 1952, and from then on the condition described in this essay will gradually become rarer until it goes the way of scurvy, rickets, and congenital syphilis.

Summary

Attention is drawn to the importance of tuberculous abdominal glands as a cause of pyrexia and abdominal pain in childhood. Twenty cases are described, including examples presenting with pain, pyrexia, attacks resembling acute appendicitis, tuberculous rheumatism, and the coeliac syndrome. Reference is made to the experience at Lübeck in 1930.

Treatment with 50,000 units of calciferol daily for six weeks is recommended as a means of expediting the natural process of healing. This is not expensive.

The incidence of abdominal tuberculosis has been investigated. It is concluded that in the area under review it is now nearly as common as pulmonary tuberculosis. It seems to be more common in boys than in girls.

A survey of unselected normal schoolboys led to the discovery of further cases which had in the past caused baffling symptoms. In this group abdominal tuberculosis was more common than pulmonary.

The relation between the incidence of the disease and the consumption of raw milk is discussed.

I have much pleasure in placing on record my thanks to Dr. John Apley for his continued encouragement and for providing ready access to cases under his care; and to the consultant

surgeons of the Bath clinical area, particularly Mr. F. Kohn, who assisted with the translation of the account of the Lübeck disaster; the general practitioners who referred cases: Drs. O. H. Blacklay, D. Hall Brooks, C. J. C. Davey, M. Dietrich, J. D. O. Fearnley, R. J. K. Fleming, B. Hancock, B. L. Hodge, A. K. James, A. E. K. Price, W. H. Royal, J. A. Taylor, C. N. Vaisey, and W. Winch; Dr. B. A. Astley-Weston, M.O.H. for Bath; Dr. J. Borman Lowe, lately M.O.H. for Wiltshire; Dr. C. D. L. Lycett, M.O.H. for Wiltshire; Dr. J. F. Davidson, M.O.H. for Somerset; Dr. P. Mann for advice on epidemiological matters; my house-physicians; Miss R. Tilden-Smith (sister in charge of the sanatorium at Kingswood School); Dr. S. Gauvain for information; the consultant radiologists, Drs. H. J. Johnson, G. D. Steven, and A. C. P. D. Thomson, for their ready co-operation; and Dr. Victoria Smallpeice for information about Case 5.

ADDENDUM.—Since this essay was written cases of tuberculous mesenteric adenitis have been encountered with undiminished frequency, and another case of tuberculous rheumatism has been seen. The main problem encountered has been the diagnosis of cases in which the clinical picture is typical, the tuberculin test is positive, no other tuberculous lesion can be found, but no calcification is seen on x-ray examination. In these cases the diagnosis is vague, being arrived at by exclusion and therapeutic test. The use of radioactive calcium for tracing the process of calcification in the glands might be of value. Unfortunately no suitable isotope has yet been discovered.

A COMPARISON OF VACCINATION WITH VOLE BACILLUS AND B.C.G. VACCINES

BY

HUGH W. O. FREW, M.D., D.P.H.

Area Supervising Tuberculosis Physician, Renfrewshire and
Bute Chest Department

J. ROMANES DAVIDSON, M.D.

Medical Superintendent, Orphan Homes of Scotland

AND

J. T. W. REID, M.B., Ch.B., D.P.H.

Deputy County Medical Officer, County of Renfrew

B.C.G. vaccine was first used as a measure to prevent tuberculosis in human subjects in 1922. While, so far, there is no direct evidence that B.C.G. vaccination does in fact protect against tuberculosis, the experience gained in many countries, such as Denmark, goes far to support such a contention, and the vast majority of tuberculosis physicians throughout the world advocate the extension of anti-tuberculosis vaccination, believing that if it was adopted on a wide scale it would quickly reduce the number of new cases. A murine form of acid-fast bacillus found in voles was described in 1937 by Wells (1946), and from this organism he prepared a vaccine which he showed produced tuberculin conversions and acted in a manner very similar to B.C.G.

The course of vaccination with B.C.G. has been fully described: it is usually uneventful and produces little or no discomfort. However, there appear to be good reasons for carrying out investigations into new forms of vaccination. B.C.G. vaccine is not necessarily the ideal immunizing agent, as it is an artificial organism which might lose its potency. It would be wise to have available a proved substitute, and vole vaccine might well be suitable.

Any investigation of the action of vole vaccine must be controlled by a corresponding group treated with B.C.G., and all the conditions regarding surroundings and observations must be identical.

As vaccination with either B.C.G. or vole vaccine is a harmless procedure, neither giving rise to any systemic reactions, a comparison between the two vaccines can best be made by noting the ease of administration: the conversion rates; the early local reactions; the reversion rates; and the late reactions, or the late cosmetic effects. The final comparison must obviously include a note of any subjects who subsequently develop tuberculous disease. This is a matter of a long-term observation and cannot be completed until a period of at least fifteen to twenty years has elapsed.

The present investigation, which is being carried out at the Orphan Homes of Scotland, Bridge of Weir, began in the autumn of 1951. Of the 783 children between 1 and 15 years of age resident in the homes, the 575 included in the initial series and the 130 in subsequent series were negative reactors to 100 I.T.U., using old tuberculin. Details of the preliminary tuberculin survey have already been reported (Frew *et al.*, 1953). In all the cases x-ray examination by the M.M.R. unit failed to show any chest lesions. For the principal series, in 1951, two equal groups were selected by random methods, care being taken to ensure that both groups were as nearly as possible equal in regard to sex, age, school class, and cottage. B.C.G. was given to 288 children and vole vaccine to 280.

Administration

The B.C.G. vaccine was obtained from normal supplies prepared in the State Serum Institute in Copenhagen and given in the normal manner.

The vole vaccine used was in three forms: (a) Dry, reconstituted vaccine (2 mg. dry weight per ml.), used in 1951. (b) Liquid vaccine (2 mg. dry weight per ml.), used in 1952. (c) Liquid vaccine (half-strength) (1 mg. dry weight per ml.), used in 1953.

In 1951 the under-5-year group (numbering 55) were given the vole vaccine by intradermal injection, the dosage and method being identical to those used for B.C.G. In the case of the children of 5 years and over, vaccination was carried out by multiple puncture. The apparatus used consists of a spring-loaded gun which, on release of the trigger, projects 40 needles through a predetermined distance. For the present work the needles were adjusted to penetrate a depth of 2 mm. A sterile circle of rice paper of the same diameter as the end plate of the gun was dipped into the vaccine, applied smoothly to the skin, and the punctures were made through it. Little pain was felt, many of the children stating that they felt only a dull knock, and no dressings were required.

Conversion Rates

1951 Group.—Routine tuberculin-testing was begun at the end of the second week and was continued at weekly intervals until each case was recorded as positive. In children of 5 years and over, Mantoux-testing, using 100 units old tuberculin, was used, while in children under 5

years the tuberculin jelly test was used without flourpaper. The conversion rates for the various groups are shown in Table I. Very rapid conversions were noted in the B.C.G. group, the percentage after three weeks being 93% (99% in those over 5 years of age). The conversion rate in the vole group was slower, being 66% after three weeks and 79% after four weeks. Table I shows, however, that by

TABLE I.—B.C.G./Vole Conversion Rates

Total	Positive					
	2nd Week	3rd Week	4th Week	6th Week	8th Week	
B.C.G.						
Kinder- garten (1-4 yrs.)	56	18 (32%)	39 (70%)	48 (86%)	53 (95%)	55 (98%)
Primary Sec. and outside schools	174	86 (49%)	171 (98%)	172 (99%)	173 (99%)	174 (100%)
	58	48 (82%)	58 (100%)	58 (100%)	58 (100%)	58 (100%)
	288	152 (53%)	268 (93%)	278 (96.5%)	284 (98.6%)	287 (99.6%)
Vole						
Kinder- garten (1-4 yrs.)	55	18 (32%)	42 (76%)	53 (96%)	54 (98%)	55 (100%)
Primary Sec. and outside schools	169	27 (16%)	102 (60%)	119 (70%)	160 (94%)	167 (98.8%)
	56	27 (48%)	40 (71%)	49 (87%)	53 (95%)	56 (100%)
	280	72 (26%)	184 (66%)	221 (79%)	267 (95%)	278 (99.3%)

the sixth week the percentages were B.C.G. 98.6% and vole 95%; and 99.6% and 99.3% at the eighth week. Further testing at 12 weeks showed that in both groups there was a final 100% conversion. It was also noted that in the under-5-year group (intradermal vole) the rate of conversion was more rapid than in the corresponding B.C.G. group, and it is interesting to note that subsequent tuberculin testings at 6, 12, and 24 months have shown that no reversions have occurred in this vole group.

1952 and 1953 Groups.—In these groups tuberculin-testing was carried out at three and six weeks, and by the latter date complete conversion had taken place (Table II).

TABLE II.—Vole Vaccine Conversion Rates

	Total	3rd Week	6th Week
1952	38	—5 years 42% +5 .. 92%	100%
1953	49	—5 .. 38% +5 .. 86%	100%

Local Reactions: 1951 Series

B.C.G.—The reactions followed the usual course—macule, papule, and ulcer. On the whole they were rather more severe than expected and greater than met with in similar groups vaccinated as contacts or school-leavers. In the under-5-year group ulceration was noted in 96% and enlargement of the axillary glands in 48%. This adenitis was first noticed at five weeks, but in two cases it did not develop until the fourteenth week. In only one case did the condition progress to abscess formation. The average diameter of the ulcers noted was 4–5 mm. They were usually at their largest at approximately seven weeks, and healing occurred in from eleven to twenty weeks. In the children of 5 years and over ulceration was noted in the majority. The ulcers were on an average from 5 to 8 mm. in diameter (in nine it exceeded 8 mm.); they were at their greatest size at from five to eight weeks and healing took place in a very variable time from nine to twenty-six weeks. In five cases an axillary abscess formed between the third and ninth months, and in two cases acid-fast bacilli were demonstrated in the pus obtained from the abscesses. The presence of pus did not seem to have any adverse effect on the rate of healing or on the rate of conversion. Auto-inoculation was noted in a number of cases—usually on the skin of the arm adjacent to the vaccination.

Intradermal Vole.—The local reactions in this group were marked by their severity. Deep ulcers were noted in 100% of the cases, and all showed enlargement of the axillary glands. This adenitis was first noted at three weeks, and in all cases was present by eight weeks. Axillary abscesses occurred in 25 cases, or 45%. Several of these axillary abscesses were late in developing. Examination of the pus obtained from these glands showed acid-fast bacilli in 18 out of the 25 cases. The ulcers were 7 to 8 mm. in diameter, were deep, and reached their largest at seven to eight weeks, and, on an average, healing took place in from fourteen to twenty-eight weeks. A feature of this group was the very satisfactory healing which followed the admittedly very severe local reactions.

Multiple Puncture Vole.—In vaccination by multiple puncture no generalized reactions were noted and no child complained of pain or discomfort. The typical rosette began to develop in two to three weeks and varied greatly in size. Ulceration was noted in one case, but this was due to secondary infection following a severe blow on the vaccination site. In only three cases did an abscess develop in the axillary glands—one at a very late date—and in none of these cases was this complication accompanied by any systemic upset. Acid-fast bacilli were demonstrated in the pus obtained from the glands in all three cases. In no case was there any suggestion of auto-inoculation.

Local Reaction: 1952 and 1953 Series

The multiple-puncture vole vaccinations followed the pattern already described. The development of the rosettes was more satisfactory and the percentage of complete rosettes greater than in 1951. A 100% conversion was obtained by the sixth week.

Reversion Rates: 1951 Series

The data so far collected, relating to reversions, concerns the 1951 series only. Tuberculin-testing was carried out at six months, one year, and two years. As before, Mantoux-testing was employed in those aged 5 years and over, and the tuberculin jelly tests—without using flourpaper—in the under-5-year group. The initial Mantoux tests were carried out using 10 I.T.U. and all negative reactors were retested with 100 I.T.U.

Since the beginning of the investigation an increasing number of children have left the homes. We have made every effort to have these children followed up by the local public health departments, but unfortunately it has not been possible to carry out the periodic tuberculin-testing in all. The number of reversions reported here are a percentage of the children actually tested at the periodic surveys.

Table III shows that the percentage of reversions at six months and one year showed little difference between B.C.G. and vole groups, but by the end of the second year the

TABLE III.—Reversion Rates

	Under 5 Years				5 Years and Over			
	Vole		B.C.G.		Vole		B.C.G.	
	No. Tested	Reversions	No. Tested	Reversions	No. Tested	Reversions	No. Tested	Reversions
Start	55	0	56	0	225	0	232	0
6 months	54	0	55	0	223	0	219	2 (0.9%)
1 year	53	0	54	0	221	4 (1.8%)	217	4 (1.8%)
2 years	50	0	45	1	200	14 (7%)	195	20 (10.3%)

percentage of reversions was higher in the B.C.G. group. Furthermore, no reversions had occurred in the intradermal vole group at the end of the second year. No case which had reverted to negative at one year was found to be tuberculin-positive at two years. It was noted at each routine tuberculin-testing that a number of cases required retesting with 100 I.T.U. The number of such cases was small at six months, larger at one year, and much greater at two

years. The number of children requiring retesting was definitely greater in the B.C.G. than in the vole group (Table IV).

TABLE IV.—Cases Requiring Retesting with 100 I.T.U.

	Vole				B.C.G.			
	No. Tested	—5	5+	Total	No. Tested	—5	5+	Total
6 months	277	—	12	12	274	1	19	20
1 year	274	3	37	40	271	1	71	72
2 years	250	4	61	65	240	10	86	96

It is too early to place much importance on these figures, but they appear to suggest a greater diminution of allergy in the B.C.G. than in the vole group.

The percentage of reversions would seem to be high. Routine retesting of a group of contacts in the County of Renfrew shows a reversion rate of 1.5% after two years and 5.2% after three years. In this connexion it should be noted that the children in the homes were all examined by the M.M.R. unit each year and that no cases of active tuberculosis were found at any of these visits. They therefore did not receive the minimal doses of infection such as one would expect if they had been living outside the homes, and this fact is very possibly responsible, at least to some extent, for the high reversion rate.

Reversion Rates: 1952 Series

Routine tuberculin-testing carried out at one year confirmed these findings. The fact that further tuberculin-testing with 100 I.T.U. was required in 26.5% of the B.C.G. group as against only 5.1% of the vole group again suggests that the allergy produced by the vole vaccine is more permanent, or at least stronger, than that resulting from vaccination with B.C.G.

Late Cosmetic Results: 1951 Series

The late results of the B.C.G. vaccinations were those normally observed, and no ugly or objectionable scarring was noted. It was particularly pleasing to note the excellent healing and absence of bad scars which followed intradermal vole vaccination in spite of the severe early reactions. In multiple-puncture vole vaccinations the routine weekly inspections showed that the individual puncture marks developed induration which became progressive and subsequently increased over a period of nearly one year. This induration was first noted in the older children during the seventh and eighth weeks, and in the younger ones during the tenth week. At the final reading of the entire series, at the end of six months, induration was noted in 62 cases (30% of those available for inspection). At the end of the first year 154 (67%) out of the 229 cases still resident in the homes were inspected, and the results of this inspection are summarized in Table V.

TABLE V.—Cosmetic Results with Vole Vaccine

	1951 Series				1952 Series	
	After 1 Year		After 2 Years		After 1 Year	
	No.	%	No.	%	No.	%
A. Complete healing, with no residual marks	50	32.5	60	44.1	4	10.5
B. Small needle prick (size of original ones) still seen (no induration)	20	13.0	14	10.3	11	28.9
C. As for B, but individual marks a little larger	66	42.9	30	22.1	19	50.0
D. Indurated arms	8	5.2	20	14.7	2	5.3
E. Complete healing, with residual scarring	10	6.5	12	8.8	2	5.3
Total Satisfactory	154	95%	136	89.7%	38	95%

It was noted that complete fading had occurred in 32.5%; almost complete fading in 13%; while in a further 42.9% the resultant scars were slight and could not cause any

adverse criticism. In 88.4% the rosette had completely or almost completely disappeared. The 6.5% which showed scarring were not in any way unsightly, and our inspections have therefore shown that in almost 95% of the cases the late appearances of the vaccinations were satisfactory. In 5.2% of the cases, however, definite induration of the individual parts of the rosette was noted, and in 4% this was severe.

Inspection of the rosettes was repeated at the end of the second year and 136 arms were seen at this examination. The results are classified in Table V.

During the second year the proportion of arms with complete healing and no residual marks increased from 32.5% to 44.1%. Arms showing induration of the lesions rose from 5.2% to 14.7%, being slight in 4.4% but definitely unsightly in 10.3%. All these reactions were in children vaccinated by the multiple-puncture method. The term "induration" is used to describe local reactions of a lupoid character, varying from a few dry, indolent, crusted spots to a confluent, raised patch, similar in size to the area of the multiple-puncture gun. The increase in the proportion of lesions of this type between the observations made after one and two years was surprising and quite unexpected. Equally unexpected and disappointing was the fact that the appearances noted in arms showing marked induration at one year showed practically no change at the inspection at the end of two years. Several recorded at two years were seen in arms which had been regarded as healed at the end of one year and no explanation can yet be advanced to account for them. They are lupoid in appearance. While their cause is obscure we feel that trauma and possibly superinfection in the wide area of vaccination by the multiple-puncture gun are contributing factors. There has never been any suggestion of any lupoid reaction in any of the children receiving intradermal vole vaccine.

The 1952 series of vole multiple-puncture vaccinations were inspected at the end of one year, and the results were similar to those noted in the previous series. These late reactions are tabulated for comparison in Table V.

Discussion

After considerable experience with both methods we believe that multiple puncture has many advantages. There is no danger of injecting the vaccine at too deep a level, as may happen with the intradermal method in young and nervous children.

It is too early to draw firm conclusions on the results. Even though conversions take place more quickly with B.C.G. vaccine, the fact that by six to eight weeks the rates in the B.C.G. and vole are equal, and that conversions ultimately took place in 100% of our cases, indicated that the allergy produced is equally satisfactory with both vole and B.C.G. vaccines. When the reversion rates are considered there is no doubt that those relating to vole vaccine are more favourable. In our first series of cases, which have already been followed up closely for over two years, the proportion showing late lupoid reactions after multiple-puncture vole vaccine is, we consider, too high, and although the vaccine has distinct potentialities, we feel that it cannot be employed on more than an experimental basis until these difficulties have been overcome. We have noted that conversion always took place if any part of the rosette developed. We felt that satisfactory results could be obtained with half-strength liquid vaccine. The 1953 vaccinations were carried out to test this point, and so far we can report 100% conversion after six weeks.

All our 1951 cases have been followed up for over two years, and no case of tuberculous infection has yet been reported. One point which must be kept in mind is the definite loss of allergy after two years. What percentage of reversions can be expected after three, four, or five years? Any final comparison and decision regarding the merits of the vaccines must obviously await further testing of each of the three (and any other) groups over a further period of at least three to four years.

Summary

This report describes an investigation designed to compare vaccination with B.C.G. and vole bacillus vaccines, and records the preliminary results after one and two years. The B.C.G. was given in the routine intradermal manner and the vole vaccine by multiple puncture to those of 5 years and over and intradermally to those under 5 years. Vaccination by the multiple-puncture method is probably slower than by intradermal injection, but it is considered to be the method of choice and is simpler and more certain in young children.

The rate of conversion after vole vaccination is a little slower than after B.C.G., but the percentages—95% after six weeks and 100% after twelve weeks—are very satisfactory, and compare closely with those obtained with B.C.G.

We believe that vaccination with vole bacillus has certain advantages because of the milder clinical course and the smaller rate of reversions.

The periodic surveys showed that induration developed in a substantial proportion of the cases receiving vole vaccine by the multiple-puncture method, and that, later, lupoid reactions occurred in the vaccination area. These later complications were noted in 5% and 15% of the cases inspected after the first and second years. The discovery of lupoid reactions at the second yearly inspection in arms regarded as healed at the first yearly inspection was unexpected and unfortunate, and we regard the rate of these reactions to be too high to permit of the routine use of the vaccine until these difficulties have been overcome.

We are indebted to the Council of Management of the Orphan Homes of Scotland for permission to carry out the investigation; to Dr. J. S. M. Gray, County Medical Officer of Health, Renfrewshire, for help in carrying out the work; and to Professor F. R. G. Heaf, Dr. A. Q. Wells, and Dr. K. Neville Irvine for advice and assistance.

Wells, A. Q. (1946). *Spec. Rep. Ser. med. Res. Coun. (Lond.)*, No. 259. London.

At the North of England Education Conference held in Sheffield on January 6, Mr. L. J. BARNES, director of Social Training at Oxford University, unfurled, in the words of the *Manchester Guardian* (January 7), "the banner of professional syndicalism." "We know," Mr. Barnes said, "that health centres don't exist because in the main the doctors don't want them." There was no evidence, however, of any opposition among teachers to county colleges. If the doctors wanted health centres they would get them; educationalists did not get county colleges whether they wanted them or not. The difference lay in the different types of professional organization in the two fields. The National Health Service, Mr. Barnes said, had come into being on the basis of professional syndicalism, subject only to parliamentary control. The doctors had managed it very cleverly and ingeniously, and he believed they were right to have done so. Professional syndicalism, subject only to lay control at the top, was the traditional pattern of the British public services; in education alone there was not yet any trace of it. "That fact is a great misfortune," Mr. Barnes concluded. "We shall never get anywhere in the field of adolescent education and welfare until the teaching profession takes effective steps in the direction of professional syndicalism."

TREATMENT OF PAPILLOMA OF
BLADDER WITH RADIOACTIVE
COLLOIDAL GOLD AU¹⁹⁸

BY

FRANK ELLIS, M.D., M.Sc., F.F.R.

AND

R. OLIVER, M.Sc., A.Inst.P., A.M.I.E.E.

(From the Department of Radiotherapy, Churchill Hospital, Oxford)

Villous papillomata of the bladder are usually multiple, and the possibility of distinguishing between benign and malignant tumours is an open question, both from the urologist's point of view, depending on interpretation of cystoscopic appearances at one and successive examinations, and from the point of view of the interpretation by the pathologist of the histological findings. In a proportion of patients papillomata in other situations, such as the larynx, breast, large intestine, and rectum, undergo malignant change, and it may be that villous papilloma of the bladder could correctly be regarded as a pre-malignant condition, as suggested by Riches (1948).

Buerger (1915) suggested that changes in size and staining properties, atypical mitoses, and multinucleate cells are evidence of malignant change. These changes would probably now be called "carcinoma *in situ*," but the further changes which he has described—invasion of the basement membrane and subsequent infiltration of the connective-tissue stroma of the papilloma and the presence of epithelial cells in the bladder wall and in blood vessels—are undoubted evidence of carcinoma. In 30% of 52 cases of carcinoma of the bladder reported by Buerger the carcinoma had been preceded by a papilloma. The true proportion of such malignant changes is masked by the fact that the papillomatous nature has been lost when a large, frankly malignant tumour is first found. These facts, and the fact that clinically benign and malignant papillomata often co-exist in the same bladder, accord with the view of Willis (1953) that pathological distinction between benign and malignant papillomata may be impossible.

Methods of Treatment

The treatment of these lesions by cysto-diathermy has for many years been the method of choice, but the results of such treatment are difficult to find. It is certain, however, that a number of patients develop incurable malignant disease after many years' cystoscopy and diathermy. Others may be cured by total cystectomy, which has been advocated as the treatment of choice even in relatively early cases. Total cystectomy, however, has a mortality and a morbidity which seem a high price to pay in the early cases.

X-ray treatment is used, but involves treating the whole bladder and some of the surrounding pelvic organs to a high dose of radiation.

The use of an intravesical rubber balloon containing radioactive solutions (Walton and Sinclair, 1952) or a central solid radioactive source emitting gamma radiation (Cones and Gregory, 1952) in a suitable balloon has also been tried, but, although the dose falls off relatively rapidly from the surface of such a balloon, the dose given to the subepithelial connective tissue is likely to be 70–90% of the dose to the bladder wall, and is likely to result in undesirable vascular and connective tissue changes which may, after some years, produce atrophic or metaplastic changes in the bladder epithelium.

Rationale of a New Method of Treatment

Because of these considerations, when presented with a patient suffering from haematuria due to myriads of papillomata covering the whole bladder surface, it was decided to explore the possibilities of using beta radiation to treat the papillomata. If the radioactive fluid could be used to fill the bladder without any containing balloon, the papillomata would float freely in it and be irradiated from all sides. The normal bladder wall, on the other hand, would be irradiated from only one aspect and the limited range of the beta emission would provide a very rapid fall in dose. Thus only the epithelium of the bladder would be treated and the subepithelial connective tissue would be almost unirradiated.

For such a method radioactive colloidal gold from A.E.R.E., Harwell, appeared to be the most suitable material available, since its beta emission (0.96 MeV) had a half-value layer of about 0.3 mm., which is comparable to the thickness of the papilloma as shown in Fig. 1, and its colloidal nature would militate against its absorption. It had the advantage that it could be introduced through a catheter, without opening the bladder, in a sufficient concentration to give a large enough dose of radiation during the relatively short time before the patient had to empty his bladder. It was estimated that some 300 mc. should be given in about 100 ml. of saline, so that, taking account of the dilution by urine passing into the bladder from the ureters, the dose to the bladder wall in two to three hours would be of the order of 3,000 r.

Fig. 1.—Relation of the half-value layer to thickness of the papilloma.

Preliminary Tests

Dangers in using such a large amount were anticipated from two points of view: (1) The absorption into the blood or lymph of 5 or 10% of such a large dose might have undesirable consequences. (2) The retention by sticking to the bladder wall of a relatively small amount could result in huge doses (about 1,000,000 r for 1 mc. per square cm.) of radiation to the bladder epithelium. (This had been found to occur in similar work with thorium-X before artificially produced isotopes were available. Thorium-X is an alpha-particle emitter with a range of only about 10 microns, however, and only beneficial results were observed.)

It was necessary to confirm that the colloid would remain in suspension while in the bladder. The solution is supplied slightly alkaline (about pH 8 in samples tested), and it was considered that the gelatin might become unstable and the colloid precipitate in acid conditions. Alkalinization of the urine would prevent acidity in the bladder but lead to a large excretion, diluting the radioactive solution and limiting the maximum period of retention.

Actually a sample of inactive gold colloid was acidified with HCl to about pH 2 without any precipitation occurring immediately, on standing, or after incubation at 56° C. for about half an hour. Therefore 95 ml. of this inactive gold was introduced into a male patient's bladder through a catheter, which was then tied off. After two hours 340 ml. of fluid was drained off. The pH was only about 7 and no precipitation could be observed.

On the next occasion a similar volume of colloid was used with a total activity of about 400 µc. After two and a half hours 235 ml. of fluid was drained off and the bladder washed out three times with saline, each lot of fluid being retained. Also urine was collected for the next 12 hours. The activities of these samples, determined by comparison with a standard dilution from the original colloid,

were 97%, 4.5%, 0.5%, 0.05%, and 0.05% respectively in fluid drained from the bladder, in the first, second, and third rinses, and in the urine. This total (102%) corresponded to the whole of the injected activity within the experimental accuracy. The gamma count rate over the bladder was not significantly above background, and a blood sample taken just before the bladder was drained showed no detectable activity.

Treatment

As these tests showed that the colloid was not precipitated in the bladder or absorbed, it was decided to proceed with treatment. Following cystoscopy, a Foley catheter was passed into the bladder. Three hundred mc. of radioactive colloidal gold in 100 ml. was taken into a syringe, a small sample was retained for making a standard dilution, and the rest was introduced into the bladder after the balloon of the Foley catheter had been inflated with 5 ml. of fluid. The end of the catheter was then securely tied off and the catheter fixed by strapping so that the balloon was used to close the neck of the bladder. After two and a half hours the bladder contents were drained off and the bladder washed out eight times with warm saline, by which time the washings were practically colourless.

The fluid and rinses were retained for activity measurements, and urine was collected for 24 hours. Care was taken to avoid leakage round the catheter and spillage of the active fluids during injection, draining, and rinsing. Gamma counter measurements were also made over the patient immediately and about 24 hours after the bladder was emptied. It was estimated that very much less than 0.5% of the injected gold was retained in the bladder and no other site of activity was observed. The dose received by the bladder epithelium was estimated to be 3,000 r (2,700 rep beta dose, 300 r gamma dose).

After two months the treatment was repeated, using an ordinary catheter, and a dose of about 2,400 r was delivered to the bladder wall.

When examined cystoscopically six weeks later, no papillomata could be seen except for a ring of small nodules around the internal urethral meatus where the contact of the Foley bag had protected them from the beta radiation. It was decided to treat these locally with radioactive cobalt so arranged in a Foley balloon at the neck of the bladder as to give a dose of 3,000 r, using a source-epithelium distance of 1 cm.

The patient is now well and symptom-free, and at his last cystoscopy, 15 months after the last treatment, his bladder wall was normal in appearance throughout. No other treatment has been given. The case summary is given below.

A man aged 67 was referred on September 8, 1952, by Mr. Till. He had had three weeks' haematuria in June, 1952, and occasionally since, and dysuria and nocturnal frequency since June, 1952; now D'S=3-hourly 2-hourly. Cystoscopy on August 29 had shown that the bladder was covered with villous papillomata, the main mass of growth being above the right ureteric orifice and around the left ureteric orifice.

October 10.—Biopsy: transitional-cell papilloma. Injection of non-radioactive colloidal gold into the bladder for two hours to test for possible precipitation. Blood: Hb, 81%, white blood cells, 5,000 per c.mm.

October 14.—110 ml. slightly active colloidal gold for two hours to ensure that no residual radioactivity remained after washing out the bladder.

October 18.—Radioactive colloidal gold, 377 mc. in 105 ml. for three hours. Total dose to surface, 3,000 r.

January 9, 1953.—Cystoscopy. Two papillomata: (A) above right ureteric orifice; (B) medial to left ureteric orifice; (C) fronds at bladder neck. Suggested diathermy of (A) and (B). Radium in Foley catheter to (C) and another treatment with colloidal gold.

January 27.—Coagulation of (A) and (B) (Mr. A. S. Till). Second injection of radioactive colloidal gold, 274 mc. in 100 ml. for three hours. Total dose to surface, 2,950 r.

April 14.—Radioactive cobalt in Foley catheter to treat neck of bladder, 3,000 r in 5 hours 20 minutes. Blood urea, 27 mg. per 100 ml.

June 16.—Cystoscopy. Redness of bladder wall. No neoplasm.
December 1.—Cystoscopy. Normal bladder mucosa. Symptom-free except for nocturnal frequency. The patient says this is a habit—he empties his bladder whenever he wakes up. Blood: Hb, 96%; white blood cells, 5,100 per c.mm.
April 20, 1954.—Symptom-free. Cystoscopy: normal bladder.

Suggested Routine

As a result of this treatment, experience has now been gained which makes it possible to recommend the following routine procedure in centres where the drill for the handling of isotopes is established.

1. It is necessary to get the permission of the Medical Research Council to use the method.

2. After cystoscopic examination the plan of treatment of the case is decided, bearing in mind the morbid anatomy and pathology and the possible effects of the various surgical and radiotherapeutic steps in treating and possibly spreading the growth. For instance, in a recent case with multiple large malignant papillomata the plan decided upon was 3,000 r x rays (275 kV) to the bladder, 4,000 r with radioactive cobalt in a balloon introduced via a perineal urethrotomy, diathermy of any residues six weeks later, and then gold to be used only if seedlings began to develop subsequently.

3. Having decided to use the colloidal gold method, fluid intake is forbidden on the day of treatment. An ordinary rubber catheter of a large size is introduced, the bladder emptied, and the end of the catheter double tied. In females a purse-string linen suture is passed around the catheter at the external urethral meatus and tied tightly so as to prevent any risk of leakage.

4. Using the special protective gun (see Figs. 2 and 3) which has been made to enclose a 100-ml. syringe, some 300 mc. of colloidal gold is drawn into the syringe and made up to 100 ml. with saline.

FIG. 2.—Lead-protected gun for 100-ml. syringe.

D/R in MR/min. for 300 mc. Au^{198} in 100 ml.

FIG. 3.—Diagram of the syringe gun with 5-mm. lead protection.

5. The solution is injected, using a thin Record needle passed obliquely through the wall of the catheter.

6. Two samples of about 2 ml., one taken at the start and one at the end of the injection, are retained as standards for measurement of the activities of the fluid drained from the bladder and washes.

7. The patient is returned to the ward and put to bed. If he is active the solution mixes well with the urine passing into the bladder, but if he is sleepy following an anaesthetic it is necessary to move him about, tilting the bed and turning him on to his side so as to ensure mixing. This has been done because in one patient, who was asleep and stationary until the bladder was emptied, the bladder contents showed definite lack of mixing.

8. At the appropriate time (two and a half hours to three hours, determined as being likely with the dose used and the expected dilution to have given a dose of 3,000 r), with suitable precautions, the contents of the bladder are run off into a glass jar, and the bladder is washed out five or six times with warm saline into a succession of glass jars until the washings are free from the colour of the gold colloid.

9. The percentage of the gold in these washes is determined and the gamma-ray measurements are made over the suprapubic region with a counter, so as to determine if further washing is needed. This has not been necessary so far.

10. The urine is collected for 24 hours.

11. The dosage is estimated as described in the Appendix below.

Discussion

The points which it is required to know in connexion with any new method, apart from its rationale and technique, are: (a) if it is safe and if there are any untoward effects; (b) the type of case in which it is effective; and (c) other possible uses.

Safety

The method as detailed above has now been used on 22 occasions with no untoward effects on the patient and no suggestion of danger to staff. All patients have been sufficiently free of radioactive material and free of symptoms to leave hospital the next day.

Type of Case

(i) As previously indicated, the method was designed to treat cases of multiple villous papillomatosis. We have had only one such case referred. This has been described in detail above.

(ii) The method has been used also to treat the bladder in cases of papillomatosis with carcinoma. It is clear that the thickness of the tumour must determine the dose it receives, and so, when there are thick papillomata or a carcinoma, the dose received at a depth below the surface will be too small to be effective. Nevertheless, in some cases a rapid shrinkage may easily be obtained of part of a tumour, making easier a decision regarding subsequent treatment. This is illustrated by the following case summary:

A married woman aged 79 was referred by Mr. D. C. Corry on January 9, 1953. Her history was that she had the first attack of painless haematuria three years ago for two to three days and the second attack two weeks ago. She saw Dr. Wase after one week and continuously since.

January 5, 1953.—Cystoscopy. Papilliferous tumours of base of bladder obscuring both ureteric orifices. Suggested radioactive gold to clear the bladder and diminish the size of the tumour. Then Co^{60} balloon.

January 20.—Radioactive colloidal gold, 289 mc. in 86 ml. for three hours. Total dose to surface, 3,050 r.

February 24.—Cystoscopy. Tumour much smaller. Ureteric orifices seen. Three papilliferous tumours seen close to right ureteric orifice.

March 10.— Co^{60} in balloon. 5,500 r in ninety-three hours at 3.3 cm. distance.

May 1.—Cystoscopy. Tumours still smaller, but three papillomata still present.

August 14.—Cystoscopy. Biopsy of one lesion remaining just above right ureteric orifice. Transitional cell carcinoma—Broders's Grade 1.

August 21 to 28.—Treatment by uterine and vaginal radium to base of bladder—2,500 mg.hr. in uterus and 2,500 mg.hr. in vagina.

(iii) Treatment with radioactive colloidal gold has also been used as a method of treating the bladder to diminish the surface activity of a malignant growth three to four weeks before opening the bladder in cases in which cystostomy for implantation of radium, radon, or radioactive tantalum or for partial cystectomy was intended.

(iv) It would theoretically be possible to treat with radioactive colloidal gold the pelvis of a kidney which is the seat of papillomata. However, it is doubtful whether accurate diagnosis of such cases or adequate follow-up afterwards will ever be possible.

Summary

A technique is described for the treatment of multiple villous papillomatosis of the bladder whereby some 300 mc. of radioactive colloidal gold (Au^{198}) may be introduced per urethram so as to deliver a dose to the bladder epithelium of about 3,000 r in three hours. The recommended course is two such treatments with about two months' interval.

The procedure is safe for the patient and for the staff, if properly carried out.

It has caused complete disappearance for fifteen months of myriads of papillomata in a 67-year-old man, leaving him symptom-free.

In cases unsuitable for complete treatment by this method it may be used to bring about the disappearance of multiple small tumours and to stop haemorrhage. Accurate cystoscopic examination may thereby be rendered possible and the surface of a carcinoma devitalized preparatory to subsequent cystostomy.

APPENDIX

Estimation of Dose.—Beta Dose: The maximum range of the Au^{198} beta particles is only some 3.8 mm., so that with any layer of active fluid of thickness greater than this the dose rate at the surface will be half that in an infinite medium and will be proportional to the specific activity. From data given by Marinelli, Quimby, and Hine (1948) the dose rate at the surface for an activity of 1 mc. per ml. would be 405 rep/h.* (340 rad/h.†). The depth dose will be small, falling to 50% at 0.3–0.4 mm. depth. **Gamma Dose:** Au^{198} also emits gamma radiation of 0.41 MeV energy, and the gamma dose rate at the surface will depend on both the specific activity and the dimensions of the cavity. If the bladder is considered as a sphere of radius r cm., the dose rate is given by 15.1 r (see Mayneord, 1950). This figure is based on a dose rate of 2.4 r/h. at 1 cm. from 1 mc. The depth dose here will be greater, but will have fallen to 50% at depths of 0.75–1.5 cm. for radii of 2.5–5 cm.

Deducting the volume of the catheter itself, the initial bladder volume is taken as equal to the volume of fluid injected, and the volume of fluid drained from the bladder is measured. It is assumed that urine drains into the bladder to increase the fluid volume at a constant rate, and the initial and final beta and gamma dose rates are calculated from the corresponding specific activities and volumes. The gamma dose rate does not, of course, increase linearly with volume, but, as this contributes only 10–15% of the total, the surface dose is given with sufficient accuracy from the average beta and gamma dose rates.

A nomograph for calculating these dose rates is given in Fig. 4.

We acknowledge the helpful co-operation of Dr. C. Lewis and Dr. P. J. van Miert in carrying out this technique, of surgical colleagues on the staff of the United Oxford Hospitals and Swindon Hospitals in referring patients for treatment, and of Mr. G. E. J. Jackson in the design and construction of the protected syringe gun.

SPINAL DISK LESIONS

AN ASSESSMENT AFTER TWENTY-ONE YEARS

BY

JAMES CYRIAX, M.D., M.R.C.P.

Physician to the Department of Physical Medicine,
St. Thomas's Hospital*"One-third of all orthopaedic out-patients complained of low backache. Had the panel any suggestion for coping with this vast number?"**"They had none."* (One of the questions put at the autumn meeting of the British Orthopaedic Association.)

In 1934 Mixter and Barr published their epoch-making paper describing relief from sciatica after the removal at laminectomy of part of a low lumbar disk. At the time the lesion was thought most rare, but in due course increasing experience enabled this diagnosis to be made more often. By ten years later the common cause of what had been called "sciatic neuritis" was beginning to be recognized as a low lumbar disk protrusion. Actually, Goldthwait (1911) had already ascribed lumbago and sciatica to disorders of the lumbo-sacral joint.

Cervical disk lesions soon came to the fore—the analogy was obvious—and by, say, 1950, root pressure from a cervical displacement was beginning to be widely regarded as a common cause of "brachial neuritis."

Thoracic disk lesions have only just begun to gain appreciable acceptance as the cause of "intercostal neuritis."

So much for root pain. But it had been known for centuries that lumbago often led to sciatica; that scapular "fibrositis" usually preceded brachial neuritis, and that "intercostal neuritis" might follow posterior thoracic pain. By 1950 the idea was gaining ground that lumbago was caused by internal derangement at a low lumbar level (Cyriax, 1945), and soon afterwards, that scapular and thoracic "fibrositis" might have their source in disk lesions at the relevant spinal levels (Cyriax, 1948). All this has now ceased to be particularly controversial, and the concept of a disk lesion causing pain solely in the trunk is already firmly established. Given that this is so, what effect has all this new knowledge had on the prescription of treatment? To-day, attending every hospital are large numbers of patients correctly diagnosed as suffering from disk lesions causing pain in trunk or limb. Is enough effort being made to employ effective measures on this large number of patients, some already severely disabled, and others in danger of such disablement unless given immediate attention? The answer is "no."

Cervical Disk Lesions

These usually present a unilateral scapular aching associated with pain on moving the neck. At this stage the displacement is small and immediate manipulative reduction succeeds in 99% of all cases, provided that general anaesthesia is avoided. One, seldom two, sessions suffice. Traction has been shown by radiography (Cyriax, 1954) almost to double the space at the intervertebral joint; strong manual traction is therefore maintained while the manipulations are carried out. Only slight discomfort is felt. This simple measure not only affords immediate relief from the scapular pain but prevents the later onset of brachial neuritis.

Occasionally a cervical disk protrusion causes central neckache or bilateral scapular discomfort, or bilateral brachial pain or paraesthesiae in the upper, lower, or all four limbs. In such cases immediate reduction is more important than ever: for any of these events implies that the protrusion is passing backwards in the midline. Since it has become evident that pressure from a central herniation on the spinal cord (Middleton and Teacher, 1911; Brain, 1954) and on the anterior spinal artery is responsible for cases hitherto diagnosed as amyotrophic lateral sclerosis or progressive muscular atrophy, it is reasonable to suppose that immediate reduction followed by its repetition whenever necessary may spare patients crippledness in later years.

Once root pain down the arm has begun, manipulative reduction is more difficult. When muscle paresis is absent, it remains successful in two-thirds of all cases; if a marked root palsy has supervened, failure is almost certain. The change from scapular discomfort to root pain may take years in one patient, hours in another. Hence there should be no delay; in each suitable case the manipulation should follow the establishment of the diagnosis within a few minutes.

Thoracic Disk Lesions

Whether causing posterior or anterior thoracic pain, a protrusion irreducible by manipulation during manual traction is a rarity. Should one be encountered, daily sustained traction seldom fails. By keeping the prevalence of thoracic disk protrusion in mind and examining the thoracic spinal joints for articular signs, the clinician can avoid many mistaken diagnoses of visceral lesions, hitherto obscure pain of months' or years' standing being found relievable within a few minutes. Moreover, since a thoracic protrusion can compress the spinal cord, reduction provides the prophylaxis of one cause of postero-lateral sclerosis and paraplegia.

At the thorax the maintenance of reduction is difficult. Lordosis is unobtainable; hence the patient must do his best not to stoop or lift; for eventual redisplacement is a virtual certainty. Manipulative reduction must then be repeated.

Lumbar Disk Lesions

These often start by causing chronic backache in women and attacks of lumbago in men. In the former case a small posterior displacement is present the whole time; in the latter the patient suffers bouts of acute lumbar pain and fixation caused by a major attack of internal derangement, but is symptom-free between-whiles. In backache, manipulative reduction, without anaesthesia, is usually successful; should it fail, sustained traction is called for. Between 100 and 200 lb. (45 and 90 kg.) is applied while the patient lies on a special couch for up to an hour daily. Manipulative reduction is also the treatment of choice in lumbago if the patient can bear it. If he cannot, epidural local analgesia is indicated; this abolishes the pain for one and a half hours, during which time he lies prone on a couch in hyperextension. The pain seldom returns to anything like its previous intensity.

Once reduction has been achieved redisplacement is obviated so far as is possible by postural instruction in the maintenance of lordosis and the provision, when necessary, of a corset or a plastic jacket. I have no patience with those who apply a plaster—belladonna or plaster of Paris—to the patient without reducing the displacement first. No one would dream of applying a plaster to a fracture without reducing it first, and, in my view, identical considerations apply at the lumbar spine.

When root pain has come on, reduction is often successful when straight-leg raising is limited but conduction is either not affected or only slightly. Should manipulation fail, traction is often quickly successful. Marked root paresis designates a protrusion too large ever to retrace its steps, but often implies an early cessation of pain; it is often best left alone. Primary postero-lateral herniations—that is, root pain without previous backache—in young patients are usually best left to recover spontaneously, with

or without the help of epidural local analgesia. Long-standing sciatica can sometimes be cured outright by one or two epidural injections.

When conservative treatment fails and the symptoms warrant, operation is indicated, but it is important not to confuse minor lesions in hypersensitive patients with major lesions. Laminectomy or arthrodesis is called for in 1 in 200 of the cases seen by me. It is difficult to escape the impression that, were conservative treatment on the lines set out above employed, many cases would not get to the point of laminectomy at all. Certainly many patients who had been considered unrelievable except by laminectomy have been found to respond satisfactorily and quickly to the above methods of conservative treatment.

Discussion on Treatment

Though the patient does not realize it, a disk lesion is a medical emergency. Future trouble is obviated so far as is possible if reduction can be carried out as soon as the diagnosis is established. Not only does the patient lose his symptoms there and then, but stretching of the posterior longitudinal ligament is reduced to a minimum. Since this ligament forms the only bar to further protrusion, every effort must be made to spare it the prolonged pressure of continuing displacement, especially at the cervical and thoracic regions, where the spinal cord is in danger. Moreover, nearly all disk lesions set up pain in the trunk before the root pain supervenes; hence if reduction is carried out at this stage increased protrusion leading to root pressure is avoided.

This has been the policy for years at our physical medicine department. The methods are based on logic, are simple, and have proved effective. Manipulative reduction is usually carried out by the physiotherapy staff and students; they too attend to traction. My registrars and I give the epidural injections. In the last 17 years I have given some 15,000 such injections to unprepared out-patients without serious mishap.

The fact remains, however, that there is scarcely a hospital in the country where a minor disk subluxation is manipulated back into place while it remains minor and easy to reduce. Since patients with reducible displacement of part of a disk abound in every hospital, and the technique of reduction involves manipulation without anaesthesia, we have found that there is seldom any need for the doctor to give the treatment himself. This is delegated to trained personnel, and for the last 10 years our physiotherapists have carried out these manoeuvres with manifest success.

The adoption of mechanical traction has proved less tardy, and within only five years of its advocacy for disk lesions (Cyriax, 1950) a number of hospitals have installed, or are considering installing, a traction couch. Epidural local analgesia appears everywhere unobtainable as an immediate out-patient measure. It is sad to reflect that these three main stand-bys of early treatment are not available to most sufferers. Only recumbency, a plaster jacket, and operation remain—all methods that, in my view, are called for only should the simple and quick methods fail.

But the patients know better. They go to the lay manipulator. And many medical men, knowing that neither themselves nor their hospital can help in such cases, recommend osteopathy. But why, when doctor and patient know that manipulation is the treatment of choice, is the patient forced to have recourse to a layman—not only that, but to pay him as well? Such a state of affairs would be unthinkable in any other branch of medicine and would not be tolerated for one moment were the displacement osseous. Yet a cartilaginous displacement requires reduction no less than a bony one. It is remarkable that this medical hiatus exists in the case of the spinal joints only—the very joints at which internal derangement is most frequent. The gift to the unqualified manipulator represented by this situation must astonish him; for great public esteem attaches to

instantaneous relief from pain. Doctors thus render their own profession great disservice when the possessor of the common reducible disk lesion is left to wander to a layman.

Manipulation by Laymen

Neglect by medical men to consider manipulating a spinal joint, even after they themselves have stated internal derangement to be present, has created a group of laymen styling themselves osteopaths, chiropractors, and bone-setters. Patients do not wish to seek treatment outside the medical profession—even less so now, when they already pay the State for all medical care—but they discover that the appropriate treatment is not obtainable within the Service. So they have to go to a lay manipulator. And one must admit that, though devoid of diagnostic skill, such laymen often, in spite of not realizing the nature or the level of the lesion, relieve the patient immediately by a few simple manipulations. How easy it must therefore be for doctors or trained physiotherapists, with their anatomical knowledge, and basing themselves on a proper diagnosis, to do so too (Cyriax, 1949).

Were manipulation of the spinal joints restored to the medical sphere, not only would all suitable patients be relieved at once and the liability to further trouble be reduced to a minimum, but much abuse would be avoided, since the evil inherent in unsupervised recourse to laymen would cease—namely, repeated, fruitless, and expensive visits for conditions insusceptible to manual treatment.

Sooner or later, public agitation that spinal manipulation shall be obtainable within the Health Service will encourage the osteopathic fraternity to press again for State recognition. Luckily their fantastic claims put them outside the pale at the inquiry at the House of Lords in 1935. Let medical complacency not go too far; in Switzerland osteopaths are officially recognized, and in France osteopathy is a compulsory subject for medical students. The medical profession of Great Britain would be put in a most awkward position were another inquiry held to-day and the question asked of a number of hospitals—what arrangements exist in your out-patient department for spinal manipulation? Are the medical students shown, and the physiotherapy students at your school well grounded in, manipulation for disk displacement? It is no answer to say that manipulation is obtainable under anaesthesia by the orthopaedic surgeon on in-patients; this approach touches only the fringe of the problem, as the existence of some two thousand lay manipulators in this country demonstrates. The orthopaedic surgeon has many far more important operations to perform and, with the best will in the world, cannot deal with more than a tiny fraction of suitable cases, even if the beds were available.

Medico-legal Aspect

This has its anxious side. When a patient consults a medical man and is found to have a fracture out of alignment, a dislocated bone, or a displaced cartilage at the knee, reduction (usually by manipulation) is the accepted treatment. Were no effort made to reduce the displacement, or a good reason for refraining not set out, the attending practitioner might well find himself in medico-legal difficulty. In these times of increasing litigation it will not be long before some enterprising patient, after he has developed a major disk lesion, points out that, when he first consulted his doctor, the displacement was slight and that no effort at reduction was then made. Moreover, it may well happen that after various medical men have been consulted—and it is agreed by all that a displacement is present—the patient gives way to his friends' exhortations and visits a lay manipulator, who may afford him immediate relief. The patient can now argue very plausibly that he had an easily reducible disk lesion but that none of those whom he consulted treated him skilfully. This might be construed as negligence, not on the part of the general practitioner, but on that of any consultant he may have seen. In my

view the time is not far off when the illogical but time-honoured attitude of leaving a minor disk lesion to get larger or smaller as fortune dictates will provide us with another legal hazard.

Economic Considerations

If a family doctor is asked how many patients in bed with lumbago he has at any one moment, the usual answer is one, two or three. This implies that between 20,000 and 50,000 patients are off work at any one time because of a displaced fragment of disk. Were patients off sick because of a stiff neck, brachial neuritis, "fibrositis," pleurodynia, and sciatica all added to the list, a huge total of largely avoidable disablement would be reached. This costs the Health Service in sickness benefits far more than the expense that would be entailed in securing adequate treatment for the sufferers. Without further research, merely by a more general application of methods already evolved and continuously tested since, a great saving in pain and disablement would accrue, with huge advantage to the financial aspect of health insurance. From the economic point of view it is the logical treatment of the common disorders of the vertebral column that would make the biggest immediate contribution to industrial health to-day.

Summary

The rediscovery 21 years ago of intervertebral disk lesions explains the cause of many pains in the trunk and limbs, previously misunderstood. This clarification has not been followed by enough change in methods of treatment. Measures thought appropriate in previous decades—for example, heat, massage, exercises—remain in use at a time when reduction by manipulation or traction is required.

At present spinal manipulation for disk lesions is largely in the hands of laymen. This is a sad state of affairs; for if a patient requires treatment for an intervertebral displacement this should be administered by a doctor; failing that, by a physiotherapist working under his direction. The economic benefit is no less important than the humanitarian aspect.

Physiotherapists should be trained in accurate manipulation and thus make treatment for the reducible disk lesion possible on a large scale within the Health Service. It can be done, as our experience at St. Thomas's Hospital proves, and would render lay manipulators superfluous.

The Association of Universities of the British Commonwealth has just published, as a pamphlet entitled *United Kingdom Postgraduate Awards (Fellowships, Scholarships, Grants, etc.)*, Appendices II and III of the *Commonwealth Universities Yearbook, 1955*. The *Yearbook* itself will be published in May. Appendix II contains a list of postgraduate awards "for advanced study and research tenable in the United Kingdom." It has been prepared as the result of a resolution of the Congress of Universities of the Commonwealth that each of the countries of the Commonwealth should draw up a list of postgraduate and research awards available at its universities for overseas graduates. Appendix III contains a list of postgraduate and research awards tenable outside the United Kingdom. It applies only to United Kingdom graduates and does not claim to be exhaustive. The pamphlet can be obtained from the secretary, Association of Universities of the British Commonwealth, 36, Gordon Square, London, W.C.1.

PRIMARY TUMOURS OF THE SMALL BOWEL

BY

T. A. OGILVIE, M.B., F.R.C.S.Ed.
Surgeon, Essex County Hospital, Colchester

AND

H. M. SHAW, M.B., F.R.C.S.
Registrar, Essex County Hospital, Colchester

It is now well recognized that tumours of the small bowel, though rare, account for about 3% of tumours found in the gastro-intestinal tract, and that most surgeons will encounter several in the course of their career. The incidence of tumours of the small bowel is greatest in the duodenum. Willis (1948), quoting a series published by Hoffman and Pack (1937), mentions that, of 228 small-bowel tumours, 104 were situated in the duodenum. As the distance along the small bowel from the duodeno-jejunal junction increases so the incidence of tumours decreases, the symptomatology is different, and there are types of neoplasm met with in the jejunum-ileum seldom seen in the duodenum. One may therefore consider the two categories, duodenal and jejuno-ileal neoplasms.

Tumours of the small bowel are of four main types and may be innocent or malignant:

Types of Small-bowel Tumour

	Innocent	Malignant
I. Epithelial tumours	Adenoma	Adenocarcinoma
II. Connective-tissue tumours	Fibroma, myoma, lipoma, neuro-fibroma	Fibrosarcoma, leiomyosarcoma
III. Tumours of lymphatic or vascular origin	Angioma	Lymphosarcoma, reticulo-lum-cell sarcoma, Hodg-kin's disease
IV. Special group		Carcinoid

In general, it may be said that these tumours produce symptoms in one of four ways: (1) Obstruction, which may be due to an annular stricture, to intussusception with the tumour at the apex, or to volvulus. (2) Jaundice due to obstruction at the ampulla of Vater. (3) Melaena, anorexia, and loss of weight. (4) Perforation, which is a rare method of presentation.

It is not intended to discuss the signs and symptoms in detail, but rather to present the experience gained at a provincial hospital in dealing with these tumours over a period of ten years. In this period 16 cases have been diagnosed as suffering from small-bowel neoplasms. The details of these cases are shown in the table on the opposite page.

If we consider these cases together it will be seen that 12 presented with symptoms of acute or subacute small-bowel obstruction, 2 with abdominal discomfort and jaundice, and 2 with abdominal discomfort and melaena. In most of these cases pre-operative investigation was of little help in establishing the diagnosis, as in many of them operation was performed forty-eight to seventy-two hours after admission for the relief of obstructive symptoms. However, in four cases a barium meal examination was made, but was negative in each instance. The benzidine test for occult blood was performed in four cases and in each case gave a positive result. A plain film of the abdomen with the patient

standing in order to demonstrate fluid levels was done in six cases, and in none of these were fluid levels seen. Other investigations included barium enemata and sigmoidoscopy in isolated instances with negative results. All the diagnoses were confirmed by section of material removed at operation or at post-mortem examination. We shall now consider these lesions individually in more detail—8 carcinomata, 5 sarcomata, 1 argentaffinoma, and 2 benign tumours.

Carcinoma

Adenocarcinoma of the small bowel may affect the duodenum or the jejunum-ileum, though it usually appears not more than 2 feet (60 cm.) from the duodeno-jejunal junction (Ewing, 1940); although in a series published by the Mayo Clinic (Mayo, 1940) there were 31 tumours in the jejunum and 21 in the ileum. Of those arising in the duodenum, 22.5% are situated above the ampulla of Vater, 59.2% are peri-ampullary, and 18.3% are situated below the ampulla, these figures being given in a review of the subject by Locke (1953). Those growths situated around the ampulla of Vater may in fact be arising from the lower end of the common bile duct, and it is very difficult in many cases to decide whether they are duodenal or ampullary in origin: in advanced cases it may even be difficult to decide whether the tumour arises from the duodenum or the pancreas. Adenocarcinoma of the small bowel may be proliferative, may form an ulcer or an annular stricture, or may be a mixture of these varieties. Symptoms will depend on the site and type of growth present. Lesions of the duodenum are often associated with obstructive jaundice; ulceration produces melaena, and obstruction when it occurs is late. Ulcerating lesions in the jejunum-ileum may produce melaena, but obstructive symptoms are also late owing to the fluid nature of the small-bowel contents. Vomiting is more pronounced in duodenal than in jejuno-ileal lesions. The diagnosis in

these cases may be helped by straight x-ray examination of the abdomen, which will sometimes show fluid levels above the site of the lesion. Barium meal and follow-through is sometimes of use, and is safe if a Miller-Abbott tube be first passed down to the site of the obstruction. Barium studies may show a filling defect, an ulcer, or annular constriction at the site of the lesion. In cases in which ulceration has occurred the benzidine test on the stool should be positive.

In our series there are eight adenocarcinomata, situated as follows: second part of duodenum—peri-ampullary, 3; duodeno-jejunal junction, 1; proximal jejunum, 3; terminal ileum, 1.

Of the three tumours in the duodenum, two were associated with obstructive jaundice and subacute bowel symptoms of an obstructive nature. The only symptom associated with the third case was the recent appearance of an epigastric mass in a person who had had steatorrhoea for years. Case 6 is interesting because of its mode of presentation and subsequent history.

Case 6.—A woman aged 61 was admitted in December, 1951, complaining of jaundice for three months which was becoming progressively worse. Her urine was dark and the stools were clay-coloured. There was no other relevant history. On examination she was seen to be an obese, markedly jaundiced, middle-aged woman. Abdominal palpation revealed a moderately enlarged liver, but the gall-bladder was not palpable and no other abnormality was detected. Biochemical investigation indicated that her jaundice was of an obstructive type, and straight x-ray examination of the abdomen, including the gall-bladder area, was negative. Laparotomy was carried out in December, 1951: the gall-bladder was dilated and a firm mass was felt in the head of the pancreas. No glands were palpable and there were no secondaries in the liver. A duodenectomy and removal of the head of the pancreas were done in one stage, but section showed the tumour to be a papillary adenocarcinoma of the duodenum. Convalescence was uneventful, and she remained well until June, 1953, when multiple pulmonary metastases were demonstrated.

Details of Cases

Case No.	Date	Sex and Age	Symptom	Duration	Operative Finding	Section	Result
1	18/2/51	F 82	Colicky abdominal pain	2 months	Carcinoma terminal ileum. R. hemicolectomy	Adenocarcinoma	Death, 28.6.52
2	26/1/52	F 19	Recurrent abdominal colic	1 month	Laparotomy. Reticulosarcoma. Biopsy gland	Reticulosarcoma	Untraced
3	Feb., '47	M 50	Abdominal pain—colic. Vomiting	4 days	Carcinoma jejunum. Resection and anastomosis	Adenocarcinoma	Secondaries. Death, Dec., '47
4	28/12/51	F 76	Jaundice. Vomiting. Abdominal pain	6 weeks	Laparotomy. Carcinoma ampulla of Vater. Cholecystostomy	P.M.: carcinoma of ampulla	Death, 3.1.52
5	13/12/51	M 38	Abdominal discomfort. Vomiting	1 week	Laparotomy. Chylous ascites. Thickened rigid bowel. Mesenteric glands enlarged—grey	Reticulosarcoma	Death
6	12/12/51	F 61	Painless obstructive jaundice	4 months	Hard mass 2nd part duodenum. Duodenectomy and removal head of pancreas	Adenocarcinoma duodenum	Alive. Pulmonary secondaries
7	3/8/50	F 33	Colicky abdominal pain	3 "	Multiple tumours ileum; glands	Argentaffin carcinoma	Alive
8	4/5/50	M 5	Abdominal pain. Vomiting	2 weeks	Chylous ascites. Bowel thickened. Liver, spleen enlarged. Mass in pouch of Douglas	Lymphosarcoma	Death 8.5.50
9	20/9/50	F 30	Recurrent colicky abdominal pain	3 months	Intussusception. Adenoma ileum	Adenoma	Alive
10	29/12/50	M 33	Abdominal colic. Haematemesis	4 days	Subtotal gastrectomy	P.M.: lymphosarcoma involving stomach and small bowel	Death
11	28/10/51	F 48	Repeated melaena. Epigastric pain	6 months	? Carcinoma pancreas. Duodenectomy and partial pancreatectomy	Polypoid carcinoma duodenum	"
12	3/5/50	F 50	Generalized abdominal pain. Melaena	4 weeks	Resection of terminal ileum with Meckel's diverticulum and leiomyoma	Leiomyoma	Alive
13	Sept., '48	F 65	Abdominal pain. Constipation	2 months	Carcinoma jejunum 4 in. from duodeno-jejunal flexure. Glands ++. Resection and anastomosis	Reticulosarcoma	Death
14	21/1/53	M 40	Steatorrhoea for years. Abdominal discomfort	3 "	Carcinoma duodeno-jejunal junction. Resection and anastomosis	Adenocarcinoma	Death. Thrombosis superior mesenteric artery
15	10/1/46	M 50	Colicky abdominal pain	2 weeks	Carcinoma jejunum 2 in. beyond duodeno-jejunal junction. Glands ++. Gastro-enterostomy	P.M.: adenocarcinoma	Death
16	19/8/52	F 44	Recurrent attacks of colicky abdominal pain. Vomiting	3 months	Annular carcinoma jejunum 12 in. from duodeno-jejunal junction. Glands ++	Adenocarcinoma	Readmitted June, 1953. Large mass in pelvis. Laparotomy. Krukenberg tumour right ovary

All the growths in the jejunum and ileum were associated with obstructive symptoms varying from 2-3 days to 2-3 months in duration. In each case laparotomy was performed shortly after admission. Case 3 is illustrative.

Case 3.—A man aged 50 was admitted to hospital in February, 1947, complaining of colicky abdominal pain of four days' duration; there was no vomiting. His abdomen was slightly distended and he was tender to the left of his umbilicus. His symptoms subsided with expectant treatment but recurred at intervals until April of that year. A test for occult blood was positive, but barium enema and sigmoidoscopy were both negative. Haemoglobin was 94%. In April a tender mass was noticed in his left iliac fossa and laparotomy was performed. He was found to have an annular carcinoma of the jejunum approximately 2 ft. (60 cm.) from the duodeno-jejunal flexure, and this had led to a small-bowel volvulus. Secondary glands were felt in the mesentery and peritoneal deposits in the pelvis. The affected portion of bowel was resected and an end-to-end anastomosis performed. Convalescence was satisfactory, but he died from secondary carcinomatosis in January, 1948.

The duodenum and jejuno-ileum both have an abundant lymphatic drainage, together with a rich blood supply, and this probably accounts for neoplasms of the small bowel tending to metastasize early to the mesenteric lymph nodes and to the liver. Lesions in the duodenum produce symptoms at a rather earlier stage than do those in the jejuno-ileum, even before any metastases have occurred. The treatment of choice is resection of the involved segment together with its lymphatic field, followed by end-to-end anastomosis. General experience has shown these lesions to have a very poor prognosis, symptoms severe enough to cause the patient to seek treatment not occurring until comparatively late in the disease. This is borne out by our cases.

The Sarcoma Group

Amongst our cases there were five which came within this category. Two of these patients, aged 5 and 33, were diagnosed as suffering from lymphosarcoma, while three, aged 65, 38, and 19, were shown to have a reticulum-cell sarcoma. These two diseases together with Hodgkin's disease may primarily involve the mesenteric lymph nodes and lymphatic tissue in the wall of the small bowel. They frequently cause a chylous ascites due to lymphatic obstruction. The peritoneum may be studded with firm greyish nodules of tumour tissue. Large masses may be produced by glandular enlargement and the matting together of thickened and rigid loops of small bowel, resulting in subacute small-bowel obstruction. In some of these cases the liver and spleen may be involved. Diagnosis is often difficult, though the presence of an enlarged liver or spleen or of glands elsewhere may help, but in the present series the child of 5 was the only patient with a palpable liver and spleen. Full blood examination and glandular biopsy will help in establishing the diagnosis. One patient had previously been admitted elsewhere with a haematemesis for which he had undergone partial gastrectomy before the correct diagnosis was reached. In Cases 2, 8, and 13 there was a palpable mass in the lower abdomen. In all cases, at laparotomy, a large mass was found involving both the wall of the small bowel and its mesentery. In suitable cases resection of the involved segment followed by radiotherapy would appear to be the treatment of choice, although in none of our cases was this possible. Case 2 demonstrates these points.

Case 2.—A girl of 19 was admitted to hospital on January 26, 1952, having had an attack of severe colicky upper abdominal pain. Prior to admission she had had frequent attacks of less severe pain, each associated with vomiting. Bowel and urinary history were normal, menstruation was trouble-free. On examination there was an ill-defined lower abdominal tumour, but no other abnormality was noted. Laparotomy was performed on January 29, when the peritoneal cavity was found to contain a large quantity of chylous fluid. The mesentery of the terminal ileum together with the bowel itself formed a large mass. There were numerous grossly enlarged glands, the lymphatics were dilated, and there were several large lymphatic cysts, some 3 in. (7.5 cm.) in diameter, along the mesenteric border of the bowel. The bowel itself was thickened and rigid. It was only possible to

remove a gland for biopsy, and the report was as follows: "Great increase of reticular elements at the expense of lymphoid tissue in the gland. No normal lymphoid follicles seen. Probably a reticulosarcoma." There is no record of this patient having been seen since at the hospital.

The prognosis in these cases is that of the general disease, and, as is well known, is uniformly poor. Fibrosarcoma and leiomyosarcoma may both occur in the small bowel but have not been met with in this series.

Carcinoid Tumours or Argentaffin Carcinoma

These deserve special mention, occurring as they do in two special situations, the appendix and the terminal ileum.

These tumours arise from granular cells lining the depths of the crypts of Lieberkühn. They were described by Kultschitzky and have a special staining reaction with silver stains, thus often being referred to as argentaffin cells. Freidin (1953) states that these tumours occur as a result of abnormal proliferation of the argentaffin cells, the tumour first appearing in between mucosa and the muscularis mucosa and forming a yellowish-white mass over which the mucous membrane is stretched. As the mass increases in size it comes to involve the serosal surface of the bowel, where it may be seen as a yellowish or greyish plaque which, as a general rule, does not completely encircle the bowel, and thus obstruction may not be a prominent feature. The mucous membrane seldom becomes ulcerated over the tumour. Microscopically, the tumour is made up of columns of round or polyhedral cells with a granular cytoplasm and a darkly staining nucleus. There is no attempt at gland formation.

Tumours in the appendix are characteristically single and most frequently occur near the tip: they are usually discovered following routine appendicectomy or at necropsy. Ileal growths may be multiple, but, as they may not always encircle the bowel completely, symptoms may be absent. In his series Freidin reports that 13 of 16 ileal carcinoid tumours were found incidentally at post-mortem examination, the others causing obstructive symptoms. Metastasis from appendiceal lesions is seen in about 5% of the cases. Metastasis from ileal lesions is more frequent, and secondary deposits are found in the regional lymph glands and in the liver. Though similar in appearance and in microscopic structure, appendiceal and ileal lesions have several important differences which are summarized below, the figures being taken from Freidin's series of 30 cases.

	Appendix	Jejuno-ileum
Sex incidence	M:F=4:10	M:F=14:2
Age	Average 26 years	Average 26 years
Number	Single	May be multiple
Metastasis	Rare	Common

One of our cases (No. 7) is worth reporting.

Case 7.—A married woman aged 33 was admitted to hospital on August 3, 1950, complaining of lower abdominal pain of a colicky nature which had been present for three months. A straight x-ray film of the abdomen and a barium meal and follow-through showed no abnormality. Laparotomy was carried out on August 4 and in the ileum 17 isolated yellowish-coloured tumours were found almost completely encircling the bowel. The mesenteric glands were enlarged with similar growth and there were peritoneal seedlings. Approximately 8 ft. (2.4 metres) of ileum containing these tumours together with the mesentery and as many glands as possible were removed and an end-to-end anastomosis was performed. Convalescence was uneventful and the patient was alive and well three years after operation.

This case is remarkable in that there seems to have been no progression of secondaries in the three years since operation.

Benign Tumours

Many types of benign tumours may occur in the small bowel from time to time, and in this series we have two such cases. The first of these was an adenoma situated in the terminal ileum and forming the apex of an intussusception in a woman aged 30. The intussusception was reduced and the adenoma removed. The patient was still alive and well at the time of writing. The second tumour occurred in a

woman aged 50 who presented with melaena. Laparotomy showed her to have a Meckel's diverticulum and a rounded tumour in the wall of her terminal ileum distal to the diverticulum. Resection of the involved segment of ileum was carried out, section showing the tumour to be a leiomyoma.

Summary

We have reviewed briefly the primary tumours met with in the small intestine and report a series of 16 such tumours dealt with in this hospital over the past ten years.

Adenocarcinoma is the commonest of these tumours. It occurs most frequently in the duodenum and upper jejunum. Symptoms occur late owing to the fluid nature of the bowel content at this level. Prognosis is uniformly poor, and this has been our experience. The age incidence of these growths corresponds to the general cancer age, and women were affected more often than men.

A description of the lesions produced by lymphosarcoma and allied conditions is given. Five such cases are reported, and it is suggested that in suitable cases resection of the involved segment followed by radiotherapy is the treatment of choice.

A description is given of the carcinoid or argentaffin carcinoma. The different behaviour of this tumour occurring in the appendix and ileum is discussed, and one such case is reported.

Our thanks are due to other members of the staff of the Essex County Hospital for allowing access to their case records, and to Dr. J. B. Penfold for his helpful criticism.

ASSOCIATION OF JEJUNAL DIVERTICULOSIS AND STEATORRHOEA

BY

A. P. DICK, M.D., F.R.C.P.

(From Addenbrooke's Hospital, Cambridge)

It seems justifiable to report the following single case of steatorrhoea, macrocytic anaemia, and glossitis associated with multiple jejunal diverticulosis, in view of the considerable theoretical interest of the association and the apparent rarity of the occurrence. No similar case can be found in the literature. Moreover, the diarrhoea was relieved for a period of eight months after a course of chlortetracycline ("aureomycin"), and during this time the anaemia remained in remission without other treatment.

Diverticula of the small intestine between the duodeno-jejunal flexure and the ileo-caecal valve are usually symptomless and are found by chance in the course of a barium-meal examination or at necropsy. Their incidence has been recorded as 9 cases in 2,820 necropsies at King's College Hospital and as 0.31% by Edwards (1939), but it may be commoner than this. Benson, Dixon, and Waugh (1943) state that 122 cases had been recorded at the Mayo Clinic, of which 100 were jejunal, 17 in the ileum, and in 5 cases the diverticula were present in both. They are commoner in older people (Edwards, 1939). They are said on occasion to

give rise to vague abdominal symptoms such as flatulence and postprandial discomfort, but in some instances it may be that the presence of these symptoms from other causes has led to the performance of a barium meal and the discovery of the diverticula.

Complications such as acute intestinal obstruction, volvulus in relation to diverticula (Stiven, 1934), haemorrhage (Braithwaite, 1923; Waterson, 1952), perforation (Butler, 1937), diverticulitis (Butler, 1933), and the syndrome of chronic intestinal obstruction (Phillips, 1953) have all been described. The latter consists of symptoms varying from vague abdominal discomfort to more definite colic, vomiting, and constipation with loss of weight and deterioration in general health. Phillips, in discussing this syndrome, points out that there is no organic obstruction at laparotomy, although distended hypertrophic loops of bowel may be found, and he in fact suggests that there is a "dyskinesia" of the bowel which produces this syndrome and which also causes the pulsion-diverticula. He quotes Benson *et al.* (1943) as stating that non-organic chronic small-bowel obstruction was the commonest observed complication in their series of 122 cases—and that the changes resemble those in small intestine which has been obstructed for a long period. One of two cases which he describes had loose stools.

No reference to their association with deficiency syndromes from failure of small-intestinal absorption can be found in the literature other than a single case report by Montuschi (1949). He reported the case of a man aged 66 with a history of eight years' recurrent abdominal pain and bouts of diarrhoea and four years' oedema of the legs. Investigation showed a lowered plasma albumin and a raised faecal fat. Barium examination revealed multiple diverticula in the small intestine and colon, with precipitate passage of barium through the small intestine and loss of the normal mucosal pattern. It was thought that a low-grade inflammatory process in the diverticula was probably the cause of the small-intestinal hurry which led to deficient absorption of protein.

Case Report

A housewife aged 71 was first seen in December, 1949. She had been in good health until five years previously, when she began to have two or three loose motions a day, the stools being sometimes pale. She did state that her bowels had always tended to be easily upset, but that it was seldom this occurred. Three years before she developed a sore tongue, and shortly afterwards in November, 1946, a blood count showed some macrocytosis and anisocytosis. (Details of blood counts are given in the Table.) On December 20 a barium meal showed a small hiatus hernia. On the second part of the duodenum and on the duodeno-jejunal flexure there were large diverticula, and there were multiple diverticula throughout the jejunum. These showed some stasis in the erect position (Dr. F. R. Berridge). She was apparently diagnosed as suffering from pernicious anaemia, and it was thought that the diarrhoea was due to achlorhydria.

She was treated with a purified liver extract ("ana-haemin") intramuscularly once a fortnight at first, and subsequently monthly for the next three years until she was admitted to hospital. No test meal had been done. Full particulars of her blood counts during this time are not available, but she still had macrocytosis in 1949. Her diarrhoea remained unchanged during this time, and her tongue continued to be sore most of the time, with occasional periods when it did not trouble her. One month before admission she developed much more severe diarrhoea, having 10 watery stools a day and copious vomiting. The

diarrhoea lasted for 14 days, and the vomiting for a further week, when she was admitted to another hospital and treated with gastric lavage and a fluid diet. The vomiting ceased after three days on this regime. She was transferred to Addenbrooke's Hospital on December 22, 1949, when she gave the above history. She had had no other serious illnesses in the past. Her husband and two children were alive and well and there was no family history of diarrhoea or abdominal illness.

She was a thin, white-haired woman. Her tongue was smooth, and red at the tip and round the sides, but was otherwise normal. Her abdominal wall was very thin and

intestinal peristalsis could be seen. There were no other abnormal physical signs. On December 28 barium meal examination showed multiple duodenal and jejunal diverticula and a large diverticulum on the duodeno-jejunal flexure (see Fig.). Diverticula contained fluid levels in the erect position. Barium flocculated in the jejunum and ileum. Transit time slow, 7½ hours. The calibre of the small gut was wide (Dr. F. R. Berridge). Blood count (see Table) showed a slight macrocytic anaemia.

On January 2, 1950, the serum calcium was 11.1 mg. per 100 ml.; serum phosphorus, 2.8 mg. per 100 ml.; plasma protein, 5.6 g. (albumin 2.6 g., globulin 3 g.); non-protein nitrogen, 53 mg. per 100 ml.; thymol turbidity, 3 Maclagan units; thymol flocculation, negative. X-ray film of forearm bone with control—no significant abnormality. An amino-acid absorption test was normal. A sternal puncture on January 14 showed: total cell count, 20,000 per c.mm.—megakaryocytes 6 per 10,000 nucleated red cells, M/E ratio 3.2:1; polymorphs—neut. 36.5, eos. 2.6; metamyelocytes—neut. 15.6, eos. 1.8; myelocytes—neut. 9.4, eos. 0.6; premyelocytes, 2.4; myeloblasts, 0.2; lymphocytes, 9.4; plasma cells, 0.2; monocytes, 0.6; normoblasts—late 12.6, intermediate 2.0, early 0.6; megaloblasts—late 4.0, intermediate 1.0, early 0.8; pre-erythroblasts, 0.4; haemocyto blasts, 0.2; megaloblasts of nutritional macrocytic anaemia type (Dr. Martin Hynes). On January 17 a glucose-tolerance test showed: fasting, 0.095%; 30 minutes, 0.176%; 60 minutes, 0.204%; 90 minutes, 0.148%; 120 minutes, 0.132%. A fat balance was unfortunately not completed successfully, and the patient did not wish further investigation.

She was discharged home on a low-fat (50 g.) high-protein diet, ascorbic acid, vitamin B₁, nicotinic acid, and riboflavin; and also folic acid, 10 mg. t.d.s., which was begun on January 17. The reticulocytes on January 20 were only 0.5%, and on the 27th they were 1.8%. She continued with folic acid, 5 mg. b.d., and on February 3 a blood count showed no improvement. By March 17 the red-cell count had risen, and the macrocytosis was less, but the diarrhoea had persisted, and the tongue was still sore, with a smoother appearance than previously. In April, 1950, the folic acid was discontinued for one month, with no change in symptoms. The vitamins were discontinued in

Radiograph after barium meal, showing multiple duodenal and jejunal diverticula, and a large diverticulum on the duodeno-jejunal flexure.

May, and folic acid, 5 mg. b.d., was started again. Symptoms remained unchanged, with the tongue sore most of the time, but the patient felt better in herself. By July 14 the blood count had returned to normal and the macrocytosis had disappeared. She continued with folic acid, and in spite of this in September a blood count showed a fall in the red cells and a return of macrocytosis. Her serum calcium was 9 mg. per 100 ml., plasma proteins 5.8 g. (albumin 3.6 g., globulin 2.2 g.). The patient complained of feeling generally tired and unwell, and agreed to come back into hospital, which she did on November 27.

A fat balance investigation was carried out, the balance period being four days on a standard 50-g. fat intake, and the result was as follows: dry matter, 6.4% of faeces; total fat, 28.2% of dry matter; neutral fat, 0.8%; free fatty acid, 26.2%; soap fatty acid, 1.2%; fat hydrolysed—93% of total fat. Fat intake was 202 g. over four days, and fat lost 31 g.=15.3% of fat intake. Fasting gastric juice free HCl 0.045%, total 0.073%. After histamine, free HCl 0.273%, total acidity 0.310%. Duodenal juice showed some lipase and tryptic activity, but no quantitative test was attempted. The patient complained of a sore tongue, and it was moderately smooth and reddened. She was treated with two injections of riboflavin, 10 mg., vitamin B₁, 50 mg., nicotinic acid, 50 mg., followed by a further six injections at twice-weekly intervals. Her tongue became extremely sore, and was dark red and beefy in appearance, with complete loss of papillae. She was discharged home, and her tongue remained sore.

In December, 1950, she was started on injections of crude liver extract ("plexan"), 4 ml. twice weekly. Within 14 days the soreness of her tongue disappeared and in a month it looked virtually normal. She continued on injections of plexan, 4 ml., which after a month were changed to weekly, and then to fortnightly after a further two months, until July, 1953. During this time her blood count remained very satisfactory, being normochromic and normocytic. She did, however, continue to have looseness of her bowels with three or four stools a day, and occasionally more severe diarrhoea. At intervals she experienced abdominal discomfort, vague indigestion, and occasional attacks of vomiting lasting a day or two. In May, 1953, she developed more frequent indigestion with vomiting every few days for a period of about a month.

On June 4 she was started on a course of chlortetracycline, 250 mg. six-hourly, which she continued for nine days, receiving 9.25 g. in all. The injections of plexan were discontinued in July. Following the chlortetracycline her stools became more normal over the course of a fortnight, and since July, 1953, she has had two, or occasionally three, normally formed motions each day for the first time for several years. Unfortunately the patient was unwilling to be admitted for a further fat balance investigation. This improvement in her bowels continued until March, 1954. During this period of eight months she had had only three or four slight vomiting attacks. She had no recurrence of soreness of the tongue, and her blood count, carried out at monthly or two-monthly intervals, remained normal. She is a patient who has always complained very readily in the past, but she said that she had felt better since she had the course of chlortetracycline than she had done for years.

This satisfactory state of affairs ceased at the end of March, 1954, when she began to have more frequent attacks of vomiting and developed a sore smooth tongue again. She was started again on weekly injections of plexan, 4 ml., on April 23, and these were continued for three weeks. On April 26 an analysis of one specimen of stools showed that 37.6% of the dry matter was fat. On April 30 she was started on a week's course of chlortetracycline, 250 mg. six-hourly, totalling 7 g. Following this she continued to feel unwell for two weeks, but then began to improve again. Her sore tongue had begun to improve before this, and by May 28 was normal. At the time of writing she appears to be well.

Discussion

It is of interest that although the anaemia responded to refined liver extract and to folic acid, the glossitis showed no improvement. Treatment with crude liver extract, however, resulted in disappearance of the glossitis within a fortnight, and improvement in the patient's feeling of well-being. There was no change in the diarrhoea. Following the course of chlortetracycline her stools became formed for the first time for several years, and she felt better than she had done for a similar period. The anaemia and glossitis also remained in remission without further injections of crude liver extract after the course of chlortetracycline, but this may have been the result of the necessary factors having been stored from the large quantities of crude liver she had received during the previous two years. It does appear, however, that the chlortetracycline exerted some effect on her intestinal function.

Of the various possible mechanisms whereby small-intestinal dysfunction, with impairment of absorption, may be provoked, the presence of infection inside the small bowel is one which has been put forward as responsible in several distinct pathological conditions. Cameron, Watson, and Witts (1949), in experiments on rats, showed that transection of the small gut followed by end-to-side anastomosis, in such a way as to produce a small blind loop which emptied itself downwards, was not followed by anaemia unless there was some stenosis of the opening of the blind loop causing stagnation. If, however, the blind loop was made at the end of the proximal piece of gut, so that stagnation occurred in it, a percentage of the rats so treated developed a macrocytic anaemia. These authors noted that it was important to place the blind loop in the upper or middle part of the small intestine. When the loop was in the lower ileum very few rats developed anaemia. It seems very probable that the steatorrhea associated with gastro-colic fistula is due to soiling of the small-intestinal contents by material from the large bowel. It has been suggested that the steatorrhea which sometimes develops after a Polya type of gastrectomy, and which may appear many months after the operation, is the result of stagnation in the afferent loop, with subsequent infection.

The state of affairs existing in multiple jejunal diverticulosis is clearly one in which stagnation and infection in the sacs might be expected to occur. To prove that infection is present in the diverticula is an extremely difficult matter except by the method of direct sampling should the patient require a laparotomy. Taking samples through a Miller-Abbott tube introduces too many possibilities of contamination. In this patient the reversion of the bowel habit to normal after a course of chlortetracycline does suggest that the removal of infection might have been one factor responsible, and it does seem possible that infection in the diverticula may have been in part responsible for the small-intestinal dysfunction.

Summary

A case of jejunal diverticulosis, complicated by steatorrhea, macrocytic anaemia, and glossitis, is described.

Parenteral crude liver extract produced a complete remission of the glossitis and macrocytosis. Parenteral refined liver extract, oral folic acid, and massive vitamin B therapy had no effect on the glossitis, while the macrocytosis showed a variable response to refined liver extract and folic acid.

Improvement in the diarrhoea and in general health occurred after a course of chlortetracycline, and the glossitis and anaemia remained in remission, without further treatment with crude liver extract, for a period of eight months.

It is suggested that the multiple jejunal diverticulosis was responsible for the steatorrhea in this case, and

that stagnation and infection in the diverticula may have been the most important factor in producing the small-intestinal dysfunction.

ANTIBIOTIC SENSITIVITY SPECTRA THEIR USE IN INVESTIGATING EPIDEMICS

BY

E. P. SILBERSTEIN, M.B., B.S., B.Sc.

Formerly Senior House Officer to the Pathologist, Ashford Hospital, Middlesex

Staphylococcal infections in hospital wards are the cause of considerable morbidity and mortality, and for many years bacteriologists have been devising methods to facilitate the detection of sources of infection. One of the difficulties has always been the fact that coagulase-positive staphylococci are commonly found in the upper respiratory tract and skin of apparently healthy people, and it is not practicable to eliminate all of these. "Unless the epidemic strain has some special characteristic, it is impossible to decide whether, for instance, a carrier of the species concerned is to be incriminated. It is here that the definition of individual 'types' within species has been found so valuable" (*Lancet*, 1947). Serological typing and phage-typing were used by Allison and Hobbs (1947) in their brilliant investigation of neonatal infections. Phage-typing has indeed been a new and successful weapon in tracing the sources of wound infections, but it requires some experience, and it is not used by many routine laboratories. When we were faced with investigation of an epidemic of wound infections in our surgical wards it was thought that antibiotic sensitivity patterns might help to determine the cause of the trouble.

Investigation

Between September 12 and 24, 1953, five patients developed wound abscesses seven to ten days after an elective operation. The pus from the wounds yielded pure cultures of *Staphylococcus pyogenes*, and these infections appeared to be confined to patients operated on by one surgical team.

Nose and throat swabs were taken from all the nursing staff in the theatre and wards (22 in all), from the anaesthetist, and from two members of the surgical team. (The third member of the surgical team was away for three weeks when this investigation was started, but he had been present at all the operations done on the cases that became infected.) Coagulase-positive staphylococci were found in over half of the nursing staff. It was thus most desirable to determine whether all these staphylococci belonged to the same strain. Sensitivities to penicillin, streptomycin, chloramphenicol, chlortetracycline ("aureomycin"), and oxytetracycline ("terramycin") were determined with standard pads of these antibiotics on blood-agar plates, and three different patterns were obtained from the nursing staff (see Table I). Although the organisms derived from the

wounds all gave the same pattern (Table II), this did not coincide with any of the patterns derived from the nursing staff. The pattern, however, did coincide with that derived from organisms obtained from the nose and conjunctivae of

TABLE I.—A, B, and C are Antibiotic Sensitivity Patterns of Strains of *Staph. pyogenes* Obtained from the Nursing Staff. All Coagulase-positive Staphylococci Derived from Them Belonged to One of these Three Strains

Penicillin	++	—	—
Streptomycin	+	+	—
Chloramphenicol	+	+	+
Aureomycin	+	+	+
Terramycin	+	+	—

++ = Very sensitive, + = sensitive, — = resistant.

TABLE II.—Sensitivity Spectra of Strains of *Staph. pyogenes* Obtained from the Pus of the Patients (D), and the Nose and Conjunctivae (E and F Respectively) of the Missing Member of the Surgical Team

Antibiotic	D	E	F
Penicillin	—	—	—
Streptomycin	—	—	—
Chloramphenicol	—	—	—
Aureomycin	+	+	+
Terramycin	+	+	+

+ = Sensitive; — = resistant.

the missing member of the surgical team (Table II), who had just returned from his holiday at this stage of the investigation. (While on holiday he had suffered from acute blepharitis and conjunctivitis.) Intensive antibiotic therapy was given and his infection was eradicated. There have been no further staphylococcal wound infections in the wards of his surgical team. It should be added that none of the patients operated on while he was on holiday developed staphylococcal wound infections.

Discussion

The value of *in vitro* sensitivity tests in the treatment of infections is still a somewhat controversial subject. The same can be said of our views on the action of antibiotics in their role as antibacterials. The most widely accepted and most plausible theory seems to be the one which ascribes to the antibiotics a power of interfering with some enzyme system which is essential either for bacterial survival or for their multiplication. Where a species of micro-organism displays great variations in sensitivity to an antibiotic, such as, for instance, *Staph. pyogenes*, the organisms that are sensitive would rely for survival or multiplication on some enzyme system which is interfered with by the antibiotic—for example, by poisoning, competition, or blocking—and the ones that are resistant either do not require this enzyme system or have developed an alternative one. It would seem to be a reasonable assumption that a variant strain of one species relies in its metabolism on the same or similar enzyme systems. Antibiotic sensitivity patterns may therefore be useful in tracing strains of bacteria and in finding sources of infection. The determination of antibiotic sensitivity spectra is a simple procedure that can be carried out in routine bacteriological laboratories, and if it can be relied upon to separate different strains of a species of micro-organism this should provide a useful screening test for sources of infection.

The absence of further wound infections after eliminating virulent organisms from the eyes and respiratory tract of a member of the surgical team is, it is felt, strong evidence that he indeed was the source of infection, as is the fact that none of the patients operated on during his absence developed staphylococcal wound abscesses. Antibiotic sensitivity patterns suggested that the staphylococci in the wounds and in his nose were the same strains, and thus showed us where to find the cause of our trouble and how to deal with it.

Phage-typing was carried out on some of the cultured strains by the Staphylococcal Reference Laboratory, Colindale. This showed that staphylococci with different sensitivity patterns were of different phage types and that those with the same patterns were of the same phage types (Table III). That there is a close analogy between phage

TABLE III.—Phage Patterns of Staphylococci Obtained from the Nursing Staff (A, B, C), the Infected Wounds (D), and the Surgeon (E and F)

Phage Patterns	A	B	C	D	E	F
Diluted	52A v.w.	73+	29+	75+W	75+W	75+W
Undiluted	52 52A 79	73+	29+	75+W	75+W	75+W

type and antibiotic sensitivity is also suggested by investigations on penicillin-resistant strains and their phage types (Selbie, 1953). In the case of erythromycin- and carbomycin-resistant staphylococci there would appear to be no correlation between antibiotic resistance and phage type (Robson, 1954), although the author does not state whether the phage type was checked after the development of antibiotic resistance.

Sensitivity spectra, using penicillin, streptomycin, chloramphenicol, and the tetracyclines, certainly seem to be of use in the determination of strains of staphylococci, and they were of considerable value in rapidly tracing the source of wound infection in this instance.

I wish to thank Mr. Weait and Mr. Oke, who did most of the technical work and played a vital part in this investigation, Mr. D. Morris and his surgical team for asking for this investigation to be carried out and for supplying the specimens of pus, and Dr. W. F. Hamilton for permission to publish. Dr. R. E. O. Williams of the Streptococcus and Staphylococcus Reference Laboratories very kindly did the phage-typing.

Medical Memoranda

Two Cases of Favism in Israel

Favism is an acute febrile haemolytic anaemia caused by an unknown factor present in *Vicia faba*, the broad-bean. The disease is contracted by ingestion of the fruit, leaves, roots, stem, or flowers of this plant. It has been said that even the pollen can give rise to the condition. The toxic factor is resistant to weather and heat, and is transmitted via the milk of both the cow and the nursing mother.

No age is exempt, but favism occurs chiefly in children, and males are affected more than females. Some hereditary factor may be present, as the condition has been seen in Israel only among the Oriental population—the Sephardic and Yemenite Jews and the Arabs. So far no authentic case has been reported in the European or Ashkenazi communities. There is a definite seasonal incidence. Most of the cases occur in spring, during February, March, and April, when the broad-bean blossoms. Favism has an affinity with two other haemolytic anaemias—namely, Bagdad spring anaemia and the acute febrile haemolytic anaemia of Lederer. The former, an acute haemolytic anaemia, occurs in Bagdad during a few weeks in the spring, and is said to be due to an allergic reaction to contact with flowers (*Verbena hybrida*) and young fruits. Lederer's anaemia, which gives rise to a similar clinical picture, is said to be due to an allergic response to the streptococcus, the pneumococcus, or the dysentery bacillus. It occurs chiefly in children. The following two cases of favism occurred in Be'erva, a Yemenite village situated some nine kilometres from Acre in Western Galilee, Israel.

CASE 1

A boy aged 12 suddenly fell ill on the night of April 17, 1952. At 7 p.m., after supper, he felt sick and vomited twice. Up to that time he had been perfectly well. A little later he passed a small amount of "bloody" urine and felt very faint; at about 9.30 p.m. he had a fit (probably due to acute central anoxia). Some relatives obtained transport and called me, and I reached his bedside at 10.15 p.m. The boy was shocked, very pale, and semicomatose. Ocular and tendon reflexes were present and brisk, but there was no plantar response. The limbs were twitching spasmodically. There was no neck rigidity. He was sweating profusely and the extremities were cold. The pulse was small and thready, with a rate of 140 a minute, and the tongue dry and coated. There were no abnormal signs in the chest. The liver was palpable two fingerbreadths below the costal margin, but the spleen could not be felt. Rectal temperature was 100.4° F. (38° C.). The urine was of a deep port-wine hue, and almost opaque against the light. There was no history of malaria or intake of any drugs. The only positive fact in the history was that the patient, like everyone else in the village, had been eating broad-beans for the past two weeks.

After receiving 2 ml. of nikethamide intramuscularly, the patient was taken to the Haifa Government Hospital, arriving there 45 minutes later. His haemoglobin was found to be 3 g. per 100 ml. (Sahli). He was transfused immediately with 500 ml. of bank blood, and the next morning his haemoglobin had risen to 5 g. per 100 ml. A further 750 ml. of blood was given, and the haemoglobin rose to 7 g. per 100 ml. and the erythrocyte count to 2,360,000 per c.mm. The results of other investigations were:—Urine: acid, albumin +++, haemoglobin +++, and crystals of haemin +++ in the deposit. W.B.C., 22,000 per c.mm. (polymorphs 80%); serum bilirubin, 10 mg. per 100 ml.; thymol turbidity and Takata-Ara, negative; Weltmann, 8 units; plasma proteins, 7.6 g. per 100 ml. (albumin globulin ratio 1.81:1); blood urea, 100 mg. per 100 ml.; blood cholesterol, 125 mg. per 100 ml. Mantoux, negative at 1:1000.

Recovery was uneventful and the patient was sent home after eight days, on continued treatment with ferrum redactum 3 g. daily and a full diet.

CASE 2

This boy, also aged 12, became ill 10 hours after Case 1. If anything, his condition was even worse. His haemoglobin level was 3.5 g. per 100 ml. when he left for the hospital, but by the time he reached Haifa (within one hour) it had fallen to 2 g. per 100 ml. Ultimately he also recovered after two blood transfusions, and was discharged home after two weeks. Likewise in his history there was nothing relevant, except that he also had been eating broad-beans.

COMMENT

No other case of favism occurred in the village during the year (1952). Once the condition had been recognized the villagers were warned neither to eat broad-beans nor to bring them into their homes, and particularly to keep their children away from them. One does not know how far this affected the incidence of the disease, as up to then they all had been eating the bean, cooked as well as uncooked. But the fact remains that none of the other 150 children developed the disease.

Favism has been confounded with divers conditions such as food-poisoning, acute haemorrhagic nephritis with uraemia, blackwater fever, drug haemolysis, and pneumonia. Toxic haemoglobinuria due to drugs such as quinine, the sulphonamides, potassium chlorate, nitrites, pyridine, the aniline drugs, etc., also enters into the differential diagnosis. Particularly in Israel, especially in the malarious districts of upper and eastern Galilee, one must rule out the possibility of blackwater fever. Acute infections such as typhus,

septicaemia, meningitis, pneumococcal infections, etc., may at times be associated with toxic haemoglobinuria as a result of an acute haemolytic crisis.

One is struck by the dramatic onset of favism: it can result in the destruction of more than 75% of the red cells in the blood within 24 hours. However, the response to blood transfusion is nothing short of miraculous. Favism can recur, and the only prevention is to refrain from eating the broad-bean.

Acre, Israel.

Treatment of Rheumatoid Arthritis with Organic Copper Compounds

Improvement in cases of rheumatoid arthritis treated with an organic compound of copper was reported by Forestier and Certonciny (1946), who referred to the previous work of Fenz (1941) in Germany.

The drug, cuproallyl-thiourea-sodium benzoate, is a yellowish-brown crystalline powder containing 19% of copper and readily soluble in water. The solution is irritating to the tissues and must be administered intravenously. It accumulates in the liver and to a lesser extent in the spleen, kidneys, lungs, heart, and brain. Excretion is mainly by the intestine and is slow, continuing after administration has ceased.

Forestier and Certonciny, following the German workers, at first used small doses of 0.01 to 0.1 g., averaging 1 g. for a course. Finding that the drug was well tolerated, they increased the dose, giving 0.25 to 0.5 g. twice weekly, administering up to 5 g. in a course. Doses were given intravenously, dissolved in 10 ml. of sterile distilled water. Courses of treatment were repeated at the end of a month and again at intervals of two or three months. No toxic effects were encountered.

Results were better with the higher dosage. Out of a series of 40 cases improvement was noted in 80%, the result being excellent in 15%. But most of the good results were in early cases of less than one year's duration.

A trial by Tyson *et al.* (1950) in a series of 20 cases was not encouraging. Kuzell *et al.* (1951), in a group of 31 patients, failed to confirm the claims made for the drug: at the best they thought there might be a slight therapeutic effect in cases associated with psoriasis.

Through the courtesy of Lumière a small quantity of the preparation was obtained and tried in a few cases with indefinite results.

May & Baker Ltd. then synthesized two compounds: "alcuprin" (sodium *m*-(N-allylcuprothiocarbamide) benzoate) for intravenous use, and "cuprimyl" (a copper complex of 8-hydroxyquinoline bis-(diethylamine sulphonate)) for intramuscular injection. A trial was begun with these on a group of well-established cases of rheumatoid arthritis, in four of which chrysotherapy had been given. For descriptive purposes the cases are graded as follows: grade 1, physical signs slight; grade 2, well-marked physical signs but general condition good; grade 3, extensive physical signs with wasting and poor general condition; grade 4, extensive physical signs with poor general condition, wasting, and crippling.

Case No.	Sex	Age	Duration of Illness	Grade	Sedimentation Rate		Result
					Before	After	
1	M	24	3 years	1	6	3	Slightly improved
2	M	41	6 "	1	8	5	"
3	M	62	5 "	1	5	12	Unchanged
4	F	35	3 "	2	22	21	"
5	F	57	10 "	2	20	25	"
6	M	43	5 "	3	18	9	"
7	F	45	3 "	3	37	38	"
8	M	52	13 "	3	25	25	"
9	F	65	3 "	3	27	75	Worse
10	M	45	2 "	4	87	100	Unchanged

All patients had two courses of treatment, each course comprising 10 doses of 0.25 g. of alcuprin with a total of 2.5 g., or 0.5 g. of cuprimyl with a total of 5 g. Patients were under observation for three months before treatment and one year after. Toxic effects were not observed. The results are set out in the Table.

No therapeutic effect was demonstrated in the group. The trial was an exacting one on a selected group from which early cases had been excluded, and in consequence a sustained improvement could with confidence have been attributed to the drug. Early cases were excluded because the fluctuating course of some and the occasional occurrence of spontaneous remissions make assessment difficult: also the early stage of the disease may be modified by a number of drugs which have no lasting effect. Though a further trial in this early type of case seems worth while, assessment is difficult.

Two patients (Cases 3 and 5) had psoriasis, which was not influenced by the drug.

I am indebted to May & Baker Ltd. for ample supplies of both drugs for this trial.

Fat Embolism in Thoracic Operations

Fat embolism as a complication of operative procedures has been described in association with orthopaedic and abdominal surgery, but little reference has been made to its possible occurrence in thoracic operations. In view of the growing importance of cardiac surgery it is felt that the following observations are worthy of record.

Over the past two years small fragments of lung tissue from patients subjected to mitral valvotomy have been submitted for routine histological examination. During study of these biopsy specimens in two cases the large and medium-sized pulmonary arteries were found to contain bone marrow. Frozen sections stained by Scharlach R were employed on all subsequent lung biopsies from valvotomy patients, and in 4 out of 24 a minor degree of fat embolism was noted. Similar studies were made on pneumonectomy and lobectomy specimens. In one case bone marrow was present in the major pulmonary arteries, and in 10 out of 17 cases a slight degree of fat embolism was noted in frozen sections.

The occurrence of fat embolism in valvotomy patients is not altogether surprising, since the operative procedure entails continuous rib retraction and considerable trauma is possible. Fractures have even been recorded in some cases. The actual severance of ribs during pneumonectomy and other thoracic operations accounts for the higher incidence of fat embolism in this group. Vance (1931) has suggested that a slight degree of fat embolism cannot always be regarded as confirmatory evidence of trauma, since he found it in a small percentage of cases of non-traumatic deaths, but the presence of bone marrow in three cases in this series indicates a definite relationship to surgical trauma.

Whilst it is extremely unlikely that the degree of fat embolism evoked by such operative procedures as mitral valvotomy might assume clinical significance, it should, however, be borne in mind that it can occur, and even to such an extent that bone marrow is discharged into the pulmonary vessels.

Reviews

THE STORY OF GUY'S

Mr. Guy's Hospital, 1726-1948. By H. C. Cameron, M.D., F.R.C.P. (Pp. 520+xiii; illustrated. 30s.) London, New York, Toronto: Longmans, Green and Co. 1954.

It is over sixty years since there appeared the interesting *Biographical History of Guy's Hospital* by Wilks and Bettany. During this time much has happened, and with the great changes incidental to the introduction of the new health service there was need for a complete history of this famous institution. Dr. Cameron, for many years a distinguished member of the medical staff of Guy's, has undertaken this difficult and arduous task and achieved a remarkable success. It is indeed a notable feat to have compressed within 500 pages the story not only of the hospital itself but of the medical, dental, and nursing schools, not to mention short biographical sketches of about sixty of the past members of the staff. The book is well illustrated, and there are four beautiful coloured plates. We would warn the reader that many of the 174 footnotes in small print are of great interest and should not be missed.

It is impossible to do justice to this book within the limits of a short review, but some outstanding impressions remain. In the early part the figure of the famous treasurer, Benjamin Harrison junior, stands out boldly, the perfect picture of the absolute autocrat. He created the medical school and controlled it so efficiently and fully as to illustrate aptly the view that the best form of government is a wise and benevolent autocracy. In later years, when the superintendent shared with the treasurer the weight of administration, Cooper Perry was most influential. The tradition of complete independence and self-sufficiency, very satisfactory in the earlier years, later became a drag on the wheels and appears to have been responsible for the late adoption of some methods which had already proved their worth elsewhere. One reads with amazement of the bitter dispute between the medical staff and the governors over the introduction of the nursing reforms of 1880.

Dr. Cameron's deep knowledge of the history of the Society of Apothecaries enables him to throw much light on the growth of the medical curriculum; indeed, he gives a better outline of the history of medical education in this country during the past century than can be found anywhere else.

In the short biographies of past members of the medical staff one finds many pen-pictures which remain in the memory: Addison denouncing the system of scholarships and prizes because he thought they encouraged the student to concentrate too much on one subject; Bright demonstrating albuminuria by heating a little urine in a teaspoon with the aid of a candle; Cooper Perry, looking the picture of misery in the lecture room, sitting down with his head between his hands and his eyes glued to his manuscript; Herbert French writing his famous *Index* while he was being whirled along in a car to a distant consultation; the kindly and hard-worked Rowlands speaking fluently in English but always thinking in Welsh; the earnest young Ryle taking the names and addresses of out-patients whom he later visited with a view to helping them out of difficulties—these and many other pictures delight the reader.

We should think that every good Guy's man will want to have this book on his shelves, and we are sure that everyone interested in the history of medicine or medical education will need to refer to it.

ZACHARY COPE.

HUMAN PHYLOGENY

Man's Ancestry: A Primer of Human Phylogeny. By W. C. Osman Hill, M.D., F.R.S. (Pp. 194; illustrated. 21s.) London: William Heinemann Medical Books Ltd. 1954.

Dr. Osman Hill's book had its origin in a course of lectures given at Edinburgh University to a group of students, mostly of social anthropology, some of whom had no previous bio-

logical training. His aim has been to provide a short textbook for students of human affairs who need to understand something of man's evolutionary origins, and in doing this to cater also for the intelligent layman. In general he has succeeded admirably, although the book, being set out in the systematic fashion appropriate to a student's text, may seem rather heavy going to the layman whose interest is not very determined.

Dr. Hill paints on a broad canvas. The first chapter summarizes the general evidence for evolution, the emphasis being on a rather old-fashioned approach which tends to neglect the more recent genetical work. There follows a summary of the phylogeny of invertebrates and then of chordates as deduced from comparative anatomy. We then pass on to an outline of the evolution of the nervous system, and thus to the rise of the primates. This is illustrated by clear diagrams of the various tracts in the brain as they appear to the morphologist. These have considerable heuristic value, but the caution in their interpretation suggested by recent physiological analysis might have been more stressed.

Finally we come to the core of the book—four chapters devoted to the anthropoids and the emergence of man. This contains an adequate and systematic survey of the fossil evidence, and most of the current theories concerning this controversial field are briefly mentioned. Dr. Hill's own views tend to be conservative; he considers the South African Australopithecinae to be much nearer apes than man, and he seems unwilling to accept fully the recent work which suggests that Piltown man was a fake. In his final section also, on the evolutionary mechanisms which brought about the rise of man, little attention is paid to the recent developments of evolutionary genetics. Nevertheless Dr. Hill's book will undoubtedly be very useful as a text for students who are making their first acquaintance with this complex subject.

C. H. WADDINGTON.

PERIPHERAL CIRCULATION

Peripheral Circulation in Man: A Ciba Foundation Symposium. Edited for the Ciba Foundation by G. F. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Jessie S. Freeman, M.B., B.S., D.P.H., assisted by Joan Etherington. (Pp. 219; 72 illustrations. 25s.) London: J. & A. Churchill Ltd. 1954.

This book contains not only the papers read at a recent meeting sponsored by the Ciba Foundation, but also a full account of the discussions that followed. These add greatly to its value and reproduce some of the give and take of a successful scientific meeting. It provides a stimulating account of progress in an important field of vascular physiology, and is complementary to a previous similar volume on visceral circulation.

All the articles reach a high standard. Burton contributes an admirable critical survey of methods available for the measurement of peripheral blood flow which could be read with advantage by anyone interested in general physiology. A new and versatile method of detecting and measuring changes in blood flow by the electrical strain gauge is described by Whitney. Those to whom it appeals would be well advised to read the discussion of this paper, which brings out clearly its merits and defects. Von Euler gives an authoritative account of the capacity of the suprarenal glands to produce either adrenaline or noradrenaline to meet the homeostatic requirements of the body. Whelan describes the effects of these substances on the blood flow through human skeletal muscle in a short paper which led, however, to the longest and perhaps most illuminating discussion in the book.

Various aspects of blood-flow responses to alterations in temperature are dealt with by Carlson, by Greenfield, and by Barcroft and Dornhorst. The last two authors put forward the unusual view that there are in muscle two functionally independent circulations—one subserving metabolism and controlled by local conditions, and another concerned with circulatory homeostasis subserved by the sympathetic nerves and certain hormones. Papers with a more direct bearing

on clinical problems are provided by Dible in a thoughtful article on peripheral ischaemia in man, and by Guttman on the circulation in spinal man. Martin outlines the methods of investigation he has found most helpful in surgical practice.

The book is highly recommended to all those who are interested in circulatory problems.

E. J. WAYNE.

EXPERIMENTAL ALLERGY

Experimental Allergic Reactions Induced by Simple Chemical Compounds. By Mitsuteru Ishikawa, M.S., M.D. (Pp. 122; \$2.00.) Tokyo: Maruzen Company, Ltd. 1953.

This is an account of a series of studies of the inducement of hypersensitivity to simple chemical compounds. The compounds include arsenious acid, aspirin, salicylates, picric acid, and formaldehyde. Hypersensitivity was induced by intracutaneous injection; better results were obtained if the compounds were mixed with horse serum or with other adjuvants, including gum arabic and agar. The hypersensitivity was manifested by mild delayed skin reactions rising to a maximum in 20 to 24 hours after the inducing compound had been injected into the skin; all that is said about the histology is that the characteristic changes were swelling of the fibrous tissue and diffuse hyperaemia of varying degrees. Hypersensitivity could be transferred to normal skin by injection of serum of a sensitized animal; this is unusual in this type of hypersensitivity. As all but two of the 168 papers quoted are in Japanese and some of the results are rather unexpected, it is a pity that some of the experiments are not described in fuller detail. Neither Landsteiner nor Chase is mentioned in the discussion.

J. R. MARRACK.

RADIOLOGICAL DIAGNOSIS OF THE CERVICAL SPINE

Funktionelle Röntgendiagnostik der Halswirbelsäule. By Dr. C. Buetti-Baumli. (Pp 160+viii; illustrated. D.M.42.) Stuttgart: Georg Thieme. 1954.

This monograph on functional radiodiagnosis of the cervical spine was awarded its Jubilee Prize by the Swiss Röntgen Society. It is a brilliant and thorough discussion of a difficult and important subject and will well repay careful study. It is fully illustrated by 154 radiographs, taken with great skill and ingenuity and superbly reproduced full-scale. They show normal and abnormal conditions of the cervical spine in various positions, each taken in such a way as to bring out clearly the precise details required. Each is accompanied by a short account of the case and frequently by an explanatory diagram.

It is indeed a remarkable volume, founded on wide experience, infinite patience, and quite exceptional ingenuity. The descriptions are brief and accurate, and with the accompanying radiographs give a clear view of each case. We could not imagine any account of greater value to those who wish to study the complex and difficult conditions which may arise in this region of human anatomy.

HENRY SOUTTAR.

CHILD CARE

Babies and Young Children: Feeding, Management, and Care. By Ronald S. Illingworth, M.D., F.R.C.P., D.C.H., and Cynthia M. Illingworth, M.B., B.S., M.R.C.P. (Pp. 360 +vii; illustrated. 18s.) London: J. and A. Churchill Ltd. 1954.

A new book called *Babies and Young Children* by Professor R. S. Illingworth and his wife should really be reviewed by the mother of a family. The authors make it clear that they are writing for parents and not for doctors, and it is in this light that it must be judged. In general they appear to have succeeded well in imparting information in an easily understood style, although here and there a bit of jargon creeps in. A description of some phenomena

as of no significance may be quite plain to the medical mind, but for the lay parent it would perhaps have been better to say that it was "nothing to worry about." Again, it is of doubtful value to say much about common ailments in a book which is primarily intended to preach health and prevention. However, perhaps the intelligent mother will like these sections. The reviewer was especially pleased with the sections dealing with the psychological aspects of child development. Two chapters headed "On Love and Security" and "Discipline" especially go to the root of the matter.

Clearly Professor and Mrs. Illingworth have learnt much from their own family, and this gives a personal touch to the book. The drawings and photographs are well chosen. Family doctors should have no hesitation in recommending this book to parents. Despite the authors' declared intention, most doctors, including paediatricians, will also learn from it.

ALAN MONCRIEFF.

RADIOLOGY OF THE DIGESTIVE TRACT

The Digestive Tract in Roentgenology. Volumes I and II. By Jacob Buckstein, M.D. Second edition. (Pp. 1202 the two volumes; illustrated. £12.) Philadelphia, London, and Montreal: J. B. Lippincott Company. 1953.

The second edition of this work runs into two volumes, with over 1,500 illustrations—half as many again as the single-volume edition of 1948. A very large amount of clinical material is discussed in the illustrative cases described under different disease entities, all being beautifully illustrated. Discussion in all sections is clear and precise, and adequate bibliographies are included. Many useful clinical as well as radiological comments are made by the author, and for this reason alone the book deserves the attention of all interested in the subject. Though rare diseases are discussed in detail, balance has not been lost, and important subjects like the radiological diagnosis of malignant ulceration of the stomach receive merited treatment. The section dealing with small-bowel conditions is most valuable, and the radiologist faced by the occasional neonatal small-bowel obstruction or mesenteric tumour will find them dealt with comprehensively. In any publication of this size omissions are almost inevitable, and when dealing with ulcerative colitis the author makes no mention of the possibility of carcinoma of the colon developing as a late feature in the chronic case in which clinical cure appears to have been achieved. Again, in the section on diverticulitis of the colon the differential diagnosis of diverticulitis and carcinoma is not discussed, though the fact that one may simulate the other is referred to. Yet these are only minor faults in an excellent book, of which the only really unpleasant feature is its price.

F. PYGOTT.

PNEUMOCONIOSIS ABSTRACTS

Pneumoconiosis Abstracts. Volume II. Reprinted from the *Bulletin of Hygiene* for the years 1939 to 1950 inclusive, by permission of the Honorary Managing Committee of the Bureau of Hygiene and Tropical Diseases. Foreword by Charles Wilcocks. (Pp. 518. 80s.) London: Sir Isaac Pitman and Sons, Ltd. 1954.

This book is the second of two volumes in which are collected all the abstracts relating to pneumoconiosis which were published in the *Bulletin of Hygiene* from 1926 to the end of 1950. The first volume was reviewed in the *Journal* of January 2 of last year (p. 30). The second volume is arranged similarly to the first and maintains the same high standard of editing and indexing. The two volumes will be of very great value. It is to be hoped that they may be followed by further similar volumes every five years or so: the series so constituted would become an indispensable standby for all who are interested in industrial pulmonary disease.

J. G. SCADDING.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 15 1955

FAMILY CENSUS

The science of demography, the study of human populations by statistical methods, makes much use of facts about mortality and fertility, two subjects of interest to medical men. As used by demographers the word "fertility" means not the ability to have children ("fecundity") but the actual occurrence of births; and, since the concern is primarily with the influence of fertility upon population, often only live births are considered. Much detailed information about the trend and pattern of fertility in Great Britain has just been published in the form of a report¹ on the Family Census of 1946, constituting the sixth and final volume of the papers of the Royal Commission on Population, which was appointed in 1944 and reported in 1949.²

During the nineteenth century mortality statistics aroused much interest. But fertility statistics were largely neglected until 1911, when a fertility census was undertaken as part of the general census³—pioneer work which threw much light on trends of fertility during the latter half of the previous century. This rather dated information, supported only by the very limited new official registration data that were becoming available as a result of the Population (Statistics) Act of 1938 and published annually in the Registrar-General's fertility tables, was insufficient for the Royal Commission, which on the recommendation of its Statistics Committee therefore undertook an *ad hoc* sample inquiry into the fertility of British women: the Commission published some of the preliminary results in one of its earlier papers.⁴

The Family Census was undertaken during January and February, 1946. A random 10% sample was

selected, from food office and national registration records, of women who were or had been married, and they were sent a questionnaire about date of first marriage, the number and date of birth of their liveborn children, and occupation of husband. Of the million or so women asked to supply such information some 87% responded, a remarkably successful achievement in a voluntary inquiry of this kind. No serious bias was found as a result of the sampling or the failure of 13% of women to co-operate, and it was considered that the resulting data could be safely used for the study of fertility movements and patterns in Great Britain. The two-part report just published consists of some 300 pages of commentary and about 800 tables, preceded by an admirably succinct and informative summary chapter presenting the main findings. The picture that emerges now provides a national pattern with which can be compared the results of such local studies as that in Luton in 1945.⁵

From an analysis of the experience of women with completed families, comprising, more or less, women married twenty years or more before the Family Census, the outstanding and not unexpected picture that emerged was one of diminishing family size. The average completed family of a woman married in 1870-9 was 5.8 children; and, of a woman married in 1925, 2.2 children. Of marriages in 1870-9, 8% were childless, at all events as regards liveborn children, a proportion which became double for 1925 marriages. Completed families of five or more children formed 60% of the total from 1870-9 marriages but only 11% from marriages in 1925, of which half of the families so far produced consisted only of one or two children. One of the factors that much influences fertility is age at marriage: a woman marrying for the first time at the age of 40 has little time left to produce a large family. This effect of age has remained fairly stable up to the time of the Family Census, though with some lessening in relative age differences among more recent marriages compared with earlier ones. Continuously there has been a low level of childlessness among women marrying under the age of 20, for the reason that many of them are already pregnant when they marry. Other factors that influence fertility are occupation and social status, something that was known to demographers as long ago as the seventeenth century,⁶ and in the analysis of the results of the Family Census nine "social status" categories have been based on husband's occupation. Relatively, the differences in family size between the various categories have remained little changed between marriages at the very

beginning of this century and in 1925, fertility being highest amongst labourers, agricultural workers, and manual wage earners, intermediate for farmers and farm managers, and low for professional, salaried, and other non-manual workers. The general situation remains similar to that described by Stevenson⁷ from his examination of the results of the 1911 Fertility Census. Differences in the age at marriage between different occupational groups do not account for the different levels of fertility. For example, farmers' wives marry later than the wives of other non-manual workers (with which farmers are grouped), yet have considerably larger families. If people in different occupations all married at the same average age, they would still not have the same average size of family.

The request for information about the dates of birth of children, omitted in 1911 but introduced in 1946, gave results which allowed the study of family trends and patterns to be brought up to date, freed the authors from being confined only to the study of completed families, and even permitted them to make some tentative forecasts for the future. In addition it has provided some information about spacing of births. The decline in family size has been characterized more by compression of the span of years during which children of a marriage have been born than by more widespread spacing; that is to say, women complete their families earlier in their marriage than they did formerly. The interval between marriage and first live birth is closely related to the ultimate size of the family. For marriages in 1920-4 this interval was 27 months for families totalling only the one child, and 13 months for families ultimately totalling four liveborn children. The decline in child-bearing has been greatest at the later stages of married life (within the childbearing ages), and this decline in fertility with increasing length of married life is especially marked among women of the non-manual occupational groups. In considering the future trend of family size, the authors point out that examination of the data suggests that family limitation is now more widespread in Britain than had been previously estimated, and that further reductions in family size are unlikely to occur simply through the extension of family planning; nor will possible improvements in contraceptive techniques be likely to have much effect.

Analysis of the results of this Family Census suggests that a new stability in family size has been established in recent years, but accompanied throughout the community by the spread of a small family pattern. There is nothing to suggest a change from this pattern in the near future.

RUGBY FOOTBALL INJURIES

In a notable review of 590 cases of injuries sustained by Rugby football players, Mr. T. C. J. O'Connell,¹ of St. Vincent's Hospital, Dublin, analyses various types of injury observed by himself and his colleagues during twenty years of close association with the game in Ireland. Among these injuries were 129 to the head, 110 to the shoulder, 77 to the remainder of the upper limb, 75 to the knee (ligaments and cartilages), 42 to the ankle (ligaments), and 35 to the spine and pelvis. In addition, there were 53 fractures of the lower limb. He records also four fatalities—three from fracture dislocation of cervical vertebrae (through charging into or collapse of the scrum) and one from an undiagnosed rupture of the spleen.

In the last thirty years the popularity of Rugby football has led to the widespread growth of clubs whose members come from more varying walks of life than heretofore. Those who now play on Saturday afternoons, instead of being drawn mainly from public school, Services, and university circles, as was the case in the early part of the century, now include artisans, students, young businessmen, manual workers, and members of professions; and to all of them the economic aspect of injuries is one of great importance. Employers nowadays are often less inclined to take a lenient view of absences due to injuries sustained while playing games, and most Rugby players would welcome any action that can be taken to prevent or mitigate severe injuries, relatively infrequent though they may be.

Risks arising from faulty equipment, such as buckles on clothing, bad boots, poor studs, and insufficient protection for shoulders and shins could be easily eliminated. Flexible, snugly fitting boots with toe-caps that are not too heavily reinforced will do much to prevent awkward ankle injuries, for they can then be laced up quite firmly, while detachable studs of rubber or aluminium, that can be varied for dry and wet weather, are much less dangerous to other players than the leather ones that are apt to become conical in wear and sometimes develop protruding nails. Footwork in Rugby is done mainly by means of the arch and instep, so reinforced toes and steel-plated soles, so beloved by bootmakers, are more of a hindrance than a help.

Protective clothing such as is worn by American footballers hardly seems justified for our game, but O'Connell advocates shoulder protection for forwards, either by reinforcement of the acromio-

¹ *J. Irish med. Ass.*, 1954, 34, 20.

clavicular area of the jersey (by extra layers of material such as quilting) or by providing pockets into which thin sponge-rubber pads can be slipped to cover the same area. This undoubtedly does ease the friction in the scrummage and might also help to diminish the frequency with which outsides sustain a fractured clavicle or acromio-clavicular strain from falling on the point of the shoulder. A "sweat band" made of broad elastic worn around the forehead and over the ears will protect the ears of forwards, who periodically suffer from haematoma or rupture of the ear cartilage. This is infinitely preferable to the cumbersome, old-fashioned scrum-cap, which often blocks the meatus with its flaps and causes discomfort to the cheeks and chin with its tapes. Shin guards should not be considered as "cissy," and are almost essential for front-row forwards; but they must be light and not made from material which becomes sodden and heavy in wet weather. Felt is preferable to leather and sponge rubber better than either, especially if cut to shape and attached by elastic loops above the calf and beneath the instep. Well-fitting clothing can be a protection in itself, and the player with flapping waistbands and dangling stockings is often his own worst enemy.

O'Connell rightly stresses the importance of maintaining muscle tone. "Taking up the slack" is by far the most important measure in the prevention of serious injuries, and also in the restoration of fitness after injury. The strength of joints does not depend on ligaments, but on the firm bunch of muscles above and below. Too often the injured player attempts to return to the game before fully regaining muscular tone, lays himself open to further damage, and becomes accident prone. Nor should any player take part in a game if he is feverish or has a septic infection, for serious damage can be caused thereby. The custom of going on to the field for a kick-about before the game, sometimes even before changing, was a useful insurance against injury, and it is a pity that it seems to have become unfashionable.

Many strains and muscle injuries occur in ill-trained individuals early in the game in cold weather. Few spectators who saw a recent international game played in a snow-storm at Twickenham after a six weeks' interval from play due to frost will forget the spate of cramps and muscle pulls that occurred during and after that game. It clearly showed that the only real training for Rugby football is Rugby football.

Moving from a consideration of the player to the obstructions on the field, O'Connell suggests that the

lower end of the goal-posts might be padded, as is the custom on some New Zealand grounds, and that corner flags should be made of thick rubber or similar yielding material that does not splinter on impact. These are wise precautions which could easily be adopted. The Saturday afternoon player is often apt to leave treatment of minor injuries over for two or three days, thus prolonging recovery. First-aid boxes should be in every pavilion, and an "accident treatment centre" open at week-ends in the large urban centres would be of great value to players who find that an injury is more serious than they thought it was in the heat of the game. O'Connell quotes one case of fatal tetanus, and there have been others in which early treatment (or, better still, prophylactic immunization) might have saved life.

TUBERCULOUS MESENTERIC ADENITIS IN CHILDREN

The King's evil—scrofula—was a common complaint in children during the last century and the first quarter of this, but has now largely disappeared. Out-patient departments are no longer crowded with children with chronically discharging sinuses and red, boggy swellings in the neck, and operating-lists in the theatres of children's hospitals no longer consist of cases for excision or curettage of cervical glands—previously an almost regular feature. Similarly, tuberculous peritonitis, which was as common in the medical wards as scrofula in the surgical wards, is now a rarity. Improvements in hygiene and particularly in the heat treatment of milk—especially pasteurization in urban areas—have been responsible for this change.

The primary tuberculosis still to be seen in children is usually intrathoracic, although a primary abdominal focus is by no means rare, especially in rural areas, for pasteurization is not yet carried out in all of them. In such areas cases of primary abdominal infection may rank nearly as high as intrathoracic. It is not always easy to diagnose tuberculous mesenteric adenitis, as Dr. H. R. E. Wallis shows in an article at p. 128 of the *Journal* this week. He lists thirteen differential diagnoses apart from all the cases of "P.U.O." Recurring abdominal pain is the predominant symptom; it may be colicky or aching in character—more commonly it is colicky—and the bouts may be accompanied by fever. Although the prognosis in Wallis's series was generally good, nevertheless fatal tuberculous meningitis can follow a primary abdominal focus just as readily as it can a primary intrathoracic focus, and the ingestion of raw milk—even in small quantities—by

infants and young children is to be condemned as a means of immunization against tuberculosis. The use of an attenuated organism such as B.C.G. is a more rational approach. Wallis rightly points out that calcification in the abdominal glands, while evidence of a tuberculous infection, is not necessarily evidence of complete healing; but, although he says that isoniazid, for example, is not necessary in treatment, it is always possible that it may become necessary. Tuberculous mesenteric adenitis is usually benign, and all will agree, therefore, that the routine giving of tuberculostatic drugs is both unnecessary and unwise. In view of the difficulty sometimes encountered in making a diagnosis the family doctor may well wonder whether he should have the abdomen x-rayed. This would entail considerable time and expense, and a simple tuberculin test is the real prerequisite to the diagnosis. If this is negative, no tuberculous calcification in the mesenteric glands will be found. Only those children reacting positively will need to have an x-ray examination. It would be interesting to know the findings of Russian paediatricians on the symptomatology of intra-abdominal calcification, for all infants in the U.S.S.R. are given B.C.G. orally at intervals, and there must be many thousands of children who now have calcified mesenteric glands.

Whether the pain is caused by pressure or by the drag of the calcified glands on the mesentery is not clear. Certainly such glands are found by chance in many children being x-rayed for some other condition—an intravenous pyelogram, for example—in whom there have been no abdominal symptoms at all. Clearly not all cases with these symptoms and calcified glands are necessarily suffering from active tuberculous adenitis. The other symptoms described in this condition—for example, vomiting, sweating, lassitude, and loss of weight—are likely to be connected with some activity of the tuberculous process, and it is in children with such symptoms who also have fever and a raised sedimentation rate that the use of isoniazid may have to be considered. The association of pain and vomiting with slight fever must often raise the question of appendicitis. In any doubtful case laparotomy should always be undertaken. A radiograph of the abdomen showing calcification is no guarantee that acute appendicitis is not present, and it would be most unwise to wait for 48 hours to see the result of a tuberculin test. Of the physical signs of tuberculous mesenteric adenitis, local tenderness and palpable masses are the most frequent, but both are more commonly due to constipation than to tuberculosis; radiographs must therefore be taken and calcification confirmed before the diagnosis can be

accepted with certainty. If the diagnosis is still seriously entertained in the absence of any visible calcification, a negative tuberculin test will exclude the condition.

STERILIZATION METHODS

The Report of the Central Pathology Committee of the Ministry of Health on the Sterilization of Hospital Equipment, issued to hospital authorities on December 31 last, contains directions in the light of which hospitals are invited to review their present practice, and it will serve a useful purpose. It deals chiefly with surgical equipment; "bowls, baths, bedpans and urinals, crockery and cutlery are excluded since they usually come under the direct supervision of the ward sister." Discussing autoclaving, the authors lay proper emphasis on the necessity for loose packing of fabrics, and assume that the autoclave is of a type from which only two-thirds of the air can be exhausted; they therefore recommend a double evacuation. Autoclaves now exist from which air is completely expelled by downward displacement, and some mention of the advantages of this type might have been made. For the disinfection of bedding the Report suggests that a pressure of only 5 lb. per square in. (0.35 kg. per square cm.) of steam should be used, giving after a preliminary 20 in. (50 cm.) vacuum a temperature of 100° C. This is a reasonable compromise to minimize shrinkage of blankets and other damage. The Report does not discuss the circumstances calling for this treatment, and as much damage could perhaps be prevented by stopping unnecessary disinfection as by modifying the method. It is clearly necessary for the bedding of a septic or infectious case, but in many hospitals disinfection is practised after death from any cause and in all cases of cancer, a proceeding based rather on sentiment than on any scientific reasoning. The Report gives a full account of methods for the care and sterilization of syringes and needles: autoclaving and a dry oven at 160° C. are given as alternative methods, without the expression of a preference for either. It mentions that the performance of any dry oven must be checked, but not that some types may have very wide variations in temperature between one part and another. The recent experiments of E. M. Darmady and Barrington Brock,¹ made by inserting thermocouples at multiple points in ovens of different types and thus obtaining a continuous record of temperature rise, seem to show that gas-heated

ovens are most unsatisfactory, and that even those electrically heated perform consistently only when fitted with a fan to circulate the contained air. These authors also recommend loading the oven while it is hot, whereas the Report states that it should be cold.

Two of the articles in commonest use in surgery seem to occasion the greatest difficulty in sterilization. Methods for sharp instruments are the most diverse, mainly because heat in various forms is reputed to blunt them. That advocated here is boiling in 2% sodium carbonate. The procedure advocated for rubber gloves, the other troublesome article, at least in British surgical practice, is open to criticism. The report recommends that after cleaning they should first be boiled, and then, because higher temperatures spoil them, autoclaved at a pressure of only 5 lb. per square in. (0.35 kg. per square cm.). It then admits that "such treatment by itself does not ensure complete sterility so that gloves which may have become heavily contaminated with sporing bacteria, e.g., in a case of gas gangrene, should be destroyed." It seems in the first place a pity that the hoary old operating-theatre myth about the special infectivity of gas gangrene should thus be officially perpetuated. *Cl. welchii*, the principal cause of gas gangrene, is a normal inhabitant of the human lower bowel, and the precautions called for when it happens to produce infection are equally necessary after any operation on the colon, rectum, or anus. The instructions given for sterilization conflict at every point with those of C. W. Walter,² whose monumental work on surgical asepsis is the most complete of its kind and reflects the best American practice. He states categorically that gloves should not be boiled, because they imbibe water and thus lose tensile strength. He also states that "gloves withstand sterilization by saturated steam but deteriorate rapidly in mixtures of air and steam." In other words, what matters is not absolute temperature but the admixture with steam of hot air (presumably the damage is an oxidation effect). In an autoclave giving an atmosphere of pure steam gloves can be sterilized at 15 lb. per square in. (1 kg. per square cm.) at 121° C. It is sometimes suggested that this should be maintained for only 15 minutes, but at the Peter Bent Brigham Hospital they maintain it for 30 minutes, as in autoclaving other materials, simply for the sake of uniformity, and have no complaints about the effect on the quality of the rubber. It may be concluded from the experiments of B. Schmidt and E. Möller,³ who compared the effects of 120° C. for 30 minutes and 134° C. for 5 minutes on the strength and elasticity of rubber gloves—slightly to the advantage of the former—that sterilization at full pressure is also the usual practice in

Germany. Surely the truth in this very important matter should be finally determined, and British surgical practice brought into line with it if the facts demand a change. That gloves, of all things used in an operation, should be of doubtful sterility is intolerable. If it is a fact that hot air and not steam is what damages gloves—and anyone doubting this can test the statement by experiment—then all that is needed is an autoclave giving an atmosphere of pure steam and its use as for sterilizing any other materials.

PAPILLOMATOSIS OF THE BLADDER

The treatment of diffuse villous papillomatosis of the bladder is peculiarly difficult, since despite the simple nature of the lesions they are often present in such numbers that control by cysto-diathermy or endoscopic resection is impracticable. Moreover, a proportion of tumours appear eventually to undergo malignant changes, thus adding to the hazards of incomplete destruction by such means. Alternatively, extirpation by total cystectomy may seem unnecessarily radical in early cases, while radiotherapy from a remote source carries the disadvantage of exposing the surrounding tissues to an excessive dose of irradiation. During the last few years efforts have been made to overcome this last difficulty by devising methods of intracavitary irradiation, whereby the tumours may be treated more selectively. The use of radioactive solutions (instilled into a rubber balloon within the bladder) has allowed a diffuse irradiation of the mucosa with limited deeper penetration depending on the quality of the isotope and on the screening effect of the containing sheath. In practice, however, technical difficulties have greatly narrowed the margin of safety between securing adequate destruction of the tumour and avoiding subsequent radionecrosis of the bladder wall. On the one hand the rubber sheath has discriminated unfavourably in reducing the surface dose (while permitting the passage of more penetrating rays), and on the other hand the tumour has been pressed against the bladder wall, thus permitting only one surface to be fully irradiated.

Elsewhere in this issue Dr. Frank Ellis and Mr. R. Oliver describe a modification of radiotherapy which gives promise of proving both safe and effective in the treatment of superficial papillomatosis. The essential difference in their technique lies in the direct instillation of a radioactive solution into the bladder, thus allowing the papillomata to float out and become exposed to irradiation from all sides. At the same time the screening effect of the catheter bag is eliminated and the overall dosage can thus be reduced to avoid an excessive dose in depth. Preliminary work has indicated that, with certain precautions, a standard preparation of radioactive colloidal gold is suitable for this purpose, and may be retained within the bladder for the required time without ill effect and can be subsequently evacuated by irrigation. Using this method, the authors observed the disappearance of multiple villous tumours, and they

¹ *J. clin. Path.*, 1954, 7, 290.

² *The Aseptic Treatment of Wounds*. New York. 1948.

³ *Z. Hyg. Infektkr.*, 1954, 140, 144.

describe the reduction in size of neoplasms less simple in appearance, thus making easier their eradication by other means. It must be emphasized, however, that, *a priori*, the technique is unsuitable for infiltrating growths, since effective dosage would necessarily carry the risk of damage to the normal bladder wall. Experience with previous methods has shown that late necrosis and contracture may occur up to several years after treatment, and the utmost caution is therefore required in limiting the dose of irradiation lethal to the tumour to a depth of penetration scarcely exceeding the radius of a simple papillary frond. Allowance has thus to be made for the dilution of the isotope solution by urinary secretion during its retention in the bladder, and for the ability of the patient to refrain from micturition during the prescribed period. This and other matters relating to the control of radioactive materials make it essential that for the time being further trials of this method of treatment should be conducted only under carefully supervised conditions.

EYES AND APPETITE

The use of dyes in food manufacture has become so extensive that the Food Standards Committee of the Ministry of Food has recently issued a report¹ by a subcommittee on the possible hazards arising from such practices. The report, which was briefly summarized in last week's *Journal*, provides such an astonishing record of the use of colours in food that it is perhaps reasonable to wonder whether the research resources of the food manufacturing industry are being properly used. If increased reliance is being placed on colour in order to sell food, it suggests that inadequate attention is being paid to correcting processes of manufacture so that natural colour and flavour are retained to the maximum. Doubtless there are difficulties, especially if costs are to be kept low; nevertheless there would have been much support for the subcommittee if it had taken a stronger line against this ever-growing use of artificial colours in food. The manufacturers appear to have made a plea for the retention of all the colours hitherto put to use in this country and wished to include all those permitted in other countries. In this country at present there is a short list of forbidden colours, while any others may be used. The report rightly recommends that in the future there shall be a permitted list, but when the subcommittee tried to compose such a list it had many difficulties to contend with: there are 82 different colours named on 22 permitted lists of those countries that have such lists, yet only one dye is common to them all.

Largely avoiding the technological issues and subtler matters of good taste in food manufacture, the subcommittee concentrated its attention on the possible toxic hazard from consuming these dyes. Many of the colours used have never been tested for toxicity: none has any marked acute toxic effects, and all are present in very small quantities in our diet. This raises the vexed ques-

tion of the possible possession of chronic toxic properties by these colours. Naturally the subcommittee paid most attention to the possibility of the dyes having carcinogenic properties. Some have already been incriminated as carcinogens for experimental animals: others are closely related to carcinogenic compounds either chemically or by derivation from them. Probably one shadow hanging over the inquiry is the known property of β -naphthylamine to produce bladder cancer in man. Little, however, is known about the doses needed to do this, and it is impossible to say whether a lifelong consumer of coloured foods will ever ingest a quantity of dye comparable to the amount needed to cause cancer in a worker in a dye factory where β -naphthylamine used to be handled. Ideally every dye on the permitted list should be tested in such a way as to exclude the fact that it is a carcinogen for a few laboratory animal species, but even so such screening tests might well have allowed β -naphthylamine itself to pass as harmless. Other tests for chronic toxicity are of doubtful value, and it seems questionable whether a battery of tests such as those outlined by Professor A. C. Frazer would be a practical proposition for 40-odd dyestuffs. Simple excretion tests if done on animals and perhaps on man might reveal a few dyes that the body excreted unchanged. Another important point made by the subcommittee is that these dyes are rarely manufactured specially for use in food, so that while shade may be crucial chemical purity is not so essential. It should surely be made compulsory that all dyes used in food should meet fairly rigid standards of chemical purity. This in turn might help to curtail the list, because some dyes would be more readily purified than others. The food manufacturers have successfully overcome the handicap of the withdrawal of many preservatives, and they should be discouraged from placing increasing reliance on artificial colours in order to make their products attractive. One of the great objections to mass-produced food is that it loses its natural flavour: artificial colouring, even if harmless, is poor compensation for loss of quality.

EDINBURGH MEDICAL JOURNAL

The December number of this memorial to Scottish medicine has reached us with the sad news that it is the last to appear. Rising costs of production, a sluggish circulation, and diminished revenue have combined to kill a periodical whose continuous appearance since 1805 (as the *Edinburgh Medical and Surgical Journal* until 1855) has been a steady source of entertainment and instruction to British readers, and in particular to Edinburgh graduates. Since 1908 the *Edinburgh Medical Journal* has been the property of a limited company of doctors, and its reserve funds have now all been mopped up by the cumulative losses of the last few years. This notable casualty in medical periodicals is but an example of the severe financial strains to which periodical publishing is now subject. It is indeed distressing to have to record the disappearance of a journal which traces its origins directly back to *Medical Essays and Observations* (1733-44), the fourth oldest medical periodical in the United Kingdom.

EMERGENCIES IN GENERAL PRACTICE SHOCK*

BY

Sir HENEAGE OGILVIE, K.B.E., M.D., M.Ch., F.R.C.S.

Consultant Surgeon, Guy's Hospital

The study of shock has for many years attracted the ablest investigators in Britain and America. Men like Aub, Blalock, Bywaters, Grant, Green, Gregerson, Haist, Moon, Phemister, and Wilson (the order is alphabetical rather than chronological) have paid particular attention to this problem, and by their research work in the laboratory and their clinical observations at the bedside they have added greatly to our knowledge of the reactions of the animal and human body to various forms of injury.

The treatment of shock is essentially a practical problem. We must study the research work that has been done in the laboratory, and if it has provided an answer we must apply the lesson it brings to our clinical tasks. Very often, however, the answer is "So what?" and it is extremely important that we should leave philosophical doubt behind when we come to the side of the pale listless man who has just been rushed in by the ambulance. It is right, therefore, that from time to time a clinical speaker should try before a clinical audience to bring this important subject from the laboratory to the bedside, to turn aside from a consideration of what shock might be and consider what shock is as we see it, what steps we can take to prevent it, and what we can do to save the shocked patient.

What is Shock?

We are often criticized by our scientific friends for using the word "shock" without explaining exactly what we mean by it. The word "shock" has a very definite meaning to me, and to most surgeons. To me it means a state of collapse following injury, and I shall go on calling it shock till I find I am wrong. The definitions of the experts are no more helpful than this simple statement. Blalock defines shock as "peripheral circulatory failure." Why peripheral? Why failure? In the type of shock most commonly encountered in clinical practice, that due to haemorrhage or trauma, nothing has failed. The central pump and the peripheral mechanism are working with supreme efficiency. The motor is spluttering only because the tank is running dry. Moon defines shock as "a circulatory deficiency characterized by decreased blood volume, decreased cardiac output, and increased concentration of the blood." This may be the shock of the laboratory mouse. It is not the shock of the wounded soldier; unless he is burned or crushed his blood concentration is normal or below that figure, and it falls in subsequent days. These definitions, in attempting to give an exact meaning to a comprehensive and general term, force upon it a significance foreign to its accustomed clinical use. This is hardly surprising, since many of the experiments whereby shock is produced in the laboratory bear no relation to the manner of its causation in surgical practice.

I will return to my first definition of shock and expand it slightly. "Shock is a state of collapse following injury, characterized by a depression of the circulation." All we know when we are called to the patient's side is that he has been injured, that he is collapsed, and that he lies apathetic

* Based on a contribution to a symposium at Bristol University on "Medical Aspects of Atomic War" (see *Journal*, November 27, 1954, p. 1283).

with an ashen grey face and cold clammy hands. The diagnosis is a clinical one, and, having made it, we must set ourselves urgently to seek the cause and decide the treatment.

Mechanism of Shock

The circulation of the blood depends on three things: on the action and force of the heart beat, on the volume and viscosity of the blood, and on the peripheral resistance of the arterioles. Interference with one, two, or all of them may be found in the condition of acute circulatory depression known as shock. Heart failure may resemble shock. Many factors associated with injury, particularly with battle injury—peritonitis, blast damage to the lungs, fat embolism, acute anaerobic infection, absorption of toxins from damaged muscle—may complicate and be partly responsible for the clinical state of shock. But to label them as "shock" is to make the term completely meaningless.

Traumatic shock is, in the overwhelming majority of cases, the result of a diminution of the effective circulating volume of the blood, and the word "shock" should be used for this condition alone. The other shock-like states should be called pseudo-shock. The later changes caused in the circulatory mechanism by anoxaemia, infection, or tissue toxins of various sorts should be referred to as epiphenomena or sequelae of shock, but not as shock.

In shock the diminution of volume may be due to actual loss, or to a sudden increase in the capacity of the vascular bed, the volume being unchanged or diminished to an extent that would not in itself cause shock. In wound shock the loss is one of blood, either from the wound or into damaged tissues. In the shock which follows crush lacerations or severe surgical operations the loss is of blood and plasma. In shock from burns the loss is of plasma only, from the burned surface and into the tissues underlying it. In the vasovagal syndrome, known also as primary or nervous shock, a state which may be found alone or preceding or accompanying true oligæmic shock, the circulating volume is inadequate to the vascular bed, whose capacity is increased by widespread dilatation.

Primary and Secondary Shock

Phemister has observed that "primary and secondary shock should be recognized on the basis of difference in aetiology rather than difference in time of occurrence." Primary, or nervous, shock is a condition of circulatory disturbance associated with low blood pressure due to dilatation of the peripheral arterioles, and a slow pulse due to stimulation of the vagi. It is a cardiovascular upset of reflex origin, the result of painful stimuli or of emotional disturbance, very often a combination of the two. A painful injury is more likely to cause it than a large one, and an apprehensive individual is more likely to suffer from it than a phlegmatic one. The main features distinguishing primary from secondary shock, apart from the nature of the causative injury, are that the patient does not look ill, that his skin is warm, that he is torpid or unconscious rather than apathetic, and that his pulse is slow.

Primary shock is essentially a transient phenomenon that responds to rest, relief of pain, warmth, hot drinks, and removal from distressing surroundings, and a good response to these simple measures may be the surest method of distinguishing primary from secondary shock. It is, however, less important to recognize those who respond well than it is

¹ Food Standards Committee Report on Colouring Matters: Recommendations Relating to the Use of Colouring Matters in Food, 1954, H.M.S.O., London. Price 1s. net.

to watch anxiously for those who do not or who relapse after temporary improvement, for they are suffering from secondary shock and need immediate and active treatment. If there is any doubt, needless transfusion of a patient in primary shock is a harmless mistake compared with delay in starting the transfusion of one suffering from secondary shock.

Secondary shock must be assumed where there has been much blood loss or tissue damage. Some estimate of the loss can often be made from the history given by the patient or his friends, or from observing the amount of blood on the clothing or the stretcher. But fluid may be lost into the tissues without external loss, a mechanism repeatedly stressed by Blalock. A man can bleed to death into the thigh muscles round a fractured femur without any free haemorrhage occurring. Grant, in his observations on wound shock in the Italian campaign published in 1951 in the Medical Research Council Special Report Series, No. 277, has pointed out that the amount of blood and plasma lost into the damaged tissues in extensive muscle injuries is far greater than had been previously realized, and that the loss continues and is responsible for a relapse into clinical shock after resuscitation. The view that shock leads to endothelial damage, with loss of fluid into tissue spaces throughout the body and concentration of corpuscles in the peripheral capillaries, is no longer held.

Assessment of the Shocked Patient

A man suffering from shock looks ill. His attitude is apathetic, but he is mentally alert and answers questions readily. His skin is cold, moist, and pale, with a greyish colour, particularly about the ears and lips. His hands and feet are icy cold. His eyes, with pupils dilated, appear abnormally bright. His respirations are little altered. The pulse is rapid and of low tension. He passes little urine, and is prone to vomit any fluids given by mouth. Air-hunger and spontaneous vomiting are indications of severe shock.

An index to the presence and degree of shock, but not an entirely reliable one, is the blood pressure. While the fall in systolic pressure is usually commensurate with the loss of blood volume and the degree of shock, there are surprising exceptions. Some men show a low blood pressure rising subsequently, some show periodic rises and falls, and some maintain a high pressure till just before the end. A low pulse pressure is often of more significance than a low systolic pressure.

The whole clinical picture of shock can usually be accounted for by the loss of circulating fluid alone. The degree of shock is roughly proportional to the loss of fluid: a loss of 2 pints (1 litre) leads to moderate shock, one of 3 pints (1.5 litres) to severe shock, one of 4 pints (2 litres) (roughly 40% of the blood volume) to profound shock. A known loss of 4 pints (2 litres), even though the patient may, by supremely efficient compensation, be able temporarily to keep his blood pressure up, will eventually lead to profound shock, and, conversely, profound shock means that at least 4 pints (2 litres) have been lost and must be replaced.

Restoration of the Circulation

The treatment of oligæmic shock is the restoration of the circulating volume to its former level. If possible, the volume should be restored qualitatively as well as quantitatively—that is, lost blood should be replaced with blood, and plasma with plasma—but the immediate need is for volume, and the fluid must usually be introduced directly into the circulation. Water by mouth or by rectum or crystalloid fluids intravenously are of little value when the circulatory loss has been large enough to give rise to clinically recognizable shock; under such conditions water is poorly absorbed in the alimentary canal and poorly retained in the circulatory system.

The restoration of volume should be early and rapid. While a patient is in a state of shock, all his tissues are

poorly supplied with oxygen; organs such as the kidneys and liver are by-passed to conserve blood for the heart and brain and may suffer permanent damage, and bacteria in his wounds, particularly the anaerobes, are given a chance to establish themselves. When a total of 4 pints (2 litres) or more is needed, the first two should be run in rapidly, using pressure to assist gravity, and full restoration in four hours should be aimed at.

The choice between blood and plasma depends to some extent on the availability of the two. Plasma can always be obtained, blood only when donors have been prepared, and blood in quantity only when arrangements have been made to supply it. Plasma is free from the dangers of reaction due to incompatibility, infection, or mechanical destruction of the red cells which are present with blood, but may transmit the virus of hepatitis. It is better than blood for the shock of burns, indeed for all shock characterized by haemoconcentration. In haemorrhage it is as good as blood for restoring volume, and not greatly inferior in therapeutic results when the blood loss has been moderate. It flows more easily, so that even in transfusion for severe haemorrhage it has been advised that plasma should be used for the first 2 pints (1 litre), which are given rapidly. Blood should be used to replace a haemorrhage of more than 2 pints (1 litre), and when the haemorrhage is not merely severe but is expected to continue during resuscitation or operation, blood alone should be used. Plasma cannot bring a man who has lost more than 2 pints (1 litre) of blood into a state fit to withstand a severe operation, or enable him to overcome infection or to repulse anaerobes.

"Plasma-savers" are solutions containing large molecules—of gum acacia, a polyvinyl compound, or a polysaccharide—that remain in the circulation and can replace in volume and viscosity an equal amount of blood. What is their place in the treatment of shock? The answer is in the seventh chapter of St. Matthew's Gospel: "What man is there of you, whom if his son ask bread, will he give him a stone?" The plasma-savers provide volume and viscosity and can restore the blood pressure, but they do not carry oxygen, and they do not provide energy or any substance used by the body. On the other hand, they tend to clump the red cells, thus interfering with grouping, and they are finally fixed by the reticulo-endothelial system. By restoring the blood pressure before the cause of hypotension has been arrested, they may restart a haemorrhage that has stopped and wash out the life fluid with a fake substitute.

There is one legitimate place for the plasma-savers: to keep a patient alive in a desperate emergency till blood or plasma can be obtained. If a man has lost 5 pints (2.5 litres) of blood rapidly, or if his systolic pressure has dropped to 50 mm., his central nervous system and his kidneys will suffer irreparable damage and his acid-base equilibrium will be upset beyond recovery unless the pressure can be raised within half an hour. Plasma-savers must be given till blood arrives, for desperate situations demand desperate remedies.

I hold that every surgeon who is called upon to treat acute injuries in healthy men should act upon the belief that no haemorrhage need be fatal if it can be stopped and the lost blood can be replaced early enough and fast enough, and no shock need become irreversible if it can be reversed in time and with sufficient energy. Shock becomes irreversible chiefly because prolonged anoxia has been allowed to wreck the machinery of recovery. Many more lives are lost by tardy, hesitant, or inadequate transfusion than by excessive transfusion or transfusion for the wrong indications.

Ancillary Measures

I must touch briefly on some of the other measures used in the treatment of shock. Warmth may be beneficial in primary shock, but in secondary shock it is harmful. Experimentally shocked animals are more likely to die in a warm room than in a cold one. The cold skin of shock is an index of a peripheral vasoconstriction the purpose of which is to reduce the volume of the vascular bed and to maintain

the arterial pressure, and a drop in body temperature is beneficial in reducing the general metabolism to a level more adapted to the reduced oxygen-carrying capacity of the blood. The "shock-cradle" can be a shock producer. Patients expend their ebbing strength in trying to throw it off, and in this demonstrate that the physiological call of instinct is wiser than the teaching of the textbooks.

Morphine must be used with great caution. No more than $\frac{1}{4}$ gr. (16 mg.) should be given at a time, and it should be given into a vein, since in a state of shock it is absorbed slowly from the subcutaneous tissues. A second and larger subcutaneous dose is apt to be given if the first fails, and when later the circulation is restored the accumulated amount is absorbed and may produce a profound stupor.

The use of pressor drugs, including the adrenal preparations, is unwise. They may do good in primary shock accompanied by vasodilatation, but here they are unnecessary. In oligæmic shock, which is associated with vasoconstriction, the real need is for an increased supply of blood and oxygen to the tissues rather than for a raised systolic pressure, and further vasoconstriction may therefore do more harm than good.

When Normal Services Fail

The treatment I have discussed demands, not necessarily hospital conditions, but at any rate facilities for careful examination and constant supervision, the provision of shelter and bed-clothing, and a supply of the necessary fluids, drugs, and apparatus.

Should a casualty be moved to hospital before shock has been combated? A man in profound shock can easily be killed by a rough journey, particularly if his fractures are not adequately splinted. But part of the shock seen immediately after an accident is nervous in origin, and the patient will recover considerably after a short period of rest during which he is kept warm, reassured, and given fluids. The apparatus for intravenous fluid replacement is seldom available at the scene of an accident, but it may arrive with the ambulance. Should blood or dextran be given before the casualty is loaded for the journey? The answer depends on the state of the patient, the nature of the injury, and the length and quality of the coming journey. When in doubt it is better not to transfuse, for transfusion without control of the blood loss is apt to increase that loss, particularly if it raises the blood pressure above shock level during a bumpy trip. However, if the bleeding can be controlled by ligature or tourniquet, it may be wise to start transfusion before the man is put into the ambulance, and to send him off, with the transfusion running, as soon as a palpable pulse has returned.

What should be done in a major disaster when normal services are absent, inadequate, or disrupted? Three things that can be given to all are reassurance, warmth, and fluids. Reassurance alone will restore most cases of primary shock and benefit all. No one can dispense it better than the doctor, who by his quiet confident actions can do most to assure the victims that the crisis is over and the situation is in hand. Warmth and fluids must be dispensed with more caution, but here, fortunately, the customer is always right. The man who feels cold needs blankets. The man who is cold and does not feel it is better left uncovered. With water, also, personal desires can usually be trusted: the man who asks for a drink can usually be given one, the man who does not want water or vomits when it is given him should be left alone or given fluids another way. Pain must be allayed if the means are available, and morphine, given intravenously, is the best analgesic in shock. The administration of blood plasma and dextran will depend on whether these fluids are available; they cannot be improvised on the spot.

We must always remember that even the most severe shock is not necessarily fatal. Men have recovered after lying out all night on an icy battlefield who might have died had they been found earlier and subjected to the additional trauma of movement. The one thing that must

be remembered is that a shocked man will not stand an anaesthetic or an operation, and if the means of treating shock actively are not available he will stand a better chance if nothing is done to his injuries beyond splinting fractures, stopping haemorrhage, dressing his wounds, and keeping infection at bay by the administration of sulphonamides at regular intervals, than if he is subjected to surgical excision of wounds and mechanical cleansing of burns while still in a state of shock.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 18s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

BACTERIAL GENETICS

[FROM A SPECIAL CORRESPONDENT]

An informal meeting on bacterial genetics was held at the London School of Hygiene and Tropical Medicine from December 14 to 17, 1954. The intention was to provide reviews of the main topics in terms comprehensible to those not well acquainted with the subject, and for the most part the speakers succeeded reasonably well.

Experimental Production of New Strains

The first day was devoted to some of the methods by which two bacterial strains can interact to produce a new "hybrid" strain. In the pneumococcus, the influenza bacillus (*Haem. influenzae*), and the meningococcus, cells treated with deoxyribonucleic acid (D.N.A.) extracted from some other strain of the same species may acquire some heritable character from that strain. Many different traits can be transferred in this way; and it has recently been discovered that some pairs of traits are linked—that is, that absorption of a single particle of D.N.A. by a bacterium may confer on it two distinct new hereditary properties. These facts make it at least very probable that D.N.A. constitutes the genetic apparatus of the bacteria concerned, and that single macromolecules of D.N.A. contain differentiated regions regulating different bacterial characters—that is, different genes. The latest development in this field was reported from the Biophysics Research Unit at King's College, London. By chromatography on a column of histone adsorbed on kieselguhr it has been possible to divide D.N.A. from streptomycin-resistant pneumococci into a series of fractions which differ not only in their chemical composition (ratio of bases) but also in their ability to transform streptomycin-sensitive pneumococci into resistant ones. It remains to be seen whether the ability to effect different transformations will be found concentrated in a single fraction or distributed amongst different ones. In the latter case the isolation and chemical characterization of a specific gene may not be quite so remote a possibility as it has hitherto seemed.

The recently discovered phenomenon of transduction of characters from one salmonella strain to cells of another by treatment with a cell-free filtrate of a lysed culture now appears in essence similar to the D.N.A.-mediated transformations; the main difference being that in salmonella the genetic material requires a phage particle to carry it across from the lysed cells to the cells of the recipient strain. The chemical nature of this phage-transported salmonella

genetic material is unknown, but it seems likely that it also is D.N.A., present as contaminant material within the shell of the phage particle, and protected by its situation from deoxyribonuclease, which inactivates free D.N.A., but not the transducing activity of phage-lysed salmonella cultures.

Mating

Genetic recombination in *Bact. coli* K12 was reviewed by Dr. W. HAYES, of the Postgraduate Medical School of London. In this organism pairs of strains can be crossed, but only if the cells of the two strains are allowed to come into direct contact. In this respect the process resembles sexuality in higher organisms, but many anomalies await explanation. In particular, most of the recombinants derive the great majority of their characters from but one of the two parent strains—that is, from the strain described as *F*—, since it lacks the "fertility factor," *F*, which must be present in at least one parent strain if a crossing is to be fertile. The *F* factor may be a phage-like particle which carries across a variable amount of bacterial genetic material from an *F*+ cell to an *F*— cell with which it has fused, or it may be an "elimination locus" on the bacterial linkage group which commonly causes loss of a segment of this group after formation of a normal zygote. Dr. J. L. JINKS, of the University of Birmingham, presented a new analysis, based on the latter hypothesis, which, he stated, provides a satisfactory explanation both for his own recombination data and for all earlier data published by others. Fuller details of this work will be awaited with interest. The nature of the *F* agent is one of the most interesting problems in bacterial genetics. One of its more surprising properties is that *F*— cells readily acquire the *F*+ character if grown in mixed culture with *F*+ cells, but that they cannot be made *F*+ by treatment with any cell-free extract of *F*+ cells. If the *F* agent is indeed a particle transmissible by infection, it seems that direct cell contact is required for infection to occur.

Bact. coli K12 continues to provide surprises for the bacterial geneticist. It has been known for some time that many, but not all, sub-lines of this strain are lysogenic for a phage called λ , and that active growth of the latent phage, and lysis of the cell, can be induced by ultra-violet irradiation. Recent work in Paris shows that, when a lysogenic strain carrying the *F* factor (or its variant form called *Hfr*.) is mixed with a non-lysogenic *F*— strain, many cells lyse and liberate phage λ , and it has been proved that this results not from infection of non-lysogenic cells by free phage but from transfer of latent phage or pro-phage into sensitive cells by cell fusion (or adhesion). In matings of this kind it seems that many or most of the pairs of mating cells, and so of the potential recombinants also, are lost through this "erotic induction" of the active growth of latent phage. In other work on K12, the inheritance of lysogenicity has been studied, using precautions to avoid induction of phage activity. The property of lysogenicity behaves as though it resided at a particular locus in the bacterial linkage group, and there now seems little reason to doubt that the genetic material of the carried phage is in fact attached to, or incorporated in, the linkage group of the host at this locus, and that the pro-phage or latent phage is indeed "a parasite at the genetic level."

From the discussion on the genetics of bacteriophage it appeared that it has been established that phage particles contain a series of mutable genes which are arranged in one or more linear linkage groups, as in higher organisms, and that after infection of a cell by more than one particle of differing genotype recombination may occur. A model based on the hypothesis that recombination results from a series of matings of pairs of particles, with mutual exchange of genes, so as to produce two recombinants per mating, accounts satisfactorily for the experimental data. But another model proposes that a single recombinant arises as a result of replication in part of one "parent" particle and in part of another, so that a pairing produces one recombinant only, not two of complementary composition, and

this model also is said to be satisfactory. It seems that the bacterial cell conceals unexpectedly well the essential nature of the sexual or parasexual process in bacteriophage.

Bacterial Adaptation

One session was devoted to a discussion of bacterial adaptation. Sir CYRIL HINSHELWOOD, F.R.S., gave a brief exposition of his well-known theory which provides a satisfactory explanation for the inheritance of acquired characters in bacteria. It now appears that in this controversial field all parties are agreed that some spontaneous mutations occur, and that some adaptive changes are specifically induced by the environment. The one disagreement is on the interpretation of the experiments which purport to show that specifically induced adaptive changes are inherited in the absence of the stimulus which provoked them.

Virulence

In a session on the applications of bacterial genetics much attention was devoted to the virulence of bacterial pathogens. Dr. T. W. BURROWS, of Porton, discussed some of the characters required by an organism to make it a successful disease-producer. One such character is the ability to grow in an environment of the chemical composition of the tissue fluids of the host, and he has shown that this character may be successfully investigated at the genetic level. In a strain of *Salmonella typhi* most nutritionally exacting mutants were of about the same mouse-virulence as the parent strain, but mutants needing to be supplied with purines to enable them to grow were almost or entirely avirulent; and it appears that this is because the peritoneal fluid of the mouse does not contain enough purines for the needs of the mutant bacterium. Administration of purines to the host enables the bacteria to multiply and kill it, and loss of the exacting character by back-mutation restores the original virulence. This constitutes a new instance of the loss (and regain) of virulence as a result of alteration of a single gene regulating a character indispensable for virulence. It is noteworthy that the first instance of bacterial hybridization—that is, the type-transformation of pneumococci discovered by Griffith in 1928—was detected by study of another such character, encapsulation. Dr. D. ROWLEY, of the Wright-Fleming Institute, presented new data on the mechanism of the differing virulence for mice of two strains of *Bact. coli* of the same serological type. His experiments indicate that the difference in virulence results from the susceptibility of one strain, and the resistance of the other, to the bactericidal action of complement and properdin, in the absence of specific antibody. The genetic basis of this difference remains to be discovered.

Dr. L. F. HEWITT described work on the conversion of non-toxicogenic diphtheria strains to toxigenicity by treatment with certain phages. So far as can be judged at present, it seems that the process involved is neither genetic transfer nor the selection of spontaneous mutants, but a specific effect of lysogenization with certain phages on the metabolism of the host. This is the only known instance of such a consequence of the lysogenic state, and its mechanism is unexplained.

Population Studies

The population genetics of bacteria was briefly reviewed by Dr. P. ARMITAGE. In this field theoretical analysis has now provided adequate explanations for much that has been observed on bacterial cultures growing *in vitro*; the more difficult problems of changes in virulence of bacterial pathogens under natural conditions, and of the forces tending to maintain the constancy of bacterial characters in the wild, remain as yet little studied. Their importance for medicine is emphasized by, for instance, the increasing proportion of antibiotic-resistant strains in some bacterial species harboured by certain human populations.

In closing the meeting, Professor J. B. S. HALDANE, F.R.S., envied the microbiologists the rapidity with which they could obtain results in genetic experiments, and drew attention

to various parallel problems in the genetics of micro-organisms and of larger plants and animals. He contrasted the variety of mechanisms by which recombination of hereditary characters could occur in bacteria with the almost exclusive reliance of the metazoans on sexuality. He congratulated the microbiologists on their grasp of "classical" genetics, but regretted the absence of a control world in which the discoveries of microbial genetics would have had to be interpreted without preconceived notions; for this, he felt, might have produced useful new ideas. To the writer, however, it seems that until recent years most bacteriologists did indeed interpret their results in just such ignorance of the genetics of sexual organisms, and that the process was on the whole a very barren one.

SOCIAL PROBLEMS OF THE YOUNG DISABLED

A study of a cross-section of disabled persons aged 15-45 is the subject of a report to the Leverhulme Research Awards and the South-east Metropolitan Regional Hospital Board by Mrs. M. U. SHARP, a member of the Association of General and Family Case-workers. Thanks to the co-operation of the Kent County Council, certain voluntary societies, the National Assistance Board, and the Ministries of Pensions and of Labour, Mrs. Sharp has been able to get in touch with over 400 disabled persons in Kent, a few of them long-stay patients in hospital, but by far the greater number at home or in some institution. They were suffering from various incapacitating diseases—most of them from anterior poliomyelitis and polioencephalitis, spastic diplegia, disseminated sclerosis, and rheumatoid arthritis.

Mrs. Sharp was impressed by the need for grouping the younger patients together in small special units. Of the 354 persons in their own homes or in institutional care, about 210 were so severely handicapped as to make life a major problem for them. She found in the homes of many of these disabled persons a tendency for relatives to be too protective—an attitude responsible in some cases for preventing young people from going away for training or employment. She also makes the useful suggestion that certain gadgets which make life easier for such persons in dressing, toilet, and feeding should be supplied under the National Health Service. Such gadgets lighten the task both of the relatives and of the disabled person himself to a surprising degree, and the National Association for the Paralysed has published a useful handbook on them. But unless the patient is in a hospital which has a physical medicine department it is very difficult for him to obtain the requisite gadgets. They might well be scheduled appliances. Loneliness and idleness are the bane of the handicapped. Mrs. Sharp in her survey of the 400 persons found about 30 who needed some diversional occupation but could not make saleable products, and about 60 who could do really good handiwork but lacked a suitable market. She states that the home workers' scheme of Remploy Limited requires for home work that the disabled should work at least 30 to 35 hours a week, have two good hands and good eyes, and be prepared when trained to come off their benefits. Many people covered by her survey were incapable of sustained effort for so long, and were not prepared to risk the loss of an assured source of income.

One of several recommendations which she makes is that section 29 of the National Assistance Act, concerning welfare services for handicapped persons other than the blind and partially sighted, should be made obligatory on local authorities rather than permissive; and that welfare committees, in conjunction with county education committees, should pay special attention to the future needs of children still at school who will require institutional care, and should arrange an aftercare service for those who are considered unsuitable for either training or employment on returning to their homes.

Correspondence

Low Backache

SIR.—Dr. L. S. Calvert (*Journal*, December 18, 1954, p. 1488) makes a plea for the enlargement of departments of physical medicine to treat chronic backache. His letter suggests that orthopaedic surgeons are failing in their responsibility for dealing with backache, and that, moreover, they are tending to a dog-in-the-manger attitude. There must be many, doctors and patients alike, who share Dr. Calvert's concern, and it seems necessary that steps should be taken to attempt to teach the public "the facts about backache" so that they may know what they are entitled to expect, or not to expect, from an enlightened, humane, and sympathetic Health Service.

If the taxpayer is to foot the bill for the treatment of the backaches of his fellow citizens, he is surely justified in expecting the medical profession to be unanimous on the following three points: (1) that in the majority of cases there is a significant organic cause; (2) that the rationale of treatment is scientifically sound; and (3) that the results of treatment are worth the financial outlay, either in terms of crude economics or as a gift to human happiness. The experience of orthopaedic surgeons, with all the technique of physical medicine at their disposal, as well as many others not available to physiotherapists, suggests that these three criteria are satisfied only in a minority of cases. It is to the credit of orthopaedic surgery that it does not pamper every ache and pain in the community which the setting up of increased facilities for physical medicine undoubtedly would encourage.

The orthopaedic surgeon faces the backaching multitudes with five principal ideas in mind: (1) to make a diagnosis and, as far as possible, to exclude early and serious diseases masquerading as "low back pain"; (2) to attempt, again as far as possible, a rough assessment of the proportion of organic and functional elements in the pain; (3) for the vast majority, to reassure without treatment; (4) to treat by physical medicine, corset or plaster jacket, a selected small proportion; and (5) to operate (spinal fusion) in the hand-picked residue.

It is the problem of reassurance which is the most important yet the least satisfactory, both to surgeon and patient. In the first place, one can only reassure an intelligent, decent, and sensible patient. Most of the patients to whom these adjectives can be applied have already been reassured by the first two doctors they have seen—that is, the general practitioner and the first health service consultant on the "periphery." This means that the teaching hospitals, as final courts of appeal, accumulate an astonishing number of patients of a type impossible to reassure, and yet who have already received one or more complete courses of physical treatment at their local hospitals.

In the second place, the process of attempting to reassure a patient by sympathetic explanation is extremely exhausting for a conscientious consultant when he knows he is talking to a "brick wall." It takes a much longer time, and satisfies this type of patient less, than to send them off for a six weeks' course of quackery in the 30 seconds it takes to sign a chit. Unlike the bottle of coloured water, the cost to the State of placebo physiotherapy is fantastic. Many of these patients have the impertinence to say that "nothing has been done" for them after x-ray examinations (often in two or three hospitals), interviews with several consultants, and the fitting of a corset, when to get the same service over the same period of time in private practice would easily add up to £50.

If orthopaedic surgeons were to relax their strict grip on *ad lib.* physiotherapy, within as short a time as three years the backache problem would become totally unmanageable. Physical medicine can never cure low backache, and if pampered the first time the majority of these patients will be back again with another attack of chronic lumbago a year or so later. If given physical medicine the first time, it becomes humanly impossible to deny a second course if the patient is convinced, *post hoc propter hoc*, that the first course "cured" her. There is hope that in the near future pain arising in "collagen degeneration" may be brought

under control, which research is common ground for rheumatology, physical medicine, and orthopaedic surgery. Until this happy day dawns I believe that the majority of orthopaedic surgeons show a very highly developed sense of perspective in regard to pain and the public purse.—I am, etc.,

Manchester, 3.

JOHN CHARNLEY.

Anaemia of Newborn Following Anterior Placenta Praevia

SIR,—We were interested to read the article on this subject by Drs. N. R. Butler and J. D. Martin (*Journal*, December 18, 1954, p. 1455). They have performed a useful service in drawing attention again to the risk of blood loss from the foetal circulation if the placenta is damaged during caesarean section—although their title hardly does justice to the urgency of the post-haemorrhagic shock which may occur in the affected babies. Your annotation (p. 1472) refers to our study of the same problem, reported elsewhere,¹ and rightly emphasizes the preventive aspect. We should like to report our further experience of this aspect.

During the period covered by our study the placenta had been encountered in the uterine incision on 20 occasions: 7 of the babies had lost sufficient blood to require a transfusion, and one of them actually died at the age of 3½ hours from post-haemorrhagic shock. During the subsequent 20 months meticulous attention has been paid to the details of the delivery in all cases of this type, and the technique used has been that described in our earlier report and in your annotation. There have been 15 cases in which the placenta was encountered: none of the babies has required a blood transfusion, and in only 8 babies has it been considered necessary to carry out serial skin-prick haemoglobin estimations, after our preliminary assessment based on the relevant factors noted at the time of delivery. This experience confirms that the obstetrician can almost eliminate the hazard of foetal post-haemorrhagic shock in cases of anterior placenta praevia by using the recommended method of delivery.

But the hazard can never be completely eliminated, as illustrated by case 6 in our previous report, and we fully agree with Drs. Butler and Martin in their recommendation that appropriate arrangements should be made for dealing with such an emergency whenever caesarean section is performed in a case of placenta praevia. We are, however, surprised by their reliance on the haemoglobin level in the cord blood as an indication of the amount of blood lost. We have been astonished by the speed with which haemodilution does in fact occur in some of these babies, as judged by the fall in the haemoglobin concentration in skin-prick blood during the first few hours of life, but it seems a little much to expect a significant fall immediately, or at the most within a few minutes of the haemorrhage, particularly if the estimations are made by a method whose margin of error is as great as that of the Haldane technique. It seems wiser to make an estimation as soon as possible after delivery and regard this as a base-line; subsequent serial estimations can then give an idea of the rate of haemodilution. We have found skin-prick blood satisfactory for this purpose if the foot is well warmed and a deep "prick" is made with a scalpel blade, and the M.R.C. "grey-wedge" photometer is used for making the estimations.—We are, etc.,

Pure Red-cell Anaemia

SIR,—May I be allowed to make the following remarks on the interesting article of Drs. J. N. Marshall Chalmers and K. Boheimer (*Journal*, December 25, 1954, p. 1514)? The now popular name "pure red-cell anaemia" comprises several, at least three, different morbid entities. The disorder which I described in 1927¹ as erythrophthisis, and in 1952² as erythronophthisis, is acute or subacute, fatal or self-limited, non-haemolytic, and does not respond to any

known treatment except blood transfusions. It is identical with one example of "aplastic anaemia" described previously by Kaznelson.³ The second disorder, which Cathie⁴ aptly calls erythrogenesis imperfecta and which was previously known as the Blackfan-Diamond type of hypoplastic anaemia, is congenital, has often in the early stages signs of increased haemolysis, shows some improvement with A.C.T.H. therapy and sometimes spontaneous amelioration after years of duration. A disturbance of tryptophan metabolism with excretion of anthranilic acid in the urine has been claimed, but this I could not confirm in one examined case. The third disorder is that described by Chalmers and Boheimer. The association of two such rare diseases as thymic tumour and pure red-cell anaemia is certainly not fortuitous. While the two other forms of pure red-cell anaemia occur only or mainly in children, this form seems to occur in adults only. It is of interest that the association of myasthenia gravis with thymic neoplasms (lympho-epithelioma), which is not uncommon in adults, has also not been observed in childhood. This form of anaemia may show recovery or remission after thymectomy, splenectomy, and A.C.T.H. therapy, or it may progress to typical aplastic anaemia, as in the case observed by Dr. Brewer.⁵ Finally, we have to bear in mind that an aregenerative anaemia involving only the red blood corpuscles may occasionally develop as the result of Rh iso-immunization. This I observed in a pair of twins, who, in addition to signs of increased haemolysis, such as hyperbilirubinaemia without bilirubinuria and increased amounts of faecal pigments, had very low reticulocyte counts and a decreased number of nucleated red cells in the marrow. The nucleated red cells are very scanty or absent in the bone marrow in all above-mentioned disorders, and such as seen are of the most mature type. Only in the first weeks of life in erythrogenesis imperfecta normoblasts may be slightly increased in number.—I am, etc.,

Tuberculous Patients in General Hospitals

SIR,—I wish to give my wholehearted support to the call of Dr. Arnold B. Cowan (*Journal*, November 20, p. 1227) for the medical profession to rise as a body against allowing patients suffering from pulmonary tuberculosis to be admitted into the wards of general hospitals. Until a few years ago we built sanatoria specially designed for the treatment of tuberculosis on what was regarded as the most healthful site, on the sound and established knowledge of the disease, and no patient with tuberculosis was allowed to be admitted into the wards of general hospitals, and if during treatment for any other condition any patient was found to have developed pulmonary tuberculosis he was immediately sent out. There was good reason for this. The general hospitals were not constructed to treat tuberculosis with safest and best methods, and student nurses are at the most susceptible age to contract tuberculosis. The exacting nature of their closed institution work for the sick, the strains to which they are subjected on duty, and the ever-increasing diminution of their leisure and rest brought about by the need for preparation for examinations constantly elaborated by the ever-increasing demands of the specialists, render them highly sensitive to tuberculosis. The Prophit Tuberculosis Survey¹ showed instances of nurses who had contracted the disease and had been kept on duty in spite of clinical and radiographic evidence of progressive disease—indeed, until, on leave, the parents detected the obvious decline.

We are short of nurses, more particularly in tuberculosis and mental institutions. The authorities have offered increased salaries and other inducements; they have repeatedly announced their needs in the public press, and have used all the methods of inducement which propaganda

offers, but the girls will not respond. The explanation is obvious to every unbiased layman. Therefore these demands for enforced labour in these institutions during the training will obviously result in less girls taking up nursing. Why should girls seek posts demanding self-sacrifice and self-denial when there are plenty of posts which have conditions which permit the commendable self-indulgence of the Welfare State?

It has been abundantly shown that improvements in housing and standard of living are far more important than quantity of medical care. Due to the former, the death rate from tuberculosis has been steadily and consistently falling from 80,000 to 8,000. There is no better place to treat tuberculosis than the home, and no one better fitted than the general practitioner to supervise it, particularly now that he ought to have available the effective drugs. Make the homes of the people fit for the general practitioner to treat the case at home and you will not only abolish the disease but lessen the enforcing factors which prevent girls becoming nurses.—I am, etc.,

Birmingham, 15.

Premedication of Children for Tonsillectomy

SIR,—I am particularly interested in the correspondence following Dr. Christine M. Rendell's article (*Journal*, December 11, 1954, p. 1397) on the use of methylpentynol for premedication in children, as I myself have for some time been working on the same subject. I would suggest that the only satisfactory way of assessing a child's reactions to the experience of tonsillectomy is for a trained and independent observer to visit the child in its own home before and after its stay in hospital. It is obviously quite unreliable to ask the child while still in strange surroundings. The other way of recording a child's reactions is by means of a cinematograph record, such as was done by Robertson, of the Tavistock Clinic, in his film, "A Two-year-old Goes to Hospital." Both these methods have been carried out by me and are at present under preparation for publication.

I have been convinced that the elixir of "oblivion" as put up by Schering is of very great value for children. Admittedly no medicine will replace careful and tactful handling, but, having for years used atropine only as advocated by your correspondents, I have been very impressed by the ease of handling and induction since I have used oblivion. This shows very well in my film record. The incidence of vomiting I frankly do not understand. I have not met a single incident in about 500 cases. The oblivion should be given one hour before induction and followed by the atropine half an hour later. The child does not then mind this insult to its feelings. To those cases which arrive in the induction room still not fully sedated I then give a small "sleep dose" of intravenous thiopentone, quite a safe and easy procedure in a quiet and peaceful child, and not followed by any unsafe respiratory depression. But I hope your correspondents will see my film when it is ready. This will be more convincing than any letter.—I am, etc.,

Worthing.

F. R. GUSTERSON.

Mobile Physiotherapy Unit

SIR—Dr. G. A. Powell-Tuck's letter (*Journal*, December 11, 1954, p. 1422) rightly stresses the value of physiotherapy in the home. There is no doubt that many who need treatment are denied it because they cannot afford to pay private fees and cannot face the travelling and waiting involved in attending busy hospital departments.

A mobile physiotherapy unit was started 11 years ago to help these people, and the service is now available in about 20 areas. It could usefully be multiplied many times, but is restricted by lack of money. There is, I believe, only one unit financed by a local authority. The majority rely upon voluntary public subscriptions, contributory schemes, and help from existing charities. Where the need exists and

enthusiasm can be aroused, advice upon starting a unit is to be had from the Mobile Physiotherapy Services Association of 12, South Audley Street, London, W.1.—I am, etc.,

Redhill.

HENRY S. ATKINSON.

Chairman,
East Surrey Mobile Physiotherapy Unit

Intussusception in the Newborn

SIR,—I have read the article by Mr. Stewart Feggetter (*Journal*, December 4, 1954, p. 1335) about a case of intussusception in a newborn baby. Recently I have sent an article to a Spanish medical review in which I refer to a case operated on by me of a strangulated inguinal hernia in a 15-day-old baby. Like Mr. Feggetter's case, my patient had melaena and I suspected an intussusception. After a complete examination the diagnosis of strangulated inguinal hernia was clear. The operation was done with good results, and I think it worth emphasizing—in agreement with Mr. Feggetter—that the operative shock in the newborn is frequently well tolerated. I agree with the author that nurses experienced in this type of work are very important. In my case I had aiding me an English nurse who specialized in babies' cases, and her work was perfect.—I am, etc.,

Rio Tinto, Spain.

T. DE VEGA RUIZ.

Fatal Rupture of Retro-pharyngo-oesophageal Abscess

SIR,—In reference to the report (*Journal*, December 25, 1954, p. 1530) of a previously healthy girl, aged 10, dying as the result of fatal rupture of a retro-pharyngo-oesophageal abscess, is it not possible that if no antibiotics had been given the natural resistance of the girl would have localized the infection, an abscess would have been discernible, incised, and recovery taken place? In a report of an address given by Sir Heneage Ogilvie entitled "The Future of Surgery" (*Journal*, December 18, p. 1435) he gives a profound warning in reference to the dangers of the indiscriminate use of the antibiotics.

Is it not significant that no record of a case resembling the one reported could be found?—I am, etc.,

Hurstpierpoint.

KENNETH EDRED PEMBREY.

Carcinogens in Cigarette Smoke

SIR.—Professor R. D. Passey (*Journal*, December 18, 1954, p. 1485) states that it is striking that "the increase of cigarette smoking has not been matched by increase in the incidence of carcinoma of lip, tongue, larynx, or buccal cavity," and that "a reduction in these sites, which, of course, are those exposed to the greatest concentration of smoke," is strange. At least three factors are concerned in carcinogenesis—namely, the concentration of particles in intimate contact with the surface concerned, the period of the latter's exposure, and its sensitivity to the particular carcinogen. Thus the mule-spinner develops scrotal carcinoma due to the prolonged contact of his oil-soaked garments on a particularly sensitive epithelial surface, and the process of carcinogenesis due to aromatic amines in bladder carcinoma takes some 15 to 20 years to develop.¹ I would suggest that these factors in carcinogenesis are more marked in the respiratory tract distal to the trachea than in the other sites described.

Concentration.—Smoke taken into the mouth is admittedly present in considerable concentration in the air, but, as it is mostly expelled at the next expiration, relatively few particles pass into the fluid lining the buccal cavity. In the respiratory tract, particularly in those inhaling deeply, it will be less rapidly cleared, and particles will tend to be retained, and reach high concentration in the mucus layer lining the tract. **Sensitivity.**—The effect of cigarette smoke on the bristling eyebrows of men and the hair-covered skins of mice, which have the function of protection as their main office, is in no way comparable to the effect of that smoke on the sensitive, delicate "naked" respiratory mucosa. Further, the specific sensitivity of two mucosae, say buccal and bronchial, to a given carcinogen could well vary, particularly when histological differences are taken into account. **Period of Exposure.**—Normally, the particle-collecting respiratory

mucus layer is passed by ciliary action, or coughing, to the larynx and thence to the pharynx to be swallowed. A heavy smoker will tend to chronic bronchitis, and, although the frequent coughing will tend to clear the trachea and proximal parts of the main bronchi, reducing their exposure time, the deleterious effects on the mucus-propelling ciliary action will result in a raised active exposure time. The cilia, further, are more abundant in the smaller bronchioles than in the larger ones and the bronchi, and predilection of carcinoma for the latter may well be due to the relative stasis of the carcinogen-bearing mucus layer at these sites.

Relative to these factors, the rapid passage to the pharynx of the particles passing into the profusely secreted and frequently swallowed buccal fluids leaves little opportunity for prolonged or concentrated buccal carcinogenic activity. There is probably some hold-up of these buccal and the returned respiratory carcinogenic particles at the crico-pharyngeal sphincter between the pharynx and oesophagus (the hypopharynx), and it is interesting to note that the incidence of carcinoma in this site has about doubled in the last decade.

Professor Passey's second point, that of the decrease of carcinoma at various sites, is not easily explained—the decrease being absolute, not relative. An awareness of the dangers of introducing carcinogens such as clay-pipes and tar-coated thread into the mouth is now widespread, and, with improvement in dental conservation and prosthetic treatment, the chronic irritations of the jagged tooth and ill-fitting dental plate have decreased. Further, and most important, with a considerable decrease of incidence of syphilis the occurrence of advanced syphilitic leucoplakia with its precancerous and malignant stages is now rare. These factors are not pertinent to the decrease in laryngeal carcinoma. This decrease, however, is not outstanding, the figures¹ for male incidence in the years 1943, 1947, 1951, and 1953 being 827, 769, 805, and 737. This may be explained by assuming that the respiratory tract is, in some unspecified way, varying sensitive to carcinogens; then individuals in the high sensitivity group are more likely to develop the bronchogenic carcinoma in the 45 to 50 age group, and leave fewer to succumb in the 55 to 65 laryngeal carcinoma group.—I am, etc.,

Manchester, 13.

Ultra-violet Light Therapy in Paget's Disease

SIR.—It does not appear to be generally known that some cases of painful Paget's disease of bone derive a measure of relief from ultra-violet light therapy and that it is worth a trial when other measures have failed. It appears desirable to produce mild erythema and pigmentation of the skin and to irradiate not less than one-third of the total skin area. These patients are usually elderly, and the precautions or contraindications proper to their general condition must be followed. I regret that I do not remember the source of my original information in about 1938 so that due credit might be given.—I am, etc.,

Watford.

H. RHYS DAVIES.

Operator and Anaesthetist

SIR.—May I reply to the letter of Mr. S. I. Freedman and his colleagues (*Journal*, December 11, 1954, p. 1416)? I have never said that thiopentone should not be used in the dental chair, only that the operator-anaesthetist might have difficulty in defending himself against a charge of negligence. Refinements of technique may make anaesthesia safer but cannot make it absolutely safe. We have to consider the law of averages. Sooner or later a complication such as laryngeal spasm or heart failure will occur, when I venture to predict that the complaints of the patient's surviving relations will be as nothing compared with the reproaches of the operator's conscience. What good purpose is served by taking useless risks?

The suggestion that the patient's doctor should be asked to certify that the patient is in a fit state of health for outpatient anaesthesia does not come from me but from a

learned judge. The circumstances of the case (which is quoted in the article I referred to¹) and our general experience show that the suggestion is not unreasonable and is in the patient's interest. Dental surgeons may disregard it if they choose, but only at their peril. I disagree with the writers' statement that contraindications to out-patient anaesthesia "are few and obvious," and also with the opinion expressed in the last sentence of their letter, which is contrary to general experience.—I am, etc.,

London, W.1.

Chlorpromazine

SIR.—There is a simple explanation for the occurrence of jaundice following prolonged oral administration of chlorpromazine, as reported by Dr. Bryan Eagles (*Journal*, January 1, p. 46). It has been shown¹ that chlorpromazine exerts a reversible depressant action on all forms of cellular life in a concentration of 1/400,000. Cells which possess a high degree of specialized activity, like the cells of the brain, are particularly susceptible to this action, which in part at least explains the drug's central action.

When given orally, the drug is presumably absorbed from the alimentary tract and passed into the general circulation by way of the liver, which is submitted to a relatively high concentration of the drug, before it is diluted by the general circulation. Next to those of the brain, the cells of the liver are as highly specialized and active as any in the body. It is not surprising, therefore, that after several weeks exposure to a dose of 75 mg. daily (approximately 1 mg. per kg. or 1/100,000 of gross body weight) signs of liver failure begin to appear. Even in these circumstances it is possible that some other factor depressing liver function must be present, for jaundice does not appear to be a common complication in psychiatric practice where high oral dosage over prolonged periods appears to be the rule. Nevertheless, it is a point worth bearing in mind, and the effects of continued high dosage on the livers of experimental animals needs further careful study.

In large single dosage the drug is relatively non-toxic. In one instance a patient made a complete recovery in three days after attempting suicide by taking 70 25-mg. tablets—a total dose of 1,750 mg.² This is more than can be claimed for barbiturates, prolonged oral administration of which in their early days was reported to cause serious liver damage and jaundice.—I am, etc.,

London, S.E.11.

Herpes Zoster Treated with Vitamin B₁₂

SIR.—In response to inquiries which have reached me from time to time about my letter (*Journal*, April 22, 1950, p. 959) on the use of vitamin B₁₂ in herpes zoster, may I request the courtesy of your columns for further comment? In that letter I described the extraordinarily rapid results I had obtained in the treatment of shingles by giving injections on the first, second, and fourth days respectively of 50 micrograms of B₁₂ each, and the avoidance in most cases of post-herpetic neuralgia. Treatment and dosage schedules were unavoidably in general practice, empirical.

A consulting dermatologist friend of mine was kind enough to inform me some time ago that he had been able to diagnose a severely ill child, admitted to hospital on account of meningism, as a case of herpes zoster involving the ninth cranial nerve and therefore presenting the typical eruption of shingles on the soft palate. He gave B₁₂, and to everyone's joy and satisfaction the child was well within four days. Other doctors have also taken the trouble to let me know of their experiences, and to them I wish to extend my sincere thanks. The general consensus of opinion would seem to be that this treatment is of great value. Since then I have tried variations in frequency and dosage

of the injections, but my impression is that the original schedule suits the majority of cases, and I was unable to observe any benefit from doubling the dose. Leitch¹ has recently treated cases by a single injection of 1,000 micrograms with very good results, and I am anxious to try this.

I have, however, supplemented the treatment of my more severe cases by oral administration of B₁₂, giving some 150 micrograms q.d.s., and this has undoubtedly speeded up resolution, and in one particular case of an old lady, who had a herpes zoster ophthalmicus but who "could not stand the needle," I followed her first and only injection with oral administration of the vitamin, and she was completely well within eight days. Lastly, in view of the known but aetiotogically uncertain connexion between herpes zoster and varicella, I have in the past two years been trying the effect of B₁₂ in chicken-pox, in doses ranging from 150 micrograms t.d.s. to 200 q.d.s., depending on age, and results have been most gratifying. The rash has usually cleared within a week, there has been very little or no general malaise, and my main difficulty has not infrequently been to convince the mother that the rapidly disappearing rash has indeed been that of chicken-pox.—I am, etc.,

West Bromwich.

K. E. JOLLES.

Footnote to History

SIR.—I was interested to read Dr. E. Ashworth Underwood's comment, in his review (*Journal*, January 1, p. 42) of Dr. William Brockbank's FitzPatrick Lectures, that neither he nor Dr. Brockbank had ever seen cupping performed with therapeutic intent. It fell to my lot to carry out both dry and wet cupping on several cases of nephritis when I was a house-physician in Glasgow in 1924. This fascinating, if archaic, manoeuvre took place in the Royal Infirmary, but I rather think Dr. Underwood was a student at the Western Infirmary, which had presumably outgrown these foolish things. As for Manchester, I imagine cupping was abandoned when the Infirmary moved from Piccadilly to Oxford Road. It is unlikely that the vessels survived the flitting.—I am, etc.,

Sheffield, 10.

W. A. RAMSAY.

Kaposi's Varicelliform Eruption

SIR.—The case reported by Dr. A. Fry (*Journal*, January 1, p. 28) appears to be wrongly named Kaposi's varicelliform eruption. Kaposi required the presence of eczema. An excellent paper written by Dr. G. I. Barrow (*Journal*, February 27, 1954, p. 482) covers practically all aspects of the subject. Reference to this paper, and indeed to many other papers, will reveal that Kaposi's varicelliform eruption arises on a basic eczema from infection by either herpes simplex virus or vaccinia. I suggest Dr. Fry's case is one of accidental vaccinia, the diagnosis suggested by the Home Office consultant who saw the patient.—I am, etc.,

Bradford, 8.

ALLAN BIGHAM.

SIR.—Even four swallows do not of necessity make a summer, and Dr. A. Fry's patient (*Journal*, January 1, p. 28) with four lesions of accidental vaccinia was not, as he reports, a case of Kaposi's varicelliform eruption. M. Kaposi¹ described his eruption as a very alarming complication of eczema larvale infantum. He realized that the lesions were not varicella though they resembled it. They tended to be clustered most thickly on the eczematous areas, but smaller groups appeared on the previously intact skin in the neighbourhood. He had never seen any lesions appear elsewhere. Kaposi suggested that eczema herpetiform would perhaps be the most appropriate term, and the condition is accepted to-day as being a generalized herpes simplex.

It is true that vaccinia in an eczematous individual may be as widespread as Kaposi's eruption. In fact, generalized vaccinia in such individuals is regarded by some as another form of Kaposi's eruption—in this case eczema vaccinatum. The requirements for a diagnosis of Kaposi's varicelliform

eruption are not, as Dr. Fry states, contact with a vaccinated person and the presence of vaccinia virus. They are an asthma-prurigo patient infected either with herpes simplex or with vaccinia virus.—I am, etc.,

London, W.1.

Still Going Strong

SIR.—I was interested in Sir Cuthbert Sprawson's letter (*Journal*, December 4, 1954, p. 1359) reporting the great age of Dr. Abdul Karim, who is still practising his profession at the age of 98. This is possibly a record. However, in Prince Edward Island, Canada, still practising at the ripe old age of 97, is Dr. Roderick MacDonald still driving his car, and out in all weathers. In Canada Dr. MacDonald is most famous, and I had the pleasure of meeting him at a Medical Society meeting in Charlottetown, Prince Edward Island, some years ago.

During the war I remember meeting in Bassingham, Lincolnshire, a physician (the father of a friend of mine) who was also practising to a very ripe old age—his name, Dr. Osborne Johnson. Dr. Johnson, besides being a physician highly thought of in the countryside around Bassingham, was also something of a poet and an artist. I remember enjoying one of his poems, "Bayard's Leap," written at that time. Dr. Johnson, I understand, refused to have a telephone installed in his home. He believed if the patients wanted him they would come and get him. Perhaps Dr. Johnson had a point! It will be interesting to know of any other nonagenarians or centenarians still in practice.—I am, etc.,

Ayer, Mass., U.S.A.

KENNETH I. E. MACLEOD.

Pre-operative Transhepatic Cholangiography

SIR.—I would be grateful for the courtesy of your columns for the following request for information. The Association of Surgeons at its meeting in Glasgow next April is discussing the subject of diagnostic procedures in obstructive jaundice. I have been asked to collect information on the position of pre-operative transhepatic cholangiography. This procedure has not been frequently carried out, and I would be grateful if any of your readers who have had experience of it would let me have a brief account of their results, including particularly any complications.—I am, etc.,

121, Harley Street,
London, W.1.

DAVID H. PATEY.

POINTS FROM LETTERS

Low Backache

Dr. HARRIS AVERY (London, S.W.16) writes: Dr. Leonard S. Calvert (*Journal*, December 18, 1954, p. 1488) does a service in reopening correspondence on the treatment of backache by manipulation. I do not think that the fault lies in the absence of efficient physical medicine departments. To my mind the whole attitude of the profession (and of our teaching) is faulty in this matter. Manipulation as a treatment is either ignored or misrepresented. I have a great respect for Mr. H. Osmond-Clarke as an orthopaedic surgeon and have often sought his opinion, but I was dismayed to read in your report of his lecture on cervical disk lesions (p. 1481): "Occasionally a manipulation under anaesthesia was a help" (the italics are mine). . . . Personally, I find the neck the easiest part of the spine to manipulate, since the muscle spasm can readily be overcome by steady, gentle manual traction. The neck should never, indeed need never, be manipulated under anaesthesia.

Medical Aspects of Boxing

Mr. T. A. MASON (London, N.8) writes: With reference to the article by Drs. J. L. Blonstein and E. Clarke (*Journal*, December 25, 1954, p. 1523) and the leading article (p. 1535), I find it curious that no mention is made in text or bibliography of Dr. Jokl's book, *Medical Aspects of Boxing* (1941, Van Schaik, Pretoria). This is full of factual matter on the subject in question.

Obituary

Sir ARTHUR KEITH, M.D., LL.D., D.Sc.
F.R.C.S., F.R.S.

We record with regret the death on January 8 of Sir Arthur Keith, whose anatomical and anthropological researches were world-renowned, and whose powers of exposition added lustre to an already highly distinguished scientific career. He was 88 years of age.

"To hear Keith," the late Lord Moynihan once said, "you would think he had never done anything—and he has re-made anatomy. The valley of dry bones, thanks to him, is full of living men." But Sir Arthur Keith was more than an anatomist; he was a physiologist, a pathologist, an anthropologist, above all a thinker. He interpreted to his own generation life in its origin and development, and no one could endow anatomy with more lively significance. In his teaching the long pathway of human history became suddenly illuminated. Like a detective reconstructing a crime from a broken lock and a finger-print, he was able from a few fossil remains to illustrate the evolutionary progress of man in a way which carried conviction with it. He made people feel that it must be so, that no other hypothesis was possible.

It was only necessary to glance at his facial contour to know that Keith came of East Scottish stock. To Aberdeen he was bound by many ties. He was born on a small farm near there, at Old Machar, in 1866, son of John Keith and Jessie Macpherson, who had ten children. One of Arthur's brothers, Robert Donald Keith, was principal of the King Edward VII Medical School at Singapore at the time of his death in 1918. Arthur Keith left school for a time at 13, but his father decided that his education must be continued. After a short time at Gordon's College he went on to study medicine at Marischal College, the founder of which, in 1593, was a Keith. He graduated M.B. in 1888, and proceeded M.D. of Aberdeen, with the highest honours, in 1894. In later life he was made LL.D. of his old university, and nearly fifty years after entering it as a student he was elected and remained three years its rector.

After graduation Keith went into general practice in Mansfield for a short time, and then, answering the call of adventure, went out to Siam as medical officer to a gold mine. Here, until the mine failed, he studied the anatomy of the Catarrhine monkeys, and on his return home he was awarded the Struthers medal and anatomy prize at Aberdeen University for his written account of

his observations. After further study at University College, London, and at Leipzig, he eventually got the start he needed in a career of scientific achievement when he was appointed senior demonstrator of anatomy at the London Hospital in 1896. He soon became recognized as an outstanding teacher, and from 1899 to 1902 he was secretary of the Anatomical Society of Great Britain. It was at this time that he wrote his well-known work, *Human Embryology and Morphology*, which has since passed into several editions. At the London Hospital Medical School he took as his guiding principle that the men he taught would do their ward work all the better if they knew something of the history of the human body. To him the criterion for the admission of new matter into the teaching of morphology was its historic value—that is to say, the

light which it threw on the origin and nature of the human body. He insisted throughout his teaching career on the close link between anatomical teaching and clinical experience. It was while Keith was at the London that he and Dr. Martin Flack discovered the sino-atrial node (often called the pacemaker of the heart) at the junction of the superior vena cava with the sulcus terminalis of the right auricle.

In 1908 Arthur Keith, who had been a Fellow of the Royal College of Surgeons already for fourteen years, became Hunterian professor and conservator of the museum, a position he held for a quarter of a century. When on a May morning in 1941 only the ruins of the museum remained after a night of enemy bombing, the thought uppermost in many minds was the tragedy that

this must mean to Keith, although by that time he had been retired from Lincoln's Inn Fields for eight years. Many men helped to make that museum the priceless thing it was, but Keith was chief among them. His knowledge and imagination and devotion made it the greatest collection in the world, illustrating the phenomena of life in both health and disease. He made it far more than a museum: he gave it character, significance, and unity. It became a great centre of instruction, a thesaurus of reference, a museum of history. Apart from the value of the specimens, which was beyond compare, it had for Keith—at least the nucleus of it—the sacredness of a legacy from John Hunter, like himself a Scotsman, a master of anatomy, a philosophic inquirer, a teacher, dissector, and experimenter. Hunter never had a more ardent disciple: nothing delighted Keith more than to show how some new advance had been foreshadowed in Hunter's teaching.

In 1932, after a severe breakdown in health from which he made a slow recovery, he resigned his work at the

J. R. Miller, Barne

College in Lincoln's Inn Fields to become Master of the Buckston Browne research farm at Downe, in Kent. Six years before, as president of the British Association, he had made an appeal for the preservation of Down House as a memorial to Darwin, who lived there for forty years, and Mr. (later Sir) Buckston Browne came forward and established a fund for that purpose. The research farm was added later. It fell to Keith to declare Down House open to the public. He spoke of the profound impression made upon him on first visiting that place: "I obtained a background for a mental picture in which the living Darwin moved, experimented, and thought. Science cannot be separated from personality. In making this place a national heritage we are acknowledging that sentiment has a place in science—not in the work of the laboratory, but in the heart of the worker." Here in his later years he found a grateful task in supervising the work of the young surgeons who studied on the research farm. Speaking of his work as Master of the Buckston Browne research farm, he said: "It brings to my door the keenest and most enterprising minds to be found in the surgical youth of the rising generation. It gives me young and congenial company." Despite his years he remained remarkably active, and when going to inspect the farm from his house, "Homefield," he still had a robust Scots look, wearing a tam-o'-shanter and a kape. Only the day before he died he was pruning his fruit trees.

Keith's first published work was his *Introduction to the Study of Anthropoid Apes*, published in 1896. Then came *Human Embryology and Morphology*, already mentioned. In the preface to the fifth edition of that work he said that successful textbooks were particularly exposed to the danger of overgrowth. Just as dominant stocks of animals have been hurried to extinction in past geological ages because their bodies became so big as to be unwieldy, so most valuable and prosperous textbooks have been killed by overgrowth. But Keith was as adept with the blue pencil as with the pen. Another work of his early years was his editing of Hughes's *Practical Anatomy*; he also assisted in Treves's *Surgical Applied Anatomy*. Later works of his bear such titles as *Ancient Types of Man*, *The Human Body*, *Nationality and Race*, *The Religion of a Darwinist*, and *Concerning Man's Origin*. For a succinct account of the evolution of man, including the lessons to be learned from the fossil skulls found in various parts of the world, Keith's article in the fourteenth edition of the *Encyclopaedia Britannica* cannot be bettered. He was for many years an occasional and much-valued contributor of signed and unsigned articles and reviews to this *Journal*. Nothing dull ever came from his pen: he seemed to enjoy writing; at any rate there was no hint of effort, though the MS. showed evidence of careful revision. The only task he declined for the *British Medical Journal* was to write about the Hunterian Museum after its bombardment, pleading (with truth) heart-sickness. Since the war he had published three books, including his long autobiography, and a book entitled *Darwin Revalued* will be published shortly. Both in his autobiography and in his *Antiquity of Man* Keith explained how he came to accept the Piltdown findings only with some critical hesitation: and in a letter to a friend (published in the *Sunday Times* of January 9), commenting on the recent discovery of the hoax, he wrote: "The story of the evolution of

man, so far as we yet know it, has not in any way been damaged. . . . The tragedy of the situation is a loss of faith in the testimony of our fellow workers. That is how the Piltdown fraud strikes me."

His eminence in the world of anthropology and anatomy is attested by his presidency of the Royal Anthropological Institute, the British Association, and the Anatomical Society, his Fullerian Professorship of Physiology at the Royal Institution from 1917 to 1923, his secretaryship of the Royal Institution from 1922 to 1926, and his honorary doctorates of six universities. In 1913 he was elected a Fellow of the Royal Society and a member of the Société d'Anthropologie de Paris. He was knighted in 1913. Lady Keith (formerly Cecilia Gray, daughter of Tom Gray, the artist), whom he had married in 1899, died in 1934. There were no children of the marriage.

We are indebted to Sir GORDON GORDON-TAYLOR for the following appreciation:

"Maecenas waits me on the Esquiline;
Hither to-night go I . . .
And shall this dawn restore us, Virgil mine,
To dawn? Beneath what sky?"

These lines from Kipling which refer to the passing of Horace so soon after the death of his patron and friend Maecenas have been ringing in my ears ever since I heard the news of the death of Arthur Keith which has followed so rapidly that of his most illustrious pupil in the world of anatomy: both Wood Jones and he were conservators of the Hunterian Museum in Lincoln's Inn Fields, and when considerations of age imposed their decree on the continuance of that office each was privileged to go on serving the Royal College of Surgeons of England in a diverse capacity till "the end of the road," and each man died, as he would have wished, in harness and full of years. It is less than two months since we read Arthur Keith's charming obituary notice of "Freddy" Wood Jones in the *Annals* of the College of Surgeons, and the admiration and affection existent between the two will be self-evident to those who did not know them intimately from the terminal paragraph in Keith's notice, which I venture to quote and which is in fact a letter from Wood Jones on Keith's birthday, February 5, 1949:

"This is to carry from Gertrude and from me all good wishes, and all hopes that these good wishes may be repeated for many years to come. It is a long time ago (1897) that as a first-year student I sneaked into, and was fascinated by, a lecture you gave on a boy with an extra pair of legs (a parasitic foetus) who was on show in Wonderland. That's more than fifty years ago. I have a fancy that in parental fashion you still look on me as a wayward youngster [which was quite true, A.K.]—(you do, don't you?); but I would have you know that I am over 70 now and almost grown up. Seventy or 20 it is no matter. I loved and admired you then and I still do and will. And Gertrude and I send our love to you."

I hesitated before acceding to the request that I would contribute something on Arthur Keith towards the columns of the *British Medical Journal*, for I feel at all times abysmally humble in the presence of Fellows of the Royal Society and deeply self-conscious of any attempt of mine at appraisal of scientific worth and stature, and it is only my loyalty to the memory of Arthur Keith that makes me take up my pen. His roots were grounded in the Turiff-Huntly area of the north-east of Scotland, where his father farmed and whence sprang my own maternal forebears: he trod the same academic groves that I was to tread more than a decade later; he was cradled in the basic sciences and in the clinical subjects by men under whom I myself was trained or who were friends of my family—men like "Jimmy" Trail and Alleyne Nicholson, and Japp, and "Johnnie" Struthers, who first stirred Keith's interest in anatomy; Smith Shand

in medicine and Alec Ogston in surgery, to whom he proudly refers in that delightful book, *The Menders of the Maimed*; Stephenson—nicknamed "Howdy"—the obstetrician; and that great old clinical teacher, Angus Fraser. But best of all he breathed the air of the Granite City and learned to work as perhaps the Aberdeen student alone can or could work in the last quarter of the nineteenth century.

Arthur Keith's connexion with the London Hospital round the beginning of the century brought him in contact with a coterie of men from the north-east of Scotland—William Bulloch, J. J. R. Macleod, and Henry Souttar had at least a temporary lodgment in old Aberdeen. I first came in touch with him personally over fifty years ago, when with characteristic generosity he lent Victor Bonney and myself all his manuscript notes and drawings dealing with the myology of the Primates, which represented his work in the Eastern Archipelago in his early postgraduate years. Although I never enjoyed the privilege of that intimate friendship with Keith that I had with Peter Thompson and F. G. Parsons, I used to see him at meetings of the Anatomical Society up to the outbreak of the first great war. Those were the days of Dan Cunningham, father of the distinguished Admiral and General, and George Thane; of Arthur Robinson, Howden, Hepburn, Waterston; of Paterson, of Liverpool; Ernest Frazer and Dixon, of Dublin; and Duckworth, of Cambridge. Fawcett made his three-monthly contributions on the ossification of still one more cranial bone; Lockwood still looked in occasionally; and there was always the stupendous frame of William Wright radiating happiness and good nature. Symington was busy cutting the body in sections, and Grafton Elliot Smith working on the morphology of the cerebrum, and the Hunterian Museum is enriched by his industry. Christopher Addison was still teaching anatomy, although already imping his wings for his brilliant flight into the empyrean of politics. War had not yet translated Auckland Geddes to ministries and an embassy. And Bertram Windle was still writing on monsters and abnormalities. Perhaps at no period was there such a galaxy of stars in the anatomical firmament, and from this group Keith was elected in 1908 to be conservator in Lincoln's Inn Fields.

In the days of his conservatorship the Museum which had for a hundred years been a lodestone for the surgeon and savant as well as for the curious became a Mecca as never before: specimens of every kind poured in, and when the Museum suffered from Hun bombardment there were some quarter of a million specimens, mounted or in the stores.

Keith's breadth of vision was enormous: although in later life he became more and more interested in anthropological problems, he always retained his interest in embryology as well as anatomico-pathological problems. I still possess a letter which he wrote me in the beginning of April, 1918, acknowledging the safe arrival of a specimen of a gunshot wound of a Meckel's diverticulum, which I resected during the terminal phase of the Fifth Army retreat in March, 1918, saying that its safe arrival during such a period of chaos was a "harbinger of the favourable tide of fortune which was shortly to roll in our direction." His Scottish industry was unflagging, and more and more he became involved in anthropological problems. He wrote books, brought out new editions; and he extended his hand to all.

The exigencies of war and the remoteness of his ivory tower at Downe curtailed the frequency of our meetings, but he was much loved by those who worked at the farm. But the vision still remains with me of the tall, active figure flitting in his white coat along the corridors and galleries of the College; and one can still hear the small, piping voice, the Scottish—though not the Aberdeen—accent, and the hurried sentences which were so attractive as they flowed from the lips of this kindly gentleman. In the words of Tacitus, writing of the Roman Agricola: "What we loved, what we admired in you endures, and will endure in the souls of men."

Professor A. J. E. CAVE writes: Keith's contributions to human anatomy embraced a wide range of original inquiries into such matters as visceral topography, the mechanism of respiration, the structure, function, and innervation of the bowel, the phylogenetic modifications of the axial skeleton, the growth of bone in health and disease, the effects of the upright posture upon the skeleton and soft parts, the growth, mensuration, and racial variations of the skull, cardiac physiology, and the development of the heart and great vessels. In investigating respiratory and alimentary function he unhesitatingly experimented upon himself in his determination to understand personally the working of the human machine. For Keith never dissociated any structure from its function, thereby proving himself a natural disciple of his fellow Scot, John Hunter, whose Museum he served with distinction as conservator for 25 years. Keith's principal anatomical achievements were perhaps his studies of the auricular musculature (1902-4), his verification (1905-6) of the Tawara cardiac conducting system, and his discovery (1906) with Martin Flack of the sino-atrial (Keith-Flack) node. His numerous and sustained researches were directed to practical ends and designed to satisfy both anatomist and clinician; his early studies in physiology, teratology, primatology, and gross anatomy fruited in later years in his valuable and distinctive addresses, official lectures, and publications. His clinical sympathies were reflected in masterly studies of progeria, acromegaly, diaphyseal acclasia, pedal orthopaedics, and the nature and origin of hernia.

As anthropologist Keith became early on in his career a principal authority on questions touching ancient and modern man, his past and present racial origins, and his phylogeny, though herein his latter-day views found more public than professional acceptance. For years he examined and reported upon ancient human remains from Britain, Europe, Asia Minor, and elsewhere, and studied the racial composition and origin of the British people. In anthropological technique he invented a special craniometer, devised and promulgated the use of the sub-cerebral plane, and stressed the significance of cerebrospinal fluid streams in the interpretation of endocranial casts. He partook in the assessment of the status of *Pithecanthropus* and *Australopithecus* and of Rhodesian and Wadjak Man; described the Galilee neanderthaloid skull and (with T. D. McCown) elaborately monographed the Mount Carmel fossil Palestinians. In the original Piltdown controversy his anatomical experience put him initially in the right and, but for his militant Darwinism, might easily have bared the underlying truth. For overlong perhaps he maintained an undue antiquity for *Homo sapiens*, an attitude not unassociated with his unfortunate championship of the Galley Hill cranium and the Ipswich skeleton. Despite his modification of outlook in later years, he never wholly surrendered his belief in a direct common ancestor for man and anthropoid ape. His numerous publications on ancient man gained a wide popularity, but his later pronouncements in the field of social anthropology, wherein he abandoned accepted anthropological terminology, failed to command a comparable respect.

H. W. B. writes about Sir Arthur Keith when he was head of the department of anatomy at the London Hospital: In his early 40's Keith had a face of singular charm, with a quality of ascetic beauty, blue eyes, an aquiline nose and a forehead surmounted by a wave of fair curly hair, and furrowed by lines which gave him an air of rather anxious perplexity. He had an engaging manner with a hint of diffidence. His voice was gentle, with at times a pleading lilt in it, and his whole personality would seem to have belied the bitterness which according to his autobiography clouded some of the controversies of his long life as a scientist. There always seemed something elusive about him, especially when he wished to escape from the importunities of the dissecting room to the quiet haven of his laboratory and research. He then wore a slightly guilty

air, and with a quaintly sidling gait seemed to be taking evasive action against his students, some of whom made it a point of honour to try to hinder his progress with questions about some real or imaginary difficulty relating to some part under dissection.

In his routine teaching his declared aim was to make anatomy of practical help to the G.P. in his daily work. To this end he devoted many of his lectures to clinical and surface anatomy, and his blackboard sketches, though of no artistic merit, usually clearly illustrated what pages of description would have left only vaguely complicated. In this facility he was perhaps equalled by that gifted teacher, Russell Howard, then his senior demonstrator, whose similarly effective diagrams were grotesquely crude, but whose knack of welding an elusive fact on to a reluctant mind with the white-hot flame of sarcasm was probably unique. Keith, as befitted a Scotsman, was given to occasional shafts of pawky humour. When bones were to be handed round his class, he was wont to remark that as with umbrellas, so with bones—no borrower ever thought it necessary to return them.

It fell out that his last lecture at the London was on bones. On his arrival the anatomy theatre was crowded with his students, who were determined to show their affection for him in no uncertain manner. All who could had secured a suitable bone from among those laid out for demonstration. By luck I had attached a fine specimen of the femur. At the end of a quiet and orderly lecture a pandemonium of cheers broke loose, and desks were pounded appreciatively by every available element of the human skeleton. In one segment at least of desk surface there was a deep acetabular-shaped depression, and a fine femoral head had lost its shape and its articular cartilage. Thus did Arthur Keith's students say farewell to a beloved teacher with the bones which were so much the powerful levers of his philosophy.

CLAUDE RUNDLE, O.B.E., M.D., D.P.H.

Dr. Claude Rundle, for many years medical superintendent of the Fazakerley Infectious Diseases Hospitals and Sanatorium, Liverpool, died suddenly at his home at West Looe, Cornwall, on December 24, 1954, at the age of 81. His parents belonged to Cornwall, but they lived for a time at Plymouth, where he was born on July 20, 1873. Other members of his family also achieved success in the careers of their choice: Engineer Rear-Admiral M. Rundle is his brother, and his sister, Miss Mary S. Rundle, who died in 1937, was the first secretary of the Royal College of Nursing, where she worked for nearly 18 years.

Claude Rundle was educated at Plymouth Corporation Grammar School and received his medical training at St. Mary's Hospital, London, qualifying M.R.C.S., L.R.C.P. in 1895. He graduated M.B. from London University in 1898, obtained the D.P.H. of the English Royal Colleges in 1901, and proceeded to the M.D. in 1904. His early appointments in the public health service included those of medical officer at the Gore Farm Convalescent Hospital, Dartford, senior assistant medical officer at the Grove Fever Hospital, Tooting, and medical superintendent at the Orchard Smallpox Hospital, Dartford—all under the old Metropolitan Asylums Board. In the great smallpox epidemic of 1901-2, which seriously affected London, he gave devoted service on hospital ships in the Thames estuary.

These experiences seemed to settle the course of Rundle's future career by creating in him an interest in the communicable diseases, and he was appointed medical superintendent of the two isolation hospitals at Fazakerley in 1906. The heavy incidence of the commoner infectious diseases as well as of tubercu-

losis in Liverpool had prompted the city council in 1898 to purchase a large estate of 118 acres at Fazakerley for hospital purposes, and when Rundle arrived to take up his new duties part of the scheme had been completed. His first important task was to deal with the organization and staffing of the main isolation hospital of 350 beds opened in the year of his appointment. During the next few years this hospital, together with the annexe built in 1901, became one of the most noted and efficient of the country's infectious diseases hospitals, and it was visited by doctors from all over the world. An additional unit was completed in 1917 under Rundle's guidance, and in 1920 a large sanatorium of 265 beds was opened on part of the estate, and he became its first medical superintendent, though retaining his responsibilities in connexion with infectious diseases. From 1920 until he retired in 1934 Rundle was in charge of all the units on the Fazakerley estate, amounting in total to more than 900 beds. He had been largely responsible for the planning and building of nearly half of this great system of hospitals and wholly, as they were completed, for their organization and administration over the long period of 28 years. *Si monumentum requiris, circumspecte.*

Rundle held a commission in the Territorial Army from 1908 onwards and attained the rank of lieutenant-colonel in the R.A.M.C. during the first world war, commanding the Berrington War Hospital and No. 55 General Hospital in France. For his services he was appointed O.B.E. in 1919. A few years later he was appointed one of the deputy lieutenants for the county of Lancaster. He was for many years lecturer in infectious diseases in Liverpool University, and accepted responsibility for the revision of the third edition of Ker's *Manual of Fevers* (1927) and the third edition of Ker's *Infectious Diseases* (1929). He published many articles in the medical journals, some on bed isolation, of which in his work at Fazakerley he was a pioneer. In his late fifties he had two severe attacks of pneumonia, and as a result retired from the service of Liverpool corporation in 1934 rather sooner than was normally required. Even before his retirement he had built a small but charming house at West Looe in his own county of Cornwall. He leaves a widow, formerly Miss Florence M. Kerruish, and a daughter, Mrs. Patricia M. Valentine, both of whom are members of the medical profession.—W. M. F.

E. A. B. writes: I had the privilege of working under Dr. Claude Rundle for 14 years, and can recall his dignified military figure riding a bicycle from ward to ward on his daily rounds, and later driving an ambulance. This was essential, as the hospital was scattered over 118 acres of ground. Infectious diseases were very prevalent at this time, and frequent epidemics called for urgent action. Dr. Rundle was at his best dealing with these emergencies. His capacity for work was prodigious, and he set a high standard of work. He suffered neither fools nor slackers gladly but made allowances for human weaknesses. He was the pioneer of bed isolation methods of nursing and showed his implicit faith in them when after an operation for appendicitis he was nursed in a ward where various infectious diseases were treated under this régime. Dr. Rundle's equanimity was proof against all the strains and stresses that medical superintendents were in those days apt to come up against. His great wisdom and diplomacy poured oil on many troubled waters. From what I have written it may be thought that Dr. Rundle was difficult to work with; on the contrary he was a delightful and most approachable superior, whose personal kindness matched his profound knowledge, for he was always ready day or night

to give advice and help to his staff, medical or nursing. There are many to-day who remember him with affection and deep gratitude.

H. N. WEBBER, B.Chir., F.F.A. R.C.S.

We record with regret the death on December 24, 1954, of Dr. H. N. Webber in University College Hospital, which he served for over 20 years as honorary anaesthetist.

Harald Norris Webber was born in 1881 and was educated at Brighton College and at St. John's College, Cambridge, where he took the natural sciences tripos in 1903. He remained at Cambridge for another five years, doing research work with the late Dr. W. H. R. Rivers, who was lecturer on experimental psychology. Rivers was Croonian Lecturer of the Royal College of Physicians of London in 1906, and his lecture—on the influence of alcohol and other drugs on fatigue—was published in book form two years later. Webber never drank alcohol at all, and he was therefore an ideal subject for this investigation, and the lecture was based largely on experiments performed on him. Rivers and Webber collaborated further in the publication of papers on the action of caffeine and alcohol on the capacity for muscular work. In 1908 Webber entered University College Hospital and soon became dresser to Professor Arthur E. Barker, who had been the first man to introduce spinal analgesia to this country three years earlier. After qualifying in 1912 Webber became successively house-surgeon, house-physician, and resident medical officer at the West London Hospital. In the first world war he served in the R.A.M.C. from 1917 to 1920, attaining the rank of major. While with the Egyptian Expeditionary Force he developed a very severe attack of typhus, which left him in indifferent health for the rest of his life. On leaving the Army he was appointed assistant medical officer to the London Fever Hospital, and in 1922 he became resident medical officer at University College Hospital. During his term of office he had to administer anaesthetics in many emergencies, and this work led him to specialize as an anaesthetist. He had at one time intended to be a surgeon, but an accident resulting in a permanently stiff finger prevented this. In 1924 he was appointed anaesthetic registrar, and six months later he was elected to the honorary staff of University College Hospital. He was also elected to the staffs of St. Paul's Hospital and the Royal Chest Hospital, and he served for a time as anaesthetist to the Central London Throat, Nose, and Ear Hospital and the Royal Dental Hospital. He took the B.Chir. in 1928, and in 1948 he was elected one of the first Fellows of the newly established Faculty of Anaesthetists of the Royal College of Surgeons of England. He was a prominent member of the Section of Anaesthetics of the Royal Society of Medicine, being secretary from 1935 to 1937, president in 1940-1, and vice-president from 1941 to 1944.

Webber did not make many contributions to medical literature. His chief work was the textbook written in conjunction with his colleague, Dr. Felix S. Rood, entitled *Anaesthesia and Anaesthetics*, which appeared in 1930 and which for many years was the standard work on the subject. He also wrote the chapter on anaesthesia in Gwynne Williams's *Minor Surgery and Bandaging*. A few years after Boyle's original apparatus came out Webber introduced a modification which placed the ether and chloroform bottles in parallel instead of in series, thus preventing the passage of

chloroform vapour into the ether bottle. This apparatus is still in use at University College Hospital and is preferred by many of Webber's colleagues to more modern apparatus. He was a sound teacher, always striving to follow the precept of his predecessor, J. L. Clover, that a man on leaving University College Hospital should be competent to give a safe anaesthetic without recourse to complicated apparatus.

Webber was reserved in character, but had a keen if rather sardonic sense of humour. His punctuality was proverbial, and on the rare occasions when he was late he would make a brief apology, and only when the afternoon's work was finished would he relax and smilingly give an account of the complications which had been encountered in the previous patient and which caused him to be late. He was wrapped up in the welfare of his hospital and devoted unsparingly his energies in working for it. Scrupulous in his care of patients, he always visited them before and after operation. During the last war he worked at University College Hospital in the Emergency Medical Service and seemed to be completely without fear, for, after being twice bombed out of his own house, he took a top-floor flat next door to the hospital. On retiring from the staff under the age limit in 1946 he became visiting medical officer to the Hostel of St. Luke in addition to carrying on his work there as honorary anaesthetist. He was a man of strong religious feelings, and gave to his patients there the same unsparing devotion he showed throughout his career right up to the time of his last illness. A year before he died he had to undergo a major abdominal operation which he met with characteristic fortitude. He married Madeleine Mary, daughter of Major J. J. Ryder, who survives him, and to whom we offer our deepest sympathy.

G. W. MILLER, D.S.O., M.B.

Dr. G. W. Miller, a general practitioner who was held in high regard in Dundee and beyond, died in a nursing home at Dundee on January 5 at the age of 80. He had been ill for some months.

George Waterston Miller was born on July 27, 1874, the son of one of Dundee's most popular and respected practitioners, Dr. J. W. Miller, and he followed closely in his father's footsteps. He was educated at Dundee High School and at Edinburgh University and first graduated B.Sc. in 1895, winning Professor Geikie's medal in geology, before he turned to medicine. As a student, as well as in later life, he was popular with everyone. Fond of dancing, and a good singer, he was also a keen athlete, a first-class swimmer, a cross-country runner, and an excellent Rugby forward. He took the M.B., Ch.B. degrees in 1898 and then acted as resident physician under the late Sir Byrom Bramwell at Edinburgh Royal Infirmary. Returning to Dundee in the following year, he was resident physician at the Royal Infirmary for a year before settling in general practice. He continued his association with the Royal Infirmary, of which he was assistant physician from 1908 to 1919, and for almost the same period he rendered good service to St. Andrews University as assistant to the professor of medicine.

A keen Volunteer, Miller passed from the Dundee Rifles to the Black Watch in Edinburgh, where he was a member of the first Maxim gun team in Scotland, a team which also included E. C. (later Sir Eric) Geddes. He held a combatant commission as a Volunteer from 1891 to 1904, when he obtained a commission as a

medical officer. During the first world war, at the outbreak of which he held the rank of major in the R.A.M.C., T.A., he served in France with the 51st (Highland) Division from 1915 to 1919, being in command of a Highland field ambulance towards the end of the war. He was twice mentioned in dispatches and was awarded the D.S.O. in 1917 and the Croix de Guerre with silver star two years later. After the war he was in command of the 152nd Highland field ambulance from 1920 to 1924 and was A.D.M.S. with the rank of colonel, of the 51st (Highland) Division for four years from 1924. His services to the Volunteer movement were recognized by the award of the Territorial Decoration some years earlier.

An enthusiastic supporter of the St. Andrew's Ambulance Association, for which he worked as a lecturer and examiner for nearly fifty years, he was awarded the King's Medal with five bars in 1949. In 1908 he was appointed an honorary Associate of the Venerable Order of St. John of Jerusalem. He was a member of the British Medical Association for fifty-five years, and served on the Council for three periods, from 1922 to 1935, 1938 to 1940, and in 1943-4. He was also president of the Dundee Branch in 1922-3 and chairman of the Scottish Committee from 1927 to 1929. During the last war he acted as secretary of the Dundee Medical War Committee and was the local emergency officer. He was a good committee-man, his benevolent smile being typical of his kindly and honest disposition. His colleagues and patients will miss him sadly. He married Miss Maria L. Gilbert in 1901, and she, with their only daughter, survives him, his only son having predeceased him.

Dr. CHARLOTTE R. BROWN died in hospital at Banbury on January 1 at the age of 86. Charlotte Rhoda Brown was born in Tipperary, the daughter of Mr. William Hodgins, on October 18, 1868. Her early years were spent in her native country, and during her long life she never lost her interest in all forms of natural history, an interest bred in her as a girl through living in a house with a large garden in rural Ireland. She received her medical education at the London (Royal Free Hospital) School of Medicine for Women and took the Scottish triple qualification in 1895 and the Brussels M.D. in the following year. After holding several postgraduate appointments she was in general practice at Bradford until her marriage to the Rev. Richard E. Brown in 1901. She was the only woman medical practitioner in Bradford at the time, being one of the early band of women who qualified under difficult circumstances and against some opposition. She took an active part in the women's suffrage movement before the first world war, and any branch of work outside the home in which women played a part was of great interest to her. She was a member of the Medical Women's Federation for many years. In 1916 she joined the staff of the East Anglian Sanatorium at Nayland, and thenceforward specialized in the treatment of tuberculosis. In the following year she was appointed tuberculosis medical officer to the Essex County Council, and in 1919 she became medical superintendent of the Children's Hospital for Surgical Tuberculosis at High Beech in Epping Forest, where she remained until 1932, when she retired, combining the work of the post with that of a child welfare appointment. She and her husband then went to live at Welwyn Garden City, where they took a very real, although not a vocal, interest in the activities of the neighbourhood. Dr. Brown was a very lovable woman with a large circle of friends in Welwyn. She had a good sense of humour and would tell many stories against herself. She was excellent company, and her Irish background—the background of the Somerville and Ross "Irish R.M." stories—gave her an endless fund of anecdote and reminiscence.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 25 (No. 51) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1954					1953				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire
Diphtheria	15	2	4	0	1	15	0	7	0

Vital Statistics

London's Health in 1954

According to a preliminary report by the County Medical Officer of Health, Dr. J. A. Scott, the 50,920 births gave a birth rate of 15.2 per 1,000. Deaths numbered 36,200. The provisional death rate was 10.9 per 1,000, the lowest ever recorded. The infant mortality rate was 22 per 1,000 live births, also a record low figure. The neonatal mortality rate was 16 per 1,000 live births, and compares with 16.1 in 1953 and 15.8 in 1952. The maternal mortality rate was 0.43 per 1,000 live and stillbirths. The incidence of epidemic diseases was low. After a rise in 1953, the infantile-diarrhoea death rate fell again and was the lowest recorded. 24 children under 2 died from this cause, compared with 65 in 1953; 8 years ago 269 died. The diminished mortality from this disease accounts for a large part of the drop in the general infant death rate.

Influenza

No reports have been received of further outbreaks of virus-B influenza in the northern and north-western regions or in Wales, and in these areas and in Scotland the infection is waning. In the north midlands and midlands fresh outbreaks continue to be reported in some areas not previously attacked, and additional outbreaks are apparently occurring in the south, south-west, east, and south-east. In London there are indefinite reports of a considerable amount of illness, much of which may be due to influenza. Clinically the disease on the whole remains mild. There is also some evidence of an increased incidence among adults.

Week Ending January 1

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 707, whooping-cough 1,722, diphtheria 13, measles 8,320, acute pneumonia, 1,108, meningococcal infection 31, acute poliomyelitis 23, dysentery 340, paratyphoid fever 11, and typhoid fever 4.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The notifications of infectious diseases in England and Wales declined during the week ending December 25, as is usual at Christmas time; the falls included 683 for measles, from 6,523 to 5,840; 577 for whooping-cough, from 1,833 to 1,256; and 125 for scarlet fever, from 798 to 673.

The largest declines in the incidence of measles were 48 in Lancashire, from 2,392 to 1,912, and 127 in Durham, from 433 to 306, and the largest increases were 161 in Yorkshire West Riding, from 397 to 558, 54 in Northumberland, from 39 to 93, and 49 in Staffordshire, from 173 to 222. A fall in the incidence of scarlet fever was recorded in most regions, but no large local variations were recorded. The largest falls in the incidence of whooping-cough were 108 in Lancashire, from 227 to 127; 68 in Staffordshire, from 96 to 28; and 42 in Durham, from 127 to 85. 15 cases of diphtheria were notified, being 3 fewer than in the preceding week. The chief feature of the returns of diphtheria was a fall from 9 to 2 in Lancashire.

Only 9 cases of acute poliomyelitis were notified, and this was the lowest number for any week for the past five and a half years. The notifications were 18 fewer for paralytic and 9 fewer for non-paralytic cases than in the preceding week. 2 cases were notified in Leeds C.B., the only area with multiple cases.

340 cases of dysentery were notified; this was the same total as in the preceding week. The largest returns were Lancashire 71 (Oldham C.B. 32); Norfolk 46 (Norwich C.B. 25); Yorkshire West Riding 41 (Sheffield C.B. 16); London 33; Warwickshire 20 (Birmingham C.B. 15).

56 deaths were attributed to influenza in the great towns, 10 fewer than in the preceding week.

Smallpox in France

The French Ministry of Health states that the port of Vannes in the Morbihan Department in Brittany has been declared infected with smallpox. Up to January 4, 13 cases, including two deaths, have occurred. Sanitary measures have been applied from that date to departing ships.

Quarterly Return for Eire

The birth rate for the September quarter of 1954 was 21.6 per 1,000 of the population, being 0.3 above the rate for the third quarter of 1953. The infant mortality rate was 30 per 1,000 births, and this was the lowest rate recorded in any quarter and 3 below that of the third quarter of 1953, the previous lowest level. The death rate was 10.5 per 1,000 of the population, being 0.8 above the rate for the September quarter of 1953 and 0.3 above the average of the five preceding third quarters. Deaths from the principal epidemic diseases included 39 from gastro-enteritis (under 2 years), 12 from influenza, 12 from whooping-cough, and 4 from acute poliomyelitis. Deaths from tuberculosis included 181 from respiratory and 45 from other forms. These deaths were, respectively, 8 above and 22 below the number registered in the preceding third quarter, and 142 and 67 fewer than the average of the third quarters of 1949-53.

Medical News

Sir Robert Robinson, O.M., F.R.S., was installed as president of the British Association on January 7. Sir Robert is Waynflete Professor of Chemistry at Oxford. He is perhaps best known to medical men for his wartime work on the structure of penicillin and for his more recent studies on the synthesis of steroids.

Pharmacology Laboratories at Leeds.—A new suite of research laboratories has been added to the Department of Pharmacology at the Leeds School of Medicine. This has been made possible by a grant of £10,000 provided by the Wellcome Trust. The new laboratories were opened on January 6 by Sir HENRY DALE, O.M., F.R.S., chairman of the Trust, during the recent meeting of the British Pharmacological Society in Leeds. The suite consists of five laboratories, office, store, and darkroom. The head of the department is Professor W. A. BAIN.

Clinical Research Fellowships.—The Medical Research Council invites applications for Fellowships in Clinical Research, tenable at centres in the United Kingdom during the academic year 1955-6. These Fellowships are open to suitably qualified medical graduates. The intention is to give each Fellow, as part of his training, an opportunity to study research methods in the basic subject most relevant to his particular clinical interest. Awards will be for one year in the first instance, and renewable annually up to a maximum of three years. Stipend will start at £850 per annum, rising by annual increments of £75 to £1,000 per annum, with superannuation provision in addition. Forms of application and further details may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications should be lodged as soon as possible, and in any event not later than March 1.

Certificates for Meat Exports.—A certificate signed by a medical officer of health will in future be required to accompany all British exports of meat (and meat products) to Belgium. This is the result of a recent agreement between the two governments. Private certification of meat exports from Britain is quite common both to ensure customs clearance and to facilitate sales, but there are only two other official schemes—with the United States and Canada—and these date from about 1930. The reason for the new scheme is not any change in the nature of our meat trade, but recent domestic legislation in Belgium. The certificate declares

that the meat has been derived from animals subjected to ante- and post-mortem examination, that it is wholesome and fit for human consumption, and that it has been handled only in a hygienic manner in this country. Specimen certificates may be obtained from the Ministry of Food, the Department of Health for Scotland, or from the Ministry of Agriculture, Belfast.

British Journal of Anaesthesia.—With its current issue, the *British Journal of Anaesthesia* becomes a monthly. Founded in 1923 as a quarterly, during the war and until 1950 the journal appeared only twice a year. In 1950, under the joint editorship of Dr. T. CECIL GRAY and Dr. E. FALKNER HILL, quarterly publication was resumed, and last year six issues were printed. To meet increased costs the subscription has been raised to £3 15s. inland (£4 4s. overseas).

Lepers in Revolt.—Newspapers report that on January 11 the 300 patients on Trinidad's leper island, Chacachacare, seized control of the island. They were protesting against the recall of their medical superintendent, Dr. MICHAEL CORCOS, for granting many of them Christmas leave on the mainland.

Italian Honour for Cerebral Palsy Worker.—Mrs. EIRENE COLLIS, head of the Cerebral Palsy Unit at Queen Mary's Hospital, Carshalton, was decorated last month with the Star of the Order of the Italian Republic. The occasion was the opening of the third congress of the Italian Society for Medical Gymnastics in Milan. The decoration was for her work in helping to establish cerebral palsy clinics in three Italian cities. Mrs. Collis is a pioneer in this field: it was at her instigation that in 1942 the London County Council established the Carshalton unit, claimed to be the first of its kind in Britain.

Chelsea Centre for Spastic Children.—An experimental day centre for the diagnosis and treatment of children under 5 years of age suffering from cerebral palsy will be opened shortly at Cheyne Hospital for Children, 61, Cheyne Walk, London, S.W.3. By arrangement with the London County Council educational facilities will also be provided. The centre will be administered by the Chelsea Hospital Management Committee, and will be closely associated with St. Stephen's Hospital, Fulham Road, the Westminster Hospital, and establishments dealing with the treatment of cerebral palsy. Parents living in south and west London wishing to apply for admission of a child should communicate with the Group Secretary, Chelsea Hospital Management Committee, St. Luke's Hospital, Sydney Street, Chelsea, S.W.3, through their family doctor.

William Gibson Scholarship.—The Royal Society of Medicine announces that the next award of the William Gibson Research Scholarship for medical women will be made in July. The scholarship, valued at about £200 a year, is tenable for two or occasionally three years. Candidates must be British subjects. Details may be obtained from the secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1.

Mr. B. W. Rycroft has been invited to become an honorary member of the Ophthalmological Society of South Africa.

COMING EVENTS

Radio and Television.—Tributes to Dr. ALBERT SCHWEITZER on the Light Programme at 8.30 a.m. and on the Home Service at 9.15 p.m. on Sunday, January 16. "Atoms for Export," a programme from the Radiochemical Centre, Amersham, on television at 9.45 p.m. on Tuesday, January 18.

Oxford Graduates' Medical Club.—Winter dinner at the Royal College of Surgeons, Lincoln's Inn Fields, on February 11, 7 for 7.30 p.m., under the chairmanship of Professor H. R. DEAN. Tickets (25s.) from Mr. SELWYN TAYLOR, 3, Roedean Crescent, Roehampton, London, S.W.15.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, January 14

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., at Institute Lecture Theatre, open clinical demonstration by Dr. J. Smart and Dr. K. F. W. Hinson: Pulmonary Aspergillosis.

Saturday, January 15

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, Kent, 3 p.m., clinical meeting.

Monday, January 17

HUNTERIAN SOCIETY.—At Mansion House, 8.30 p.m., Hunterian Lecture by Professor J. Adams-Ray (Stockholm): Some Observations on a New Symptom-pallor in the Inflammation Syndrome.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. Macdonald Critchley: Parietal Symptomatology.

Tuesday, January 18

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. Douglas McClean: Substances that Increase Tissue Permeability and their Relation to Infection and Fertilization.

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Dr. P. M. F. Bishop: Treatment of the Menopause. Members of the Stratford Division, B.M.A., are invited.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. M. S. Thomson: Tuberculosis Cutis.

OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., Dr. S. R. Gerber (Cleveland): Case of the Osteopath's Wife.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Goulstonian Lecture by Dr. G. M. Bull: The Uraemias.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. G. W. B. James: Neurosis in Gynaecology.

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., Dr. M. M. Gatt: How a Treatment Centre for Alcohol Patients was Established at a State Mental Hospital and How it Works.

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Dr. P. E. Camps: Forensic Medicine and the Law.

Wednesday, January 19

EUGENICS SOCIETY.—At Royal Society, Burlington House, W., 5.30 p.m., Professor L. S. Penrose, F.R.S.: Genetics of Microcythaemia (Thalassaemia) (with a film).

HYPNOTHERAPY GROUP.—At Eastman Dental Hospital, Gray's Inn Road, W.C.1, 8 p.m., papers by Dr. W. Moodie, Dr. D. Stafford-Clark, Dr. G. F. Newbold, Dr. G. J. Ambrose, and Mr. E. Wookey.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: The Eosinophilic Granulomas of the Skin.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. R. Thomson: Laboratory Aids to Diagnosis.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Ashford Hospital, 3 p.m., clinical cases; 4.30 p.m., Mr. F. G. Ward: Rehabilitation and Resettlement.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 154, Great Charles Street, 8.15 p.m., Sir Stanford Cade: Progress in the Treatment of Cancer.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Dr. E. J. M. Bowley: Maternal Care and Mental Health.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., John Burns Lecture by Professor W. W. Mushin: Physiological Principles in the Care of the Unconscious Patient.

WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, 8.45 p.m., discussion: Some Common Dermatological Topics. Speaker, Dr. I. Muende.

Thursday, January 20

BRITISH INSTITUTE OF RADIOLOGY.—7.45 p.m., special general meeting, followed by ordinary meeting which papers will be read as follows: Dr. A. H. E. Marshall, Some Actions of Hormones and Pharmacological Agents upon the Acute Skin Damage produced by X rays and Carcinogenic Hydrocarbons; Dr. L. E. Houghton, Dr. J. B. Walter, and Mr. D. E. A. Jones, The Modification of X-ray Damage by Cortisone; Dr. K. Sieber, A Clinical Trial of A.C.T.H. in Radiotherapy.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. D. G. Melrose: Cooling of the Whole Organism.

EDINBURGH CLINICAL CLUB.—At 7, Drumshugh Gardens, 8 p.m., Professor G. H. Percival: Bullous Eruptions.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Honorary Presidential Address by Mr. Roland Barnes.

LIVERPOOL MEDICAL INSTITUTION.—At Liverpool Royal Southern Hospital, 3 p.m., afternoon clinical demonstration.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At the Emergency Bed Service, Fielden House, 28, London Bridge Street, S.E., 5.30 p.m., meetings.

OSLER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., Colonel L. W. Harrison: Neisser and Neisserian Principles in Venereology; Dr. David Nabarro: The Decline and Fall of Congenital Syphilis. (Meeting in honour of Albert Neisser, January 22, 1855-1916.)

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. C. Naunton Morgan: Advances in Surgery in Diseases of the Colon and Rectum.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Goulstonian Lecture by Dr. G. M. Bull: The Uraemias.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Ophthalmology Lecture by Professor Arnold Sorsby: Outstanding Problems in the Treatment of Ocular Infections.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, London, W., 7.30 p.m., Professor R. M. Gordon: Symposium on Loniass. Speakers will include Mr. W. Crewe, Mr. H. Oldroyd, Dr. B. O. L. Duke, Professor J. J. C. Buckley, Sir Philip Manson-Bahr, Dr. F. Hawking, and Dr. W. E. Kershaw.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Professor R. E. Tunbridge: Some Problems of Diabetes Mellitus.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Dr. Desmond Carran.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Clarendon Restaurant, Hammersmith Broadway, 8.30 p.m., debate on the Motion: This House considers that Money spent on Research into Rheumatism has been wasted. Proposed and seconded by Dr. Dudley Hart and Dr. C. J. M. Clark; opposed and seconded by Dr. Oswald Savage and Dr. J. Glyn. Preceded by dinner at 7.15 for 7.30 p.m.

Friday, January 21

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members. FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Radiotherapy Section meeting. Discussion: Cancer of the Larynx. Openers, Mr. G. S. Seed and Dr. J. R. Nuttall.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. G. B. Mitchell-Heggs: Chronic Granulomas.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., at Institute Lecture Theatre, open clinical demonstration by Mr. Vernon Thompson: Bronchiectasis.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Mr. W. S. Mack: Modern Trends in the Surgery of the Bladder and Prostate.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Professor D. M. Dunlop: Present Status of Cortisone in Practical Therapy.

SOCIETY FOR CULTURAL RELATIONS WITH THE U.S.S.R.: MEDICAL SECTION, 14, Kensington Square, London, W.—8 p.m., Dr. Alex. Comfort: Soviet Science; 9 p.m., annual general meeting of section.

Saturday, January 22

BRITISH ASSOCIATION OF ALLERGISTS.—At Royal Society of Medicine, 11 a.m., general meeting. Papers by Professor R. J. S. McDowall, Dr. J. R. Riley, Mr. W. E. Brocklehurst, Dr. F. J. Prime, and Dr. H. G. J. Herxheimer.

APPOINTMENTS

ALDERS, NICHOLAS, M.D., F.R.C.S.Ed., M.R.C.O.G., F.I.C.S., Part-time Consultant Obstetrician and Gynaecologist to Bournemouth and East Dorset Group of Hospitals, South-west Metropolitan Regional Hospital Board (appointment dated June 3, 1954).

COPE, D. H. P., M.B., B.S., F.F.A.R.C.S., Consultant Anaesthetist, the Middlesex Hospital, London, W.

FLEMING, G. M., M.D., D.P.H., Medical Officer, Ministry of Education.

GEDDES, J. E., M.D., Senior Consultant Chest Physician and Supervising Tuberculosis Physician; City of Glasgow Area Western Regional Hospital Board.

HOLMAN, REGINALD ALBERT, M.D., Primary F.R.C.S., Senior Lecturer in Bacteriology, Welsh National School of Medicine, Cardiff.

MCGRATH, S. DESMOND, M.R.C.P.I., D.P.M., Resident Medical Director of St. John of God Private Psychiatric Hospital, Sillorgan, Co. Dublin.

MURPHY, JOHN T., M.B., B.Ch., D.P.H., Medical Officer of Health, Borough of Faversham; Urban District Council of Sittingbourne and Milton; Rural District Council of Swale; Isle of Sheppey Joint (Medical Officer of Health) Committee; Faversham Port Health Authority.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. V. Mainprize, M.B., Ch.B., part-time Assistant Venerologist at Torbay Hospital, Torquay; G. O. M. Neatby, M.R.C.S., L.R.C.P., D.O.M.S., Clinical Assistant in Ophthalmology (S.H.M.O.) at Bath Eye Infirmary; H. I. Leigh, M.B., Ch.B., Registrar in the Department of Neurological Surgery, Frenchay Hospital, Bristol; B. V. Earle, M.D., M.R.C.P., D.P.M., Consultant Psychiatrist in Exeter Clinical Area; H. D. Moore, M.B., B.S., F.R.C.S., F.R.C.S.Ed., Consultant Surgeon in Exeter Clinical Area; J. W. Payne, M.B., Ch.B., F.R.C.S., D.O.M.S., Consultant Ophthalmologist in Plymouth Clinical Area.

WARREN, JOAN E., M.B., Ch.B., Medical Registrar, Worthing Hospital.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Wolf.—On December 15, 1954, at the Whittington Hospital, London, N. to Catherine, wife of Dr. Frederick Wolf, a son—Peter.

DEATHS

Atkinson.—On January 7, 1955, George James Smith Mounay Atkinson, O.B.E., M.R.C.S., L.R.C.P., aged 78.

Brown.—On January 1, 1955, Charlotte Rhoda Hodgins Brown, M.D., of 60, Brockwood Lane, Welwyn Garden City, Herts.

Grieve.—On December 30, 1954, at 53, Beverley Road, Hull, Yorks, Robert Grieve, M.D., F.R.C.S.Ed.

Hardman.—On December 24, 1954, Richard Smith Hardman, M.B., Ch.B., J.P., of "Hopetoun," Chester Road, Woodford, Bramhall, Cheshire, aged 83.

Joekes.—On January 2, 1955, at 16, Stoeplaan, Wassenaar, Holland, Theodor Joekes, M.B., aged 72.

Lee.—On January 6, 1955, at 39, Ivenhoe Road, Liverpool, Mary Buchanan Lee, L.R.C.P.&S.Ed., L.R.F.P.S.

McCreadie.—On January 3, 1955, at 22, Bankfield Road, Shipley, Yorks, Anthony John McCreadie, M.C., M.B., F.R.C.S.Ed., aged 65.

Macintosh.—On December 28, 1954, at The Gabes, Syston, Leicester, Alexander McCheyne Macintosh, M.B., Ch.B., aged 60.

McIntosh.—On December 27, 1954, at 57, Magdalen Yard Road, Dundee, David Glass McIntosh, M.B., Ch.B., M.R.C.P.Ed., D.P.H.

Maclean.—On December 25, 1954, at Newcastle-upon-Tyne, Murdo Maclean, M.B., Ch.B., aged 75.

Moberley.—On December 17, 1954, George Keble Moberley, L.R.C.P.&S.Ed., L.R.F.P.S., of Kloof, Natal, South Africa, aged 83.

Roberts.—On January 8, 1955, the result of an accident, Adeline Mary Roberts, O.B.E., M.D., J.P., late of Welbeck Hotel, London, W.

Rundle.—On December 24, 1954, at his home, Green Borders, Looe, Cornwall, Claude Rundle, O.B.E., M.D., D.P.H.

Somerset.—On December 27, 1954, William Ralph Somerset, M.B., Ch.B., of Wolverhampton, Staffs, aged 80.

Stewart.—On January 2, 1955, at Dial House, Bourton-on-the-Water, Glos, Robert Bell Stewart, M.C., M.B., Ch.B., D.P.H., D.T.M.

Sweet.—On December 27, 1954, Samuel Henry Sweet, M.R.C.S., L.R.C.P., of Heston Lodge, Heston, Middlesex.

Webber.—On December 24, 1954, at University College Hospital, London, W.C., Harold Norris Webber, B.Chir., F.F.A.R.C.S.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Treatment of Salmonella Carriers

Q.—We have lately had an epidemic of enteritis in this area, and *Salmonella typhi-murium* has caused a number of cases apparently. The patients are now all symptomless and very fit, but the public health authorities are excluding children with the salmonella in their stools from school for weeks and sometimes months. I am urged to treat the children with succinylsulphathiazole, then sulphadiazine, then chloramphenicol, and finally oral streptomycin if the carrier state has not meanwhile settled. This regime does not seem effective in many cases. Can you advise me, please?

A.—The treatment of the salmonella carrier state has always been a troublesome problem, and no infallible solution to it is known. In attempts to eliminate an organism altogether, as distinct from suppressing its growth during an acute infection, an actively bactericidal drug is preferable to one which is only bacteriostatic, and on this ground oral streptomycin is the most promising of the three treatments mentioned. It might well be tried first instead of being used as a last resort. The dose should be 0.5 or 1 g. according to age, four times a day for five days. Recently American workers have recommended combinations of oral antibiotics for treating intestinal conditions, and a mixture of streptomycin or neomycin and polymyxin (e.g. streptomycin 250 mg., polymyxin 200,000 units, in each dose) might well be tried, although, so far as we are aware, this would be purely experimental. All these antibiotics are unabsorbed when given orally, and there is thus no risk of toxic effects. They act only in the bowel, and would therefore be ineffective if the infection involved the biliary passages, as it sometimes does. Although antibiotics, when given parenterally, are excreted in the bile, some in high concentration, there is probably no drug treatment which can be depended on to cure the carrier state when it involves this area.

Surgery in Congenital Pulmonary Stenosis

Q.—What results may be anticipated from the surgical treatment of congenital pulmonary stenosis? What cases are suitable for surgery, and at what age should operation be performed? What regime is advised for infants and children awaiting operation?

A.—It is impossible to answer all the problems contained in this question in a short paragraph. The term "pulmonary stenosis" is a generic one covering various types of abnormality. There are considerable differences in both the clinical features and the management of those due to a pulmonary valve stenosis with a normal aortic root and those of the Fallot group in which the stenosis is associated with a ventricular septal defect.

In general, operation should be considered in all cases of pulmonary stenosis unless the condition is very mild or unless the patient is *in extremis* or has other grave defects. Cases of pure pulmonary valve stenosis should be operated on, however young the patient, if the condition is severe enough to satisfy general criteria. In the Fallot group it is generally better to wait until the age of 4 or 5 years, unless there are grave features, such as severe cyanosis or syncopal attacks.

While waiting for operation the children need chiefly the general care and protection from physical strain that most

parents are only too eager to accord; special medical attention includes avoidance of the perils of catarrhal and other infections; these children are especially prone to upper and lower respiratory infection. In spite of the polycythaemia iron may be needed.

Surgery offers hope of great relief, where before there was none. In good hands the mortality is not high, ranging from 5-15% for mild to severe cases. The results are good or excellent in about 70% of survivors; the child may appear completely normal in every way. Certainly life is transformed for both the child and the parents. When the cardiac lesion is complicated (for example, tetralogy of Fallot) the late prognosis is as yet uncertain. Operations have not yet been done for as long as ten years, and a longer time must elapse before this can be assessed. In cases of isolated pulmonary valve stenosis treated successfully by valvotomy the late prognosis is probably excellent.

Toxic Effects of Amphetamine

Q.—What toxic effects may arise from prolonged use of dexamphetamine sulphate? I am particularly interested to know whether there is any risk of blood or hepatic changes, chronic dyspepsia, carcinogenesis, and such-like serious effects.

A.—The actions and toxic effects of dexamphetamine sulphate are similar to those of amphetamine sulphate, but the D-isomer is claimed to be effective in smaller dosage. Both substances have been safely used for lengthy periods in narcolepsy or obesity in doses up to 60 mg. daily. The development of psychoses has been reported, as for example in the man of 49 who had taken 250 mg. daily for five years. Reports have also appeared of damage to bone marrow: pancytopenia occurred in a girl of 21, and acute aplastic anaemia in a man of 26 who took 290 mg. during 19 days. Habituation may also occur, though this is probably not very common. Withdrawal symptoms observed included hallucinations, restlessness, and insomnia. These symptoms, together with anorexia, may be expected to follow prolonged administration in most patients. Many of those receiving amphetamine possess personality defects and may be especially prone to exhibit these side-effects. Tachycardia and hypertension have also been reported, but I am not aware of any evidence of carcinogenesis or liver damage from prolonged use of dexamphetamine.

*This answer is taken from the third book of *Any Questions?* Copies of both the second and third books of *Any Questions?*, each containing some 200 expert answers, are available from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller, price 7s. 6d. a copy (postage 6d.). The third book contains a cumulative index.

Blushing

Q.—A girl of 19 who appears to be perfectly healthy has complained for the last year of involuntary blushing. This occurs regularly every afternoon and sometimes during the evening. There is a feeling of burning of the skin of her face and neck, which become suffused with blood and remain so for an hour or so. There seems to be no association with digestion: the blushing happens after a very light lunch or even no lunch at all. Nor is there any menstrual disturbance. She has a fair, healthy skin, is active and intelligent, and has no sign of thyroid dysfunction. Her main complaint is of getting her leg pulled unmercifully.

A.—Not much is known of the physiological mechanism of blushing, except that it is not affected by cervical sympathectomy. It is probable, however, that the mechanism of capillary dilatation over the blush area is inherently less stable in some people than others. In view of the fact that the girl is healthy, one can presumably exclude gross lesions such as hypertension, polycythaemia, pheochromocytoma,

carcinoid tumour, and the like. The condition must therefore be an exaggeration of the normal act of blushing, which, the psychiatrists tell us, is incompatible with complete innocence or modesty. It is supposed to occur typically in individuals in whom there is conflict between morality and sexual impulses and to be particularly common and severe at phases of life when these conflicts are especially acute. It is often associated with feelings of inferiority, and teasing is therefore quite the worst treatment. "Shyness springs from secret shame," and it would be worth trying to discover tactfully whether the lady has some such secret. An inquiry into the first onset of the symptom and the reason for its occurrence in the afternoon and evening might be helpful.

Prosthesis after Mastectomy

Q.—What is the best method to adopt after mastectomy to provide a natural and comfortable bust? Most supports lift upwards on the operation side owing to the lack of weight and in spite of artificial padding.

A.—I do not think there is any real difficulty in fitting artificial breasts. Many firms supply good ones, matching exactly the breast on the other side. They are made of sorbo rubber and are contained in washable covers. Any tendency to lift can be prevented by hooking the lower edge of the cover to the corset or other garment. No method of plastic remodelling of the removed breast is altogether satisfactory, and reliance should always be placed on some such prosthesis.

Two Cases of Fetishism

Q.—(a) A wife has asked my advice about her husband, aged 40 years. They have been happily married for 16 years, have three children, and have enjoyed a completely satisfactory sexual life. However, the husband, an apparently healthy, athletic type, has always shown a strong desire for his wife to wear, on occasions, only various plastic and rubber raincoats, etc. She has been quite happy to acquiesce to his wishes until she read somewhere that it indicated some type of mental disease and must therefore stop, in case it "leads to something worse." She is rather frightened to let her husband know that she has mentioned her husband's peculiarity, and really only wants reassurance. Is there any book which might help to give some semblance of a sensible answer to these and other similar problems should they crop up? (b) A boy aged 5 years has since infancy shown an abnormal desire to touch and handle silk. His mother had hoped this little habit would have disappeared as he grew up, but the reverse is the case. Very embarrassing situations are arising, as he is not averse to touching clothing of complete strangers. Already there has been some trouble at school, as he has gone so far as to "borrow" little girls' ribbons and has taken home quite a collection of them. He has also been touching the clothing of women in shops and buses. Should I advise psychiatric advice or let well alone? The mother is quite willing to "do anything."

A.—(a) The wife in the first question may be reassured. Her husband's peculiarity is a form of sexual disturbance termed *fetishism* in which the sexual feelings are aroused in association with an inanimate object. This well-known condition, which appears not to occur in women, dates from early childhood and may be associated with emotions concerning breast feeding or with fantasies concerning the female genital organs. The condition is often relieved by psychotherapy. It is not a mental disease but a symptom of emotional disturbance. Nor is the symptom the forerunner of "something worse," which presumably means the type of sexual perversion reported in the sensational press. Rubber and plastic raincoats, often of black material, women's shoes, and corsets and many other articles of women's attire are common fetishistic objects. The husband should be advised

to consult a psychiatrist if he finds his condition distressing. But this may be impracticable. Meanwhile the couple may resume marital relations, under the old conditions, in the certainty that no disaster will befall them.

(b) The second question concerns a fetishism for silk. The "little habit" is not likely to disappear spontaneously. The mother should at once get advice at a child guidance clinic. As he grows older the boy will learn to control the wish to touch and handle silk. But he may collect silk ribbons, etc., and keep them secretly and obtain erotic pleasure by feeling them. The habit and urge, although personally distressing and even hated, can acquire a compulsive power difficult to resist. The husband mentioned in the former question can probably recall childhood experiences comparable to those of the little boy of 5.

Fetishism and allied topics are described in *Mental Health and the Psychoneuroses*, by Dr. J. A. Hadfield (Allen and Unwin, 1953), and in *The Sexual Perversions and Abnormalities*, by Dr. Clifford Allen (Oxford Medical Publications, 1949).

Treatment of Meningococcal Meningitis

Q.—What is the accepted treatment of meningococcal meningitis? Has intravenous oxytetracycline ("terramycin") any place in its treatment?

A.—Sulphonamides are usually sufficient. For a severe infection in an adult give 2 g. "soluthiazole" (a soluble form of sulphathiazole) intravenously along with 1.5 g. sulphathiazole by mouth: repeat the oral dosage every four hours for three days, reducing to 1 g. six-hourly for a second three days. Alkaline fluids should be given by mouth throughout the course. Penicillin is not usually required, but if the cerebrospinal fluid is turbid it is sound practice in any meningeal illness to give 10,000 to 20,000 units intrathecally at the first lumbar puncture pending laboratory reports on the causal organism: if meningococci are reported, further penicillin is rarely necessary. Chloramphenicol given by mouth readily passes into the cerebrospinal fluid and has been used successfully in the treatment of meningococcal meningitis, but, on the score of expense and toxicity, has no advantage over sulphonamides. There is no obvious place for intravenous oxytetracycline. In *Prescribers' Notes* issued by the Ministry of Health for November, 1954, meningococcal meningitis is listed (p. 85) as one of the infections in which chlortetracycline ("aureomycin") and oxytetracycline ("terramycin") are not indicated, being less suitable than sulphonamides.

Tincture of Belladonna

Q.—I have a patient who is taking 5 minims (0.3 ml.) of tincture of belladonna each day as an antispasmodic. Is it possible that this dose could be cumulative in its effect?

A.—This dose of tincture of belladonna is equivalent to 1/600 gr. (0.1 mg.) of atropine. It would be wholly destroyed and excreted in 24 hours and would not be cumulative.

HUMAN NUTRITION AND THE SOPHISTICATION OF FOODS AND FEEDING HABITS

SOME OBSERVATIONS, IMPLICATIONS, AND SPECULATIONS*

BY

B. S. PLATT, C.M.G., Ph.D., M.B., Ch.B.

Human Nutrition Research Unit, M.R.C. Laboratories, London, N.W.3

In the Constitution of the World Health Organization health has been defined as a state of complete physical, mental, and social well-being. Good nutrition undoubtedly contributes to the attainment of this state, so "food and health" would be a happier theme than "food and disease." Unfortunately, we are not so accustomed to measure healthiness as we are to recognize the signs of illness, so that for the most part the effects of food have been analysed in relation to evidences of ill-health and the occurrence of diseases.

Failure to feed properly—overfeeding, underfeeding, or taking a diet in which the proportion of nutrients is imbalanced—leads to primary malnutrition; nutritional disorders may also be secondary to infections and infestations (Platt, 1954a). Since these aspects of malnutrition are now familiar, I shall consider food and disease in a context which is perhaps not so well known and which may be of special interest to the general practitioner of medicine in the years to come.

SOPHISTICATION OF FOODS

Sir Edward Mellanby (1951), commenting on the increased incidence in the past fifty years of certain morbid conditions, said that he found it "difficult to avoid the conclusion that some at least of these increases in disease are due to errors in living recently introduced or greatly expanded in modern times," and that "it may be that one of these errors is the ingestion of food treated by unnatural chemical substances." In the past, chemical manipulation or, as I shall call it, sophistication of foods was, apart from gross adulteration amounting to fraud, largely concerned with preservation, but there is now a formidable array of chemical and other treatments for a variety of purposes; these provide "at least a subject worthy of inquiry" and one which "might well be considered whenever a disease commonly found in countries which use these methods has resisted all efforts of the investigator to find a satisfactory aetiological basis" (Mellanby, 1951).

Examples of the deliberate introduction of chemicals into food for human consumption and their accidental occurrence are included in the accompanying Table.

*Based on a contribution to the Plenary Session on "Food and Disease" at the Annual Meeting of the British Medical Association, Glasgow, 1954.

which also gives references to some sources from which further information may be obtained. It will be clear, even from this limited bibliography, that the subject is so extensive that it will be possible here to make only brief comments on some selected aspects. These are dealt with in the same order as followed by the sections set out in the Table.

Unintentional Chemical Additives

The report of a Working Party on Toxic Chemicals in Agriculture and Residues in Foods (Ministry of Agriculture and Fisheries, 1953) contains a list of more than a hundred preparations, and these include some of the most powerful known poisons. The seriousness of the hazards to agricultural workers and others handling these aids to food production is recognized: but the Working Party, like a number of other authorities, reports that it has "been unable to discover any specific instances of illness which have resulted" from eating food treated with or exposed to some toxic chemical. "The position," it concludes, "does not therefore appear to have been established" (my italics) "as one of immediate danger." On the other hand, it does not consider that "it is one which allows of complacency."

I would be the last to deny the need for measures towards increasing crop production and preventing losses in storage, particularly in those parts of the world where food supplies are short. We have, however, to recognize in this, and indeed in the whole field of food technology, the possibility of a conflict of interests in which, as the *British Medical Journal* (1954) remarks, "It is doubtful if the influence of any such reformer [posing as a champion of the individual safety and protector of the public welfare] would ever equal or exceed that of a powerful commercial interest anxious to introduce a new material or technique into food production." The need for a strong and well-informed body of opinion is indeed well illustrated by an observation of the Working Party, commenting on the employment of bacterial rodenticides.

"The Public Health Laboratory Service and the Medical Research Council consider that the risks are such that the use of bacterial rodenticides should be discouraged with a view to their discontinuance. The Ministry of Agriculture's Infestation Control Division advise that immediate policy

should concentrate on ensuring proper care and attention in the preparation and use of these cultures and that any hasty action against these methods might lead to a serious dislocation in commercial rat destruction services." (Ministry of Agriculture and Fisheries, 1953.)

It is specially important to realize that much more is known about the hazards to health of these bacterial preparations than about many of the chemicals used in food whose presence may be difficult to detect and whose

effects on the human body may be subtle, insidious, and long-delayed. The problem is not so difficult when, as in the case of D.D.T., evidence has been obtained of the effects of acute poisoning in man. It is much more difficult to decide whether the occurrence of D.D.T. in the milk of cows and in a number of staple foodstuffs treated with this insecticide may have insidious and possibly long-delayed effects on the human body (House of Representatives, 1952).

Intentional Additives

Many chemicals are added to foods in an attempt to satisfy the supposed desire of the consumer for uniformity of certain qualities of food products; for example, it is said that a large well-piled loaf of bread is demanded. Uniformity can be carried too far, and sometimes we have to deplore the success of the caterer in producing a sameness of taste whatever the dish. Those of us who are concerned with the application of the principles of nutrition do not want to conflict with the efforts of the food technologist and caterer; in fact, we believe that our interests are, or could be, in many respects identical, and often the methods of preparation of food by which the best flavours are secured are also those which retain or enhance the biological value of foodstuffs. The next section in the Table is concerned with increasing the nutritive values of foods by methods known as enrichment and fortification.

The fortification of foods is now a well-known procedure; however, the wisdom of removing a number of naturally occurring nutrients from wheat-flour and replacing them by a limited number of synthetic substances is open to question. It has been shown (Richards, 1945) that an animal given an imbalanced mixture of synthetic B vitamins may show no signs of deficiency, but if the animal bears younger offspring may show signs of deficiency of one of the factors which has not been restored to the mother's diet. When a dietary deficiency develops it would seem to be obvious that the diet should be improved—for example, by adding natural concentrates. In medicine, developments in bacteriology since Pasteur have been almost exclusively concerned with the study of micro-organisms pathogenic to man, but in food some micro-organisms may be not only non-pathogenic but actually beneficial to mankind. I would regret the passing of fermentative procedures, a natural way of improving the value of food which I have called "biological ennoblement" (Platt, 1946).

The conventional preservatives in current use are the successors of the spices of earlier days, which were used to disguise the flavours of food which had "gone off"; some of these spices also had bacteriostatic or fungistatic properties. To-day the microbiologist is wisely directing his efforts towards eliminating the contamination of food products with pathogenic organisms so that chemical preservatives should not now be so necessary.

Chemical substances added to food may not only be toxic themselves but may also destroy, alter, or interfere with the absorption or utilization of nutrients, and the altered nutrients and their decomposition products are themselves sometimes harmful: for example, the effect on flour of agene is to convert the essential amino-acid methionine into a substance, methionine sulphoximine (Bentley *et al.*, 1950; Campbell *et al.*, 1951), which has a striking effect on the behaviour of some animals. This compound belongs to a fascinating group of substances known as anti-metabolites (Woolley, 1952).

Physical Treatment

As well as the problems associated with the addition of chemicals to food there are also problems which result from the physical treatment of foods by such methods as cooking, heating, drying, canning, and freezing (Lepovsky, 1953). Although, by definition, cooking is heating, the word does imply much more than this: its aim should be to retain or enhance flavours and to make the food appetizing and palatable. It is well known that flavours and food values are lost when the art of cooking is lost; in particular, the loss of ascorbic acid has been thoroughly examined (Stewart, 1946). In some respects the retention of ascorbic acid is a guide to good cooking, as flavours, colouring agents, etc., are dependent on the presence of chemical substances which, like this vitamin, may be leached out or destroyed in the course of many cooking methods.

It has been known for some years that fats and oils decompose on heating, fortunately at temperatures which

are high compared with those normally employed in cooking, and that carcinogens are produced (Peacock *et al.*, 1953). The phenomena of denaturation of proteins and the "browning" or Maillard reaction between proteins and carbohydrates have also been familiar to biochemists for many years; they have now been associated with the lowering of the biological value of protein; there is evidence that in these changes the essential amino-acids lysine and methionine may be destroyed. With the rapidly increasing interest in protein malnutrition (*British Medical Journal*, 1952) which is now known to be prevalent in so many parts of the world these effects are likely to receive increasing attention. Are there any reasons for believing that they are relevant to unsolved problems in medicine in this country?

Lysine we know to be required for growth and for maintaining a normal blood picture; methionine and the other sulphur-containing amino-acid, cystine, are important in the nutrition of skin and hair (Platt, 1953). A relative methionine deficiency has been shown (Mann *et al.*, 1953) to be in monkeys a factor in the production of hypercholesterolaemia and atherosclerosis. The aetiology of a number of disorders of the blood, skin, blood vessels, and eyes is still in question; a case might be made out for investigating these in relation to recent developments in food technology. I want to stress the point that there may not necessarily be merely deficiency of a nutrient following destruction during some process, but this insufficiency may be combined with the effects of the altered nutrients behaving, for example, like the anti-metabolites.

Technical Difficulties

Attempts to assess the effects on the consumer of all these procedures raise great technical difficulties. Barnes (1951) states that "any substance added to food must display no demonstrable toxicity for animals and must satisfy rigorous standards of purity," but this toxicologist concludes that "the problem of the adulteration of food by chemical substances will come to lie within the field of nutrition rather than in the more strictly limited one of toxicology." It is difficult to reconcile with this the views of a pharmacologist who, for reasons which are by no means clear, would exclude nutritional and palatability effects from those used in determining an effective dose level, though he concedes that "it seems advisable that the effect of food additives on the nutritional value of the diet should be known" (Frazer, 1953). Animal experiments may afford some help, but we must face the conclusion that "it is impossible to conceive of animal experiments which will provide complete information about the toxic effects of chemicals on human beings" (Barnes, 1951). The demonstration by experimental or other techniques of the dangers to human health of a procedure introduced into food technology may follow its introduction only after a long lag period. We may note here that agene was in use in the flour-milling industry for 30 years before its toxic effects, even in animals, were recognized and explained.

If there are hazards, then I consider that they may be relatively greater if exposure occurs during the period when biochemical changes are most intense—that is, during growth; and the clinical results may appear only with advancing age. As in industrial medicine, so in food technology, each new development may raise new medical problems. The onus of assessment of hazards to the health of the consumer must be accepted by the medical profession, which must lose no opportunity to obtain, scrutinize, and weigh the evidence before countenancing existing practices in food technology and sanctioning new developments in this field.

SOPHISTICATION OF FOODS AND FEEDING HABITS

Changes have occurred and others are still occurring which affect the foods and feeding habits of mankind; prominent in the dietary history of this country are the results of the introduction of potatoes and, earlier still, the

change in the meat supply consequent on the provision of root crops for livestock. Alternating periods of shortage and comparative plenty, markedly seasonal variations in the diet, and very localized peculiarities of taste and custom are still to be found in many primitive communities. In sophisticated communities feeding now is generally characterized by an evenness of supply throughout the year and a uniformity of diet amounting often to monotony; this has been the result of advances in agriculture, food technology, and modern methods of transport. The health of the community may be affected, for better or for worse, to the extent to which these developments affect the predominating foodstuffs and influence feeding habits. I shall now discuss only one such development—the artificial feeding of infants with some form of cows' milk.

Infant Feeding

Two centuries ago, in this country, breast-feeding by the mother or wet-nurse was almost universal and was probably continued for two or even three or more years, as it still is in many parts of the world to-day (Platt, 1954b). In Western countries nowadays, however, the child is often artificially fed from its earliest days or is weaned from the breast at 6 to 9 months of age. It must be admitted that until quite recently there has been no very convincing evidence for the superiority of human milk to cows' milk (Platt and Moncrieff, 1947), and the preference for the feeding of human infants at the breast instead of with cows' milk has been almost entirely a matter of faith. Such differences as a calcium content five to six times greater in cows' milk than in human milk have been overlooked. However, the curves showing the relation between the calcium content of the infant and the duration of feeding on cows' milk and human milk are reminiscent of those mentioned below relating nitrogen content of the body to age. After six to ten months' feeding on cows' milk the proportion of calcium in the infant's body is more than half as much again as that in the infant fed on human milk (Stearns, 1939).

The fact that so few infants show gross clinical, pathological, and biochemical changes in the early months of life is a comment on the point made below about the differences that are likely to occur between individuals; there are here, however, grounds for apprehension about the possible delayed effects of excessive intake of calcium in artificial feeding. It has been stated (Lancet, 1954) that hypercalcaemia "must be quite a common disorder, for 42 cases have been reported in this country alone in the last year and many more have been recognized." The frequency with which a history of feeding on cows' milk is reported suggests that the practice is an important if not a determining factor in the causation of the condition.

I want now to offer some observations which have led me to speculate about the possibility that modern infant-feeding practices may be concerned in the causation of certain diseases which we associate with modern conditions of life and living, and for the occurrence of which we have as yet no satisfactory explanation. I have found (Platt, 1954c, 1954d) that milk in the infant rat's stomach separates into curds and whey. The curds, which are laid down in successive layers, are slowly digested and normally do not leave the stomach for 15 hours or more. The whey, however, leaves rapidly, and the greater part of it passes through the pylorus in 30 to 40 minutes. The casein of the curds appears to be broken down into its constituent amino-acids, but there are some grounds for believing that the components of the whey not only behave differently in the stomach, but may not be completely broken down before absorption. We do not know if milk behaves in a similar way in the human baby's stomach; indeed, very little appears to be known about this subject. It is customary, in the study of gastric function, to start by ensuring that the stomach is empty. If the infant animal takes milk into a stomach which has been empty for some time, an undifferentiated clot forms which contains pockets of air and mucus, and only after several hours is the usual pattern of

layers restored. I suspect (Platt, 1954b) that there may be physiological as well as psychological grounds for a return to the recently reinstated system of feeding "on demand."

Since 1892 it has been known from Ehrlich's work on mice (Ehrlich, 1892) that antibodies can be transmitted in colostrum or milk from mother to offspring. Similar observations on the transference of immunity factors have been made on calves (Howe, 1921; Orcutt and Howe, 1922; Smith and Little, 1922), and these have been confirmed by electrophoretic methods for the pig (Foster *et al.*, 1951) as well as for the calf (Smith, 1948). The low serum cholinesterase of newborn puppies has been shown to be increased (McCance *et al.*, 1949) when they were fed on bitches' milk containing this enzyme, but not when they were fed on cows' milk or human milk. There is also an interesting observation made by Rutman (1950) on rats; he found that the infants of one strain, in which a poor ability to incorporate methionine into protein was demonstrated, acquired this ability when fed by mothers which had an efficient capacity for this process; presumably this was acquired by transference of some factor in the foster-mother's milk.

The importance of the protein components of colostrum and early milk may not be so great for the human infant as it appears to be for many species of animals. However, on the basis of the evidence available, I have wondered whether we should regard the mother during lactation not merely as a provider of food but also as a supplier of substances ready made for use by the infant until such time as he can synthesize them for himself. Is breast-feeding, therefore, a device by which provision is made for a transition between complete dependence on the mother before birth and complete independence after weaning from the breast?

Galactose and Myelination

A main component of whey is milk sugar—lactose—which is entirely contained in the whey. It is a disaccharide which is made up of glucose and galactose. As well as being present in milk as lactose, which is in part combined with neuraminic acid (Trucco and Caputto, 1954; Heyworth and Bacon, 1954), galactose is known to be a component of several substances found in the mammalian body. It is found in the cerebroside of the central nervous system and in mucopolysaccharides in connective tissue (references to the occurrence of these are given below), in a galactan (Wolf from *et al.*, 1947; Wolf from *et al.*, 1952), and in the protein-bound carbohydrates of seromucoid, certain serum globulins (glycoproteins), and the carbohydrate of chorionic gonadotropin (Werner and Odén, 1949). We do not know if the human infant is able, in his early life, to synthesize galactose; indeed, we do not know if galactose can be synthesized in any human tissue at any age except in the mammary gland (Reiss and Barry, 1953). Galactose, therefore, may be a substance for which the human infant is dependent on his food—that is, in this case it would be an "essential" nutrient in the sense that some amino-acids and the accessory food factors are "essential" and the origin of any galactose laid down in later life is quite obscure.

The cerebroside is the principal lipid of myelin, most of which, as is well known, is laid down after birth (Johnson *et al.*, 1949). Myelination continues until perhaps the fifth to sixth year of life (Kennard, 1952), and the progress of myelination of nerves may well be determined by the activity of the muscles with which they are connected. In this connexion I wish to draw attention to an observation (Stearns, 1939) the significance of which has not, so far as I know, been explained. This is that an infant fed on cows' milk stores nitrogen at a much greater rate than one on breast milk, and that at 6 months of age the percentage of nitrogen in the bodies of infants fed on cows' milk is about twice that in the bodies of those fed on human milk. Presumably most of this nitrogen is stored as muscle protein, and we may infer that in the cows'-milk-fed infant the rate of muscle development may be more rapid than in the breast-fed infant. If this also entails more rapid myelination of the appropriate nerves, and if the galactose for the

synthesis of myelin must come ready synthesized from the food, we have to take account of the fact that the cows'-milk-fed baby gets only two-thirds of the amount of lactose which he would receive if he were being fed the corresponding amount of human breast milk. Does this possible extra demand, coupled with the reduced supply of galactose, have any adverse effect on the subsequent health of the individual?

We know that when unusually large quantities of cerebroside are synthesized, as in Gaucher's disease, those from the spleen and from the brain may contain glucose (Woolf, 1954). There was a report last year (Montreuil *et al.*, 1953) that glucose occurs along with galactose in the cerebroside of normal brain. It has been reported that in mammals there is a positive correlation between the percentage of lactose in the milk of the species and the cerebroside content of the brain (Brody and Sadhu, 1947). On feeding dextrose to young pigeons, glucocerebrosides were found to constitute one-third of the total cerebroside, there being none in the brain of the normal birds (Sadhu, 1953a). Changes in the proportion of cerebroside to other lipids have been observed when weanling rats are fed whole milk as compared with skimmed milk (Sadhu, 1953b). It would seem from these observations that an investigation of the composition of the cerebroside of myelin of the human infant's nervous system should be made with a view to determining whether the substitution of cows' milk for human milk has any effect on it. I suspect that the effect on the composition of myelin may be particularly profound when an infant is artificially fed on a "humanized" cows' milk preparation which may supply as little as one-third of the lactose obtainable from human milk.

If glyocerebroside occurs as a substitute for part of the galactocerebroside, does it persist into adult life? We do not know the answer to this question. It might at first be thought, in view of the dynamic equilibrium of substances in the human body, that glucose would ultimately be replaced by galactose. This would depend on whether galactose could be synthesized in the brain or elsewhere in the body, and, if outside the central nervous system, could it pass through the haemorrhagic barrier, which seems to be more difficult to cross in the mature than in the growing subject (King, 1939)? There is some evidence from isotope studies that metabolically the brain is somewhat isolated from the rest of the body. Thus there appears to be no significant turnover of C^{14} in rat-brain protein after the isotope has been incorporated in the organ during its period of growth (Schubert and Armstrong, 1949), and the general conclusion has been expressed that "there seems to be in the brain a degree of spatial permanency" (Folch-Pi, 1951). It may then be that, like proteins, the brain lipids remain throughout adult life within the brain metabolic pool.

Possible Consequences of Imperfect Myelination

If abnormal cerebroside occur and persist, do they have any adverse effect on the subsequent health of the individual? In my contribution to the symposium on Food and Disease (Platt, 1954e) I contented myself with asking whether, if the composition of myelin is affected as a result of the sophistication of a feeding habit, this might have some possible relation to the prevalence of disseminated sclerosis. I shall now, so far as I am able, discuss this possibility in more detail.

Lumsden (1951) suggests two alternative views of the causation of disseminated sclerosis, one of them being that it is "a specific form of reaction on the part of the nervous system peculiar to certain individuals and, within limits, independent of its immediate precipitating cause." May the presence of an abnormal cerebroside determine the occurrence of this specific form of reaction? If this were so, it would fit in with a recent interpretation of the meaning of the haunting term "abiotrophy" introduced by Sir William Gowers and defined as a primary nervous system disorder in which local tissue resistance is overcome, with consequent disintegration of that tissue. In a recent study of a familial

myelinating disease it has, however, been stated that "there is more than suspicious evidence that the term primary is misleading, and that actually one deals with a primary disorder of metabolism with a secondary nervous system disorder" (Stadler *et al.*, 1954). There is, it seems, an important and relevant conclusion to be drawn from the study of the pathology of disseminated sclerosis—namely, that "some property of myelin determines the localization of the pathology" (Adams and Kubik, 1952).

If a poor supply of galactose in the infant's diet contributes to this specific form of reaction, then it might well be expected that disseminated sclerosis might be even more common than it is. There are, however, two possible considerations which might account for a comparatively low incidence: (a) the occurrence of the postulated "immediate precipitating factors," and (b) individual differences in rates of development of muscle and nervous system. Lumsden offers the hypothesis that, whatever the precipitating factors may be, the pathological changes may result from the action of a myelinolytic ferment; could it be that this is a cerebroside and that the glyocerebrosides may be more readily hydrolysed than the normal compound, or that there is no anti-enzyme for this reaction? These points are now being investigated.

So far as development of muscular and nervous systems is concerned there is now good evidence of quite remarkable differences in the ages at which various behaviour patterns are seen in infants (McGraw, 1943). How far these are associated with differences in the extent of myelination does not appear to be known, nor does there seem to have been any investigation of the possible relationships between the methods of feeding infants and their rates of maturation. There is evidence that there are differences for certain forms of behaviour up to 3 to 4 years of age (McGraw, 1943), that myelination may not be complete till 5 to 6 years of age (Kennard, 1952), and that breast-feeding is uncommon nowadays beyond 1 year.

Douglas (1950), in a survey in the United Kingdom, found, out of over 40,000 infants, only nine who were breast-fed up to 2 years of age. If the amount of galactose supplied to the infant is crucial then obviously the amount of breast milk taken, the duration of breast-feeding, and the amount of galactose obtainable from other dietary sources are all important. Materials containing galactose are known to come from plant sources (Black and Cornhill, 1954), but there is no evidence that they are assimilated; galactose-containing substances are also found in snails and slugs, and it is known that small "dew slugs" were at one time recommended for the nourishment of backward children (Hartley, 1954). In communities where breast-feeding is usual, and is continued for two to three years, disseminated sclerosis is rare and the cases reported are often unconfirmed by pathological evidence. Also, in other communities where feeding with carbohydrates, including cane sugar, is common in infancy—for example, in the West Indies—a syndrome with the features of a transverse myelitis is not uncommon and is suspected to be of nutritional origin. Inquiries are being made about the precise nature of this condition.

Dietary Damage in the Young

There may be some difficulty in accepting the hypothesis of a dietary defect in infancy resulting in a disease whose earliest clinical manifestations may be delayed till the second decade in life, or later. It is, however, being increasingly recognized that dietary damage in the young—or even prenatally (Giroud, 1954)—may have effects only late in life. Acute choline deficiency in the young rat may result in hypertension, but only in later life (Hartroft and Best, 1949) and after a period equivalent in man to about 20 years. Similarly, the development in a strain of mice of a type of arthritic degeneration occurring in older animals has been shown (Silberberg and Silberberg, 1952) to be strikingly affected by the nature of the diet throughout life. There is a good deal of evidence of the occurrence of a lag between a biochemical disturbance and the appearance of

pathological and clinical manifestations: one of the longest intervals is that recorded (Henry, 1946) in the development of epitheliomata of the scrotum and penis many years after exposure to the carcinogenic agent.

Most of the evidence that disorders in early life may produce tissue changes at an advanced age is derived from observations on animals, and, whilst it may be misleading to apply inferences from experiments in animals to the explanation of disease processes in man, it is obviously convenient to study such changes in animals with a short life-span. In the human species the period of growth is uniquely long in proportion to the life-span (Brody and Ragsdale, 1922-3), and in the study of human disease, therefore, we must be particularly concerned about disturbances during growth, neonatal as well as post-natal, and be on the look-out for sequelae in the adult. Thus the possible effects of artificial feeding of infants may not be seen for many years, and perhaps only after the tissues have been exposed to stresses or the effects of noxious agents. We may indeed be reaping in medical practice and in the post-mortem room to-day the results of methods of feeding infants and young children which were prevalent 20 to 30 years ago.

A conclusion about disseminated sclerosis on which there seems to be agreement is that "the major histopathologic changes seem to conform to those seen in degenerative diseases of the central nervous system" (Davison, 1950). The phylogenetically newer systems—the pyramidal tracts and the proprioceptive system—commonly suffer permanent damage (Martin and Elkington, 1946). These observations are of interest, since presumably the maturation of the neuromuscular mechanisms of the older systems is completed early in infancy; the swimming behaviour of the newborn infant, one of the oldest phylogenetic functions (McGraw, 1943), disappears in most infants in the first few weeks of life. Many disorders of nutrition and metabolism have clinical features in common with those of old age; and it has been stated that during "the involutionary period, the individual loses his capacity for homeostasis as if involution were a mirror image of adolescence with senescence as a return to the physiological instability of infancy" (Frank, 1946). It might be, though I am not sufficiently well informed to do more than make the suggestion, that in the clinical signs of disseminated sclerosis may be found the mirror image of development, but as reflections which are revealed early and distorted as a result of imperfect myelination.

"Collagen Diseases"

Galactose is, as mentioned above, a constituent of some components of extracellular material (ground substance) and connective tissue. There has in the past been an almost exclusive interest in the biochemistry, physiology, and pathology of the cell, and until recently little consideration has been given to the nature and functions of the extracellular structures and substances. The concept of an "extracellular space" is being replaced and some of the properties hitherto attributed to the membrane of the cell are being ascribed to the extracellular matrix. One suggestion made recently is that the blood-brain barrier may be due to the existence of ground substance (Woollam and Millen, 1954).

The possibility that galactose might be a constituent of the mucopolysaccharides of the cornea was suggested by Suzuki (1939) and confirmed recently by Woodin (1952) and Meyer *et al.* (1953); its presence in connective tissue (Consden *et al.*, 1953) and in human subcutaneous tissue (Consden and Bird, 1954) has now been established. Several times has the presence of galactose in collagenous material been reported, and Glegg *et al.* (1953), who review these observations, have evidence that it is the reticular fibres of connective tissue which appear to have the sugars galactose, glucose, and mannose as integral constituents. During some work on wound healing Penney and Balfour (1949), in my unit, demonstrated the importance of mucopolysaccharides in skin for healing, and they associated this substance with

the formation of reticulin fibres, an observation which is supported by the recent demonstration of Glegg *et al.* (1953) on the composition of these fibres.

Interest is growing in a group of disorders of connective or mesenchymal tissue which have been called "collagen diseases," and Robb-Smith (1952) has claimed that there is quite a lot of evidence that the mechanisms of formation of abnormal glycoprotein are associated with the morphogenesis of these diseases. I want to do no more here than to suggest that the supply of galactose—or substitution of glucose for this sugar—in the feeding of the infant and young child may affect the nature, composition, and reaction to stress in later life of the extracellular matrix and connective tissue, and may thus be a factor in the occurrence of a number of diseases which might be identified with the sophistication of living. I would add to Mellanby's suggestion, quoted at the beginning of this paper, a plea for a study of the effects of changes in feeding habits consequent on the various methods of sophistication of foods, and conclude with the support of a pathologist (Robb-Smith, 1952) that "yet more profit may be gained by considering the biochemical morphogenesis of which something is known and more can be learnt than by restricting oneself to aetiology of which almost nothing is known."

TREATMENT OF SCHISTOSOMIASIS WITH "NILODIN"

BY

B. A. KING, M.B., B.Ch.

(From the Witpoort Native Hospital, Brakpan, Transvaal)

A mine medical officer in the Union of South Africa has undeniable advantages in assessing the effects of treatment of schistosomiasis. In the first place, the mines of the Witwatersrand and Orange Free State are situated in "clean" areas, whereas the labour force is to a large extent drawn from heavily infested areas; therefore once the disease has been successfully treated the question of reinfection is not likely to arise to cloud the issue. In the second place, a wholly adequate follow-up of cases is possible, as natives recruited from the infested areas do not sign labour contracts for periods of less than nine months, and furthermore any mine employee can be recalled for re-examination at any time. Thirdly, a very large percentage of the tropical labour force, especially the Portuguese East African contingent, is infected with both *Schistosoma haematobium* and *S. mansoni*, so that an adequate number of cases are available for treatment and assessment.

At the Brakpan Mines in the Transvaal a trial was made of the use of "nilodin" brand of lucanthone hydrochloride (1-β-diethyl-aminoethylamino-4-methylthioxanthone hydrochloride; "miracil D") in the treatment of both urinary and rectal schistosomiasis. In the former the infecting organism was *S. haematobium*, and in the latter *S. mansoni*. In reporting the results certain aspects, such as the clinical diagnosis, presenting symptoms, tribal incidence, and haematology, have been omitted for the sake of brevity.

In both forms of infection the diagnosis was based on laboratory examination of specimens of urine and faeces respectively for the presence of viable ova. Ova are considered to be viable if free-swimming miracidia are present or there are active movements of miracidia within the ova. Occasionally an ovum remains motionless after exposure to water in high dilution, but the flame cells can be observed beating in the organism and the cilia may be moving. An ovum with none of the above signs but morphologically normal is referred to throughout this paper as "inert." After treatment ova are passed which can be referred to only as "macerated." They contain an amorphous mass; no movement or "pulse" of flame cells can be observed. Some ova are shrunken, while others appear to have swollen and burst. It is

common to observe "globules" within macerated ova which are not seen in normal ova.

The nilodin used throughout the trial was in the form of tablets each of which contained 200 mg. In these circumstances it was usually impossible to adhere strictly to a particular scheme of dosage based on body weight. No patient was started on less than the specification decided upon, and when part of a tablet was indicated a whole tablet was given. Thus when the dosage was 20 mg. per kg. of body weight a day, a patient weighing 56.5 kg. would actually receive six tablets = 1,200 mg. daily instead of the 1,130 mg. indicated by his weight.

URINARY SCHISTOSOMIASIS

Results of treatment in a total of 46 cases of infection with *S. haematobium* are presented. These are divided into two series in which the dosage, the course of treatment, the method of follow-up, and the method of urine collection differed.

Series 1

This series originally consisted of 37 cases, but 13 of these were excluded from the investigation for various reasons: in 9 cases the follow-up was inadequate, 3 proved to be cases of rectal schistosomiasis, and in the other case no viable ova were demonstrable before treatment. The remaining 24 cases were followed up for at least three months. Cases were re-examined once a week for the first three months and thereafter at monthly intervals.

Laboratory Examination

In most of these cases viable ova or miracidia were found in the first (casual) specimen of urine passed. In no case were more than three specimens required to make a positive diagnosis. The technique of urine examination used for both diagnostic and follow-up purposes is as follows.

The conical glasses of urine are allowed to stand for a variable period after collection, but not less than 15 minutes. The supernatant urine is then decanted; the remainder is well stirred, poured into a centrifuge tube, and spun down at 3,000 r.p.m. for three minutes. The supernatant urine is now discarded, and the centrifuge tube filled with tap water and again spun down. The supernatant water is discarded and the sediment shaken up in the few drops remaining. With a clean pipette in every instance the remaining drops are placed on a slide and examined. The search for ova can be made very satisfactorily with the low-power objective of the microscope, but to establish viability of an ovum the high-power lens (×800) is required. It is of the greatest importance that the complete sediment—that is, four drops as a rule—be examined at every re-examination. Each centrifuge tube as used contains 14 ml. of urine.

The great advantage of this technique for follow-up purposes is that the viability of ova can be established almost at once, it being common to find miracidia swimming in the drops upon examination immediately after preparation of the slide. The World Health Organization Expert Committee on Bilharziasis (1953) recommends that centrifuging be limited to 1,000 r.p.m. to obviate the risk of ova disintegrating. I have never, however, found excessive centrifuging, either for too long a time or at too high speed, to cause disintegration of ova.

Dosage

The dosage of nilodin was worked out to give 20 mg. per kg. of body weight per day divided into three equal doses. However, as explained above, the strength of the tablets made it impossible to conform exactly to this amount; consequently, and taking into account reduction of dosage because of toxic symptoms, the average daily dose received by these patients was 22 mg. per kg. No case received less than a 12-day course of treatment, and in one case the treatment extended over 13 days.

Toxicity

Of the 37 cases in which treatment was started 21 (56.7%) had toxic symptoms. These were easily controlled and in no case was it necessary to discontinue treatment, although

the initial dosage of the drug had to be reduced in 11 cases (29.7%). (In two cases the dose had to be reduced on two separate occasions.) A list of toxic manifestations with their frequency is presented in Table I.

TABLE I.—Toxic Manifestations

Symptoms	No. of Cases	Percentage of All Cases (21) with Toxic Symptoms	Percentage of All Cases (37) Treated
Nausea and vomiting	12	57.1	32.4
Abdominal pain and discomfort	5	23.8	13.5
Anorexia and nausea	3	14.3	8.1
Suprapubic pain	1	4.8	2.7
Total	21	100.0	56.7

Toxic symptoms first appeared as early as the third day and as late as the tenth day (one case each), the average time being the sixth day. Phenobarbitone, 1 gr. (65 mg.) twice daily, was used to control such symptoms; if this was not effective, the dosage of nilodin was reduced by 200 mg. a day. Although "jaundice" has been reported (Haseeb, 1952) to occur during nilodin therapy, this was not noted in the present series. In all cases there was a very deep reddish-brown pigmentation of the palms and soles, but the conjunctivae were not affected. The urine became bright yellow and so did the tongue—the latter merely from contact with the pills. Examination of the blood on the last (12th) day of treatment in 19 consecutive cases showed that not one had a total serum bilirubin level above 0.5 mg. per 100 ml. and that the highest icteric index was 7. There was no apparent effect upon the kidney glomeruli as evidenced by tests for albuminuria following treatment. Toxic symptoms developed more rapidly and were worse, however, in patients whose renal function was already impaired.

During the 12 days' treatment 22 (59.4%) of the 37 patients had a weight loss ranging from 1 to 17½ lb. (0.45 to 7.7 kg.), with an average of 7 lb. (3.175 kg.). Of these 22 patients 14 complained of toxic symptoms, so that there is a fair correlation between weight loss and toxic effects. Loss of weight was accompanied by a marked diuresis in certain cases.

Results

The clinical response was good. In most cases of frank haematuria the bleeding stopped on about the eighth day; in only two or three cases did it persist, and was then due to granulomata. Patients who continued to pass blood were examined cystoscopically to exclude the possibility of the presence of carcinoma; if there was any doubt a urologist's opinion was sought. In pyrexial cases the temperature responded by the sixth day at the latest, and this response was obtained with nilodin alone. The temperature would probably have fallen much sooner had urinary antiseptics been used to combat the secondary infection which was usually present, but, as the effect of such drugs on *S. haematobium* infection was not known, this might have nullified any claim that the assessment was accurate. Results can be assessed correctly only by an adequate follow-up, which must extend over a period of at least six months. The more examinations which can be made in this period the more accurate will the assessment be.

Of the 24 cases reported five relapsed within the three-month period. In two more cases relapse occurred after this period, in one case eight and a half months and in one six months after treatment. Only ten cases which did not relapse within the first three months could be followed up for six months. There was only one further relapse among these ten cases. Nevertheless, out of 15 cases in which either relapse occurred or the full six-month period of follow-up was completed, six relapsed. (See Table II.) It is therefore obvious that relapse does occur up to, and even after, six months following treatment. I would like to stress that the term "relapse" is here used in its strictest sense. If only one viable ovum or miracidium was observed at any time after the first week following treatment, then

TABLE II.—Results of Follow-up Examinations

Series No.	After Three Months				After Six Months			
	No. of Cases	No. of Re-examinations	No. of Cases Relapsed	% of Cures	No. of Cases	No. of Re-examinations	No. of Cases Relapsed	% of Cures
1	24	13 each	5	79	15	16 each	6	60
2	22	4 "	5	77	18	9 "	12	33

that case was considered to have relapsed. In actual fact only one "clinical" relapse occurred.

In this series, therefore, we claim to have achieved a 60% "six-month cure," although as this figure does not include the case which relapsed after eight and a half months it is somewhat optimistic. I would, however, stress that, with only one exception, every case was of extremely long standing or chronicity. The cases which relapsed all had very heavy infections, as judged by the number (usually hundreds) of miracidia and ova found at the diagnostic examination.

It is necessary to explain why the cases in which viable ova continued to be passed seven days after treatment cannot be considered as relapses. In the first place it takes an average of six days for nilodin to reach its highest concentration in the serum, as shown by the time taken for the deep pigmentation of the palms, the coloration of the urine, and the toxic symptoms to develop. Therefore the drug is still acting on the worms six days after stopping treatment. Secondly, any ova found at the first re-examination were certainly laid at least 24 hours, and probably three to four days, previously. In chronic cases with much induration, and even calcification, of the bladder wall it may take a considerably longer period for an ovum to penetrate into the lumen of the organ. This being the case, the viability of these ova is no criterion of the state of the parent worms. Once encased within its shell, it is questionable whether the miracidium is as vulnerable to the action of a drug as the adult worm. Furthermore, the eggs lie in the tissue and not in the main blood stream and are thus not exposed to the same concentration of drug. Thirdly, any ova found at the first examination after a 12-day course were not normal; they can only be described as "deformed." Within the ovum large vacuoles and globules had formed, and any movement present was extremely sluggish. When such ova hatch the miracidia are grossly abnormal in shape; the smooth outline is lost, to be replaced by a wavy, irregular periphery; movements are sluggish and the clear protoplasmic outlines are obscured by a degenerate mottling. These changes may have been due to the effect of the drug on the egg-producing organs of the female worm, or possibly on the eggs held up in the tissues.

Of the seven cases in which relapse did occur, three were noted to have viable, though abnormal, ova at the first re-examination. This may be a prognostic point in cases treated with nilodin, as only six cases were observed to have viable ova at the first examination and three of these relapsed later. The mean time of relapse was at the seventh week after treatment.

Series 2

The second series consisted of 22 cases. Every case was seen one week after completing treatment, and thereafter at monthly intervals for six months. Four of the cases did not complete the full six-month period. Four months after completion of treatment every patient was readmitted to hospital for three days, during which time a different method of collecting urine for examination was employed. At all other examinations urine was simply passed into a urine-analysis glass, whereas, in hospital, urine was collected after each patient had taken a 15-minute "ride" on a physiotherapy bicycle every morning for three consecutive mornings. One "24-hour" specimen of urine was also collected. This was voided into a Winchester bottle, and then by a repeated process of decanting and settling a volume of urine and sediment small enough to be centrifuged and examined was obtained.

Dosage

The aim in this series was to give a more concentrated course of treatment over a shorter period. Accordingly the initial dosage was scheduled to be not less than 25 mg. per kg. of body weight per day and the course covered nine days. After the dose had been reduced in two cases because of toxic symptoms the average total dose was 225 mg. per kg. of body weight, so that the average daily dose was in fact 25 mg. per kg.

No specific notes on toxicity were made in this series, as nilodin had been proved by the first series to be relatively non-toxic and without after-effects. In this connexion it will be sufficient to point out that the dosage had only twice to be reduced.

Results

The clinical response was much the same as in the first series. Of 18 cases in which a six-month period of follow-up was completed, 12 (67%) relapsed (Table II). Of these only one was a clinical relapse and 11 were technical relapses. In 7 (58%) of these 12 cases viable ova were found at the first weekly re-examination following treatment. This would seem to confirm that the presence of viable ova at the first weekly re-examination may be a useful prognostic point. In one case relapse occurred seven months after treatment, in this instance a full clinical relapse.

Thus, regarded in the very best light, a 33% "six-month cure" was obtained. Once again this figure is optimistic when it is remembered that one case relapsed after seven months.

Discussion

The results in Series 2 are far worse than those in Series 1, but it is difficult to decide whether this should be attributed to the different scheme of treatment or to the different method of follow-up. A comparison of the three-month post-treatment period in the two series reveals that in Series 1 relapse occurred in 20.8% of cases, or 71.4% of total relapses, whereas in Series 2 the corresponding figures are 22.7% and 38.4%. This difference is due to the fact that the cases in Series 1 had three times as many re-examinations during this period as those in Series 2 (see Table II). A comparison of the six-month results shows that in Series 1 only 15 cases had either relapsed or were still undergoing re-examination. The relapse rate was 40%—6 cases out of 15, including five cases which relapsed in the first three months. In other words, only one new relapse was found in the second three-month period. Of 18 cases in Series 2 which completed the six-month follow-up, 12 (67%) relapsed. This, too, includes five cases which relapsed in the first three months. In this series, however, three cases of relapse were discovered by the special examination at four months described above, without which these cases might have been missed. Excluding these cases the relapse rate was still 50%, as compared with the 40% of Series 1. Four cases were recognized as having relapsed when examined five or six months after treatment, though they had been missed at the four-month special examination. This examination did not prove as effective as it was hoped.

To my mind the follow-up in Series 1 was more adequate than that in Series 2. In the former each case had at least 16 re-examinations in the six months following treatment, whereas in the latter each case had only nine re-examinations in that period. The fact that in Series 2 the results were worse despite a less adequate follow-up would seem to indicate that the important factor in treatment is the length of the course rather than the daily amount of the drug given. Shorter courses of treatment as previously tried have proved, in my experience, even less effective.

In any event the important fact that emerges from this investigation is that even with a nine-day course of treatment only a 33% "cure" can be expected. Even this figure may be too high. In the light of claims that have been made of an 80% cure rate following a five-day course, this should serve as a warning against over-optimism. Such claims can be attributed only to an inadequate follow-up.

It appears from the above that a good method of follow-up would be a fortnightly re-examination for six months following treatment, with a special examination, as described, at the end of that period, and thereafter a monthly examination for another six months.

Mode of Action of Nilodin.—From one to two months after treatment with this drug I have often observed abnormal, non-viable ova in patients' urine which are from one-half to one-third the normal size. Although small, these ova have a perfectly formed shell, but contain only an amorphous mass. They are totally unlike "degenerate" ova which have been held back in the tissues in chronic cases. It is my belief that these may be "sterile" or unfertilized ova, and that the male worm may be more susceptible to treatment than the female. It is also possible that oviposition in the female is affected by the drug, and even temporarily stopped completely. In cases in which such ova are found relapse may occur later or, on the other hand, the urine may become perfectly clear of ova. Another factor is that nilodin may cause temporary immigration of the worms to the liver plexuses. In view of these points it would seem that the only real test of cure would be a complement-fixation test. This would have to be done a fairly long while after treatment.

RECTAL SCHISTOSOMIASIS

In view of the paucity of information about the effect of the newer drugs on rectal infection with *S. mansoni* a short account of our treatment of this condition with nilodin may be of interest. Although a goodly number of cases have been treated, the results in only four cases which have been followed up are presented.

Method of Examination

In all cases in which dysentery was the presenting symptom the diagnosis could be easily arrived at by examination of the faeces, especially of the mucus contained in the stool. Usually the first few fields were enough to demonstrate the presence of ova. The technique used was to tease apart strings of mucus in a drop of tap-water on a slide. The first examination was made with the lowest-power objective lens available. If no ova or miracidia were seen, then a cover slip was placed over the specimen and the high-power lens used in a search for parasites of pathological import. As the clinical manifestations of amoebic dysentery and rectal schistosomiasis so closely resemble each other the differential diagnosis can be made only by an adequate examination of the stools.

In cases without dysentery and in which formed stools were passed examination for *S. mansoni* ova called for a different procedure. In such cases a proctoscope was passed with the patient in the lithotomy position on an operating table. The rectal mucosa was cleaned and then scarified until bleeding occurred by means of a clean swab held in the artery forceps, the mixture of blood and debris removed being transferred to a clean, dry slide. Two slides were prepared in this way so that a fairly large amount of material could be examined. Water was dropped on to the specimen and two cover slips placed on each slide. Slides were examined under the low-power objective of the microscope. In addition all positive cases were examined for the presence of urinary infection.

Every case was re-examined by the direct proctoscopic method—weekly, when possible, for the first three months. Thereafter a monthly proctoscopic examination was conducted until the patient left the employ of the mines. In addition, in every case the urine was examined for *S. haematobium* ova weekly for the first three months and then at monthly intervals while the patient was available. In only one case in this series was there a double infection, *S. haematobium* and *S. mansoni* infesting the urinary tract and *S. mansoni* the rectal plexuses.

Dosage

The daily dosage of nilodin aimed at was 20 mg. per kg. of body weight, though as the tablets of the drug were not divided, as explained above, patients received slightly more

than this amount. Three cases were given a 12-day course of this treatment, but the remaining case had only six days' treatment. No adjuvants were employed apart from intravenous infusion of saline and glucose in two cases in which the patient was suffering from a salt-depletion syndrome on admission to hospital.

Clinical Response

Provided that the patient's general condition was treated adequately, then the response was good. On treatment with nilodin alone, without any antibiotic therapy for the secondary infection, the cases with dysentery made a complete response by the sixth day. It is noteworthy that in many cases (not included in the present series) with symptoms due to stricture of the bowel, treatment of the schistosomal infection had no effect on such symptoms, and where necessary one had to resort to surgery.

Results

Of the four cases here reported not one relapsed clinically during the follow-up period. I stress "clinically" because in one case viable ova were recovered from the rectal mucosa on two occasions after the end of treatment. In another case an inert ovum was recovered on one occasion. This ovum was morphologically normal but the flame cells were not beating. This case should be regarded as having relapsed because, in my experience, successful treatment results in the recovery of macerated ova from the mucosa. The recovery of an inert ovum at the 20th week after treatment, as in this case, should be regarded as highly suspicious.

Results in the four cases are shown in Table III. Two of these cases had previously had courses of "fantorin" (antimony pyrocatechol sodium sulphonate)—in one case

TABLE III.—Results of Follow-up Examinations

Case No.	Length of Course (Days)	Length of Follow-up (Weeks)	No. of Re-examinations	Clinical Relapse	Technical Relapse	Time of Relapse
1	6	24	14	No	No	—
2	12	23	16	"	Yes	10th and 13th weeks
3	12	22	13	"	?	20th week
4	12	18	11	"	No	—

two months, and in the other three months, earlier. Both cases had a clinical relapse with the demonstration of viable ova in the stools. They were then given nilodin treatment as described.

Discussion

Too few cases are presented for any scientific assessment of the results. However, many more cases have been treated with nilodin although not followed up, and in all the clinical response was good.

The case of mixed *S. mansoni* and *S. haematobium* infection of the bladder is particularly interesting, because during the follow-up period macerated ova of *S. mansoni* were recovered from the urine at 7 out of 15 examinations; on one occasion, too, a macerated ovum of *S. mansoni* was recovered from the rectal mucosa.

The stumbling-block to the correct appraisal of a particular method of treatment in cases of *S. mansoni* infection is the follow-up. There seems to be no really accurate technique available, and certainly none that is simple to carry out.

With the method of follow-up here described I have been pleasantly surprised at the high proportion of positive diagnostic results obtained. At re-examination, however, recovery of ova was variable. In the first of the four cases only one macerated ovum and one macerated miracidium were recovered in the course of 14 re-examinations; in the second case macerated ova were recovered twice, and viable ova twice, in 16 re-examinations; in the third case macerated ova were recovered at seven, and an "inert" ovum at one, of 13 re-examinations; and in the last case macerated *S. mansoni* ova were recovered at only one out of 11 re-examinations of the rectum, while they were present at 7 out of 15 re-examinations of the urine.

When regarded in the light of claims made for other methods of examination our technique would appear to be very poor; but this is no doubt due to the fact that it was applied after treatment—an important point. When used to establish a diagnosis it was highly effective, although no records were kept to substantiate this claim. Furthermore, our results show that if ova are present in the mucosa this technique reveals them. This is exemplified by the third case, in which ova were recovered at 8 out of 13 examinations.

I have come to the conclusion that there is little variation in the susceptibility of *S. haematobium* and *S. mansoni* to nilodin when given in adequate dosage over a long enough period. This contention is well borne out by the case of mixed infection of the urinary tract. For this reason I am of the opinion that research workers should concentrate on urinary schistosomiasis, in which assessment of the results of treatment is much easier and far more accurate.

Summary and Conclusions

Two series of cases of urinary schistosomiasis (*S. haematobium*) occurring in mine-workers in the Transvaal have been treated with nilodin (lucanthone hydrochloride). In the first series (24 cases) an average daily dose of 22 mg. per kg. of body weight was given for twelve days, and in the second (22 cases) a daily dose of 25 mg. per kg. for nine days.

Results did not come up to expectation in either series. A "six-month cure" of 60% was obtained in Series 1 and of 33% in Series 2, the poorer results in the latter being due to what is considered an inadequate course of treatment. One case in each series relapsed after the six-month period of follow-up, so that final results were less good.

Toxic symptoms, though frequent (56.7% of cases), were never severe and were easily controlled. Loss of weight and diuresis were a striking feature in some cases. Toxicity was greater in cases in which there was renal insufficiency.

Results are also given of the treatment with nilodin of four cases of rectal schistosomiasis (*S. mansoni*). Clinical response was excellent. No case of clinical relapse occurred, though in two cases there was a "technical" relapse, as shown by the recovery of viable ova from the rectum.

An interesting case of *S. mansoni* infection of the vesical plexus which was apparently cured by the treatment is described.

Nilodin was found to be easy to administer, and, considering the high percentage of cures if it is adequately used, relatively cheap. It should be stressed that the clinical response to treatment is exceptionally good and that every case benefits in some degree. Treatment should extend over a period of at least twelve days, and preferably sixteen days, and patients should be followed up for at least six months.

It is concluded that, provided an adequate course is given, nilodin is highly effective in the treatment of *Schistosoma* infections in the non-European mine labourer in South Africa; also that the mines of the Witwatersrand and Orange Free State are ideal testing grounds for anti-schistosomal drugs.

I wish to thank Dr. G. F. Eagle, M.B.E., Chief Medical Officer of the Witpoort Native Hospital, for much helpful advice and criticism. My thanks are also due to Dr. J. H. G. Van Blommestein, D.S.O., Chief Medical Consultant, Anglo-American Corporation of South Africa, for permission to publish this paper.

THE TREATMENT OF ASTHMA WITH CORTICOTROPHIN

BY

J. E. G. PEARSON, D.M., F.R.C.P.

Physician in Thoracic Diseases, Bristol Royal Hospitals

Stimulation of the adrenal cortex by adrenocorticotrophic hormone (corticotrophin, A.C.T.H.) has been used with success in various hypersensitivity conditions, and was the subject of a review by Rackemann (1951). Naturally, asthma has featured among the disorders so treated, and further assessment of its use and possible abuse seems desirable in this condition, which has been increasingly recognized as liable to cause a fatal outcome in severe cases. While cortisone has also been used in trials by mouth, by injection, or by inhalation, its use is not here considered.

Present Cases

When the present series of 10 asthmatic cases was treated, A.C.T.H. was still scarce, and certain strict criteria were imposed before giving such treatment: (1) all were admitted to hospital suffering either from severe status asthmaticus or from prolonged and incapacitating asthma; (2) they showed little or no response to other routine forms of therapy, including intravenous aminophylline; and (3) so far as possible, they were unaware that A.C.T.H. was being given lest the idea of some new magic treatment should play a largely psychological part in any improvement. Most of the cases were so severe that it was felt scarcely justifiable or necessary to risk fatalities by a control series such as that usefully described by Ball (1954).

Case 1

A farmer aged 40 had for seven years had repeated infections of the accessory nasal sinuses, requiring operation more than once. Eighteen months before admission he had asthmatic symptoms which were thought to be mainly of infective origin. He entered hospital in a mild status asthmaticus, and treatment, including antispasmodics, penicillin, physiotherapy, and intravenous aminophylline, produced only slight improvement. X-ray examination of his sinuses showed widespread infection; he was producing on an average 1 fl. oz. (28 ml.) of purulent sputum daily.

A.C.T.H. was started in a dosage of 30 mg. eight-hourly intramuscularly, and within 36 hours he was much less distressed than he had been for many weeks. The dosage was gradually diminished until a total of 510 mg. had been given in seven days. Two days later he was able to return home in quite a comfortable state.

He started to relapse after a few weeks, and four months after discharge he had to be readmitted urgently. During bronchoscopy under thiopentone anaesthesia he suddenly collapsed and died, and at necropsy his whole bronchial tree was full of sticky mucopurulent secretion.

Case 2

An intelligent and sensible housewife aged 53 was seen at home as an emergency in status asthmaticus so severe that two hours previously her own practitioner had thought her to be on the point of death. In spite of intravenous aminophylline she was still extremely shocked and distressed in her breathing.

She was at once admitted to hospital and given A.C.T.H., 30 mg. intramuscularly six-hourly. Within 12 hours she was comfortable, and within 48 hours she was completely free from wheezing. The total dosage was 730 mg. in nine days.

It was possible to discharge her from hospital on the ninth day, and, although two further admissions were necessary in the next 12 months, she did not require further A.C.T.H. until two years later, when she was readmitted to hospital in a similar, almost moribund, condition. With 100 mg. of A.C.T.H. in the first 24 hours, followed by 200 mg. of A.C.T.H. gel in the next four days, she again made a remarkable recovery.

Case 3

A bill-poster aged 19 gave a six-year history of asthmatic attacks at intervals of some months for no known cause. He was admitted to hospital in severe status asthmaticus, which showed poor and transient response to injections of adrenaline and intravenous aminophylline. Although of fine physique, he was becoming very exhausted, and on the fifth day A.C.T.H. was started. Some improvement was achieved with a total dosage of 425 mg. in five and a half days, but 48 hours after stopping treatment his asthmatic state gradually became worse than ever. No infective element was apparent. After an interval of 12 days, a further course of A.C.T.H. was begun with a higher initial dosage, 150 mg. in the first 24 hours, and on this occasion he showed great improvement within 48 hours. The total dosage for the second course was 500 mg. in seven days, and the patient has remained remarkably well since that time, for a period of over one year.

Case 4

An unemployed man aged 47 dated his asthmatic symptoms from 1940, when he was subjected to blast and exposure followed by evacuation from Dunkirk. From 1950 to 1952 he was under constant out-patient supervision and was twice admitted to hospital for treatment, which had included left hilar denervation; to none of these attempts did he make any satisfactory response and he was never found to be free from some degree of wheezing, although his vital capacity was always well above 4,000 ml. For a few years he had also complained of Raynaud's phenomenon in both hands, and during the two-year period of observation he was unable to resume his work in a tobacco factory.

On his third admission a course of A.C.T.H., 1 g. in 12 days, was given; this produced considerable temporary improvement in his Raynaud's phenomenon, but the relief to his chest was negligible.

Case 5

A housewife aged 36, who had always had a mild asthmatic tendency, had been very much worse since the birth of her child six months previously. She was admitted in status asthmaticus and A.C.T.H. was started; after receiving 120 mg. in 48 hours her chest symptoms were greatly relieved, but mental confusion with euphoria caused the A.C.T.H. to be discontinued.

Within three months she again had to be admitted to hospital in a relapse, which responded to routine measures sufficiently well for her to take her own discharge on the third day.

Case 6

A professional man aged 41, of the keenest intelligence, was one of the series who knew he was receiving A.C.T.H. and appreciated the significance of it. In infancy he had had eczema and in childhood some asthma, which moderated during adolescence. During the preceding five years he had had several attacks of infective bronchitis during the winter, and for three months he suffered numerous bad asthmatic attacks. In view of the possible infective factor of recent years, he was admitted for investigation, including bronchography, which did show dilatation of a few scattered bronchi in either lung.

Possibly, he thought, because of the bronchogram or possibly for psychogenic reasons, he shortly had another severe asthmatic attack, which was unabated after three weeks, by which time his response to intravenous aminophylline was very poor.

He was readmitted, therefore, and A.C.T.H. therapy was started with 30 mg. six-hourly. After the second injection he described a cessation of spasm with a great feeling of relief, and a total dosage of 540 mg. was given in four and a half days. Relapse occurred on two occasions at approximately three-monthly intervals after this, demanding further A.C.T.H. therapy for nine days on each occasion. The results were good, though not quite so remarkable as during the first course.

Case 7

A housewife and schoolteacher, aged 49, with a previous history of "hay-fever" from the age of 18 up to 40, had 10 months previously started getting violent spasms of cough with tenacious sputum, soon accompanied by asthmatic symptoms. She stated that she had not had a single undisturbed night for nine months on this account, and severe exacerbations had occurred on three occasions. She was a nervous woman, severely distressed physically and mentally by constant dyspnoea, and repeatedly in mild status asthmaticus, which was only slightly, if at all, relieved by intensive routine measures, including bronchoscopic aspiration under general anaesthesia. A.C.T.H. gel was given intramuscularly in daily doses of 100, 60, and 60 mg.; and then 40 mg. for seven days.

Great improvement was felt within 24 hours, and within three days she was much clearer than she had been for many months. Although a relapse occurred three months later, it was ultimately controlled by routine measures without A.C.T.H.

Case 8

A housewife aged 54 was the most chronic asthmatic of the whole series. During the 34 years of her trouble she had seen a vast number of doctors, undergone numerous investigations, and received the widest variety of treatments. For eighteen months she had been getting worse than ever, and she stated that for six months she had never been free from wheezing unless she used an atomizer, from which she was inseparable. Every night for five years she had woken in an attack, and it was clear, as she herself admitted, that the psychogenic factor was by far the most important in the aetiology of her asthma.

Worn out mentally and physically as she was by her almost constant mild status asthmaticus, she was given 100 mg. of A.C.T.H. gel intramuscularly one evening at 6 o'clock. At 9 p.m. a kind but unwitting night nurse gave her two codeine compound tablets unaware that she was sensitive to aspirin. Within three hours the patient was in the most severe status asthmaticus, shocked, and almost pulseless, recovery taking place shortly after an intravenous injection of aminophylline, 0.48 g.

Further treatment with A.C.T.H. gel was interrupted for 10 days; she then received a total of 400 mg. in 10 days. By the third day of this course improvement was evident, and by the sixth day she stated that she felt clearer on the chest and better than she had done for many years. At this time her lungs were completely free from adventitious sounds.

She continued fairly well at home for many months after this treatment, requiring many fewer "remedies" than before, although adrenaline injections and her atomizer were still in use. For eighteen months she did not approach a state severe enough to warrant further A.C.T.H. therapy; her husband then started to obtain supplies of A.C.T.H. gel from America, and for many months she had been receiving a maintenance dose of about 20-40 mg. twice weekly. She has not attended for follow-up during this time, but reports from her own practitioner and from her husband seem to indicate clearly that the previous efficacy of the substance is much reduced and may soon be negligible.

Case 9

A woman aged 57 had suffered from asthmatic attacks for many years and had needed admission to hospital on several occasions. Complicating factors were gross sinus in-

fection and scattered fibrosis with bronchiectasis in both lungs. A well-marked psychological element also played a part in perpetuating her symptoms, and when the time came for her to undergo the most necessary sinus operations she admitted that the fear of operation and anaesthesia added very much to her chest troubles. She entered hospital in severe asthma, which was showing scarcely any improvement on routine measures, including intravenous aminophylline. She was despondent and exhausted from lack of sleep. As penicillin was having no effect on her infection chloramphenicol was substituted. After two days, although her sputum was somewhat cleaner, she was still very breathless. A.C.T.H. was started next day, and after 48 hours she showed great improvement physically and mentally. A total dosage of 300 I.U. in six days rendered her well enough to undergo operation in the following week.

Case 10

A retired man aged 72 who had suffered from a cardiac infarct two years previously, had complained of asthmatic symptoms for only about five months before admission, though he had probably experienced mild bronchitic trouble for some years. Since the onset of his bronchospasm, he had had treatment in various parts of the country with numerous medicaments and had on several occasions received a course of A.C.T.H., with the result that he had become very reliant on it and very introspective about his condition.

He was admitted, together with a vast number of drugs and remedies, in severe status asthmaticus, occasioned very largely by the misguided administration of two injections of morphine $\frac{1}{4}$ gr. (16 mg.), with atropine, 1/100 gr. (0.65 mg.), based on the idea that his asthma might have been of cardiac origin. He had already placed himself again on A.C.T.H., but clearly, after 24 hours, it was making little or no impression on his asthmatic state. Intravenous aminophylline, an iodide mixture, and physiotherapy were much more successful in producing steady improvement, with expectoration of increased amounts of slightly infected sputum.

After two weeks' relative freedom from symptoms his wheezing again flared up acutely, resulting in great

Summary of Cases

Case No.	Sex	Age	A.C.T.H. in mg.	Duration (Days)	Remarks	Response
1	M	40	510	7	Chronic asthma—infected	Good
			730	9	Severe status asthmaticus. Comfortable in 12 hours	Excellent
2	F	53	100 + 200 gel	5	" "	"
			425	5½	Status asthmaticus	Moderate
3	M	19	500 (12 days later)	7	"	Very good
4	M	47	1,000	12	Chronic asthma	Very poor, but Raynaud's phenomenon relieved
5	F	36	120	2	Status asthmaticus	Good, but treatment stopped on account of mental confusion
6	M	41	540	4½	Status asthmaticus	Excellent—relief within 36 hours. Slower improvement
			820	9	"	"
7	F	49	670	9	Chronic asthma in mild status	Excellent
			500 gel	10	"	"
8	F	54	400	10	Chronic asthma in status	"

10	M	72	415 Several previous courses	8	Recurrent status asthmaticus	Fair

despondency; for two days he struggled on with the previous regime, finding his physiotherapy more and more exhausting, and then he felt he must demand further A.C.T.H. Starting with 30 mg. four-hourly, he experienced relief within eight hours, and was able to be transferred home within 10 days. It was clear that, in this case, the possible psychological effect of having A.C.T.H. could not be excluded; he admitted that it did not have such a dramatic effect in relieving his symptoms as on some previous occasions.

A summary of the salient features of the cases is set out in the Table at the foot of the previous page.

Discussion

In 10 cases of severe and intractable asthma treated with A.C.T.H. the initial response was considered to be very poor in one, fair in one, good in four, and excellent in four; in one of the latter it was probably life-saving on two occasions.

All patients showed relapse of symptoms sooner or later after cessation of treatment, but only three required more than one course of treatment (excepting one who had an immediate relapse). Two of these patients knew they were receiving A.C.T.H., felt the need of it during a severe exacerbation of symptoms, and were agreed that its action was slightly slower and less dramatic on each subsequent occasion.

An initial dosage of 25-30 mg. (I.U.) intramuscularly six-hourly, or even eight-hourly, appeared satisfactory, usually producing great relief within 12-36 hours; it was possible to reduce the dosage after 48-72 hours to 20 mg. eight-hourly for the next two to three days, and then to 10 mg. eight-hourly for a further two days. An average course of seven days' treatment with this diminishing dosage therefore totalled about 450 mg. However, in any statement of dosage used and compared with other authors, it must be remembered that the potency of different extracts may have shown considerable variation. The longer-acting A.C.T.H. gel, used in two cases, seemed just as efficacious as the more standard product, in a daily dosage of about half the amount, and with the added advantage of necessitating only one injection in 24 hours. It is noteworthy, perhaps, that in one of these cases an injection of 100 mg. of A.C.T.H. gel did not prevent a violent asthmatic reaction to aspirin given some three hours later.

In only one patient (Case 3) did the amount of the initial dosage seem important; a higher dose of 150 mg. in 24 hours for an immediate relapse after his first course produced a remarkably good effect, whereas 100 mg. in 24 hours had been somewhat disappointing.

An ill effect was noticed in only one patient: this woman was of rather an unstable temperament, and marked euphoria necessitated stopping treatment after 48 hours. Other reactions are unlikely to be troublesome with the dosage and duration of treatment described, while a mild degree of euphoria may be considered helpful, although not of primary therapeutic importance.

The good effects obtained are not evidently counteracted by some degree of bronchial infection, but in this series measures were being taken simultaneously to treat any such infection with antibiotics and physiotherapy when necessary. In the most heavily infected case (No. 9) it is doubtful if the patient would ever have been rendered fit for her much-needed radical sinus operation without the use of A.C.T.H.

The findings are in agreement with most other authors, that in A.C.T.H. we have a potent substance in the treatment of asthma. Friedlaender and Friedlaender (1951b) gave it to 10 severe chronic asthmatics in a dosage of 52 mg. six-hourly, intramuscularly, with total dosage of 600-870 mg. in 6-13 days. They found dramatic improvement in six patients within 24-36 hours, fair response in two, and no real improvement in two. They pointed out that the relief was of brief duration before recurrence, and that seasonal hypersensitive cases should therefore give the most satisfactory results. Possibly, symptoms recurring after

such treatment might more easily be controlled by "conventional" therapy, but the reverse could also occur.

Segal *et al.* (1951) treated 20 severe asthmatics with courses of A.C.T.H. in total dosage of 240-900 mg. over periods of 24-19 days. As five patients needed more than one course, 27 courses in all were given, and, of these, 24 produced partial or complete remission of symptoms, as follows: eight for one to two weeks, 10 for two to four weeks, and six for four weeks to seven months. They concluded it was better to give short intensive courses of A.C.T.H. therapy rather than try a prolonged maintenance dose.

Rather less impressive results occurred in 18 patients similarly treated by Arbesman (1951), as six of these showed no improvement whatsoever; the average length of remission of symptoms achieved in the rest was three to six weeks. Brown *et al.* (1951) treated 30 chronic asthmatics ambulant over 10 months, the patients giving their own injections and deciding their own requirements, which ranged from 10 mg. twice daily to 12 mg. on alternate days. Relapse of symptoms occurred in all patients soon after cessation of treatment.

Levin (1953) pointed out the benefits of using A.C.T.H. gel: he achieved good or excellent results in 10 adults and six children, some of whom were treated ambulant. One injection of 40-60 mg. was given daily for two to five days; the injections were remarkably painless and there were no undesirable reactions. He considered that with such treatment available the asthmatic should never need A.C.T.H. by intravenous drip.

The exact mode of action of A.C.T.H. in asthma remains somewhat obscure. Elkinton *et al.* (1949) made careful studies in a 12-year-old boy to assess whether adrenal cortical stimulation was proportional to the clinical improvement. With eosinophil blood counts, balances of chloride, sodium, sugar, potassium, and nitrogen, and study of 17-ketosteroids they could find no such correlation, and it has been suggested from the findings that in asthma the beneficial effect may depend upon some special function of the hormone. The lack of any definite correlation between clinical response and the eosinophil count has been confirmed by Friedlaender and Friedlaender (1951a) and by Feinberg *et al.* (1951).

It cannot be over-emphasized that the treatment described should in no way replace attempts at full assessment of the asthmatic case, so that more rational and radical therapy can be given whenever possible. If used, it is thought preferable that the patient should not know what he is receiving, as, if its dramatic effect is evident to him, he may demand it for ever afterwards when distressed, and morally it may prove very difficult for the practitioner to withhold it. In fact, one can visualize the asthmatic almost as addicted to A.C.T.H. as, say, to his inhaler, and, worse still, if used too often this substance might gradually lose its beneficial effect, a point strongly suggested by two cases in the present series. I am also of the opinion that, at present, it is wiser to restrict the use of A.C.T.H. to the relief of a severe exacerbation of symptoms by a short course, to be repeated if necessary.

Conclusions

A.C.T.H. is most efficacious in the treatment of severe status asthmaticus, and can be life-saving when all else fails.

As it should not be necessary in such a case for treatment to last for more than five to nine days, very few ill effects are to be expected.

An average initial dosage of 25-30 mg. six-hourly is satisfactory, and must be reduced gradually after improvement has occurred, usually within 48 hours.

It is suggested that the use of A.C.T.H. should at present be restricted to very severe cases that are resistant to other forms of treatment, and, if possible, the patient should not know what he is receiving.

Heavily infected cases respond as well as others do, but should be treated with extra caution.

There is no convincing evidence in the present series or in published cases to suggest that a longer remission of symptoms occurs after A.C.T.H. therapy than after any other treatment which succeeds.

A.C.T.H. in no way avoids the expediency of all the other established methods in the assessment, treatment, and management of the asthmatic case.

Summary

The use of adrenocorticotrophic hormone is described in 10 asthmatics. In eight of these there was a remarkable relief of severe acute respiratory distress, resistant to other forms of therapy.

It is suggested that this substance should at present be used in asthma only as an emergency measure.

EXCHANGE TRANSFUSION AS A MEANS OF REMOVING BILIRUBIN IN HAEMOLYTIC DISEASE OF THE NEWBORN

BY

G. H. LATHE, M.D., Ph.D.

Biochemist, the Bernhard Baron Memorial Research Laboratories, Queen Charlotte's Maternity Hospital, London, and the Institute of Obstetrics and Gynaecology, British Postgraduate Medical Federation, University of London

Damage to the brain occurs with varying frequency in haemolytic disease of the newborn. Exchange transfusion, as ordinarily carried out, is not entirely effective in preventing it.

It is now known that brain damage is found in association with a great excess of plasma bilirubin in the following conditions: (1) haemolytic disease of the newborn from iso-immunization relative to blood-group antigens D, E, A, and S; (2) prematurity without haemolytic disease; and (3) some types of "familial" hyperbilirubinaemia. Claireaux *et al.* (1953) have shown that in the first two conditions the yellow pigment in affected brains is the indirect-reacting plasma bile pigment, bilirubin. They have reviewed the evidence that this pigment is damaging to brain tissue, and that the direct-reacting bile pigments are innocuous. Some further indications of the toxic character of bilirubin have been published by Lathe (1954).

A more detailed study of the pigment changes in haemolytic disease of the newborn was undertaken with a view to developing methods of avoiding its accumulation. It seemed possible that the role of bilirubin would be made clear from the clinical results of preventing high plasma bilirubin concentrations in infants with haemolytic disease. An encouraging report by Hsia, Allen, Gellis, and Diamond (1952) and Hsia (1953) has now come to our attention. The work described here confirms their observations regarding the pattern of bile pigment changes in the plasma in haemolytic disease,

and shows that it is possible to control the plasma bilirubin concentration by exchange transfusion.

Methods and Materials

Clinical Material.—Observations have been made on a series of infants affected with haemolytic disease at this hospital. The brief clinical descriptions of six of these have been drawn from the case records. Serological data have not been included individually, since there was a common basis for serological diagnosis of haemolytic disease in all six cases: (1) mother's group was Rh-negative, (2) maternal antibodies were present, (3) infant's group was Rh-positive, (4) infant cells gave a positive test with rabbit anti-human globulin serum (Coombs +). The blood specimens removed at exchange transfusion of three infants at the Hammer-smith Hospital have also been available for study. **Blood specimens** were taken from heel pricks when not otherwise stated. **Haemoglobin** estimations were made with a visual colorimeter (M.R.C. grey wedge) which was suitably calibrated—100% haemoglobin being taken as 14.8 g. per 100 ml. **Bile pigment** estimations were made on serum and plasma by the method of King (1951). In Cases 1 and 2 the relative proportions of direct- and indirect-reacting pigments were estimated semi-quantitatively by the appearance of pigment bands on chromatography columns (Cole and Lathe, 1953). In Cases 4, 5, and 6 the proportions of the two types of pigment were determined quantitatively by the method of Malloy and Evelyn (1937).

Plasma Bilirubin in Haemolytic Disease

No detailed study of bile pigment metabolism in a series of untreated cases of haemolytic disease of the newborn has yet been published. That such a study would have shown a wide variation from case to case is suggested by the data of Hsia, Allen, Diamond, and Gellis (1953), and of Mollison and Cutbush (1954). In this hospital there has been an opportunity of studying a number of affected infants who were not given an exchange transfusion because the cord blood contained more than 105% haemoglobin. Some of these infants later gave evidence of a considerable haemolytic process as shown by the changes in haemoglobin and plasma bile pigments. Two contrasting cases are described. Case 1 is an instance of haemolytic disease in which no exchange transfusion was given. In Case 2 only a simple transfusion was possible.

FIG. 1.—Changes in concentration of blood haemoglobin and of plasma bile pigments in Case 1.

FIG. 2.—Changes in concentration of blood haemoglobin and of plasma bile pigments in Case 2.

Case 1 (Fig. 1).—Two previous siblings were unaffected. The gestation period was estimated at 39 weeks. The birth weight was 8 lb. 5 oz. (3.7 kg.) and the cord haemoglobin was 109%. Cord serum bile pigment was 5 mg. per 100 ml. The infant looked slightly yellow at birth, but its condition was otherwise satisfactory. Jaundice deepened within 24 hours and lasted about a week. The blood haemoglobin concentration dropped at the rate of 8% per day for 11 days. The plasma bile pigment concentration reached a peak of 21 mg. per 100 ml. on the fourth day. No neurological signs appeared. A simple transfusion was later given to correct the anaemia.

Case 2 (Fig. 2).—There were two previous unaffected siblings. The period of gestation was estimated at 37 weeks. At birth the infant weighed 7 lb. 2 oz. (3.2 kg.) and was pale and limp. The cord blood contained 90% haemoglobin. The serum contained 6.5 mg. of bile pigment per 100 ml. Attempts at exchange transfusion failed and 128 ml. of blood was given as a simple transfusion. Following this, the blood haemoglobin fell consistently at the rate of 4.2% per day for 15 days. The plasma bile pigment rose rapidly, and when it was between 36 and 38 mg. per 100 ml. the neurological behaviour became abnormal, with irritability, head retraction, arms held stiffly extended, increased muscle tone, and disinterest in feeding. The plasma bile pigment began to drop about the third day, and fell below 20 mg. about day 6. Although much improved, the baby had not recovered normal neurological behaviour in eight months.

Course of Plasma Bile Pigment in Exchange Transfusion

It is apparent from examining a number of graphs of the rise and fall of plasma pigment in neonatal haemolytic disease that high concentrations of bile pigment are not sustained for long. Not infrequently the period of exposure to high concentrations does not exceed 36 or 48 hours. This encouraged us to seek a means of maintaining a low pigment concentration during this critical period. In the course of studying the amount of bile pigment removed at exchange transfusion it was observed that in large transfusions the blood withdrawn during the procedure contained more bile pigment than the baby's blood volume was calculated to contain at the beginning. This could be explained only by a passage of pigment from the tissues into the circulation during the transfusion. To examine this point, the bile pigment was quantitatively estimated in each specimen of blood removed in a number of exchange transfusions.

The course of plasma bile pigment concentration, together with the calculated extent of blood replacement, at each stage throughout one exchange transfusion, is plotted in Fig. 3. The replacement of the infant's blood did not lower the plasma pigment as much as was calculated on the basis of blood exchanged. It was concluded then that the plasma pigment concentration was partly sustained by removal of pigment from the tissues. The overall effect on bile pigment concentration of 10 exchange transfusions, given im-

FIG. 3.—Changes in concentration of plasma bile pigment, and the extent of replacement of the infant's blood, throughout an exchange transfusion immediately after birth. (Birth weight, 6 lb. 10 oz.—3 kg.)

mediately after birth for the purpose of removing infant red cells and maternal antibodies, and studied in this way, is given in the Table (A).

Change in Plasma Bile Pigment During Perfusion with Blood

Birth Weight	Exchange	Plasma Bile Pigments		
		Initial (mg. 100 ml.)	Final (mg. 100 ml.)	Decrease %

Treatment of Hyperbilirubinaemia

Since it seemed that exchange transfusion could be used as a means of washing bilirubin out of the tissues of affected infants, it was next applied to babies that had not been given exchange transfusions at birth (cord blood haemoglobin greater than 105%), but in whom a marked rise of plasma bilirubin was noted during the neonatal period. In the first instance of this (Case 3) the exchange transfusion was not made until neurological signs of damage had appeared.

Case 3.—Two previous siblings were unaffected. The mother had had one miscarriage. The gestation period was estimated at 41 weeks. At birth the infant weighed 7 lb. 1/2 oz. (3.2 kg.). The concentration of haemoglobin in the cord blood was 111%. The cord serum bile pigment was 1.9 mg. per 100 ml. The liver and spleen were not palpable. The plasma bile pigment at 12 hours was 7.7 mg. per 100 ml. Icterus appeared at 18 hours and became severe at 24 hours. The plasma bile pigment was 19.3 mg. per 100 ml. at 36 hours. It continued to rise, and on the third day head retraction appeared, and there were periods of limb extension, grimaces, etc. Plasma bile pigment was then 38 mg. per 100 ml. An exchange transfusion of 71 ml. per lb. (156 ml. per kg.) was made. During it, opisthotonos developed. The transfusion reduced the bile pigment from 38 to 26 mg. per 100 ml. The pigment rose again to a peak of 32.5 mg. on day 5; it then dropped to 12 mg. during the ensuing two days. The neurological signs had meanwhile improved. At four months a diagnosis of cerebral palsy was made.

The following case is a more typical example of an exchange transfusion which was undertaken when the pigment concentration reached 20 mg. per 100 ml.

Case 4 (Fig. 4).—The mother had one previous infant without any sign of haemolytic disease. The membranes were ruptured artificially during the 38th week because

FIG. 4.—Changes in concentration of blood haemoglobin and of plasma bile pigments in Case 4.

of diminished foetal movements. Caesarean section was undertaken three days later because labour had not started. The birth weight was 6 lb. 6 oz. (2.9 kg.), and cord blood haemoglobin was 128%. Cord serum bile pigments were 3.4 mg. per 100 ml., of which 2.6 were bilirubin. Jaundice appeared in 24 hours and deepened as the bile pigment rose to 20.2 mg. on the third day. An exchange transfusion of 71 ml. per lb. (156 ml. per kg.) reduced the pigment to 12.1 mg. per 100 ml. On the following (fourth) day it rose again, but after the fifth day it fell consistently. No neurological signs appeared.

This pattern of change in plasma pigment concentration is probably the one most often observed among infants of substantial weight which are not seriously affected at birth and for whom an exchange transfusion is later performed because of rising bilirubin. The rise of pigment may be much more abrupt, however, reaching 20 mg. per 100 ml. in 24 hours. The Table (B) shows the overall effect on bile pigment concentration of 10 transfusions given because of the elevated plasma pigment. Each of these was studied throughout the whole of the transfusion. Some of these were repeat transfusions.

Obstruction Due to Haemolytic Disease

Note must be taken of the type of bile pigment present in each individual case of haemolytic disease of the newborn. In early studies of haemolytic disease, and of jaundice of the newborn in which there is no excessive haemolysis (Billing *et al.*, 1954), the type of pigment present in the plasma was examined in many cases. The predominating pigment was bilirubin, and direct-reacting pigment I and II (Cole *et al.*, 1954) were present in much smaller amounts. For a period, because of the small amounts of these direct-reacting pigments, the relative proportions of the direct pigments and bilirubin were not estimated. That this practice may lead to serious error is indicated in Case 5 and Case 6.

Case 5.—Two previous siblings showed jaundice at the third and first days of life, respectively, and the second infant died. The pregnancy was complicated by toxæmia, which necessitated a surgical induction of labour at the 37th week. The weight at birth was 5 lb. 11 oz. (2.6 kg.), and cord haemoglobin was 75%. Cord serum bile pigment was 6.3 mg. per 100 ml. The liver and spleen were greatly enlarged. The infant became jaundiced within three hours. It was given an immediate exchange transfusion of 62 ml. per lb. (136 ml. per kg.), which reduced the plasma bile pigment from 10.2 to 5.6 mg. per 100 ml. Within 24 hours the pigment had risen to 19 mg., and the rise continued to 24 mg. at 48 hours, when a second exchange transfusion of 61 ml. per lb. (134 ml. per kg.) was made. At the conclusion the bile pigment had dropped to 11.6 mg., but it rose to 20.4 mg. in another 12 hours. Some indefinite neurological signs (grimacing and twitching) were reported by the nursing staff. A third exchange transfusion of 42 ml. per lb. (92 ml. per kg.) at 75 hours reduced the pigment to 10.5 mg. It rose again 12 hours later to 18.4 mg. and remained between 18 and 20 mg. for another 36 hours, when it rose to 24 mg. At this point the character of the bile pigments was examined for the first time, and it was found that, of a total bile pigment of 24 mg. per 100 ml., only 5.3 mg. was bilirubin. In the light of this evidence that obstruction was the dominant feature further transfusions were not made. The total bile pigment remained between 22 and 24 mg. per 100 ml. (bilirubin 5.6 mg.) until the middle of the sixth day, when it dropped within 24

FIG. 5.—Changes in concentration of blood haemoglobin and of plasma bile pigments in Case 6.

hours to 13.2 mg. per 100 ml., of which bilirubin was 3 mg. The infant's condition at three months was satisfactory.

The amount and type of pigments present in the early stages of this case are not known. The only specimen which had been preserved was the cord serum (total pigment 6.3 mg.), which contained equal parts of bilirubin, pigment I, and pigment II, as determined by Billing (1955).

Case 6 (Fig. 5).—The mother had three previous infants. The third, which was affected with haemolytic disease, was given an exchange transfusion, following which it developed marked signs of brain damage, which persisted until death at 10 months. The present infant was 7 lb. 2 oz. (3.2 kg.) at birth. The gestation period was uncertain. The cord blood haemoglobin was 39% and plasma bile pigment 9.2 mg. per 100 ml., of which 6.8 mg. was bilirubin. The liver and spleen were greatly enlarged. Although the clinical condition at birth was precarious, it improved greatly during the course of an exchange of 81 ml. of blood per lb. (178 ml. per kg.). Because of the desire at all costs to avoid a repetition of the tragedy of the previous sibling, and because of uncertainty concerning the significance of the direct-reacting pigment, a second exchange—105 ml. per lb. (231 ml. per kg.)—was given on the second day, when the plasma bile pigment concentration was rising rapidly. It never again reached dangerous concentrations. No abnormal neurological signs appeared.

Discussion

Liver Function

The cases which have been presented illustrate some of the fundamental aspects of bile pigment metabolism in the newborn infant affected with haemolytic disease. The plasma bilirubin concentration is determined partly by the rate of pigment formation in the reticuloendothelial system, but also by the rate at which the pigment is removed by the liver. In all newborn infants this latter capacity is probably very much reduced, and in many of the small infants the reduction is extreme—down to 1 or 2% of normal (Billing *et al.*, 1954). These small infants also take much longer to develop an adequate excretory ability.

Among infants of normal weight there is considerable variation in the excretory capacity of the liver at birth and immediately after it. This may be seen by comparing Cases 1 and 2. Although the haemoglobin concentrations fell in the first case at approximately twice the rate of the second, the peaks of bile pigment concentration are of an inverse order. The apparent difference in liver capacity may arise in part from the disparity in birth weights—8.3 and 7.1 lb. (3.8 and 3.2 kg.) respectively—and in the estimated gestation periods (39 and 37 weeks respectively). The changes of plasma bile pigment concentration in these cases also illustrate the way in which the capacity of the liver to excrete bilirubin develops rapidly during the neonatal period, since in both cases the loss of haemoglobin appears to have taken place at a relatively constant rate. It is this change in liver capacity which gives the dramatic character to the rise and fall of bile pigment (Fig. 2), and not any sudden acceleration of the haemolytic process in the neonatal period, as is often inferred. Indeed, in small premature infants unaffected with haemolytic disease the same thing takes place (on a reduced scale).

Removal of Bilirubin by Perfusion

The bilirubin produced from haemoglobin does not remain free in the body fluids, but attaches itself to various constituents, and in particular to plasma albumin, which has a marked affinity for it. At abnormally high plasma pigment concentrations appreciable amounts of bilirubin pass out of the circulation and become attached to other body constituents. This process may be reversed by the continuous replacement of the pigment-laden plasma proteins of the infant with protein which is free of pigment. This is demonstrated by the course of plasma bilirubin concentration throughout an exchange transfusion (Fig. 3). The extent of this shift of pigment from the tissues is indicated by the area between the two curves in Fig. 3. The Table shows that a perfusion of 50–60 ml. per lb. (110–132 ml. per kg.) fairly consistently results in a drop of plasma pigment concentration of 30–50%.

After an exchange transfusion the bile pigment of the plasma nearly always rises again for a variable period. Although this may partly be due to a movement of further pigment out of the tissues, it seems that the previous trend of rising pigment concentration is continued in some degree, but at a lower level, until the liver capacity becomes sufficiently developed to remove bilirubin at the rate at which it is being formed. However, another aspect must also be considered. The baby receives at transfusion a very large amount of preserved blood. In the presence of an already overtaxed ability to excrete bilirubin any breakdown of the transfused blood will add to the accumulated pigment. Recent papers reveal that 10–20-day-old blood is still being used for exchange transfusion. Breakdown of 10% of such blood would lead to the accumulation of another 25 mg. of bilirubin per lb. (55 mg. per kg.) of body weight, from which a marked rise of plasma bilirubin would follow. Because of the limited capacity of the liver to dispose of bilirubin, newborn infants require a more rigorous criterion for adequate preservation of blood than do adults. For this reason some blood depots now adopt the highly desirable procedure of issuing the blood drawn during the previous 24 hours for exchange transfusions.

"Inspissated Bile Syndrome"

The predominant plasma pigment of haemolytic disease of the newborn (Claireaux *et al.*, 1953), as well as that of non-haemolytic neonatal jaundice (Billing *et al.*, 1954), is bilirubin, which is indirect-reacting in the van den Bergh test. The occasional appearance of large amounts of direct-reacting pigments I and II due to obstruction resulting from haemolytic disease is demonstrated in Case 5 and Case 6 (Fig. 5). The simultaneous appearance of direct-reacting pigments in the plasma and of bile thrombi was noted by Aschoff (1924) in experimental haemolytic anaemia in dogs. The same relation probably holds in some severe cases of haemolytic disease of the newborn. Bile thrombi have been described (Claireaux, 1950), and direct-reacting pigment may predominate as seen above. Hsia, Patterson, Allen, Diamond, and Gellis (1952) have called attention to the fact that haemolytic disease of the newborn is a frequent cause of the "inspissated bile syndrome." It may be significant that the three cases of haemolytic disease in which we observed considerable direct-reacting pigment at birth, or shortly after, had hepatomegaly at birth.

The occasional appearance of much direct-reacting pigment emphasizes the great need for further work to establish unequivocally whether or not the direct-reacting pigments are damaging to the brain, since the evidence on this point is not yet conclusive enough to allow one to withhold exchange transfusion with equanimity.

Factors Affecting Transfusion

The facility with which high concentrations of plasma bilirubin can be prevented by exchange transfusion will depend on (1) the rate at which bilirubin is produced in the infant, (2) the effectiveness of the individual exchange operation, (3) the concentration of pigment which is considered to be a serious threat to the baby, and (4) the length of time required for the liver to attain adequate excretory function. In an affected infant the rate at which bilirubin is produced is greatly reduced by removing the infant's own cells, and where there are indications for doing this at birth it is the single most effective measure which can be taken to protect the infant. The limitation of a single exchange transfusion lies in the fact that as it proceeds it becomes increasingly inefficient in the removal of affected red blood cells. However, as shown in Fig. 3, this limitation does not apply to the same extent to the removal of bilirubin, the amount of which will be determined in large measure by the volume of blood with which the infant is perfused. Thus, under some circumstances, where the infant is quite robust and the plasma bilirubin is dangerously high, there

may be some justification for increasing the amount perfused to 100 ml. per lb. (220 ml. per kg.), as was done at this hospital on one occasion.

Toxic Level of Bilirubin

Treatment is directed toward preventing a rise of plasma bilirubin above the level at which the incidence of brain damage becomes appreciable. Mollison and Cutbush (1954) state that at plasma concentrations of total bile pigment of 19–24 mg. per 100 ml. 1 baby in 13 suffered brain damage, and that this increased to 4 out of 12 if the amount of pigment rose to 24–29 mg. per 100 ml. Above that amount the majority of infants were affected. Similar results have been observed by Hsia, Allen, Gellis, and Diamond (1952) in a series of 229 infants affected with erythroblastosis: "Kernicterus occurred in 18% of the infants whose serum bilirubin was recorded at a level between 16 and 30 mg. per 100 c.c.m., and in 50% of those in whom levels above 30 mg. per 100 c.c.m. were seen."

It has been suggested that, in addition to other indications, an exchange or re-exchange transfusion should be done each time the plasma bilirubin concentration rises to 20 mg. per 100 ml. or above (British Medical Journal, 1954; Cross *et al.*, 1954). Hsia (1953) reported that in 250 cases of erythroblastosis in which exchange transfusions were performed each time bilirubin exceeded 20 mg. there were no cases of kernicterus. The experience of undertaking exchange transfusions when the bilirubin reaches 20 mg. per 100 ml. shows that, in general, an exchange transfusion maintains the pigment concentration below the danger level for one or two days. Thereafter perfusion has to be repeated unless the pigment excretory capacity of the liver has developed to an adequate extent.

Small Infants

Small infants are more likely to require repeated transfusions, since, on the average, they need a longer period for the development of the capacity to excrete bilirubin (Billing *et al.*, 1954). It may be noted, too, that the occurrence of brain pigmentation in jaundice of premature infants that are unaffected with haemolytic disease, as well as the greater incidence of brain damage among premature than mature infants with haemolytic disease (Allen *et al.*, 1950; Armitage and Mollison, 1953), suggest that small infants may be more sensitive to bilirubin, and thus may need to be protected against bilirubin concentrations of less than 20 mg. per 100 ml. of plasma. These two aspects of the small newborn infant should be taken into account when premature delivery of infants (Watson *et al.*, 1954) is being considered.

The possibility of successfully treating infants that are severely affected with haemolytic disease (and even of premature infants) is considerably extended by the fact that the concentration of plasma bilirubin can be controlled. Of course, this does not provide a reason for delaying an initial exchange transfusion for the purpose of removing the infant's sensitized cells. On the contrary, it emphasizes the necessity of doing this as soon as there is an indication of a serious haemolytic condition. In the first instance the cord haemoglobin is of major importance, but a later rapid rise of plasma bilirubin may be a significant warning.

Summary

The changes in concentration of plasma bile pigments have been followed in cases of haemolytic disease of the newborn and throughout exchange transfusions. A drop of 30–50% in the concentration of plasma bile pigment is usually brought about by exchange transfusion, during which bile pigment is washed out of the tissues. By one or more transfusions the bilirubin concentration may be kept below the level at which the incidence of brain damage becomes appreciable. The number of times

perfusion has to be repeated will be influenced by the speed with which the liver develops the capacity to excrete bilirubin.

Because of the underlying hepatic deficit in the newborn baby the importance of using recently drawn blood for transfusion is stressed.

The significance of the large amounts of direct-reacting bile pigment that have been shown to occur in the plasma of some cases of haemolytic disease is discussed.

This study has been made possible by the close co-operation of Miss M. Ashforth in following the clinical condition of the infants and in securing specimens for analysis. She has also been responsible for most of the exchange transfusions. I am grateful to Dr. A. White Franklin for opportunities of studying infants under his care. The serological and haematological examinations have been supervised by Dr. John Murray. Specimens from the Hammersmith Hospital have been obtained with the help of Professor J. McClure Browne and Dr. J. Dean. I am also grateful to P. G. Cole, C. R. J. Ruthven, and S. Bebbington for skilled laboratory assistance, and to Dr. John Murray, Dr. A. E. Claireaux, and Dr. Barbara H. Billing for frequent discussions and suggestions.

Believed to be the only unit of its kind ever to be formed in the British Army, the Parachute Medical Team is described by Dr. J. S. Macdonald in the *Journal of the R.A.M.C.*, January, 1955. It is staffed by personnel of the 16th Independent Parachute Brigade Group and operates in the Middle East. On receiving a signal that an aeroplane has crashed in the desert, the team sets off in a "Valetta" aircraft standing by and fitted out specially for the dropping of men and containers. On finding the crashed aircraft, a suitable dropping zone is sought, a smoke canister thrown out to determine wind speed and direction, and then the medical officer and nursing orderly jump. If they find that further help is needed, they fire a green Very cartridge, and the rest of the team follow—namely, three privates R.A.M.C., and one corporal and two signalmen Royal Signals. (The main duty of one of the signalmen is to carry a radio set down, since this is still the surest way of getting these delicate instruments to the ground intact.) If the first two to jump find they do not need any assistants, they fire a red Very light, and the aircraft drops food and water. The team's task is to give such first-aid treatment as may be required until the R.A.F. ground rescue team can arrive and take them all to safety. The equipment parachuted includes intravenous fluids, splints, morphine, anaesthetics, surgical instruments, antibiotics, and a bivouac tent to provide that most longed-for solace in the desert—shade.

ALDOSTERONE IN URINE OF NORMAL MAN AND OF PATIENTS WITH OEDEMA

ITS INCREASED RECOVERY AFTER HYDROLYSIS WITH ACID AND WITH BETA-GLUCURONIDASE*

BY

J. A. LUETSCHER, jun., M.D.

(From the Department of Medicine, Stanford University School of Medicine, San Francisco, California)

Neutral lipid extracts of acidified urine from patients with the nephrotic syndrome, in heart failure, and in some other oedematous states cause sodium retention and potassium elimination when injected into adrenalectomized rats (Deming and Luetscher, 1950; Luetscher *et al.*, 1952; Luetscher and Johnson, 1954b; Chart and Shipley, 1953; Singer and Wener, 1953; Gordon *et al.*, 1954). The substance responsible for this mineralocorticoid activity has been separated by paper chromatography from urine extracts (Luetscher and Johnson, 1954a). Further work (Luetscher, 1955; Luetscher, Neher, and Wettstein, 1954) has shown that this sodium-retaining corticoid is identical with aldosterone (Simpson and Tait, 1953; Simpson *et al.*, 1954) in the following ways: (1) its high sodium-retaining potency in bioassay; (2) its absorption of ultra-violet and of infra-red radiations; (3) its reducing activity; (4) its melting point, and (5) the chromatographic mobility of the native substance, of its mono- and di-acetates, and of its oxidation products after treatment with periodate.

Cope and Garcia-Llaurado (1954) found a substance of similar chromatographic behaviour in the urine of a woman suffering from a severe potassium-losing condition. Their extracts of neutral urine from normal men yielded only traces of activity. Luetscher and Axelrad (1954) obtained a much larger yield of aldosterone from normal urine which had stood for a day at pH 1. Venning *et al.* (1954) found increased amounts of sodium-retaining substances in urine treated with beta-glucuronidase. Thus the amount of active material extracted depends partly upon the method of hydrolysis. This report compares the yields, after various methods of hydrolysis, from urine of normal subjects on their usual diet and after salt restriction. The present study also includes data on the hydrolysis of urine of patients showing an increased urinary output of sodium-retaining material.

Methods

Urine was immediately stored in a refrigerator without preservative. The total 24-hour specimen was mixed, the volume was recorded, and a small aliquot was set aside for chemical analysis. The remaining urine was frozen and stored at -20°C . until extraction. Immediately before extraction, urine was brought to 20°C . and the pH was adjusted as indicated.

* This project was supported by a grant-in-aid (A-119) from the National Institute for Arthritis and Metabolic Diseases, United States Public Health Service.

† Now at the Department of Medicine, University of Bristol.

Methods of Hydrolysis.—"Neutral" (N): These extracts were made at once after adjusting the urine to pH 6.5 ± 0.1 . "Immediate Acid" (A): Urine was extracted within 40 minutes after acidification to pH 1. "24-hour Acid" (B): Urine which had already been extracted within 40 minutes at pH 1 was then allowed to stand at 20°C . at the same pH for 24 hours; it was then re-extracted. "Control for Glucuronidase" (Cg): Urine was adjusted to pH 4.8, and 0.02 volume of 5 molar acetate buffer of pH 4.8 was added. The specimen was then incubated at 37°C . for the specified time over 50 to 100 ml. of chloroform. The pH did not change appreciably during incubation. "Glucuronidase" (G): Specimens were prepared as described for Cg and were incubated with the enzyme (Cohen, 1951). Concentrated beta-glucuronidase prepared from calf spleen (Vio-Bin Corporation, Monticello, Illinois) was used in the first experiments. Subsequently, a solution of purified beta-glucuronidase, derived from beef liver, was obtained from the Warner-Chilcott Laboratories, New York. The activities, measured by the method of Talalay *et al.* (1946), were of the order stated by the makers. The various concentrations and times of incubation at pH 4.8 and 37°C . are noted in the tables. When urine was extracted by method A before treatment with glucuronidase, the symbol AG is used.

Extraction.—Extracts were made by shaking the hydrolysed urine with four aliquots of chloroform (0.1 volume per volume of urine, but not less than 100 ml. per aliquot). Emulsions were broken by centrifugation.

Alkali Wash.—All chloroform extracts except those designated AU in Table I were cooled to 5°C . and washed twice with cold 0.1 N solution of sodium hydroxide and once with cold distilled water. The combined aqueous washings were acidified and re-extracted with chloroform only in a few instances (Table I). Chloroform was removed under reduced pressure below 40°C . Extracts were stored in 95% ethanol at 0°C .

Chromatography.—The system used was toluene-propylene glycol (Burton *et al.*, 1951). "Fraction E" is that which contains cortisone and aldosterone in this system. In a few instances other systems described by Bush (1952) were also used.

Bioassay.—The method was described by Johnson (1954). Groups of nine adrenalectomized rats were used. Results are expressed as that dose of deoxycortone acetate (D.C.A.) which would produce in the rats an equivalent response in urinary potassium-to-sodium ratio. The 95% confidence limits of this estimate are $\pm 2.15 \mu\text{g}$. D.C.A. in a range of dosage from 0 to $10 \mu\text{g}$. D.C.A. assayed in a group of nine rats. In all assays the effect on sodium output has also been calculated, and has been found to agree well with the more precise estimates based on potassium-to-sodium ratio. The term "sodium-retaining activity" has been used because this is the predominant effect measured in the bioassay. In those instances in which the test material caused increased excretion of sodium the estimate of dosage as μg . D.C.A. has a minus sign.

The dose of extract given to each rat is a known fraction of the patient's 24-hour urine extract. Each dose is expressed in minutes; for example, 20 minutes is 1/72 of the extract from one day's urine (1,440 minutes).

Effect of pH and Alkali Wash

Extracts made from urine at pH 6.5 showed insignificant sodium-retaining activity in a dose of 20 minutes (Table I, N). When the same urine was acidified to pH 1 before extraction, significant activity was found in 20-minute doses from two patients (Ro., nephrosis with oedema, extracts AU and A; Ph., cirrhosis with ascites, extract A), but not in the extract from a healthy man (Lj., extracts AU and A). Insignificant difference in activity was noted between active extracts which had been washed with cold dilute sodium hydroxide and water (A) and those extracts which had not been washed (AU). No sodium-retaining material was

TABLE I.—Effect of pH and of Alkali Wash on Sodium-retaining Activity of Urine Extracts. Effect on K/Na Ratio in μg . D.C.A. Equivalent. Dose = 20 Minutes

Subject	Age and Sex	Diagnosis	Extract at pH 6.5 (N)	Extract at pH 1 (AU)	Extract AU after Alkali Wash (A)	Extract of Alkali Wash
Ro. Jo.	4 M	Nephrosis	0.2	8.1	8.2	-0.9
Ph.	2 M	"	—	8.4	8.3	0
Ph.	4 M	"	—	1.5	0.2	-0.2
Ph. Lj.	48 M	Cirrhosis	1.9	—	3.3	—
Lj.	40 M	Normal	-0.8	-0.1	-4.0	-2.3

recovered from re-extraction of the alkali wash. Since washing with alkali removed much pigment and other material from the extract, and thus facilitated handling and chromatography, this procedure has been followed routinely with all extracts.

Activity of Various Extracts in Normal Adults on Usual Diet

Luetscher and Johnson (1954b) found that extracts made by method A from the urine of 11 normal men and women on unrestricted diets either showed no significant sodium-retaining activity or promoted the excretion of sodium in adrenalectomized rats (range $+0.5$ to $-7.2 \mu\text{g}$. D.C.A. per 20 minutes of extract). When such extracts were chromatographed in toluene and propylene glycol, fraction E contained no appreciable activity at doses of 33 minutes. Results of further studies in three of these normal adults are included in Table II. When the dose of "fraction E" of the A extract was increased to 167 minutes there was still no activity (Cases Lj., Ab., and Da.). However, extracts made from the same urine by method B contained strong sodium-retaining activity in fraction E at a dose of 167 minutes. Insignificant activity was found in fraction E prepared from one of these urines after incubation with glucuronidase.

Extracts from Adults on Diets Low in Sodium

It has been reported that when normal men reduced their dietary sodium to 11 mEq a day for five days there was consistently an increase in sodium-retaining activity of the A extracts, but the level reached was not high (Luetscher and Johnson, 1954b). In Lj., on his usual diet (Table II), the activity of the A extract was $-4.0 \mu\text{g}$. and on a low-sodium diet it rose to $+1.4 \mu\text{g}$. per 20-minute dose, and significant activity appeared in fraction E. In the extract prepared by method B, five times as much aldosterone was found with salt restriction, for on bioassay the effect produced by a dose of 30 minutes was the same as that produced by a dose of 167 minutes when the subject was on his usual diet. Likewise, on salt restriction, glucuronidase released additional sodium-retaining material (extract AG), which appeared in fraction E on chromatography. Since incubation of urine without glucuronidase at pH 4.8 and 37°C . for four hours (extract ACg) did not release appreciable sodium-retaining material, it appears that the addition of glucuronidase was responsible for the observed activity in extract AG. Observations on two other normal men (Cases Ab. and Jb., Table II) resemble those in Case Lj.

Activity of Various Extracts in Heart Failure and Hepatic Cirrhosis

Studies were made on urine of three patients in whom congestive heart failure was associated with a marked reduction of sodium excretion (Table III). In Case Bu., extracts A and B contained far more active material than comparable extracts from normal adults on a similar sodium intake, for in doses of only 20 minutes there was highly significant activity. Glucuronidase (AG) released much additional active material, while a smaller but significant yield was obtained from the control (ACg) incubated without glucuronidase at 37°C . and pH 4.8 for 24 hours. When

these extracts were chromatographed, activity was found in fraction E in each instance. In Case Ta., similar results were obtained from extracts A and AG. Case Lo. again demonstrates the appearance of much activity after 24 hours at pH 1.

Two patients, We. and Ph., had Laennec's cirrhosis with ascites and impaired excretion of sodium (Table III). In both cases, extracts A and B contained strong activity, which could be found in fraction E after chromatography.

Activity of Extracts in Children

Previous studies of four normal children on unrestricted diets showed insignificant activity in A extracts at doses of 20-33 minutes (Luetscher and Johnson, 1954a). Extracts made by method B contained measurable activity when the dose was increased to 167 minutes. When the three methods of hydrolysis were compared in one case (Rg., Table IV), method B released aldosterone in an amount only slightly

less than that found in normal adults, but extracts A and G did not contain amounts measurable in the dosages given.

Three children with oedema due to the nephrotic syndrome were studied (Table IV). The A extracts showed strong activity in two cases, while the third was not significantly active. The B extracts were highly active, and so were the fractions E derived from them. Compared with that from a normal child these B extracts from nephrotic children contained much more aldosterone; for on bioassay the effects of doses of 20 and of 33 minutes were greater than that produced by a dose of 167 minutes from the normal child.

In one case (Co.) the substance responsible for the sodium-retaining activity was isolated from extracts prepared by methods A and B. In each instance a corticosteroid indistinguishable from aldosterone was obtained.

In Case Ro. the fraction E derived from urine incubated with glucuronidase (G) showed strong activity. When this

urine was first extracted after exposure to acid by method A and then incubated with glucuronidase, a very highly active extract was obtained (AG). However, the actual amount of activity in these two glucuronidase extracts cannot be compared, because of the different times of incubation. There were similar amounts of activity in the two "immediate acid" extracts A, and acid A after G, although one was prepared in the usual way and the other after the glucuronidase extract had been made from it. These observations suggest that there are at least two forms of conjugated aldosterone, one form being more readily hydrolysed by acid, and the other by glucuronidase.

Discussion

There are obviously two separate factors which affect the activity of urinary extracts. These are the method of hydrolysis and the amount of active material present in the urine.

Effects of Methods of Hydrolysis on Yield.—In all cases studied, the sodium-retaining activity of the extract increased with time of exposure to strong acid. Negligible activity appeared in extracts of neutral urine. Extracts prepared after 40 minutes at pH 1 were more likely to contain active material; while a second extraction after 24 hours' exposure to pH 1 regularly produced strongly active material. In one instance incubation at pH 4.8 and 37° C. for 24 hours yielded the same amount of activity as brief exposure to pH 1 at 20° C. These results parallel the enhanced extraction of glucocorticoids after acidification of urine (Venning *et al.*, 1953). Beta-glucuronidase, prepared from mammalian spleen or liver, released active material in amounts equal to or greater than the initial extract at pH 1, but less than the quantity obtained after a day at pH 1. Although some of the active material was liberated by the physical conditions rather than by the enzyme, controlled experiments indicate that the beta-glucuronidase was responsible for a part of the yield. These results again resemble the effects of glucuronidase on the release of biologically active glucocorticoids, as described by Venning *et al.* (1953).

Factors Influencing Output in Urine.—The sodium-retaining activity of the various extracts was increased when dietary sodium was reduced or when the presence of disease of the heart, liver, or kidneys was associated with abnormal sodium retention. In all these cases high sodium-retaining activity was associated with low urinary sodium. These findings and other data (Luetscher and Johnson, 1954b) suggest that sodium-retaining activity of urinary extracts reflects the intensity of conservation of sodium by the body; and it appears that the stimulus to conserve sodium can be evoked in health by sodium deprivation, and in some diseases by an as yet ill-defined mechanism.

Identity of Active Material with Aldosterone.—In previous work, cited above, it has been shown that the purified active material obtained from urine in nephrosis has properties identical with those of aldosterone. This finding was confirmed with two extracts from one patient in the present work. In the other subjects, both in health and in disease, the sodium-retaining activity consistently appeared in fraction E on chromatography. Aldosterone is the only known corticosteroid in this fraction which causes sodium retention in the assay used. In several instances fractions have been carried through additional chromatographic systems described by Bush (1952) as B₂, B₃, and C. In each case the active fraction from urine has moved at the same rate as samples of authentic aldosterone, and has shown similar pharmacological properties. For all these reasons it is presumed that the active material is aldosterone in each instance both in normal men and in patients, and when released by brief or prolonged exposure to acid or by glucuronidase.

Summary

The amount of sodium-retaining corticoid that can be extracted from urine by chloroform depends partly on

the method of hydrolysis. Of the procedures studied, the greatest yield was obtained from urine after standing for one day at pH 1. Smaller quantities were obtained after brief exposure to pH 1 or after incubation at 37° C. and pH 4.8. Mammalian beta-glucuronidase caused a further release of material. Insignificant activity was found in extracts from urine at pH 6.5.

When yields obtained by each method were compared, the sodium-retaining activity of urinary extracts was small but still measurable in health on unrestricted sodium intake. Reduction of dietary sodium was followed by increased sodium-retaining activity. Patients with congestive heart failure, hepatic cirrhosis, or the nephrotic syndrome had a high output of sodium-retaining material when the urinary sodium was low.

In all cases in which urine extracts were chromatographed, sodium-retaining material was found in a single fraction. The active component of this fraction was shown to be aldosterone in one case. It seems highly probable that the sodium-retaining corticoid with similar properties, found in the other cases, was aldosterone.

We wish to thank Anne Dowdy, Julia Harvey, Way Lew, and Lee J. Poo for their invaluable assistance. Dr. C. V. Fisher, of Warner-Chilcott Laboratories, generously supplied purified beta-glucuronidase solution.

In its first annual report since its incorporation, the British Rheumatic Association describes plans for a study in a London borough "to see how many of the bed-ridden, institutionalized, and chair-bound rheumatic people could be equipped for employment in open industry or for independent living in the community." A grant for this work has been received from a charitable trust, and negotiations are proceeding with the Ministry of Health and the London County Council. Other subjects discussed in the report include the association's hostel (Bracken Hill House) for the investigation of industrial workers thought to be suffering from rheumatism; rehabilitation; and the production of a documentary film to teach patients with rheumatism how to help themselves. Last year the association's total income was £3,646, and a deficit of £720 was incurred on the year's working. However, in view of the great activity and change during the year, the honorary treasurer expressed "every confidence that there was no need to be alarmed about the financial situation."

EFFECT OF METHYLANDROSTENEDIOL
ON POST-OPERATIVE LOSS OF WEIGHT

BY

D. DAVIES, M.D., M.R.C.P.

AND

A. PINES, M.B., M.R.C.P.Ed.

(From Harefield Hospital, Middlesex)

The pattern of the metabolic response to surgical trauma is steadily becoming better defined. It is now accepted that in the early post-operative phase there is retention of water and sodium, with an increased excretion of potassium and nitrogen. In a few days there is water and sodium diuresis with potassium retention, and in less than a week normal balance of water and electrolytes is usually restored. The negative nitrogen balance, however, continues for about two weeks, and occasionally for four weeks or longer (Elman, 1940). During this period there is progressive loss in weight. This is masked in the early days by water retention. The eventual total loss in weight is often greater than that calculated from nitrogen-balance studies, and the discrepancy is probably due to oxidation of fat (Moore and Ball, 1952).

The phase of recovery is dependent on an adequate food intake. In the early post-operative phase, however, a high-protein diet and protein hydrolysates are poorly tolerated and poorly utilized (Abbott *et al.*, 1946). They seldom prevent the phase of negative nitrogen balance, and an increase in intake of nitrogen is usually mirrored by an increase in urinary excretion.

Testosterone is well established as a substance that can reduce nitrogen excretion and produce an anabolic phase in normal people and in those suffering from wasting diseases (Abels, Young, and Taylor, 1944). It has also been shown to modify to some extent the catabolic phase after trauma in man and experimental animals, and is sometimes used for this purpose, particularly after burns and in wasted patients.

Methylandrostenediol is a synthetic hormone, effective by mouth. It has been shown to have a nitrogen-conserving effect equal to testosterone but only about a tenth of its virilizing effect (Gordon *et al.*, 1951). Some reports do suggest, however, that it is quantitatively less potent than testosterone (Henderson and Weinberg, 1951). It has become a fairly popular medicament in a variety of wasting conditions and many authors claim that it is effective—for example, Albeaux-Fernet *et al.* (1952). The present study was designed to measure its effect on the loss of weight which follows operation.

Investigation

The patients in the trial were suffering from pulmonary tuberculosis. Because the metabolic response is quantitatively less in people whose tissues are already depleted, only young adults in a good state of nutrition and free from clinical evidence of toxæmia were chosen for study. Those with obesity and diabetes mellitus were not included. Patients who subsequently developed wound infection or pleural effusions requiring aspiration were excluded from the final analysis.

As the metabolic disturbance is also proportional to the extent of surgical trauma, the fairly standardized operations of thoracoplasty, extrapleural plombage, lobectomy, and combinations of these provided suitable cases for study.

Patients were weighed on the day before operation and twice weekly afterwards for a minimum of six weeks. The weighing was done at the same time of day and in the same garments. The patients were allocated by random sampling to the treatment or control group. Those in the treatment group were given 20 mg. of methylandrostenediol twice daily, starting on the day before operation and continuing for twenty-one days afterwards. In those undergoing operation in two stages the interval between the first and second varied, but was usually fourteen days. In the latter cases treatment was continued from the day before the first operation until twenty-one days after the second.

The patients remained on ordinary hospital diet throughout. Post-operative vomiting was uncommon, and patients operated on in the morning were often able to eat a boiled egg and bread-and-butter at tea-time.

Results

In patients undergoing one operation, 20 were treated with methylandrostenediol and 14 formed the control group. The groups were comparable in sex, age, and type of operation. The findings are summarized in Table I. In the treatment group the maximum weight loss varied from nil to 9 lb. (4.1 kg.), averaging 4.3 lb. (1.9 kg.). In the control group the range was 2 lb. (0.9 kg.) to 9.5 lb. (4.3 kg.), with an average of 4.8 lb. (2.1 kg.). The time of maximal weight loss was comparable in both groups.

In those undergoing two operations, 12 patients formed the treatment group and 15 the control group (Table II). Again the groups proved comparable. In the treated group one patient lost no weight, but the others lost amounts varying from 4.5 (2 kg.) to 14 lb. (6.4 kg.), the average for the group being 8.9 lb. (4.1 kg.). In the control group the loss varied from 4 (1.8 kg.) to 15.5 lb. (7 kg.), with an average of 8.7 lb. (4 kg.).

Thus there is no evidence that methylandrostenediol in the dose used has any significant effect on post-operative weight loss. No harmful effects could be attributed to its use and there was no evidence of virilization in the female patients.

Discussion

The tables show that the loss in weight after major surgery is considerable, and in some three-stage procedures studied (unpublished) it frequently exceeds 14 lb. (6.4 kg.) in people of average nourishment. The return to pre-operative weight often takes three months, and is sometimes never reached. It is generally agreed that one of the major factors in producing resistance to tuberculosis is a diet adequate in protein. Short of obesity, there is an intimate and progressive relation between gain in weight and the success and eventual result of treatment. The considerable loss of weight

* Day after second stage operation.

is therefore an unwelcome feature of the post-operative phase, and its presence may well exert an unfavourable effect on the eventual course of the disease. Methylandrostenediol has proved disappointing in its effect.

We have made no attempt at direct measurement of nitrogen balance in this investigation. Even though part of the weight loss may be due to oxidation of fat, it is reasonable to attribute most of it to nitrogen loss. It seems justifiable to assess the efficiency of an anabolic hormone in the post-operative phase by the method we have used. We feel that only when a drug can be shown to influence the weight pattern can it be regarded as effective therapy. Our results do not indicate that methylandrostenediol has no effect on nitrogen metabolism, but only that its effects are not strong enough to be apparent clinically. It remains a possibility that a fivefold increase in dose might have some measurable effect, but at this level its virilizing effect, too, would be apparent, particularly in women treated for five weeks or longer. In most reports to date, the dosage has been in the range that we have used.

Summary

The pattern of the metabolic response after surgical trauma has been described briefly.

The considerable loss of weight that takes place after operation is an undesirable feature. This is particularly so in tuberculous patients undergoing multiple operations on the chest.

Methylandrostenediol has not been found to reduce this weight loss.

We have to thank many of the medical staff at Harefield Hospital for helping us in this investigation, particularly Drs. R. S. Francis, D. Levy, and R. G. May. We are grateful to the nursing staff for undertaking the extra work so willingly.

RAPID Rh-TYPING

A "SANDWICH" TECHNIQUE

BY

F. STRATTON, M.D., B.Sc., D.P.H.

Director, Regional Blood Transfusion Service, Manchester;
 Special Lecturer in Human Serology, University of Manchester

It is necessary to perform ABO and Rh blood-grouping tests before transfusion, and recipients who are Rh-negative should be transfused with Rh-negative blood of homologous ABO group.

Blood banks are usually short of Rh-negative blood of all ABO groups and it is sometimes necessary, in the first instance, to transfuse males who have never had any previous blood transfusion, or intramuscular injections of blood, with Rh-positive blood because of such shortage. This applies only to males and to their first visit to hospital, and such a transfusion should not be continued for more than a few days in succession, nor is it desirable that Rh-positive blood should be given to Rh-negative males who will obviously require multiple transfusions. I have seen Rh antibodies produced in an Rh-negative male patient seven days after primary transfusions of Rh-positive blood.

In the case of females, all those who are Rh-negative, of whatever age, should be transfused with Rh-negative blood. It is not generally appreciated that children who are Rh-negative can be immunized as easily as adults. I have seen an Rh-negative child, 5 years old, immunized by transfusions of Rh-positive blood. Once Rh antibodies have appeared in the blood of Rh-negative females they persist for long periods of time, probably for life. In another case recently observed, Rh antibodies were present in a woman aged 73 who had never received any blood transfusions or intramuscular injections of blood and whose last pregnancy was 38 years previously.

ABO typing can be rapidly and reliably performed, but with the Rh-typing sera available the recommended techniques often take a long time, and when a cross-matching test has to be done in addition to this there may be delay before the blood can be given. Consequently some transfusions, in the minds of clinicians, become "emergency transfusions," and they take the risk of giving blood without the necessary preliminary grouping and cross-matching tests being performed. If the period of time required for the preliminary grouping tests could be reduced then perhaps fewer transfusions would be regarded as being of an emergency nature.

The purpose of this paper is to describe a rapid method of Rh-typing which can be performed on a slide in ten minutes, using Rh-typing sera ordinarily available here.

Materials and Methods

Bovine Albumin.—Armour's 30% bovine albumin and bovine plasma have both been used in this test.

Rh-Typing Serum.—Undiluted anti-Rh serum is used, suitably absorbed to remove anti-A and anti-B agglutinins so that it is universally applicable. The sera employed had been kept frozen solid for several weeks. Strengths of the reaction of a typical serum used in this test are shown in the Table.

Red-Cell Suspensions.—The blood samples are collected either as clotted or as citrated blood. If collected as clotted

Titration of Serum 474, Using Group O, R₁R₂ Test Cells

	1:1	1:2	1:4	1:8	1:16	1:32	1:64	1:128	1:256	
Saline	++	++	++	++	++	++	++	++	++	++
20% albumin	++++	++++	+++	++	++	++	++	++	++	++

blood, the cell-serum mixture is poured or pipetted off the clot. Citrated or clotted cells are then spun and the serum or plasma is removed. The cells that remain are then washed once in a large volume of saline and packed tightly in the centrifuge. The supernatant saline is then completely removed from the cell pack with a pipette.

Methods.—The saline tube agglutination and albumin tube agglutination techniques were performed according to standard methods (M.R.C., 1952).

Technique

One volume, about 0.03 ml., of the Rh test serum, together with one volume of the 30% bovine albumin and one volume of the packed cells to be typed, is placed in the middle of a microscope slide. The human anti-Rh serum and the 30% bovine albumin may be mixed in equal volumes prior to the test, and two volumes of the mixture used together with one volume of washed packed red cells. The volumes are delivered on to the microscope slide by using a marked Pasteur pipette. On the right-hand side of the slide the

Preparation of the "sandwich."

reference number of the cells that are being typed is marked in grease pencil. The slide is then held in the left hand and another microscope slide held by the narrow edge with the thumb and first finger of the right hand, and the serum albumin and packed red cells are mixed together with the narrow edge of the slide, as in making a blood film. The mixture is spread out on the slide for two-thirds of its length. The slide with which the mixing was done is then gently lowered and pushed on top of the bottom slide so that a "sandwich" is made and the albumin-Rh-serum-packed-cell mixture is spread out in a thin layer between the two slides (see Fig.). When the "sandwich" is made the slides should not be pushed tightly, but only gently, together. Any excess liquid is gently wiped away from the edges of the "sandwich."

Control tests are put up consisting of group AB serum, 30% bovine albumin, and the patient's packed cells, and the sandwich is prepared as described previously. The sandwiches are then carefully placed on a heated plate or in the incubator at 37° C. They are left for ten minutes, removed, and read, using the low power of the microscope. Several fields in the centre of the slide should be examined. If the result is positive, large clumps of cells will be seen, and if the result is negative the cells will be freely suspended. It is always desirable to examine a moving film, and the thumb

of one hand is pressed on top of the sandwich as it rests on the stage of the microscope. As the sandwich is compressed the cells will be observed to move either as clumps in the case of a positive result or as cells which are freely mobile and not aggregated or clumped in a negative one.

Results

One thousand red-cell samples were tested by the tube technique at 37° C., using an anti-D saline agglutinating serum. The results which were negative with this serum were tested with another anti-D serum and also with anti-C and anti-E sera; D^u positive cells were identified and suitable control tests were included.

The 1,000 blood samples were thus divided into D-positive types (including D^u) and D-negative types. These blood samples were then tested by the slide-sandwich technique described above, using anti-Rh serum No. 474, details of the titration of which are shown in the Table. The results were as follows: There were 851 D-positive bloods—847 were typed as positive, 2 as doubtful, and 2 as negative. The remaining 149 were D-negative and all gave negative results using the sandwich technique. The two cells which gave negative results and the two which gave doubtful results, using the rapid sandwich test, were all of variety D^u—either cD^uE/cde or CD^ue/cde.

Forty-two blood samples were also tested by the tube techniques detailed above and also by the sandwich technique, using five different anti-Rh sera (similar to No. 474) on each cell sample; the results were all in agreement. In order to determine whether cells which had been stored in A.C.D. mixture in a refrigerator could be typed by this method, one of these anti-Rh sera (No. 412) was used to test blood samples from outdated stored blood (average age, 21 days). Of 100 blood samples examined, 83 were D-positive and 17 D-negative, using the routine tube techniques, and identical results were given by the sandwich slide technique.

Discussion

Diamond and Denton (1945) introduced bovine albumin for the detection of incomplete Rh antibodies, and subsequently Diamond and Abelson (1945) introduced the open-slide test, using albumin for rapid Rh-typing. This test has been used in many laboratories and has been found to give satisfactory results, but for its success it is necessary to have an avid Rh-typing serum and to have considerable experience in the performance of the test. Such avid Rh-typing sera may mean reimmunizing human volunteers whose sera already contain Rh antibodies with injections of Rh-positive red cells. Such sera are not always available in this country. Another difficulty encountered during the performance of this test is the fact that the cell-serum-albumin mixture on the open slide tends to dry up towards the end of the test, making it difficult on occasion to read it. Furthermore, if people are not familiar with the methods of performing these tests, and if weak or low titre Rh antisera are used, a number of false-negative results occasionally occur, Rh-positive cells (often of type R₁r) being falsely diagnosed as Rh-negative.

Because of the need for a rapid slide test, the sandwich method was developed; it has a number of advantages. First, there is no trouble with drying up of the serum-albumin mixture, since although the mixture dries at the edges of the slides the mixture in the centre of the sandwich remains quite fluid. The drying of the edges is, in some respects, an advantage, since the sandwich becomes very stable, and even though dropped on the bench the slides will not come apart, and the patient's name or number cannot accidentally be rubbed off, as it is in the middle of the sandwich. Secondly, the anti-Rh sera that can be successfully used with the sandwich technique are readily available and need not be specially avid or hyperimmune. The test, furthermore, can be performed rapidly, and results were obtained at 37° C. in ten minutes.

It should be emphasized that the test is specifically designed for rapid Rh-typing before blood transfusion, and it

A SIMPLE METHOD OF Rh-TYPING

BY

PETER W. HARVEY, M.B., Ch.B.

(From Ancoats Hospital, Manchester)

is not intended to be used as a routine typing method. A number of false-negative results were obtained, but these were all of the D^u variety of Rh, which are known not to be detected by the albumin technique (Renton and Stratton, 1950).

In using this test for the purpose for which it was designed, occasional false-negative results will not cause difficulty. False-positive results were not detected in the tests that were made. False-positive results do rarely occur in special circumstances—for example, in a recent case in which the cells from an Rh-negative patient suffering from acquired haemolytic anaemia were typed, they were found to be positive, but, similarly, the cells gave clumps when AB serum was substituted, as suggested in the technique, and used as a control. This false-positive result, therefore, was readily detected. Occasionally, slight rouleaux formation was observed, but this slight aggregation of cells is rapidly dispersed on compressing the slide and watching the cells under the microscope. A similar dispersal of cells does not so readily occur in the case of true agglutinates. No serious trouble was encountered in the interpretation of the results due to the presence of rouleaux formation. In avoiding rouleaux formation, care must be taken to see that the cell suspensions are washed properly, and, furthermore, that when the albumin-cell mixture is made on the slide it is not allowed to dry at all before the sandwich is made. An additional precaution is to avoid reading the edges of the sandwich. It is assumed, of course, that the Rh-typing serum has no rouleaux-forming properties, and it is often an advantage to keep these sera frozen solid for a week or two before bringing them into routine use. The bovine albumin should also be a reliable and non-rouleaux-forming batch.

If strong anti-D + D^u typing sera are used then some of the high-grade types of D^u can be detected, using the sandwich technique. One of the objects in employing this test, however, as stated previously, was to make it useful with weaker Rh-typing sera and with Rh-typing sera containing incomplete Rh antibodies, which would not normally be used for the saline agglutination test performed in tubes at 37° C.

Summary

In order to shorten the period of time required for the performance of the compatibility test, rapid methods for ABO and Rh typing are necessary. This paper describes a slide sandwich test for rapid Rh typing.

This test is intended to be used prior to blood transfusion and can be performed in ten minutes at 37° C.: it is not intended for routine use when large numbers of specimens have to be tested.

In this technique anti-Rh sera of moderate titre and avidity, such as are ordinarily available in this country, can be employed.

In his annual report for 1953 Dr. V. Freeman, medical officer of health of Islington, refers once again to housing conditions in the borough. With an average of 76.2 persons to the acre it is one of the most densely populated boroughs in the county of London. Many of Islington's houses are out of date, being in the form of multi-story tenements, built during the early part of Queen Victoria's reign, or even earlier. Of the 82,000 private households in the borough, 53% share a water closet with other households, 42% share a piped water supply, 22% share a kitchen sink, 20% share a fixed bath, and 7% share a cooking stove. No fewer than 59% of the households are without a fixed bath. Many Islington houses are structurally sound, but it is uneconomic for the landlords to keep them in repair owing to the high cost of labour and materials.

It is generally accepted that the most reliable method of Rh-typing is that of Landsteiner and Weiner (1941), in which a suspension of red cells is incubated for two hours with an equal volume of anti-D serum in a small tube, the results being read microscopically. This method is too lengthy in cases in which blood is urgently needed, and shorter methods have been used.

The capillary-tube method originally described by Chown (1944) has been widely used, and yields results within thirty minutes. However, Poole and Williams (1951) have reported false-positive readings with this technique, and Chown and Lewis (1951) have advised that the cells should be washed for use in this test.

Poole and Williams (1951) have reported good results with a technique in which the cells and anti-D serum were first incubated at 37° C. for ten minutes and then centrifuged for five minutes at 2,000 to 2,500 r.p.m.

A modification of this technique (F. Stratton, 1952, personal communication) is called the double incubation and centrifuging method. The tubes of cells and serum are incubated and centrifuged, tapped to resuspend the cells, and then reincubated and centrifuged. This technique has been recommended by the Manchester Regional Hospital Board Advisory Committee on Pathology for use in emergencies. By this means, results can be obtained in about fifteen to twenty minutes. The method has the drawback of repeated manipulations, and it was thought that the number of manœuvres could be reduced if the centrifuge itself were heated to 37° C., thus acting as an incubator. It was hoped that this short and simple method, the "thermal centrifuging method," would yield results comparable to the standard two-hour incubation method.

Material and Methods

The cases were routine requests received in the laboratory of a general hospital. They consisted of a small number of midwifery cases undergoing routine typing and some emergency cases received in the casualty department, but the majority were composed of general medical and surgical cases admitted from the waiting-list.

Centrifuge.—This was constructed specially for these experiments by Laboratory Thermal Equipment, Ltd., of Greenfield, near Oldham, Lancs. It consisted essentially of an M.S.E. minor centrifuge, round the outer casing of which a lagged jacket was built, and between this and the casing a thermostatically controlled electrical heating element was fitted (see photograph). No special head was provided, the normal cups being satisfactory for the test. The tubes are removed from the centrifuge cups with forceps.

Cell Suspensions.—The addition of one or two drops of the patient's blood to 2 ml. of saline gives a suspension of approximately 2%. The final concentration of the test is therefore about 1% red cells.

Anti-D Serum.—For use during Experiment 1, special serum of average titre was supplied by the regional transfusion centre and used in all 64 cases. For the other experiments the routine sera supplied by the regional transfusion centre was used, and the titre of these varied. The same serum was used for all the tests made on any cell suspension. Each batch of serum was tested with known Rh-positive and Rh-negative cells.

Centrifuge with thermostatically controlled heating jacket.

Size of Tubes.—Two sizes of tubes have been used and found to be equally satisfactory for the test. These are Dreyer's tubes and Durham's tubes, the latter measuring 5 by 0.4 cm. All tubes were boiled in chromate after each test and then washed repeatedly in water and distilled water. However, Dreyer's tubes are recommended because they are easier to clean. During Experiment 1 the tubes were warmed before use in the 37° C. incubator.

Technique

In all the techniques two tubes were used for each experiment. Both tubes contained one drop of a suspension of the patient's cells. In the first tube a drop of anti-D serum was added, and in the other a drop of normal saline. This second tube was used as a control.

Standard Two-hour Method.—The pair of tubes were placed in adjacent holes, drilled in the top of a wooden block, and the block was placed in the 37° C. incubator. After two hours the block was removed from the incubator and the tubes were examined for macroscopic agglutination. The contents of both tubes were then gently pipetted on to clean slides and read under the 2/3 objective of a microscope with reduced light. The slide was tipped slowly from side to side to facilitate the recognition of agglutination in difficult cases. This method of reading the results was followed in all the techniques. The standard two-hour method is referred to as the "standard" method.

Double Incubation and Centrifuging Method.—A modification of Stratton's technique was used. The two tubes were incubated in the 37° C. incubator for seven to fifteen minutes, then centrifuged at about 500 r.p.m. for one minute, tapped to resuspend the cells, reincubated for seven to fifteen minutes, recentrifuged, and then read. This method is referred to as the "rapid" method.

Thermal Centrifuging Method.—The two tubes were dropped into opposing cups of the special centrifuge and spun in all experiments at 100–150 r.p.m. The duration of the centrifuging varied as follows: in Experiment 1, fifteen minutes; in Experiment 2, twenty minutes; in Experiment 3, thirty minutes. At the end of the centrifuging the tubes were removed from the cups and read immediately. This method is referred to as the "centrifuging" method.

The degree of agglutination was estimated by the following scale under the microscope. 0=No agglutination. 1=Occasional agglutination of two, three, or four cells. 2=A considerable number of cells agglutinated—that is, clumps up to six or eight cells. 3=Practically all cells agglutinated. Clumps of up to a dozen cells or so. 4=Large aggregates visible with the microscope or naked eye on the slide. 5=Agglutination visible with the naked eye in the tube.

Results

Experiment 1.—Sixty-four cases were tested. The methods used were the standard method and the centrifuging method, spinning for fifteen minutes. Fifty cases were Rh-positive by the standard method, and the figures denoting the degree of agglutination were added together so that the intensity of the agglutination by both the techniques could be compared over the whole 50 cases. The results are shown in Table I. There were no false positives or false negatives.

TABLE I.—Experiment 1 (64 Cases: 50 Rh-positive, 14 Rh-negative)

Method	Total Pos.	Total Aggregate of Agglutinations	False Pos.	False Neg.	First-degree Agglutinations	False Neg. + Weak Pos.
2-hour standard	50	174	0	—	5	5
15-minutes centrifuging	50	162	0	0	6	6

Experiment 2.—In this experiment 135 cases were tested and the following methods were compared: the standard method; the rapid method, using two ten-minute periods of incubation; and the centrifuging method, spinning for twenty minutes. As it was felt that the first degree of agglutination should be listed separately, such results were called "weak positives." The results are set out in Table II. There were no false positives.

TABLE II.—Experiment 2 (135 Cases: 113 Rh-positive, 22 Rh-negative)

Method	Pos.	Neg.	Weak Pos.	False Pos.	False Neg.	False Neg. + Weak Pos.	Total
2-hour standard	112	22	1	—	—	1	135
2 × 10-minutes rapid	102	24	7	0	2	9	135
20-minutes centrifuging	107	23	4	0	1	5	135

Experiment 3.—In this experiment the following methods were compared: the standard method; the rapid method, using two fifteen-minute periods of incubation; and the centrifuging method, spinning for thirty minutes. The results are set out in Table III. It will be noted that there are no false positives.

TABLE III.—Experiment 3 (50 Cases: 37 Rh-positive, 13 Rh-negative)

Method	Pos.	Neg.	Weak Pos.	False Pos.	False Neg.	Weak Pos. + False Neg.
2-hour standard	37	13	0	—	—	0
2 × 15-minutes rapid	35	13	2	0	0	2
30-minutes centrifuging	37	13	0	0	0	0

Discussion

The results of Experiment 1 show that with the fifteen-minutes centrifuging technique the aggregate of agglutinations is close to that obtained by the standard technique and there are no false negatives.

While these results show what can be achieved in the hands of experienced workers, a technique for use in emergency cases must be capable of giving satisfactory results when used by people who practise it infrequently. It was

felt that the first degree of agglutination might be too subtle for comparatively inexperienced personnel to recognize, and such results are therefore listed separately as "weak positives" in subsequent experiments. Thus, in Experiments 2 and 3, three results were possible in each experiment—"negative," "weak positive," and "positive."

The most suitable technique would be that in which there is the smallest number of false negatives and weak positives as compared with the standard method.

In Experiment 2 the centrifuging method was used for twenty minutes, as it was hoped that by lengthening the period of spinning the number of one-plus agglutinations would be reduced. It was also compared with the rapid method with two separate incubation periods of ten minutes each. This rapid method is often used in emergencies for Rh-typing, but inexperienced personnel complain of the numerous manipulations involved.

The results show that in 113 Rh-positive cases tested, the total of one-plus agglutinations plus false negatives was five for the twenty-minutes centrifuging and nine for the two ten-minutes rapid method, as compared with one in the standard technique. Thus the superiority of the twenty-minutes centrifuging method as compared with the two ten-minutes rapid method is established, the results being slightly better and the technique easier to carry out.

The results obtained by any Rh technique must depend upon the avidity of the Rh-typing serum supplied. One batch used in Experiment 2 was weaker than the rest, and it was while this was being used that a case was tested which gave a weak positive by the standard and false negatives with both the rapid and the centrifuging techniques.

In Experiments 1 and 2 no false positives were encountered—an important point in emergency Rh-typing.

Experiment 3 was carried out to compare the efficiency of the centrifuging technique with the rapid method when they were both used for a longer period, and also to find out if false positives occurred then. No false positives were encountered, and the efficiency of the centrifuging technique in the small series tested was found to be comparable with that of the standard method.

Summary and Conclusions

A new technique is described in which Rh-typing is carried out by spinning a suspension of the patient's cells with anti-D serum in a centrifuge heated to 37° C. by a thermostatically controlled jacket.

The twenty-minutes centrifuging method gives almost as reliable results as the standard two-hour method, with no false positives. It gives slightly better results than the two ten-minutes rapid method, and, since there are fewer manipulations, it is recommended as a procedure to be adopted in emergency Rh-typing.

I am indebted to Dr. James Davson for advice and encouragement, to Dr. F. Stratton, the director of the Manchester Regional Blood Transfusion Service, for reading the paper and for criticism, and also for supplying the special serum used in Experiment 1.

The *Bethlem Maudsley Hospital Gazette*, published quarterly, is a lively and entertaining journal produced for and by the staff of the Bethlem Royal Hospital and the Maudsley Hospital. The issue which came out at the end of last year contains all the usual features of a weekly professional journal, including editorials, letters to the editor, book reviews, reports of meetings, signed articles, and items of news about the hospital, and also reprints Professor Aubrey Lewis's Maudsley Lecture entitled "Henry Maudsley: his work and influence."

A FOREIGN BODY IN THE KIDNEY

BY

DUNCAN MACAULAY, M.D., B.Sc., M.R.C.P.
D.C.H.

Lecturer in Child Health, University of Manchester

AND

THOMAS MOORE, M.D., M.S., F.R.C.S.

Consultant Surgeon, Duchess of York Hospital for Babies,
Manchester

The following case is of interest because of the diagnostic confusion it caused and its unusual outcome.

Case Report

A boy of 3½ years was admitted to the Duchess of York Hospital for Babies, Manchester, on January 25, 1954. The history obtained at the time of admission was that he had been well until a month before, when he became listless and developed painful enlarged glands in his neck. Shortly afterwards his left ear began to discharge; this persisted until the time of admission. A week after the cervical adenitis developed his urine became dark. There was no dysuria, but he started to pass urine twice during the night. About the time his urine became dark puffiness of the eyes was noted. This decreased during the interval prior to admission. For two weeks before admission he had vomited occasionally. His appetite, usually good, had become poor and he had become fretful. The only relevant previous history was an admission to another hospital at the age of 1 year for repair of an inguinal hernia. Examination showed a well-nourished, lively, but rather fractious child, with slight puffiness under the eyes. There was no oedema elsewhere. The left external auditory canal was full of thick pus and there were moderately large glands palpable in the neck. No other abnormal signs were found. In view of the history a diagnosis of acute nephritis following an upper respiratory infection was made.

The urine contained albumin and many red cells but no casts. Blood urea was 55 mg. per 100 ml.; E.S.R., 70 mm. fall in first hour; haemoglobin, 56% (Sahli); white cell count, 12,400 per c.mm. (neutrophils 61%, lymphocytes 37%, monocytes 1%, Türk cells 1%); platelet count, 450,000 per c.mm.

The profuse haematuria persisted, but no casts were seen at any time. The urine output was good and the general condition satisfactory. After two weeks there was little change in his condition, and the diagnosis of nephritis was considered to be untenable. At this time the blood urea was 42 mg. per 100 ml.; E.S.R., 20 mm. fall in first hour; haemoglobin, 66%; white cells, 15,000 (neutrophils 54%, lymphocytes 41%, monocytes 1%, eosinophils 4%). The left ear was dry and the drum healed.

As the first step in a full investigation of the renal tract a straight x-ray film of the abdomen was taken. This showed a foreign body in the right upper abdomen. A barium meal showed that this body was in close relation to the duodenum, and an intravenous pyelogram indicated that it was also in close proximity to the right renal pelvis (see Fig.).

Operation was performed on February 16 under general anaesthesia. An incision was made in the line of the right twelfth rib, the anterior half of which was removed. The perinephric fascia was opened and the kidney mobilized. The upper half of the kidney was friable and swollen, and had a dark-red mottled appearance. It was very adherent to the surrounding tissues. The duodenum was firmly stuck to the anterior surface of the pelvis of the kidney. The foreign body could be felt passing from the duodenum into the upper part of the kidney. By careful dissection the

duodenum was separated from the kidney except at the site of the short fistulous track through which the foreign body could be felt to be passing. The fistula was divided round the foreign body, which was disengaged from the duodenum with a little difficulty because of the splayed-out ends, which were really broader than the diameter of the duodenal end of the fistula. It was then easily withdrawn from the kidney. No urine leaked from the sinus in the kidney, the external end of which was situated on the edge of the renal sinus just beyond its junction with the pelvis. It appeared to be of kidney substance only and to have no direct connexion

Radiograph showing relationship of foreign body to renal pelvis and duodenum.

with the caliceal system. A piece of perinephric fat was sutured over it. The small opening into the duodenum was closed with two layers of fine catgut and the wound closed in layers, a rubber drain being left to the perinephric space.

The foreign body was identified as a hair-grip of the type known as a "kirbigrip," which was 4.8 cm. long and showed some evidence of erosion of the surface. Microscopical examination of a small piece of the upper pole of the kidney which was removed showed gross interstitial haemorrhage.

The patient made excellent progress after operation and was discharged home three weeks later. Microscopic haematuria persisted for three months after discharge, but the number of red cells in the urine has shown a progressive decrease and they have now become very scanty. At the time of writing the blood urea was 32 mg. per 100 ml. and the child was very active and in excellent health.

The parents were interviewed when the foreign body was discovered, and they remembered that about four months before admission the child had announced one day that he had swallowed a hair-grip. When told he would have to go to the doctor he promptly denied having swallowed anything, and maintained this denial in the face of repeated questioning. Since he appeared perfectly well in the next few days the matter was forgotten. Two months later he had an unexplained illness in which he became listless and anorexic but had no local symptoms. He was examined several times by his own doctor, who found nothing to account for his illness, and after a week he resumed his usual robust health. From about this time his urine was noticed to be cloudy, but it did not become red until three weeks before admission to hospital.

Discussion

The remarkable feature of this case is the behaviour of the foreign body. It had become impacted in the duodenum, and the sharp ends had become firmly fixed against the medial wall of the bowel. Thereupon the rounded end slowly worked its way through the lateral wall and entered the kidney. This whole process was completely silent—unless the vague unexplained malaise two months after the hair-grip was swallowed was to be attributed to it—and finally the child came to hospital presenting the picture of an acute nephritis. He had lost a considerable amount of blood from his renal tract, since his haemoglobin at the time of admission was only 55%.

The varieties of size and shape of foreign bodies which have successfully negotiated the alimentary tract are legion. As a general rule, those which traverse the oesophagus can be expelled per vias naturales. Thus Gross (1953) reported that only 43 of 615 to reach the stomach had to be removed by operation.

We have been able to find reports of four other cases in which swallowed foreign bodies have perforated the bowel quite silently and entered the kidney. All four were young children, and in all of them the symptoms were predominantly renal. The Table gives the relevant data on the five cases now on record.

Details of Five Recorded Cases

Case	Age in Years	Sex	Foreign Body	Symptoms	Duration of Symptoms (Months)	Operation
Capon and Wells (1938)	4	F	Kirbigrip	Frequency; haematuria	7	Nephrectomy
McEnery and Fox (1946)	2	M	Bobby pin	Fever; vomiting; haematuria; pyuria	7	Removal through duodenum
Mackby (1948)	3	F	" "	Frequency; cloudy urine; fever	6	" "
Bilger and Greiner (1949)	5	M	Hair-grip	Pyuria	4	Nephrectomy
Present case	3½	M	Kirbigrip	Haematuria; malaise; vomiting	1	Removal without opening duodenum

A bobby pin is the American equivalent of a kirbigrip. The child reported by Capon and Wells was known to have swallowed a hair-grip several months before the onset of symptoms. In none of the other cases was such an incident reported. The two American cases and the other British case are practically identical with ours. In all four the open end of the hair-grip had become stuck in the second part of the duodenum and the rounded end had perforated the wall and entered the kidney. In the French case the foreign body passed as far as the large bowel before being arrested.

These cases are so similar, and the sequence of events so remarkably alike, that we suggest that this be regarded as a definite syndrome. Toddlers are notoriously apt to put things in their mouths, and in the investigation of obscure symptoms in children of this age the possibility of a foreign body as the cause should always be borne in mind.

Summary

A boy of 3½ years developed profuse haematuria three months after swallowing a hair-grip. This was found to be due to arrest of the foreign body in the duodenum and penetration of the right kidney. The foreign body was removed at operation and complete recovery ensued. Four other cases in whom a similar sequence of events occurred are referred to.

Medical Memoranda

Pyrimethamine in the Prophylaxis of Malaria

Therapeutic trials with pyrimethamine ("daraprim") have indicated that the drug could effectively control a clinical attack of vivax or malariae infection in two to three days but might fail in a certain percentage of falciparum infection (Chakravarty and Chaudhuri, 1953). The present report on the prophylactic value of the drug is based on another investigation carried out simultaneously in a malarious village.

MATERIAL AND METHOD

The prophylactic trial was carried out on 311 boys in a village school about 35 miles from Calcutta from July to November, which is usually the heaviest transmission period in the locality. A preliminary survey was done to find out the spleen and parasite rates; it showed that 60% of malarial infection was due to *P. falciparum* and the rest to *P. vivax* or *P. malariae*. During the course of treatment the blood was examined every month except October, and on its conclusion a final estimate was made of the spleen and parasite rates (see Table). Alternate classes received pyrimethamine (172 boys) and dummy tablets (139 boys) respectively, the latter serving as control. Both were given once a week, the dose of pyrimethamine being 25 mg. (12.5 mg. for boys under 10 years). The tablets were administered personally by a member of the clinical research unit, financed by the Indian Council of Medical Research, except for four weeks during the October vacation, when they were handed over to the boys to be taken by themselves in their homes.

RESULTS

The effect of prophylactic regimen on the parasite and spleen rates is shown in the Table.

Effect of Pyrimethamine Prophylaxis on Parasite and Spleen Rate per 100

Group		July	Aug.	Sept.	Oct.	Nov.	Dec.
Pyrimethamine (172 boys)	Parasite	5.7	0	1.2	—	0.7	2.3
	Spleen	16.1	—	—	—	—	11.6
Control (139 boys)	Parasite	3.6	3.7	8.6	—	6.6	9.2
	Spleen	16.2	—	—	—	—	23.9

The parasite rate in the control group rose, as was to be expected, from 3.6 in July to 6.6 in November, while in the treated group it dropped from 5.7 to 0.7 during the same period. In December, after the conclusion of the experiment, there was an unexpected rise in the parasite rate, which might perhaps have been due to prolongation of the transmission period. The suppressive effect of pyrimethamine was also reflected on the spleen rate, which showed some reduction, while there was about 50% increase in the control group. In all the parasite-positive cases in the treated group only *P. falciparum* was seen throughout the period.

The incidence of overt malaria could not be accurately recorded, as it was not possible to examine the blood during febrile attacks. However, on inquiry at the weekly visits it was gathered that the incidence of fever was much less in the treated group.

COMMENT

Following the observation of Goodwin (1952) on himself that 5 mg. of pyrimethamine daily could suppress malaria, Vincke (1952) carried out a successful mass prophylaxis in the Belgian Congo with a weekly dose of 25 mg. Covell *et al.* (1953) obtained complete suppression

of overt attack with 25 mg. of pyrimethamine weekly in non-immune subjects exposed to a West African strain of *P. falciparum*.

Our observation in a village school indicates that weekly doses of 25 mg. have an effective suppressive action against malaria. Both falciparum and vivax infections have been prevalent in the area, the majority being falciparum. The persistence of *P. falciparum* parasites in a few cases during pyrimethamine administration indicates that some falciparum strains are relatively less sensitive to the drug. However, the large majority of the cases were free from parasites during the prophylactic regimen.

Our thanks are due to the Wellcome Foundation Ltd. for the supply of daraprim and to Sri C. L. Mitter, S. Mitter, and B. Dutta for their help in this work.

Fatal Case of Agranulocytosis Due to "Novalgin"

The danger of agranulocytosis due to amidopyrine and its derivatives is now so well known that few would wittingly advise the use of these drugs, yet this may be done unintentionally by prescribing certain proprietary preparations. Frequently the proprietary name gives no indication of the precise nature of the active principle, and thus cases of agranulocytosis due to amidopyrine or closely related compounds continue to occur. It seems that the exclusion by law of amidopyrine from proprietary preparations, as is done in Denmark, is the only sure way of preventing these fatalities (*Lancet*, 1951). Meantime, publication of cases may result in a wider appreciation of this hidden danger and so help to minimize it.

CASE REPORT

A married woman aged 67 was admitted to the surgical wards of the Western Infirmary, Glasgow, on November 7, 1953, complaining of vomiting and the passage of red blood per rectum of a week's duration. She had been operated on for haemorrhoids on two occasions and had received injections of liver extract for anaemia over the previous three to four years.

On admission she did not look very ill and her temperature was 100.4° F. (38° C.). The throat was red and oedematous; proctoscopy revealed an indurated, elevated sinuous ulcer on the anterior wall of the rectum. After three days in hospital she was still febrile and appeared slightly jaundiced. The diagnosis of agranulocytosis was established by blood examination, which showed: Hb, 13.4 g. per 100 ml.; P.C.V., 43%; red cells, 4,720,000 per c.mm.; white cells, 75 per c.mm.; icteric index, 25 units. The blood film showed normal red cells and adequate platelets, but white blood cells were extremely scanty. Of the first 50 leucocytes examined 2 were polymorphs, 10 monocytes, 36 lymphocytes, and 2 Türk irritation cells.

Inquiry revealed that, to control headache, novalgin had been taken occasionally for years, but during the last month 15 gr. (3 tablets) were ingested daily in divided doses up to the time of admission. The only other medicaments taken during the previous three months were a vegetable laxative and liver extract; in particular, no barbiturate drug had been used.

Intensive treatment with penicillin brought considerable improvement and a reduction in temperature, but five days after admission she suddenly became distressed and dyspnoeic. Treatment for massive pulmonary embolism was at once instituted, but she died within two hours.

The significant post-mortem findings were as follows. Slight icterus; throat merely slightly injected. A coiled embolus 1 cm. in diameter lay across the bifurcation of the pulmonary artery. The embolus was massive and as much as 25 cm. could be removed in one piece; the right side of the heart was acutely dilated. On dissection of the leg veins both femorals were found to be clear, but the intramuscular tributaries on the right side contained thrombus; it was concluded that embolus had originated in the right femoral vein. On the anterior wall of the rectum there was an elevated irregular area of ulceration 4 by 2 cm. which extended into the anal canal. The necrotic tissue was greenish on the surface and dull yellow underneath. The necrosis extended into the bowel wall for 3 cm. and the adjacent tissues were severely inflamed and oedematous. The bone marrow was hyperplastic, red marrow extending half-way down the femur. The spleen weighed 250 g., and neither it nor any of the other blood-forming tissues showed evidence of leukaemia. The liver showed merely toxic cloudy swelling.

On microscopical examination the rectal ulcer showed the typical appearance of an agranulocytic lesion, the cellular infiltrate being composed almost entirely of mononuclears, and necrosis and inflammatory oedema being very severe and widespread. The marrow contained numerous foci of erythroblasts, and megakaryocytes were also plentiful; polymorphs were absent and myelocytes were scanty. The marrow thus showed a severe maturation arrest of granulopoiesis amounting to aplasia, but no evidence of either leukaemia or pancytopenia.

COMMENT

The post-mortem findings establish the cause of death as pulmonary embolism following right femoral thrombosis in a case of agranulocytosis. The neutropenia was clearly due to failure of granulopoiesis without there being any disease process in the marrow to account for it. Since there was nothing to suggest splenic neutropenia (Hutchison and Alexander, 1954), and no history of cyclic attacks, but a clear history of the habitual use of novalgin, a sulphonated compound of amidopyrine known to have caused agranulocytosis, it seems reasonable again to incriminate this drug. The findings in our case correspond closely with previous accounts of agranulocytosis due to novalgin (Benjamin and Biederman, 1936; Klumpp, 1937; Plum, 1937); in particular, the unusually low white-cell count which we observed has been met with in other novalgin cases (Fitz-Hugh and Comroe, 1933; Ridpath, 1934), and ulceration of the rectum is recorded in the case described by Buck (1929).

The introduction of antibiotics has altogether transformed the prognosis in cases of agranulocytosis by controlling the generalized infections which formerly proved rapidly fatal. It seems probable that had embolism not occurred this patient's life might not have been forfeit to novalgin, for under treatment with penicillin she was not profoundly ill and her blood culture was negative. It is, however, evident from examination of her marrow after death that several more days would have been required to see her out of the danger period due to agranulocytosis; the precursors of the polymorphs had not returned to the marrow, and so recovery was not yet in sight.

We are grateful to Professor C. F. W. Illingworth for permission to report this case.

Thomas's Sign, or the Silver Stool in Cancer of the Ampulla of Vater

Dr. A. M. Thomas, pathologist to the Royal Masonic Hospital, has pointed out that in cancer involving the ampulla of Vater the patient sometimes passes "silver stools"—that is, motions having the colour of oxidized silver or aluminium paint. The silver or grey stool is a combination of the white stool of obstructive jaundice and the black stool of melaena.

Biliary obstruction, whatever its cause, will produce a clay-coloured stool. Such a stool may contain blood from many sources. If the amount of blood is small it will not colour the stool appreciably. If it is large it will dominate the picture and lead to the typical black stool of melaena, but massive intestinal haemorrhage is either intermittent or fatal. If the blood comes from low down it will be red and not black. The combination of deep jaundice with steady intestinal haemorrhage coming from high up in the intestinal tract is seen regularly in cancer of the ampulla, and only rarely in other conditions.

CASE 1

A married woman aged 46 was admitted on September 30, 1952, with a history of intermittent jaundice for three months. She did not appear to have lost weight, but was very anaemic. Tests showed the jaundice to be of the obstructive type, and the stools contained occult blood in large amounts. The barium meal was reported to be normal, apart from spasticity of the pyloric antrum.

A laparotomy was performed on October 16. A carcinoma could be felt at the ampulla. The gall-bladder and common bile duct were grossly distended, and both contained white bile only. Cholecystostomy was performed. The discharge from the drain soon became green in colour. On October 30 pancreaticoduodenectomy was performed with ligature of the stump of the pancreas and implantation of the bile duct in the jejunum. Apart from some blood-stained discharge, convalescence was satisfactory.

Since discharge on January 1, 1953, the patient has remained very well, needing only small doses of insulin. She dislikes fats, but that has benefited two people—her in that she has regained her youthful figure, and me in that she sends me a regular supply of Devonshire cream.

CASE 2

A man aged 78 was admitted on February 14, 1954, with a suprapubic fistula, following prostatectomy at another hospital in November, 1953. His haemoglobin level was 50% and his general condition poor. He was given two pints (1,130 ml.) of packed cells, and shortly afterwards developed jaundice which at the time was attributed to the transfusion. His stools were sent for analysis, and Dr. Thomas reported that they had the silvery appearance that he had previously noted in Case 1. On this appearance he made a tentative diagnosis of carcinoma of the ampulla of Vater.

The jaundice deepened and the patient died on February 22 in hepatic failure. At necropsy a carcinoma 3 mm. in diameter was found at the ampulla of Vater. The haemorrhage on which the diagnosis had been made had, however, come from a colonic diverticulum.

COMMENT

The diagnosis has since been made in two further cases. So far as I am aware the silver stool has never been described before. I bring the sign to the attention of surgeons because Dr. Thomas has not yet reported it himself and, being a pathologist, he is likely to report it in a journal read only by his brother pathologists. Thomas's sign, which can be observed by a house-surgeon or nurse who is aware of its importance, is diagnostic of cancer of the ampulla of Vater, and will enable instances of this eminently curable lesion to be recognized at an early and operable stage.

Guy's Hospital and Royal Masonic Hospital.

Reviews

CEREBROVASCULAR DISEASE

Cerebrovascular Disease. By James Peter Murphy, M.D. Foreword by Percival Bailey, M.D. (Pp. 408; illustrated. 90s.) Chicago: The Year Book Publishers, Inc. London: Interscience Publishers Ltd. 1954.

This scholarly work includes a survey of the anatomy and pathology of cerebrovascular disorders. These are then related to the clinical syndromes of disturbance of cerebral blood supply. There are chapters which have great contemporary interest, notably that dealing with the vexed problem of spasm of cerebral arteries and that concerned with occlusion of the whole carotid artery itself. Although cerebral angiography has so greatly increased our understanding of the events leading to brain dysfunction through anaemia or haemorrhage, knowledge of the physiology of the cerebral circulation is still pathetically inadequate, so that we are still inclined to consider events as though they were hydrostatic, in a field where hydrodynamic pressure gradients are all-important. The study of morbid anatomical specimens has encouraged the persistence of a static anatomical attitude to the problems, and so far the observation of flows through arteriography has done little to correct that attitude. Throughout Dr. Murphy's book there is apparent an awareness of this difficulty with an emphasis upon the activity of the vascular system as well as upon its structure.

Modification of intracerebral events by change in the vascular bed and in blood flow has been attempted in a number of contemporary procedures used in patients with hemiplegia of vascular origin. These have included, on the surgical side, stellate block, perfusion, and sympathectomy of the carotid vessels, and, on the medical, the immediate use of anticoagulants. Some recovery from vascular accidents being usual without intervention, it has been difficult to assess the results of these radical methods of management, but there is already a tendency to return to the more conservative methods of management which most neurologists have not forsaken. The subject remains, however, a controversial one. While the author has discussed the whole of this question in detail, he has done so in a balanced and thoughtful way which will give comfort to the conservative. At the same time, writing as a neurological surgeon, the author has included the appraisal, not obscured by details of technique, of the radical management of vascular anomalies of the convexity and of the basal vessels.

The work is a balanced one, whether dealing with the management of the lesion itself, of the symptoms to which it gives rise, or of the patient as a whole. Each chapter is followed by an adequate bibliography and is extensively illustrated by photographs of patients, specimens, radiographs, and experimental procedures. The volume contains an opportune review of the present knowledge of a subject whose literature extends to the beginnings of medicine.

DENIS WILLIAMS.

ABOUT WOMEN

Woman: Man's Equal? By Sir Adolphe Abrahams, O.B.E., M.D., F.R.C.P. (Pp. 176. 10s. 6d.) London: Christopher Johnson. 1954.

This may be regarded as a companion volume to the author's previous work, *Fitness for the Average Man*, the change in the title being made necessary by the fact that "nobody would be so foolhardy as to regard any woman as 'average.'" Whenever I read a book by Sir Adolphe Abrahams I am forcibly brought back to Laotse's "philosophy of the old rogue." Instead of reading a book about women by an eminent Western physician, I seem to be perusing the translation of an old Chinese manuscript

written by, say, Chaung-tzu or, if not by that great master himself, at least by one of his disciples. So strong is this feeling that when I lay down *Woman: Man's Equal?* I see in imagination its distinguished author no longer dressed as usual, but suitably arrayed in Chinese robes.

Far from insulting Sir Adolphe by associating him with the philosophy of the old rogue, I am according him the highest praise, for this philosophy is the product of the highest wisdom. There is a benevolence, a charitableness, and a good-natured humour in the works of Chaung-tzu and also in this book which makes them exceedingly pleasant to read. The author has undoubtedly enjoyed writing *Woman: Man's Equal*, and now his enjoyment seems to come back out of its pages to meet us.

Sir Adolphe deals with a motley of subjects, some of which at first sight would appear to be only remotely related to women, but all combine together to form an excellent dish. Everybody will find something to enjoy in this book and something to condemn in it, for, like the subject with which it deals, it is full of paradoxes, absurdities, and contradictions. I commend it to "misogynists, philogynists, feminists, romanticists, idealists, cynics, knights errant, realists, and rhapsodists"—to everybody indeed except the humourless moron. For the sake of our reputations, therefore, it will be necessary for us all to buy it.

KENNETH WALKER.

CARDIAC CATHETERIZATION

Der Herzkatheterismus bei Angeborenen und Erworbenen Herzfehlern. By Professor Dr. Otto Bayer, Dr. Franz Wolter, Loogen, and Dr. Hans Helmut. (Pp. 191+xii; 131 illustrations. D.M. 36.) Stuttgart: Georg Thieme. 1954.

In this book on cardiac catheterization in congenital and acquired heart lesions the authors give an account of this method of investigating heart disease based on 800 cases seen at Düsseldorf. Practically all the congenital lesions which exist to an age when investigation can be carried out are included. The first part of the book consists of a general description of materials and technique. There is a full account of Professor Bayer's method of calculating the areas of the pulmonary and mitral openings. The untoward results of the introduction of the catheter into the heart are described. There are well-written clinical and pathological introductions to each section, and these are usually clear and concise.

The schematic representations of the effects of lesions on the circulation need more explanation; they appear to be imitated without acknowledgment from Courmand's book, where they are much better done. The skiagrams are good. The cardiograms do not give the unipolar limb leads, and the other leads are not always labelled. Many of the recordings are marred by alternating current, and their description is often obscured with a curious use of the word "vector." The diagnosis of intra-auricular block needs some explanation. The pressure tracings are for the most part good, but some are poor and blurred and the whole curve is not always included. The phonocardiograms are also often blurred and indistinct. It is rather confusing to read first on one page that an atrial septal defect may cause a presystolic, on another a systolic, and on a third a diastolic murmur.

There is a list of references at the end of the book. This is not free from mistakes, and there is no link between it and the text.

TERENCE EAST.

OBSTETRICAL ESSAYS

Practical Obstetrics. By Bruce T. Mayes, M.V.O., M.B., B.S., F.R.C.S.(Edin.), F.R.A.C.S., F.R.C.O.G. Foreword by John A. Stallworthy, M.A., F.R.C.S., F.R.C.O.G. (Pp. 500; illustrated. 87s. 6d.) London and Sydney: Angus and Robertson. 1954.

This book first appeared in 1947, when it represented a collection of refresher "bulletins" prepared for medical officers serving in the Forces. It is now considerably modified and enlarged, and many will recognize it as a permanent

record of lectures delivered by Professor Bruce Mayes in this country while he was the Sims-Black Travelling Professor for 1954. The 38 chapters would be better termed "essays"—essays in the style of the older obstetricians who taught by detailed and graphic description of personally observed and treated cases, sometimes pointing out the moral themselves, often leaving and stimulating the reader to reach his own conclusion by approval or disagreement. They are suitable for reading in spare moments, for each is a separate entity. Most of the subjects fall within the range of obstetrics proper, but Professor Bruce Mayes does not hesitate to wander into the bypaths of dysmenorrhoea, sterility, and consulting-room technique. To one and all, however, he brings charm, wit, neat phrase, happy aphorism, and a philosophy based on clinical experience.

The book is an exposition of the art rather than the science of modern obstetrics, and it savours of the fireside chats of a wise doctor to general-practitioner obstetricians working in conditions in which they may have to take a good deal of clinical responsibility without having expert help immediately at hand. Scientific data and explanation are not allowed to take precedence over common sense; indeed, they are sometimes omitted, invented, or slightly distorted in order to provide a simple and logical working basis. But surely this falls within the bounds of teaching licence, and it is one of the secrets of the author's exceptional gifts as a teacher. Another is an appreciation of the psychological reactions of students and readers. On page 1 of Chapter I there is a footnote: "If you are in a hurry I suggest moving on to Chapter IV." This is enough to make even a reviewer hesitate to skip Chapters, I, II, and III.

T. N. A. JEFFCOATE.

CANCER

Cancer: Diagnosis, Treatment and Prognosis. By Lauren V. Ackerman, M.D., and Juan A. del Regato, M.D. Second edition. (Pp. 1,201; 702 illustrations, 23 colour reproductions. £8 10s.) London: Henry Kimpton. 1954.

This is a very unusual book containing an immense amount of valuable information and obviously based on wide experience and an extensive study of the literature, to which there are copious references. But its character can be appreciated only when it is realized that it is the work of a pathologist and a radiologist, both of great eminence in their respective fields. Their approach is therefore quite different from that of the surgeon, with his outlook primarily clinical and technical. This is perhaps best seen in the discussion of cancer of the respiratory tract, fully illustrated by diagrams and pathological photographs. But the interest is in large groups of cases and not in the treatment of any individual case.

The volume is chiefly of value for the careful and accurate description which it gives of the origin and spread of cancer in different regions, for its discussion of the relative value of surgery and radiotherapy, and for the full bibliography which it presents. It is admirably illustrated by diagrams, photographs, and photomicrographs.

HENRY SOUTTAR.

PSYCHOTIC ART

Insanity, Art, and Culture. By Francis Reitman, M.D., D.P.M. (Pp. 111; illustrated. 12s. 6d.) Bristol: John Wright and Sons, Ltd. 1954.

Psychotic patients have made drawings and paintings from time immemorial. These were not taken seriously until the latter part of the nineteenth century, when Simon and Lombroso used the productions for diagnostic purposes. The present-day revival of interest in imaginative art is focused mainly upon its use as a therapeutic agent; the diagnostic hints conveyed in the pictures are not missed, and now and then may be used to supplement other knowledge.

Dr. Reitman considers only the diagnostic significance of psychotic paintings. This narrow topic is amplified by some reflections on the symptomatic significance of the art products of psychotics in other countries. To this end material

was collected from mental hospitals in Asia, Africa, North America, and New Zealand. The aim of this comparative study is obscure, and certainly the results are not decisive, as might have been anticipated from the small number of pictures available. The author himself appears to attach little importance to the few conclusions reached.

Commenting on symbols, the author recalls the familiar fact that Freud and Jung (and their pupils) attach different values to the word "symbol." Freud's view is not given, but Jung is misrepresented as holding that symbols express "mystic collective images." Having brushed Freud and Jung aside, Dr. Reitman tells us what symbols are "in scientific usage"; they are "objects which are attended to not for their own sake, but for the sake of something else to which they refer." By this token the ringing of the telephone bell would be a symbol. But happily "scientific usage" as here understood is not the language of artists, psychotic or otherwise.

E. A. BENNET.

ELECTRONICS FOR PHYSIOLOGISTS

An Introduction to Electronics for Physiological Workers. By I. C. Whitfield, B.Sc., Ph.D. (Pp. 236; illustrated. 18s.) London: Macmillan and Co., Ltd. 1953.

It is very difficult to-day for a physiologist to avoid the use of electronic apparatus such as amplifiers, cathode-ray oscillographs, and electronic stimulators, which have become essential pieces of equipment in almost every branch of physiological research. While expert advice can always be obtained on problems of electronics, it is obviously better for the physiologist himself to have some understanding of his apparatus and methods, however complex or specialized they may be.

This book sets out to fill a gap between the elementary radio textbook and the more specialized monograph dealing with electronics and biological research. In the earlier chapters the author gives an account of the fundamental ideas of electronics, with due emphasis on those parts of the subject which have special importance in biological work. A certain background of electrical theory and elementary physics is assumed, and these chapters serve rather as a reminder of earlier and possibly forgotten groundwork. The chapters dealing with amplifiers and oscillators are more detailed, and quantitative treatment has been given when possible, thus giving the book an essentially practical slant. The problems of "noise," interference, and screening have been clearly and simply dealt with, and the author discusses in some detail the important question of electrode and inter-electrode resistance. Throughout the book there are references for further reading; as the author points out in his foreword, this book is not for those who hope, in an idle hour, to pick up something about electronics.

W. F. FLOYD.

When Rush Medical College was opened in Chicago in 1843 about thirty other medical schools were already functioning in the U.S.A., many of them patterned after the Edinburgh school. Benjamin Rush, after whom the college was named, was an Edinburgh graduate, a friend of Benjamin Franklin, a signatory of the Declaration of Independence, and the first great American physician. He introduced clinical teaching at Pennsylvania Hospital, to which he was physician for 30 years. He died in 1813. Rush Medical College was founded by Daniel Brainard. In its first year the requirements for the M.D. degree were three years of study with a respectable physician, two courses of lectures (the second at the school) and the submission of a thesis. In 1877 the college decided to establish a hospital, which opened in 1883 as the Presbyterian Hospital. After affiliation with the University of Chicago in 1898, Rush became an integral part of the University in 1923, but as time passed the plan to confine the college to postgraduate education became less appealing to Rush and to the hospital, and the union was dissolved in 1941, leaving Rush once again independent. Its history is briefly told by Ernest E. Irons in *The Story of Rush Medical College* (Chicago, published by the College, 1953), a book of 82 pages which is a useful addition to the history of medical education in the U.S.A.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 22 1955

INFLUENZA

Our old winter enemy influenza is with us once again, though if it is any consolation to either patient or doctor it appears that virus B, which is usually associated with a less severe form of illness, has been mainly responsible so far. But it is too early to predict the future course of events. In its true epidemic form influenza presents a characteristic picture familiar to all, but there are many occasions when diagnosis on purely clinical grounds is not so simple. Influenza is not notifiable in the United Kingdom, but the certified deaths from influenza and pneumonia in the 160 great towns (formerly 126) of England and Wales indicate the general trend of acute respiratory infection. Clearly this is a very crude index of influenza, and the recent introduction of a "spotting scheme" in which selected general practitioners and regional laboratories have co-operated has already made progress in determining the part played by the influenza viruses in respiratory disease.¹ At an international level the World Influenza Centre is concerned with the serological classification of virus strains² and in tracing the spread of the disease.³

Two main serological types of influenza virus, A and B, are now recognized. A third, C, has been described, but its role in human disease is not yet understood. It appears to be associated with a minor form of illness.⁴ All major epidemics, which occur on an average every two to three years,⁵ have been associated with virus A. Virus B, on the other hand, tends to be endemic and an annual source of mild influenza,⁶ but epidemics have been caused by it.⁶ Recently virus A has been responsible for extensive and, in some areas, severe influenza—during the winters of 1950-1 and 1952-3. Virtually no influenza was encountered in 1951-2 and 1953-4.

In the past twelve months sporadic cases due to virus A occurred in February, 1954, and a few cases of influenza B in the spring, with a sharp outbreak

at a school in the midlands. During the summer virus A was detected in cases arriving by sea from South Africa, but the disease did not spread in Britain. In September influenza appeared in Wales, later on Tyneside. Within the next few weeks many cases were reported in Scotland and in general north of a line joining the Humber and the Severn. Serological evidence of virus B was obtained. By the end of the year similar cases appeared in the south and in the London area. Occasional cases of virus A and of virus C have also been encountered. People of all ages have been affected, but several reports have indicated a high attack rate in school-children. The weekly figures of certified deaths from influenza up to January 8 have been 56, 66, 56, 82, and 102; the deaths seem to be chiefly of elderly people. These figures show a fairly sharp rise and it is too early to say how the outbreak will compare with those of previous years. The general impression so far is one of increased prevalence, with local outbreaks, and is not unlike the behaviour of influenza B in 1945-6.⁶ On the whole the behaviour of virus B this winter is in keeping with the idea that influenza due to this virus is generally less severe than that caused by virus A, but it is impossible to distinguish the two on clinical grounds alone.

In addition to true virus influenza a number of less well differentiated respiratory infections have been reported. Influenza-like illnesses (but without influenza virus) have occurred all over the country; so-called influenza with vomiting (distinct from epidemic nausea and vomiting) and other cases with encephalitic symptoms have been seen. An increased incidence of virus or primary atypical pneumonia has also been reported. There is certainly plenty of scope for sorting out this mixed collection of acute respiratory infections into aetiological types.

Prophylactic immunization with killed virus vaccines prepared in the fertile egg has given encouraging results; the timing of the vaccination and the incorporation of the correct virus strains are important.^{7,8} The main disadvantages are the short-term effect of such vaccines—research into this is now in progress—and also the cost. Vaccination is likely to be practicable only in protecting selected groups of individuals rather than the population as a whole. No drug has yet been found effective against influenza or indeed against any of the small viruses. Many have been tried.⁹ Prophylactic chemotherapy to control secondary bacterial infection in uncomplicated influenza is best reserved for those patients with existing lung disease or for old or debilitated patients; on the other hand, influenza complicated by bronchiolitis or pneumonia requires energetic

treatment with antibiotics.^{10 11} Until such time as a specific anti-viral compound is produced the best advice is to stay in bed and keep warm.

POST-OPERATIVE WEIGHT LOSS

It is not clear whether the phase of weight loss and protein catabolism which follows fractures^{1 2} and surgical operations³⁻⁶ is part of the defence of the body against trauma, as Moore believes,⁷ or whether it is due solely to the restriction of caloric intake in the immediate post-operative period, as the experiments of Werner suggest.⁸ What is certain is that convalescence is prolonged and wound healing delayed in patients coming to operation in a poorly nourished state. One surgeon shares Julius Caesar's preference for the fat, who he finds stand major surgery better than thin people, presumably because they have a large store of potential calories on which to draw after the operation.⁹ Poorly nourished patients have been shown to have a "predepleted metabolic response" to operation, which consists in only small negative nitrogen and potassium balances, with a potassium/nitrogen ratio approximating to that found in the tissues.¹⁰ The protein and caloric reserve of such patients should be built up before operation, and even the frailest patient may gain weight and strength to withstand major surgery by a regime of forced feeding with a high-protein and high-caloric intake.⁹ Patients who are assessed as being well nourished before operation can, by forced feeding, retain enough nitrogen in the pre-operative period to allow for their post-operative loss and still leave them in positive balance over the whole period before, during, and after operation.¹¹

In the post-operative period some investigators have found it impossible to meet the demands of the body for nitrogen to replace what is lost in the catabolic phase.^{6 12} In this issue of the *Journal* Drs. D. Davies and A. Pines report (p. 200) that they were unable to arrest post-operative weight loss in tuberculous patients, who were taking an ordinary hospital diet,

by the administration of the protein anabolic hormone methylandrostenediol. Details are not given of the amount of calories and nitrogen their patients were receiving, and it is possible that the dietary intake may have been surprisingly low, especially in calories. Sutherland has suggested a number of reasons for this from her experience in Edinburgh, which she believes may be applicable in hospitals elsewhere.¹³ On the other hand, Riegel *et al.*¹⁴ were able to maintain their patients in nitrogen balance or positive nitrogen balance during the first five days after operation with an intake which supplied 0.3 g. nitrogen and 30 calories per kg. body weight per day. This is modest compared with the amounts Brain regards as necessary for his malnourished patients during the pre-operative period.⁹ Although in short-term experiments it is possible to maintain nitrogen balance with an adequate nitrogen intake and without additional calories,¹⁵ those who have been wholly or partly successful in anticipating¹¹ or covering the loss of weight and nitrogen after operation all stress the importance of adequate caloric intake,^{14 16} particularly for patients with burns.¹⁸

When possible, food should be given by mouth. Patients unable to take it thus in the pre-operative period may receive it through a preliminary gastrostomy or jejunostomy, though care must be taken when feeding by jejunostomy not to give hypertonic feeds, which the jejunum does not tolerate well.¹⁴ Some patients regain their appetite as their nutritional state improves on this regime.⁹ Even when there is no obstacle to oral feeding, loss of appetite may make it impossible to provide an adequate caloric intake, and in such cases tube-feeding may be necessary. This is often successful if the patient can tolerate it, but may be complicated by severe dehydration.¹⁷ The amount absorbed, even of glucose and water, is too uncertain to make rectal feeding with amino-acid mixtures a desirable method.¹⁸

When some form of alimentary feeding is not possible food must be injected intravenously. Whole protein in the form of blood transfusions, plasma infusions, and human serum albumin have been successfully administered,¹⁶ or perhaps more commonly protein hydrolysates. A. W. Wilkinson *et al.*⁶ found that the use of such preparations merely increased the urinary nitrogen excretion to an amount nearly equivalent to the amount given as the hydrolysate. Whatever the method for giving the nitrogen intravenously, it is in the provision of calories that the difficulties arise. If glucose alone is added to the source of nitrogen for this purpose, extremely hypertonic solutions must be used, which cause thrombosis in peripheral veins, though they may be infused slowly

with safety into the inferior vena cava.¹⁸ Alcohol, which has a high caloric value, has been given intravenously in mixtures with amino-acids and glucose.^{19 20} It is said to have the additional advantage of raising morale and reducing the need for morphine, and to be non-toxic in the quantities employed.²⁰ But the material of choice for the caloric component of intravenous feeding is fat. Fat emulsions have a high caloric value and high molecular weight, with a low osmotic pressure, so that they can be used in only slightly hypertonic concentrations. There is considerable evidence of their value as an intravenous source of calories,^{21 22} but unfortunately they are not generally available in Britain.

FUNGUS ALLERGENS

The dense fog that suddenly enveloped part of London last Sunday was a sharp reminder again that city smoke is a menace to health. Now another aspect of air pollution has been reviewed by Kate Maunsell.¹ She has pointed out the many problems that arise from sensitization due to inhalation of fungal spores. The potential sensitizing effect of grass pollen and *Penicillium* spores was first noted by C. H. Blackley,² of Manchester, over a hundred years ago. His observations were largely forgotten, as were his classical experiments when he demonstrated by means of pollen traps and skin tests that grass pollen was the cause of summer catarrh. After sixty years W. S. Van Leeuwen,³ in Holland, became interested in the moulds as a cause of respiratory allergy, and by 1946 H. A. Hyde and D. A. Williams,⁴ at Cardiff, had begun their systematic study on the pollen and spore content of the air. The usual method of tracing the common airborne fungi was by exposing Petri dishes containing suitable culture media, though many fungi for various reasons will not grow on the ordinary laboratory media. More recently quantitative techniques have been used. A measured sample of air impinges on a sticky glass slide, and in the automatic spore trap devised by J. M. Hirst⁵ the trapped particles can be graded in size. The number and different types of fungal spores as well as other potential sensitizers and bronchial irritants can be measured hourly or daily, and the seasonal variations can be studied.

M. Richards,⁶ when working for the Asthma Research Council, made a survey of the spore content of the air at nine different stations in Great Britain.

He found that, as well as a seasonal variation, there is a considerable difference in mould spore content between town and country. The increase in spores occurs from April to November, rising to a high peak in July and August. In patients allergic to fungus spores symptoms of hay fever, sometimes with an associated asthma, occur during the months of the heaviest spore cloud. The symptoms may be combined with other inhalant allergies, particularly to grass pollen. A knowledge of both the pollen and mould spore seasons is therefore necessary before investigating patients with seasonal symptoms. Symptoms during June to mid-July are almost certainly, if confined to this period, caused by grass pollen. Symptoms from mid-July to September are probably due to fungal spores, and generally to those of *Cladosporium*. In a pollen-sensitive patient eye irritation is nearly always one of the symptoms, while a patient sensitive to mould spores does not seem to experience this. The antigenic extracts made from mould spores are much weaker than pollen extracts. Intradermal testing with pollen extracts, except with very diluted solutions, is not recommended owing to the likelihood, except in experienced hands, of a severe constitutional reaction in a sensitive patient, while intradermal testing is the method of choice in a mould-sensitive allergic patient. In general the treatment of the mould-sensitive patient is much the same as the pollen-sensitive—a careful history, confirmatory skin tests, and hyposensitization when dust elimination or symptomatic drugs do not afford relief.

Fungi are more prevalent in humid areas, and many patients report aggravation of symptoms near rivers and in valleys, especially on clay soil. The east and south-east coasts of England suit the mould-sensitive patient, but not the coastal areas of Dorset, Devon, and Cornwall. Yet it is unwise to be dogmatic about suitability of localities, because there are marked local differences. Houses that have been slightly damaged by bombs, old houses, and houses that have had a blocked rain-water pipe may have become affected by the wood-destroying fungus of dry rot (*Merulius lacrymans*). A. W. Frankland and M. J. Hay⁷ were the first to show that dry rot, which is so often quite unsuspected in a house, can give rise to inhalant allergic symptoms. Professor P. H. Gregory and his colleagues⁸ found 75,000 spores per cubic metre of air in a cellar which contained dry rot, with 16,000 spores per cubic metre in the first-floor room. The occupational hazards of sensitization by mould spores are seen in dock workers unloading infected materials, particularly grain, second-hand furniture dealers, and gardeners, especially those growing tomato plants that become infected with *Cladosporium*. But perhaps it

is the housewife who is most exposed, since it has been found⁹ that up to 1,000,000 spores of the common fungi are present per gramme of household dust.

BACTERIAL GENETICS

The field of bacterial genetics is one in which discoveries of the highest importance, both to medicine and to genetics, have been made in recent years. Interest in the genetics of bacteria was aroused by two events: the finding by O. T. Avery, C. M. MacLeod, and M. McCarty¹ in 1944 that the capsular transforming agent in the pneumococcus was composed of deoxyribonucleic acid (D.N.A.), and the discovery by J. Lederberg and E. L. Tatum² in 1946 that interchange of hereditary material had occurred in the daughter-cells from a mixed culture of different strains of *Escherichia* (*Bacterium*) *coli*.

The report in this *Journal* last week³ of the recent meeting on bacterial genetics held at the London School of Hygiene and Tropical Medicine reveals the remarkable advances made during the last decade. The hereditary mechanism of bacteria has been found to bear many resemblances to that of higher forms of life; notably in the occurrence of a particulate (as distinct from a blending) type of inheritance, associated with mutation, dominance, linkage, crossing-over, and linear linkage groups. On the other hand, bacteria show two major differences from normal Mendelian inheritance: first, in the elimination of a segment of the hereditary material from diploid cells, such as apparently occurs regularly in *E. (B.) coli*; and, secondly, in having mechanisms for the transfer of genetic material other than by close association of parent cells. These mechanisms include the phenomena of transformation—known in the pneumococcus, in *Haemophilus influenzae*, and in the meningococcus—in which the hereditary character of cells is permanently changed by treatment with D.N.A. obtained from another strain of the same species; and of transduction—known in *Salmonella*—where hereditary factors are transferred from one strain to another by means of bacteriophage. The hereditary mechanism of viruses, and in particular of bacteriophage, is closely bound up with that of the host. There is increasing evidence that the hereditary material of both bacteria and phage is composed of D.N.A. Indeed, phages behave in some respects as though they were part of a bacterium's genetic material which has come adrift from its proper place and has multiplied at the expense of the host.

There is still much to be learned about the mechanism of inheritance in bacteria. The realization that recombination of characters is apt to occur whenever a host is infected simultaneously by more than one strain of a pathogenic bacterium is of special significance in medicine. It implies that new strains of such bacteria, differing in biochemical and antigenic properties and in virulence, are apt to arise with much greater frequency

than would be possible if these bacteria were merely propagated vegetatively. For the geneticist, the opportunity provided by bacteria and viruses for studying the properties of D.N.A. is of great value in elucidating the basis of inheritance, not merely in these organisms, but also in plants and animals generally, since D.N.A. appears to be the fabric of the gene. As mentioned in last week's report,³ the separation by chromatography of D.N.A. obtained from streptomycin-resistant pneumococci into a number of fractions differing both in chemical composition and in transforming ability opens the possibility of establishing the chemical composition of a specific gene. Moreover, if a mutation such as from streptomycin-sensitivity to streptomycin-resistance comes to be understood chemically, then the control of such mutations will be a real possibility.

HISTONES AND CANCER

The nucleic acids, and especially deoxyribose nucleic acid (D.N.A.), the characteristic nucleic acid of the cell nucleus, have attracted much experimental work because of the suspicion that they carry the genetic characteristics of the cells (see preceding annotation). It is natural that some interest should be shown in the basic proteins which accompany the D.N.A. in the chromosomes. Little is known of the nature of these compounds, except perhaps the simple protamines, which occur in a limited group of fish sperm nuclei and have been extensively investigated by Felix at Frankfurt.

The rather more complex basic proteins, known as histones, which occur in the nuclei of mammalian cells have been investigated by E. Stedman and E. Stedman.⁴ In a recent communication H. J. Cruft, C. M. Mauritzen, and E. Stedman⁵ present further evidence of the physico-chemical characterization of these substances, and claim, first, that the histones are cell-specific, and, secondly, that there is a qualitative difference between the histones of cancerous and those of normal cells. The last claim, if confirmed, would be of great importance. If the first proposition is true, the second necessarily follows. However, it would not be easy to prove this, since it would be necessary first to characterize the histones of all the normal cells of the organism. Unfortunately the characterization of the histones of even the most studied tissues, such as beef thymus, leaves a lot to be desired, and it is doubtful if the present information does much more than support a suspicion of differences between the histones of different tissues of one animal.

Even the number of histones present in normal tissues is doubtful. Cruft *et al.* regard a triple electrophoretic pattern as normal, consisting of a large central peak, which they attribute to the main histone, with subsidiary peaks on each side. J. A. V. Butler and his colleagues, however, have reported in a recent paper⁶ that a histone solution which originally showed two electrophoretic

peaks gradually developed, on standing, a third intermediate peak, owing apparently to the formation of a complex of the two original components. The evidence given by Cruft *et al.* of the specificity of histone fractions derived from different tissues is also not very convincing to those who have had experience of establishing iso-electric points. The other test proposed is the occurrence of a single electrophoretic peak when histones from different tissues are dialysed together for sixty hours but a double peak when dialysed separately and mixed just before the electrophoresis is begun, but this hardly carries sufficient conviction in view of the changes which occur on prolonged dialysis in a neutral medium.⁷ The proteins isolated by Cruft *et al.* from cancerous tissue (for example, an iso-electric point at about pH 7.0 is cited in one instance) are certainly so different from normal histones that a doubt remains whether they should be regarded as histones at all. An analysis of them would be of great interest. The conclusions reached by Cruft, Mauritzen, and Stedman may well prove to be correct, but more research is needed before a critical estimate of the position can be made. An established claim to have discovered characteristic differences between normal and malignant cells would be a most notable advance, and the matter will no doubt be pursued further.

FLUORIDE IN WATER

Although some 1,000 communities in the United States have added fluoride to their water supply, the Select Committee of the House of Representatives was rightly cautious about the effects of this measure and suggested that in areas with a high fluoride level in the drinking water investigations should be made into bone development and diseases and kidney diseases. The Institute of Dental Research of the National Institute of Health and the Public Health Service undertook the study, and a team of workers has now completed a comprehensive survey in Texas.¹ The epidemiological experience of Bartlett, with the very high fluoride content of 8 p.p.m. in the water supply, was compared with that of Cameron, where the level was only 0.4 p.p.m. Both towns were similar in geographical situation and racial composition and they were mainly agricultural communities. The composition of the drinking water differed in other respects, that of Bartlett containing four times the amount of dissolved solids as that of Cameron. The largest differences between the components were in sodium and potassium, which together were 26 times greater in Bartlett than in Cameron, and chloride, which was 11 times greater.

The investigation was begun in 1943 and included only people who had been residents in the towns for the preceding fifteen years. The medical history since birth was recorded at the start of the study and the medical experience during the period 1943–53 was carefully reviewed. The number of persons concerned was 116 in Bartlett and 121 in Cameron. In both areas the males formed only one-third of the total. The age dis-

tribution of the population differed between the towns: 44.8 of the persons were over age 50 in Bartlett in 1943 compared with 24.8 in Cameron. Deaths were naturally more numerous during the ten years in Bartlett than in Cameron, there being 14 in Bartlett to 4 in Cameron. The difference between the age-corrected death rates was not statistically significant. The incidence of abnormal clinical findings was very similar in both towns. The only abnormality which had a significantly different incidence was disease of the cardiovascular system (except uncomplicated hypertension) with a percentage of 23.9% in Cameron and 12.5% in Bartlett. Bone changes were determined from radiographs taken in 1943 and 1953. The percentage abnormalities for changes in density, coarse trabeculation, hypertrophy, spurs, and osteoporosis were measured, but none of the differences were statistically significant. The only abnormal laboratory finding which was significant in both years was the differential count of neutrophils, the value in Bartlett being 21.1% in 1943 and 29.5% in 1953 compared with 8.5% and 15.9% in Cameron. Abnormalities in the white blood count were significantly larger in Bartlett in 1943—14.7% compared with 4.1% in Cameron—but not significantly larger in 1953—14.1% compared with 8.5%. The abnormality of albuminuria was significantly commoner in Cameron in 1943, being 8.3% compared with 2.6% in Bartlett; in 1953 the respective percentages were 14.1 and 6.5, and the difference was not significant. The authors conclude that apart from dental fluorosis in Bartlett and a higher rate of cardiovascular abnormalities in Cameron there were no significant differences between the findings in the two towns.

VOLUNTEERS

Two features of the experimental situation need watching when volunteers are used as subjects for medical research: first, if inferences about average healthy subjects are to be drawn from the experiments, the subjects taking part in them ought preferably to be in that category; secondly, for ethical reasons the experimenter would wish to take only those subjects whose volunteering is entirely free of any unhealthy compulsion. A small investigation recently conducted into the psychology of a group of volunteers at the Harvard Medical School is a pertinent indicator that they may be a stranger lot than they seem at first sight. Some pharmacological experiments with drugs were being carried out on 56 supposedly healthy young men, nearly all college students, aged 21 to 28. The results of Rorschach tests on them and psychological interviews are reported by Lasagna and von Felsinger.¹ Among these 56 volunteers were found 3 with psychosis (2 of them practising homosexuality), 12 with psychoneurosis (1 under treatment and 6 seeking it), 3 with psychopathic personality, 1 alcoholic, 4 practising homosexuals (in addition to the 2 psychotics), 1 with severe peptic ulcer, and 1 with severe stutter. An investigation into the reasons for volunteering (apparently not confined to the maladjusted members

of the group) showed that some took part for the monetary rewards, which are unspecified here. Some hoped to find professional help or "a drug that might prove 'the golden key' to their personality problems." Some were in search of new experiences; some sought release from personal problems. As might be expected, the subjective effects reported by some of these men when they were tested with various drugs such as pentobarbitone or mescaline bore a sufficiently strong relationship to the subject's personality to make generalization in a wider population hazardous.

Studying the volunteer response as such, Marlow found² in the course of an investigation into women's sexual behaviour that volunteering was associated with high dominance feeling and unconventional sexual conduct. Marlow and Sakoda,³ studying some of Kinsey's subjects, report that volunteer groups consistently have a higher self-esteem score than non-volunteer groups. They recommend that when volunteers are used a test for volunteer error should be made before results of the tests are published as representative of a general population. This may be seen as the corollary of a normal practice in experimental laboratories—namely, the testing and standardization of materials with which experiments are carried out—and the Harvard investigation is a useful reminder of old principles in a rather unexpected context.

TREATMENT OF ASTHMA WITH CORTISONE AND A.C.T.H.

Although spectacular results have been obtained with cortisone and corticotrophin in the treatment of severe chronic asthma, there are four important reasons for caution. The treatment is not without danger; most patients who respond satisfactorily relapse when it is discontinued, and it is wise to presume that when cortisone therapy of chronic asthma is begun it may have to be continued indefinitely; many patients gain weight so quickly that adequate dosage cannot be maintained; and some fail to respond in any way. The rising number of fatalities is disturbing. Savidge and Brockbank⁴ recently collected from published reports the details of eleven patients with severe bronchial asthma who had died under treatment: seven were having cortisone, two corticotrophin, and two both drugs. Until more is known of the mode of action of these substances they cannot be exonerated from blame. Furthermore, fatal anaphylactic reactions have been attributed to corticotrophin. The frequency with which patients relapse after treatment is well shown by recent statistics published by Kania and Schmidt,⁵ who treated 111 patients with cortisone. Eighty-five were completely relieved, 21 were much improved, and 5 were not benefited. Relief was only temporary, and symptoms usually returned two to four weeks after cortisone was withdrawn. Unpleasant and even severe side-effects are often a consequence of long-continued treatment. The most common is the

tendency to gain weight. Usually this is due to an increase in body fat, but sometimes a rapidly developing oedema is a result of the salt-conserving action of cortisone on the renal tubules. Experimentally these drugs have caused suprarenal atrophy and decalcification of bone. In spite of these serious disadvantages the use of cortisone and corticotrophin is fully justified if they can return health and happiness to severe chronic asthmatics who have resisted all other forms of treatment. Cortisone can achieve this.⁶ Corticotrophin has been more difficult to obtain in this country, but has given excellent immediate results, notably in the relief of status asthmaticus. It has the disadvantage compared with cortisone that it must be given by injection, but the longer-acting A.C.T.H. gel seems equally effective and need be given only once daily. Elsewhere in this issue Dr. J. E. G. Pearson describes the successful treatment of 8 out of 10 patients with severe status asthmaticus or prolonged and incapacitating asthma, though his series also illustrates the tendency to relapse after treatment has ceased. This was not a blind trial of the remedy, though so far as was possible the patients were prevented from knowing that they were being given A.C.T.H.

The Medical Research Council is at present conducting a trial of the use of cortisone in the treatment of chronic asthma and status asthmaticus at a number of different centres. Trials of this kind must be strictly controlled, and so far as the doctors and patients are concerned must be blind trials. No one close to the patient must know whether cortisone or an inert substance is being used, because the knowledge that a new form of treatment is being tried is likely to have a strong psychological influence on the asthmatic patient. Some patients have done astonishingly well for many months on inert preparations; and some are loud in their praise of the benefits of cortisone, although they have never had any except in their imagination. All physicians who have had experience with these drugs emphasize that it is wise to restrict them to cases of chronic asthma in which every other treatment has been tried and failed and to cases of status asthmaticus that have resisted adrenaline injections and intravenous aminophylline given four-hourly for twenty-four hours. In most cases of status asthmaticus spasm is relieved by this treatment. Long-acting adrenaline is often not nearly so effective as frequent doses of the simple solution, and intramuscular aminophylline, besides having a much less powerful action than when given intravenously, is very painful and sooner or later will lead to necrotic abscesses.

So far as this country is concerned the therapeutic value of cortisone and corticotrophin in asthma is still *sub judice*. American opinion is much less enthusiastic than it was. Gottlieb,⁷ writing from Philadelphia, begins a masterly review of the 1953 literature with these words: "Although no one gainsays the importance of cortisone and corticotrophin as additions to our armamentarium, one senses in the voluminous literature an increasing emphasis on their limitations, on adherence to stricter indications, and on their potential dangers. . . . Few fail to indicate that avoidance of allergens, hyposensitizing injections, and other therapeutic measures are essential for proper management."

EMERGENCIES IN GENERAL PRACTICE THE DIFFERENTIAL DIAGNOSIS OF COMA

BY

M. J. PARSONAGE, M.B., B.Sc., M.R.C.P., D.C.H.

Assistant Physician, Neurological Department, Leeds General Infirmary; Consulting Neurologist, Leeds Regional Hospital Board

Coma is a state of deep unconsciousness from which the patient cannot be roused by ordinary forms of stimulation. There is a total absence of any kind of psychologically understandable response to such stimulation as pinching the skin or vigorous shaking of the patient, but the term "semicoma" is sometimes used to describe those states of less deep unconsciousness in which there may be grimacing or withdrawal movements of a limb on the application of such stimuli.

Importance of an Orderly Approach

There are many possible causes of coma, but for practical purposes a broad distinction may be made between those cases in which coma has supervened as a late development in a patient suffering from a known disease and those in which it is an early and outstanding feature. Greater difficulties in differential diagnosis are likely to be encountered in the latter circumstances, and it is with such cases that this article is mainly concerned.

In dealing with an individual case of coma it is better to adopt a systematic but relatively simple plan of approach as opposed to one which aims at all-inclusiveness at the expense of being unwieldy and unnecessarily lengthy. A scheme based upon the following lines is therefore recommended: (1) An initial consideration of the likeliest causes in the particular patient to be examined. (2) The obtaining, wherever possible, of a history of the events immediately preceding the onset of the coma from any available source—that is, from relatives or witnesses. (3) A systematic physical examination of the patient. (4) A consideration of other less common causes if the underlying disease process is not immediately evident after careful appraisal of all the ascertainable facts.

The causes of coma can be grouped in order of importance as follows:

Cerebrovascular Catastrophes and Conditions Causing Cerebral Ischaemia.—Intracerebral and subarachnoid haemorrhage, thrombosis, embolism, hypertensive encephalopathy, terminal congestive heart failure, severe anaemia due to loss of blood or blood disease, leukaemia, Stokes-Adams syndrome.

Brain injuries, including their complications.

Metabolic Disorders and Endogenous Intoxications.—Diabetes, hyperinsulinism, renal and hepatic failure, Addison's disease.

Post-epileptic States.

Exogenous Poisons.—Barbiturates, carbon monoxide, alcohol, aspirin, arsenic, lead, alkaloids, petrol fumes, carbolic acid.

Intracranial Infections and Tumours.—Meningitis, encephalitis, intracranial abscess, primary and secondary neoplasms.

Physical Agents.—Heat hyperpyrexia, electric shock, caisson disease.

Psychiatric Disorders.—States of severe stupor in hysterical, schizophrenic, and depressive illnesses.

The History

Facts obtained by the interrogation of relatives or witnesses will often provide valuable indications concerning the likely

cause of the coma, and may well be indispensable if the patient's previous health has been regarded as good or is unknown to the practitioner.

In respect of antecedent diseases likely to be associated with the later development of coma it will be necessary to make specific inquiries, first, about such conditions as hypertension, cardiovascular and renal disease, diabetes, epilepsy, alcoholism, or drug addiction, and, secondly, with regard to abnormalities of mood or behaviour suggestive of pre-existing psychiatric or organic brain disorders. Thus a history of diabetes will immediately suggest the possibility of either hyperglycaemia or hypoglycaemia, while a history of hypertension or previous strokes will be in favour of a cerebrovascular catastrophe. On the other hand, a history of progressive loss of interest and increasing apathy associated with incontinence of urine may suggest a frontal lobe tumour; a story of recent disturbing emotional experiences in a subject who has previously exhibited hysterical symptoms will lead to suspicions of a hysterical trance state; bizarre behaviour associated with delusions or hallucinations will point to the possibility of the catatonic form of schizophrenia; while a history of increasing retardation coupled with expressions of guilt and self-recrimination or of previous similar episodes will suggest a severe depressive illness.

It must be emphasized that if the patient is truly comatose an organic cause must always be assumed; a state of severe stupor in which there is suppression of voluntary activity but not unconsciousness may be either the antecedent of an organically determined coma or a manifestation of a primary psychiatric disorder.

When coma has supervened in a person whose previous state of health is unknown or has been regarded as good, inquiry will need to be directed towards the circumstances under which it occurred. Indications of likely causes will be obtained if there is a history of recent head injury, haemorrhage, circumstances pointing to a suicidal attempt or exposure to poisonous fumes, or a recent alcoholic bout.

It is important to scrutinize all circumstantial evidence most carefully; sometimes it is seriously misleading. Thus the patient with evidence of head injury may have damaged his head through falling in a stroke, the diabetic is not immune from other disease, the hypertensive may have a cerebral tumour, and the smell of alcohol in the breath is not necessarily indicative of alcoholism. Fortunately, the physical examination will usually help to place such evidence in its correct perspective and should be systematically carried out in every case of coma.

Physical Examination

In the initial general inspection of the patient a search for signs of recent head injury is an important preliminary. Bruising or laceration of extracranial tissues may indicate that the injury is incidental, but bleeding or leakage of cerebrospinal fluid from the nose or ears and subconjunctival haemorrhage spreading forward from the back of the eye usually means a head injury severe enough to have led to a state of coma. The patient's colour should be noted (cherry-red in carbon monoxide poisoning, pale in many types of coma, but cyanotic when the coma is deep whatever its cause), and also the temperature and respiration (shallow in most forms of coma, but deep in diabetes and sometimes "hissing" in uraemia). Sweating is usually pronounced, but is strikingly absent in heat hyperpyrexia. The mouth and

tongue should be inspected for scarring (epilepsy) and pigmentation (Addison's disease), and any tell-tale odours in the breath noted. Lastly, the presence of neck rigidity should be sought and evidence of dehydration looked for.

A systematic survey of function in the various bodily systems should then be made. A brief examination of the nervous system can usually with profit be carried out first and need not as a rule comprise more than a scrutiny of the fundi with an ophthalmoscope, tests of pupillary and oculomotor functions, and a decision on the probable presence or absence of hemiplegia. The presence of the latter is established when it can be demonstrated that the limbs on one side show no movements of withdrawal when pricked, and fall more inertly than their fellows when passively raised and allowed to fall. Changes of diagnostic value that may be seen in the ocular fundi are those of renal or diabetic retinopathy, and the presence (or absence) of papilloedema may be ascertained. The significance of minor inequalities in the size of the pupils is not readily assessed, but a much enlarged pupil on one side showing little or no reaction to light is likely to be due to serious cerebral compression, while a complete unilateral third cranial nerve palsy (closed eyelids, fixed dilated pupil, and abducted eye) is sometimes to be seen in cases of subarachnoid haemorrhage. In all forms of true coma the tendon reflexes will probably be much reduced and the plantar reflexes bilaterally extensor.

In the examination of the cardiovascular system search should be made for evidence of cardiac decompensation, endocardial disease, and irregularities of rhythm, concluding with measurement of the blood pressure. The lungs should be examined for evidence of gross inflammatory or neoplastic disease and the abdomen palpated for the presence of rigidity or abnormal masses. A rectal examination will be necessary if prostatic disease is suspected in a uraemic state; and if early transfer to hospital is impracticable a specimen of urine should be obtained by catheterization and tested for the presence of albumin, sugar, and ketone bodies. Similar considerations apply to lumbar puncture, which will need to be undertaken sooner or later in all cases in which the diagnosis is not obvious; it should not, however, be performed if there is any likelihood that the patient has an intracranial space-occupying lesion.

Differential Diagnosis

The final diagnosis of the cause of the coma in any given instance will depend upon a correct interpretation and synthesis of all the ascertainable facts. In order to assist the practitioner in this task the more outstanding diagnostic features in some of the commoner conditions causing coma are given. Some of these conditions will be considered in more detail in later articles in this series.

Cerebrovascular Catastrophes and Conditions Causing Cerebral Ischaemia

Haemorrhage into brain substance occurs most commonly in late middle life, is usually fatal, and will generally be associated with severe hypertension. Hemiplegia is characteristic of intracerebral bleeding and is often associated with stertorous breathing and a slow, full, bounding pulse. The head and eyes are commonly deviated towards the side of the lesion, and retention or incontinence of urine is the rule. In intrapontine haemorrhage there is likely to be bilateral limb paralysis associated with pin-point pupils and hyperpyrexia. Spontaneous subarachnoid haemorrhage (usually due to rupture of an intracranial aneurysm) generally occurs at an earlier age; in such cases limb paralyses are far less common, but neck rigidity is usually more prominent and there may sometimes be unilateral palsy of the third cranial nerve. Papilloedema and retinal haemorrhages are seen in some cases, and blood is characteristically found in the cerebrospinal fluid; the latter may also sometimes occur in intracerebral bleeding, but in such cases the presence of hemiplegia and a more deeply comatose state are helpful diagnostic features.

When coma occurs in cases of cerebral thrombosis it is usually less profound and of more gradual onset than in

the case of intracerebral haemorrhage. Hemiplegia is often present, but hypertension is less common and there may be a history of previous strokes. An onset with sudden severe headache or vomiting is much more in favour of intracerebral haemorrhage than of thrombosis.

Coma is of uncommon occurrence in cerebral embolism. A semicomatose state may occasionally be encountered when there is occlusion of a large vessel such as the middle cerebral artery; diagnosis in such cases depends upon establishing the association of sudden unconsciousness and accompanying neurological signs (hemiplegia) with the presence of a cardiac or pulmonary lesion likely to be a source of emboli (coronary thrombosis, endocarditis, auricular fibrillation or flutter, pulmonary infarct, or suppurative).

Hypertensive encephalopathy may complicate benign or malignant hypertension, acute nephritis, and eclampsia. There is usually a subacute onset consisting of transient focal cerebral disturbances (amaurosis, aphasia, hemiplegia) followed by the development of convulsions and coma. The blood pressure is always raised, especially in malignant hypertension, when the diastolic reading is usually in the neighbourhood of 130-150 mm. Hg; papilloedema with or without the exudative changes of hypertensive retinopathy may be present in some cases, and urinary changes will be found when there is acute or chronic renal damage. The focal cerebral disturbances are much more transient than those occurring in cerebrovascular lesions, and the usually good response to treatment (venesection and lumbar puncture) may be a helpful diagnostic feature.

Brain Injuries

The patient remaining in a state of coma after the receipt of a head injury must be presumed to have sustained either a contusion of his brain or an injury complicated by intracranial bleeding. The latter is particularly likely if the patient has recovered from the immediate effects of the injury and subsequently lapses into deepening unconsciousness. This indicates increasing cerebral compression and will be associated on the side of the haemorrhage with a progressively dilating pupil which fails to react to light.

A history of relapsing impairment of consciousness ranging from drowsiness to coma suggests a chronic subdural haematoma which is usually a complication of a comparatively mild head injury, although such a history may sometimes be lacking. Males are much more commonly affected than females, and localizing signs are slight or absent until a late stage, although a dilated pupil is often found on the side of the haematoma.

Metabolic Disorders and Endogenous Intoxications

In diabetic coma the onset is gradual and follows a period of severe ketosis (dyspnoea, anorexia, nausea, vomiting, drowsiness, and diffuse abdominal pain). The patient is dehydrated and collapsed, acetone is present in the breath, and the tests for sugar and ketone bodies in the urine are strongly positive.

Coma of hypoglycaemic origin is always of rapid onset. Convulsions often occur in the early stages, and it is distinguished by the absence of both dehydration and ketonuria. Focal neurological signs (hemiplegia) may sometimes be present and sugar is occasionally found in the urine.

Coma due to renal failure is characterized by dehydration and dyspnoea associated with muscular twitching, convulsions, and albumin-laden urine of low specific gravity.

In cases of coma due to hepatic failure ("cholaemia") there is an antecedent phase consisting of malaise and jaundice followed by drowsiness, delirium, vomiting, muscular twitching, and a tendency to haemorrhage.

Post-epileptic Coma

This is only likely to be a serious problem in the presence of status epilepticus. Focal neurological signs may or may not be present, but in the absence of an antecedent history of epilepsy there will sometimes be evidence of previous tongue-biting. Both albumin and sugar may be found in the urine

and some degree of pyrexia is usual. Occasionally coma in an epileptic subject may be due to overdosage with anti-convulsant drugs.

Exogenous Poisons

Here the diagnosis will usually depend primarily upon circumstantial evidence and the exclusion of other causes of coma. Special features to be noted are the cherry-red complexion in carbon monoxide poisoning; the smell of stale alcohol in the breath in alcoholic poisoning; the association of fits, raised blood pressure, and a "lead line" in the gums in lead encephalopathy; the hyperpnoea and violet urinary ferric chloride reaction in aspirin poisoning; and the normal or subnormal temperature and pin-point pupils in opium poisoning.

Intracranial Infections and Tumours

Meningitis in its various forms can sometimes be a cause of rapidly developing coma, especially the fulminating meningococcal variety. Diagnostic difficulties may nevertheless be considerable when the temperature is subnormal and neck rigidity is inconspicuous. A purpuric rash is commonly present in meningococcal infections, while in other forms there may be a focus of infection elsewhere in the body. Usually, however, the diagnosis can be established only by lumbar puncture.

In cases of localized intracranial abscess formation coma is likely to be a late event. Headache of increasing severity and drowsiness are outstanding premonitory symptoms, mastoiditis and intrathoracic suppuration being the commonest sources of infection. Occasionally coma supervenes rapidly if the abscess ruptures into the cerebral ventricles or subarachnoid space, in which case there will be neck rigidity associated with high temperature.

Coma is also usually a late development in cases of intracranial tumour, whether it be primary or secondary in origin. Occasionally it may develop rapidly when there is cystic degeneration or haemorrhage into a tumour, but differentiation from intracerebral haemorrhage is usually impossible on clinical grounds alone.

Physical Agents

Heat hyperpyrexia is a serious condition due to failure of the heat-regulating mechanism as a result of prolonged exposure to high temperatures. It is usually fatal without adequate treatment and is characterized by progressive hyperthermia, absence of sweating, convulsions, circulatory collapse, and coma.

An individual accidentally subjected to the effects of an electric current may be rendered comatose. Diagnosis will depend upon the detection of skin burns and a consideration of the circumstances.

Mental Disorders

Severe states of stupor occurring in hysterical, schizophrenic, or depressive illnesses may sometimes give rise to diagnostic difficulties. In cases of this kind the patient is not likely to be truly unconscious, since he may show some evidence of mental activity or betray the fact that he is not entirely unaware of his surroundings. Diagnosis will depend upon the absence of physical signs and evidence of psychological disturbance in the history obtained from friends or relatives. Organic disease must be assumed to be present, however, if the patient is genuinely comatose, even if there is a history suggestive of mental disorder.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

PROFESSIONAL BOXING AND THE DOCTOR

BY

J. W. GRAHAM, L.M.S.S.A.

Administrative Steward, British Boxing Board of Control; Chairman, Medical Subcommittee, British Boxing Board of Control; President, Medical Commission, European Boxing Union; Member of Medical Advisory Committee to World Boxing Union

In an editorial comment in the *British Medical Journal* of December 25, 1954 (p. 1535), the hope was expressed that the controlling body of professional boxing would listen to the advice of its medical advisers.

In order to show that the professional controlling body does, in fact, listen to its medical advisers, I propose to give a short account on the control of professional boxing, with special reference to the medical aspects of professional boxing.

Prior to 1929 the control of professional boxing in the British Isles and on the Continent was practically non-existent. Owing primarily to the efforts of the late Lord Lonsdale, the British Boxing Board of Control was formed in that year. Lord Lonsdale became the first president. The constitution of the Board is a president, two vice-presidents, and a number of stewards, all of whom have some specialist knowledge of boxing and are not in any way financially interested in boxing. The stewards serve in an honorary capacity and meet their own expenses. Should a vacancy occur, it is filled by invitation from the president and the stewards.

An account of the ups and downs of the Board of Control from 1929 to the present time, although interesting, would be out of place here, but a short account of the present organization is necessary.

Organization of the Board of Control

The Board now consists of a president, two vice-presidents, and up to 25 stewards, divided into stewards of appeal and administrative stewards, and has through its regulations complete control of all professional boxing in Great Britain and Northern Ireland, except fairground boxing booths. It has the authority to issue licences at its absolute discretion to all persons connected in any way with professional boxing (boxers, promoters, managers, referees, trainers, seconds, etc.). Without a current licence no one can officiate in any capacity at a professional boxing tournament.

The Board functions from head offices in London and is assisted by eight area councils covering the whole country and Northern Ireland. The area councils are made up of licensed members of various categories—promoters, boxers, boxers' managers, seconds, etc., elected annually by the licensed members in the area. Each area council has two representative stewards, who are elected annually by the council members, and who represent the views of their councils to the stewards at board meetings.

Before the second world war the medical arrangements were rather sketchy. A principal medical officer was appointed who was one of the administrative stewards. His main duty was to advise the Board on any medical matter which cropped up and to examine boxers where necessary on behalf of the Board.

During the second world war the control of boxing suffered, as most of the stewards were engaged in one or other of the Services. After the war, when the Board got into its stride again, it was quickly realized that a medical organization was a necessary part of the controlling body, and by 1950 such an organization was instituted as follows. An honorary area medical officer was appointed to each of the

eight areas. These medical officers, together with any medical men who happened to have been elected as representative stewards, constituted a medical subcommittee under the chairmanship of an administrative steward, who is also a medical man. Since 1951 it has been found necessary to appoint one or more deputies to the area medical officer in each area.

Since the formation of the medical subcommittee, its recommendations have been implemented without question by the Board of Control. Further, owing to the efforts of the president of the British Boxing Board of Control, the European Boxing Union was formed in 1950. This controls professional boxing throughout Europe, and is served by a medical commission elected from the principal medical officers of member countries.

The objects of the medical subcommittee are to advise the stewards on medical matters and how to make boxing freer from the isolated instances of permanent injury, particularly the results of brain injury. Some of the medical aspects of professional boxing which have been dealt with by the medical subcommittee are:

1. Medical Examinations

Every applicant for a boxer's licence is subject to a comprehensive medical examination, the results of which are reviewed by the area medical officer, who then recommends the granting or withholding of a licence. The boxer must be medically examined before and after every contest.

If a boxer has been knocked out he must be medically examined before contracting to box again. Medical officers, promoters, seconds, managers, council members, or area secretaries can insist that a boxer be medically examined at any time there is reason to think he is suffering any brain injury. Unless the boxer receives a certificate of absolute fitness from the area medical officer, his licence is suspended for a varying period or withdrawn altogether.

Only first-series—that is champion or near champion—professional boxers are allowed by the Board to box outside the British Isles, and by agreement with other members of the European Boxing Union each must be medically examined by an official medical officer and certified fit immediately before leaving for abroad. All licensed referees are examined annually before their licence is renewed, because to referee several contests during the course of an evening requires a fit man.

2. Various Recommendations Made by the Medical Subcommittee and Implemented by the Stewards

Action to be Taken by Seconds After a Knock-out.—The theory has been advanced by various observers that there are two kinds of knock-out, and experience seems to bear this out. They are adequately described by La Cava (1952), who classifies them as (1) a reflex from a hard blow on the chin, and (2) a final loss of consciousness as a result of a blow when a boxer has reached a state of collapse due to a number of blows. Managers, seconds, etc., are now instructed in words of two syllables how to treat an unconscious boxer by the first-aid methods applicable to any other case of concussion, always bearing in mind the possibility of more serious damage. Ear rubbing, strong smelling-salts, and any form of stimulation are expressly forbidden.

Haemostatics.—Formerly it was the custom for each manager or trainer to have his own particular solution to stop bleeding from a cut sustained during the course of a contest. Many of these, whilst achieving the end desired by the managers or trainers, resulted in serious tissue damage. Nowadays it is an offence for anyone to use a substance which has not been approved by the medical subcommittee. Many substances have been examined, the only one approved at present being adrenaline solution. If adrenaline solution will not control the haemorrhage, then the contest is either abandoned by the manager or stopped by the referee.

Stimulants.—No form of stimulant, either real or imaginary, is allowed by the Board, except cold water sprinkled on the body or used as a mouth wash.

Drying Out and Weight Reduction by Turkish Baths.—In the past, matches were made for a boxer at a weight which was often below that at which he was 100% fit and strong. This weight was achieved by withholding all fluids for, in some cases, up to 48 hours before the weigh-in, and by turkish baths. On the recommendation of the medical subcommittee, because of their weakening effects, these practices have been stopped and managers' licences have been withdrawn for indulging in them.

Blows to the Kidneys and Back of the Head.—The original rabbit punch, barred by the rules of boxing for many years, was a chop with the side of the hand to the back of the neck, and a similar chop was delivered over the kidney region. Either of these blows has for many years resulted in the instant disqualification of the boxer who delivered them. On the recommendation of the medical subcommittee, because of the risk of brain or kidney trauma, blows with any part of the fist to the back of the head, or to the region of the kidney, are deemed foul and referees have been instructed to see that their use is stopped.

Duration of Contests.—These have been standardized for various classes of boxers and the duration reduced to eight minutes' actual boxing for novices.

Eye Injuries.—Serious eye injuries are extremely rare. Visual standards have been fixed so as to prevent a myope being licensed, to reduce the risk of a detached retina.

Many instructions covering minor points of the medical aspects of boxing have been issued dealing with widely separate subjects such as the correct position to hold the hand within the glove, scabies or infectious skin diseases in boxing stables, and the best method of suturing cuts. The prevention of fatal accidents or permanent brain injury to boxers remains the main problem facing the medical subcommittee.

Fatal Accidents

Much has been done in this connexion. Since the war there have been five fatal accidents to professional boxers at licensed promotions. Death in all these cases, as indeed it has been in the cases reported from abroad, was due to haemorrhage from cortical veins. No case of a fractured skull has been reported. The type of injury—tearing of the cortical veins—and the history lead to the conclusion that the injury in most cases was caused not by the blow but by the boxer striking the back of his head on the ring floor, causing an abrupt deceleration of the brain mass. With this in mind, the medical committee has recommended that a special type of ring flooring developed by Cornell University, U.S.A., be obtained and tried out in this country. In the meantime, some resilient substance, such as sponge rubber, is put under the canvas of all rings.

Permanent Brain Injury

Before the days of an adequate control, an appreciable percentage of professional boxers suffered from a condition known among themselves as being "punch drunk." This condition is also met with in some steeplechase jockeys and amateur riders who have had more than a fair proportion of falls in the hunting-field or steeplechasing. The term "punchy" was often used of a boxer as an expression of contempt. Because of the stigma attaching to the name it was decided to substitute the term "chronic concussion" whenever it had to be referred to. The signs and symptoms of an established case have been frequently described by various observers. Agreement regarding the pathology, however, is not by any means unanimous. What is obvious, however, is that, as a result of a series of concussions, the brain does receive damage which, if severe, is irreversible, but which if detected in the early stages seems to clear up. In the absence of any specific treatment, it is the obvious

duty of the medical subcommittee, through the Board of Control, to prevent its occurrence, and this is being done in the following way.

All licensed referees are lectured by the area medical officer on the medical aspects of boxing, with particular reference to chronic concussion. They are instructed that they must not allow a boxer to take unnecessary punishment, and must, under no circumstances, allow a defenceless boxer to be struck. Flagrant disregard of this warning by a referee will result in his losing his licence, or being suspended for a varying period, or being degraded to a lower category of referee. During 1954, in implementing this instruction, 360 contests out of 1,973 were stopped by the referee before either a knock-out or the end of the contest had occurred. One curious result of this is that the spectators at any boxing tournament now protest vociferously if the referee in their opinion does not stop the contest soon enough.

Professional boxers have a hard system of training to follow, which, amongst other things, involves sparring. Brain injury can occur in the gymnasium as well as in the ring. All managers, trainers, promoters, and others connected with professional boxing are instructed, in the boxers' interests, to report at once any early signs of chronic concussion. The relatives and those associated with a boxer in training are the ones who notice some slight abnormality before it is detected in a normal routine examination. Obviously, area medical officers, deputy medical officers, and tournament medical officers are constantly on the lookout for any early signs of chronic concussion. Once a boxer is suspect, he is ordered to be examined by the area medical officer, and unless he is given a complete clearance his licence is withdrawn or suspended. During 1954 19 licences were withdrawn or not renewed on medical grounds. The reason for the withdrawal is explained to the boxer, and he is advised to abstain from any form of sparring in the gymnasium until given a clearance by the area medical officer.

It was thought that electroencephalography might be a means of diagnosing early chronic concussion. In this connexion the results recently published by Kaplan and Browder (1954), who spent four years studying the brain-wave patterns of 1,043 professional boxers, are disappointing, a disorganized E.E.G. showing at most that a complete physical and neurological survey is indicated.*

Conclusion

The aim of the Board is better and safer boxing. To this end they will implement any reasonable recommendation of the medical subcommittee. It is due solely to the efforts of the present president of the Board that the European Boxing Union, of which he is also the president, is in existence and that it has a medical commission. Further, again owing to his efforts, a World Boxing Union was formed consisting of a representative from the New York State Athletic Commission, one from the European Boxing Union, one from the National Boxing Association of America, and one from Great Britain and the British Empire. This World Boxing Union has, in its turn, appointed a medical advisory board.

Finally, the medical subcommittee of the British Boxing Board of Control will be grateful for any suggestion, from any medical man interested in this pre-eminently British sport, that makes for safer boxing.

La Cava, G. (1952). *Brux. méd.*, 32, 61.

*Of the 1,043 subjects, 197 had repeated electroencephalographic examinations varying in number from 1 to 6. The interval between examinations was less than one year in 141 subjects, between one and two in 29, between two and three in 21, and between three and four in six. Forty subjects had the examination repeated within 10 minutes of losing a contest. Ringside cinematography (slow-motion and ordinary) was used to assess the type and extent of trauma to the head.

PROFESSIONAL NEGLIGENCE

LECTURE BY A QUEEN'S COUNSEL

At the City of London College on January 12 Mr. J. P. Eddy, Q.C., delivered the first of a series of Travers Memorial Lectures on "Professional Negligence." He said that the main principle he was about to put forward was that before there could be negligence there must be a duty to take care or to exercise reasonable skill. That duty might arise in one of two ways: (1) in common law (as, for example, to exercise reasonable care when driving a car), and (2) under contract, as in the relationship of doctor and patient.

Three elements had to be considered when dealing with common law liability. The first was a duty to exercise care or skill or both; the second, a breach of such duty; and the third, an actual loss to the other party as a result of such breach. The late Lord Macmillan had pointed out in a case in 1932 that the law took no cognizance of carelessness in the abstract; there must be carelessness when there was a duty to take care, and it must be proved that failure in such duty caused damage. When there was a contractual relationship negligence might be a breach of such contract by act or omission.

Responsibility of the Professional Man

A man or woman who practised a profession was bound to exercise care and skill—the skill of an ordinary competent practitioner in that profession, whether it be of accountant, banker, solicitor, or doctor. The important principle had been laid down that every person who entered a learned profession undertook to bring to its exercise a reasonable degree of care and skill. He did not undertake, if he was an attorney, that his client should win his case, or, if he was a surgeon, that he would cure his patient; nor did he undertake to use the highest degree of care and skill of which some persons in his profession might be capable, but he undertook to bring to the case a fair and reasonable competence. It followed, therefore, that where the duty to exercise care and skill existed one of two things might give rise to an action for damages for negligence: (1) that the defendant did not possess the requisite skill, or (2) that, although he possessed it, he did not exercise it in the particular case.

In some cases an action might arise out of tort at common law—that is, neglect of a duty towards persons generally; in others it might arise out of contract—that is, an agreement between the parties whereby there arose a duty to exercise a reasonable degree of care and skill; and sometimes there might be an overlapping of tort and breach of contract. But the first essential was to recognize that before there could be a liability there must exist a duty—a duty in the case of a professional man to show the average amount of competence associated with his profession. The expected degree of competence varied with the times. Two generations ago surgical operations were conducted in a manner which, by the standards of our own time, would be accounted negligent.

What Constitutes Negligence?

Mr. Eddy went on to point out that in a contract as between doctor and patient only those two people were concerned; only the partners to a contract, one or other of them, could complain if there was negligence.

A person who was himself under a duty to take care could not get rid of his responsibility by delegating the performance to someone else. He was answerable for the wrongful act of his servants or agents committed in the course of their employment. The principle of vicarious liability for the wrongful acts of others rested on the legal maxim, *Qui facit per alium facit per se* (he who does anything by another does it himself). But the wrongful act must be done in the course of employment. If a doctor employed a dispenser who, while dispensing, spilt some liquid over a patient and injured him or damaged his

clothing, the doctor was liable. If, however, the dispenser was entertaining a friend in her own room and upset some hot water over her and scalded her, the doctor was not liable. Where the servant or agent was negligent in the course of his employment, then *Respondeat superior* (let the principal be held responsible).

That principle came into its own in the case of Cassidy v. Ministry of Health (1951, 2 K.B., p. 343). He took it as good law and good sense when Lord Justice Denning (and there was no dissenting judgment) declared that where a person was himself under a duty to use care he could not get rid of his responsibility by delegating the performance of it to someone else, no matter whether the delegation be to his servant under a contract of service or to an independent contractor. The Cassidy case supported the principle that if a patient in hospital suffered injury through the negligence of some member of the staff it was unnecessary for him to pick upon any particular employee. The law applied the principle *Respondeat superior* in the case of a hospital and its staff just as it did in the relation of master and servant in any other sphere of activity, professional, industrial, or other. It mattered not that the servant did work of a skilful character for which he was specially qualified. The hospital was responsible for all those in whose charge the patient was. It had taken the law over 30 years to reach this position, owing, Lord Justice Denning had suggested, to the feeling that charitable institutions should be relieved of a liability they could not afford. But the National Health Service Act, 1946, had altered the status of hospitals, and, speaking generally, it had brought about a change in the attitude of the public towards them.

In the case of Cassidy the plaintiff entered the hospital for an operation which involved post-operative treatment. At the end of the treatment it was found that his hand had been rendered useless. It was held *Res ipsa loquitur* (the thing speaks for itself), and the onus was laid upon the hospital authorities to prove that there had been no negligence on their part or on the part of anyone for whom they were responsible. The principle *Res ipsa loquitur* had been applied in other negligence actions, in particular in an action against an anaesthetist and actions against two dentists.

The Increased Litigation Against Hospitals

Negligence, summed up Mr. Eddy in conclusion, involved a breach of the duty to exercise reasonable care and skill. Such a duty might arise out of tort—that is, it might be a duty fixed by the common law—or it might arise out of contract, and where it did so arise it was a duty existing only between the parties to the contract. But, whether it arose out of tort or out of contract, the person concerned was answerable for the acts of his servant or agent if such acts were done in the course of his employment.

It was the extended application of this principle which explained the recent remarkable increase in litigation concerning the liability of hospitals in cases of alleged professional negligence. The substantial increase in the volume of litigation against hospital authorities in recent years was strikingly illustrated by the fact that in 1948–9 the payment made by hospital authorities in England and Wales in compensation of all kinds amounted to £7,500, and in 1953 it had risen to £153,000.

Mr. Eddy promised to deal with other aspects of this question in a future lecture.

The Royal Australian Air Force is in great need of additional medical officers, and the attractive terms of service have recently been outlined in advertisements in this *Journal* (December 11, 1954, advertisement page No. 27). Doctors who join the R.A.A.F. in this country are paid from the date of embarkation and given free first-class passages to Australia for themselves and their wives and families. Provision is made for postgraduate training in R.A.A.F. and civilian hospitals in Australia.

Reports of Societies

PALLIATION IN CANCER

On January 5 at the Royal Society of Medicine the Section of Surgery, with Sir HENEAGE OGILVIE in the chair, held a discussion on palliation in cancer.

Mr. H. T. SIMMONS (Manchester), who opened the discussion, said that the treatment of cancer was becoming so complicated that he would limit his remarks to the more common types. Although treatment of operable cancer was a technical exercise that could be learned fairly easily, the treatment of inoperable cancer was more complicated and needed more judgment. Surgeons were often guilty of putting an inoperable case at the end of a long operating list, and the assessment of the real needs of the patient was often equally superficial. Clear thinking rather than skill was required. Colostomy, for example, should rarely be inflicted on patients over the age of 70 with inoperable rectal carcinoma, since they were thereby made more miserable. Heroic surgery was of doubtful value and seldom justifiable. Adrenalectomy and hypophysectomy had a place in the treatment of endocrine-dependent growths, but only half the patients got significant relief and they then became dependent on a scarce and expensive drug. These operations should not be used indiscriminately. Perhaps in the future suppression of hormones by medical means would be preferable.

Palliative Surgery

Prolongation of life should not be the only consideration in patients with inoperable growth: relief of pain and of the effects of bowel obstruction or the clearing of foul discharges was equally important. The presence of metastases should not contraindicate local treatment which would bring about relief of symptoms. But short-circuit operations which did not relieve pain and discharge probably did more harm than good. Metastases giving rise to symptoms could often be removed: in such cases radiotherapy was often disappointing. In the elderly, local excision of breast tumours often relieved the pain and removed the source of offensive discharge. Skin cancer called for palliative treatment only when the face was affected: then, deep cavities should be opened up and diathermy excision applied. If this was followed by expert prosthesis encouraging results were often obtained. In carcinoma of the oesophagus gastrostomy was inadvisable, since the accumulation of saliva and inability to swallow was the most distressing symptom. Many gastric carcinomas were inoperable when first seen, and careful pre-operative assessment would avoid many unnecessary operations. It was doubtful if palliative gastro-enterostomy was ever justified; it was better whenever possible to remove the growth. Anastomosis of the gall-bladder to the duodenum was often a satisfactory operation in patients with carcinoma of the bile passages. The help from hormonal therapy in prostatic carcinoma was remarkable; the results obtained were often better when orchidectomy was done at the same time. Similarly, before the menopause, testosterone gave good results in mammary carcinoma, but the patient often resented the masculinization which followed. After the age of 60 oestrogens were more beneficial.

A Physician's Viewpoint

Dr. C. J. GAVEY (London) enunciated some broad principles in the treatment of patients with inoperable cancer. There was need for hopefulness to the end. It was most important to relieve pain, because when pain disappeared the patient's morale improved. Popular opinion wrongly held that cancer was always painful, but patients who had recovered from cancer often remarked on the lack of pain. Assessment of the degree of pain was never easy, but it was especially difficult for young doctors and nurses who lacked experience. When pain was present analgesics should be

given continuously. Mixtures with aspirin and opium could be given every four hours; and drugs of addiction were seldom contraindicated as such. Pethidine had advantages over morphine, because it did not depress the patient so much. Methadone was valuable, but might cause trouble by suppressing the cough. Phenadoxone had a long action and was of value. Chlorpromazine was of most value when vomiting was present, but it was better to reduce the dose when vomiting ceased. R 48 often abolished pain from hepatic secondaries. Morphine was most useful in the terminal stages and should never be spared. It was, however, sometimes difficult to know when to start using morphine. It was wise not to exceed single doses of $\frac{1}{2}$ gr. (22 mg.).

The second difficult problem was that of telling the patient about his illness. Patients did not share the doctor's knowledge of disease and did not therefore appreciate how patients with cancer died. When patients persistently asked for information it was morally wrong to suppress it. Frequent visiting helped in knowing when to tell the patients about their illness. The power of self-deception might be very great, and it behoved the doctor to promote this at all times. Most patients accepted the truth if it was realized slowly. There was no place for a deliberate lie or for complete silence. The problem was more difficult with intelligent patients, to whom frankness must be shown if it was sought. Medical patients themselves were often bravest and most serene when they understood their own illness. Frequent visits to the patient were fundamental, and it was the doctor's duty to help his patients in this way. It was salutary to ask if one paid sufficient attention to prevent the patient wondering if the doctor had lost interest in his case. The nursing staff were also helped by the doctor's visit, and the task of the relatives was made more simple. Sympathy by relatives was often best shown by being practical. Of paramount importance was the employment of surgery and radiotherapy. Adrenalectomy was an operation that had come to stay, especially in those cases of breast cancer with bone secondaries and pain. Requests for further opinions by the patient must be met with sympathy even if the patient wished to venture into the fields of unorthodox therapy. In the terminal stages of the disease it was wise to see that spiritual help was available to the patient.

The Role of the Neurosurgeon

Professor NORMAN DOTT (Edinburgh) said that the neurological surgeon might assist in the palliation of cancer in four several ways: (1) When he encountered metastatic cancer of the brain while the nature of the disease was still in doubt—he made the diagnosis. (2) When called upon to assist in ameliorating the course of the known neoplasia by hypophysectomy. (3) When requested to mitigate pain in known cancer. (4) When called upon to preserve important neural functions threatened by known cancer.

He pointed out that metastatic cancer of the brain had notably increased in frequency in recent years in proportion to the increase in bronchial carcinoma. In all patients over 30 years of age, with rapidly progressive cerebral tumours, an x-ray picture of the chest and other means of search for a primary pulmonary lesion were routine procedures. Not infrequently, however, the cerebral metastasis was the first recognizable lesion in this disease. When the diagnosis was made by exploration of the cerebral lesion, or by any other means, the advice of the oncologist on the management of the neoplasia as a whole was sought.

The oncologist was usually the radiotherapist, who usually had the largest experience of neoplasia in its many sites and in its various stages of evolution. An oncological team might be desirable with the radiotherapist as its leader, and with the pathologist and endocrinologist associated and other specialists called in as required. It had become essential for "system specialists," such as the neurological surgeons, to have available the advice of an oncologist on the management of the neoplastic malady as an entity, when a metastatic manifestation of it was encountered in the brain.

In the management of cancerous neoplasia it had been found that in the parasexual tumours—those of the breast and prostate—modifications of the sex hormone state might profoundly modify the progress of the disease. Administration of oestrogens and of androgens, or their diminution by castration, adrenalectomy, or hypophysectomy had been employed. Whether hypophysectomy had special indications or advantages was not yet known. Neurological surgeons stood ready to join the oncological team as assistants if hypophysectomy proved of special value in the management of cancer.

Professor Dott thought that pain due to cancer could and should be abolished in those cases in which it constituted a clamant symptom. Pain was a sensory experience and also an emotional experience—a distress. Conscious appreciation of pain as a discriminatory sensation was a function of the cerebral cortex. Conscious appreciation of the distressful aspect of pain was a function of the diencephalon. When pain was judged to be an important factor it might be mitigated by psychological methods, by analgesics, or by surgery.

Relief of Pain by Neurosurgery

Surgery for pain took two main forms: (1) Interruption of the pain-conducting pathways, so that the pain stimuli were prevented from reaching consciousness. (2) Modification of consciousness or personality on its affective aspect by leucotomy so that the distressful element of the pain experience was lessened or abolished. Surgery for pain was justified when there was a life expectancy in excess of three months and when pain was a major factor in the patient's total distress.

Instances of satisfactory interruption of pain pathways were: trigeminal nerve interruption for cancer of the face, to which could be added interruption of the glossopharyngeal, upper vagus rootlets, and upper cervical posterior roots when the floor of the mouth and throat were involved; spinothalamic cordotomy at segmental level D2 for pain below waist level, and at C2 for pain up to arm level. For disease about the thoracic inlet one could combine a C2 cordotomy with section of the upper cervical posterior roots. The techniques of these operations were discussed. It was noted that, while eminently successful in dealing with pain, their usefulness was limited to its abolition—they did not benefit other forms of distress which were often important in the cancer patient.

Leucotomy had the advantage of mitigating all forms of distress—not only those due to pain. It did not abolish physical pain sensibility, but it abolished its distress. This relief was necessarily bought at the expense of a diminished affective depth of the whole personality, and was therefore limited to those cases in which this was considered justifiable. A somewhat similar effect was procurable by large doses of chlorpromazine. There had not yet been opportunity for prolonged trial of this remedy.

Neurological surgery was required on occasion to preserve important neural functions threatened by cancer. Cranial decompression, with or without removal of a cerebral metastatic growth, could preserve vision and relieve headache and vomiting. Spinal decompression could avert paraplegia with all its distressing accompaniments. When indicated by the early symptoms of spinal cord compression, it was an operation of urgency. It could be supplemented by stabilization of the vertebral column by the implantation of rustless steel plates, if the vertebral bones were weakened by cancerous erosion.

Thus neurological surgery could play its part in the diagnosis and treatment of cancer, and in the mitigation of pain and preservation of function, even in the "hopeless" case.

Management by the Family Doctor

Dr. G. F. ABERCROMBIE (London) spoke of the difficulty in managing inoperable cases of cancer and of the problem of what the patient should be told. It had to be realized that a stage arose when surgical treatment should cease, and the practitioner was often the best person to decide on this.

Morphine helped these patients, and it had been said that "morphine exists to be given and not merely to be withheld." The increasing nursing supervision required in the terminal phases often became impossible in the patient's home; it was the duty of hospitals to readmit their patients in this phase. Surgeons often deceived the patient in the matter of diagnosis and put the general practitioner at a disadvantage. Many patients were left in ignorance to the end, but it was doubtful if this was advisable. It was a mistake not to give patients the credit for the common sense and courage they possessed. Doctors were often afraid to tell patients about their disease.

Many fallacies about cancer needed correcting. It was remarkable that many patients with cancer died with much less distress than patients with heart failure. Patients with cancer were often more content when the diagnosis was known and the relatives were spared the unhappiness of constant deceit. Dr. Abercrombie had never regretted having told a patient about cancer. The bond between the doctor and the patient was thereby strengthened and remained firm to the end.

Discussion

In the discussion that followed, Professor C. A. WELLS (Liverpool) suggested that the problem of palliating cancer had so many aspects that no one man could be expected to be familiar with all the methods or even to be competent to select the appropriate method or combination of methods in any one case. In these circumstances the difficulty might best be met by organizing a group of workers to consider jointly or in the closest possible consultation the problems involved. Indeed, he thought it probable that this type of approach was appropriate not only to the cancer problem but to a number of other states, such, for example, as arterial hypertension, in which many voices might need to be heard before an appropriate line of treatment could be decided upon and in which subsequently there might be a need for guidance from many points of view. By an extension of the same argument it was permissible to ask whether there should not be a tendency for these and other most difficult cases to move from the periphery towards the centre of various regions of surgical organization to secure for them the best advice and treatment.

Mr. MURRAY FALCONER (London) said that although hypophysectomy for parasexual tumours was in its infancy it was an operation with a low mortality and it appeared to help more than half the patients. Metastases often disappeared, but, as the follow-up periods were still short, it was not yet possible to compare it with adrenalectomy. These encouraging results made it difficult to say that there was ever a stage when treatment should be denied because the disease had become advanced and widespread.

Many other members and visitors took part in the discussion, and it was clear that varying views were held about what to tell the patient suffering from inoperable carcinoma.

LOCAL MEDICAL SOCIETIES

Liverpool Medical Institution

Addressing the Liverpool Medical Institution on December 16, 1954, on a medical pilgrimage "from the Cape to Cairo," Professor L. S. P. DAVIDSON said there were certain diseases which were much rarer in Africans than in Europeans living in the same region. They fell roughly into two large groups: (1) the so-called psychosomatic diseases such as peptic ulceration, thyrotoxicosis, essential hypertension, and rheumatoid arthritis; (2) degenerative vascular and metabolic disorders such as atheroma (and its sequence of coronary and cerebral thrombosis, and peripheral vascular disease), cholelithiasis, and diabetes mellitus. The relative rarity of these diseases might be due either to racial or constitutional causes, or to environmental causes. But, if it were true that Africans who have adopted Western methods of eating, working, and living became as liable to these conditions as Europeans, then environmental rather than racial factors would appear to be of primary aetiological importance.

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Fluoridation of Public Water Supplies

SIR,—Dr. C. G. Dobbs (*Journal*, January 8, p. 105) describes the proposal to add fluoride to the water supplies in Anglesey as undoubtedly amounting to "compulsory medical treatment with a toxic substance intended to produce a physiological change in the body, to be administered indiscriminately by medically unqualified persons." He goes on: "... no individual doctor can be discovered who claims to know much about its effects, or to be able to diagnose slow chronic fluoride poisoning if it should occur. If this is the situation the 'experiment' could do widespread damage without anyone's being the wiser."

As a member of the independent mission which investigated American experience with fluoridation and reported to the Ministry of Health, the Medical Research Council, and other interested bodies, perhaps I may be allowed to comment. The mission, in its report,¹ felt justified in drawing four main conclusions. First, there is abundant evidence, from Britain as well as America, that lifelong consumption of water containing fluorides at levels around 1 part per million results in a substantial reduction of the incidence of dental caries in children, and probably in adults also; in view of the prevalence of the disease, the shortage of dental manpower, and the absence of any other practicable preventive measure, the benefits of fluoridation (adding fluoride at a level of 1 p.p.m. to waters not naturally so endowed) are of great value. Secondly, there is no scientific evidence whatsoever that fluoridation involves any danger to health, and very considerable evidence that it is harmless. Thirdly, the amounts of fluoride added to water can be controlled very accurately. Fourthly, evidence derived from the millions of people in Britain and abroad, who use waters containing about 1 p.p.m. of fluoride, naturally present, is wholly reassuring both as to the absence of danger and as to the benefits resulting. It may be noted here that one of the earliest British reports² on dental benefits related to children evacuated during the war from a natural-fluoride area; the school dentist in the reception area was impressed by the fact that they had "remarkably good teeth—much better than those of the local children."

Dr. Dobbs uses the term "medical treatment" for a measure which does not cure dental caries but helps to prevent it. I will not indulge in what he calls "verbal quibbling," but it seems necessary to remark that, in the lay press, he has written: "The compulsory mass-medication of people via the public water-supply is the sort of thing which has not been tolerated by civilized European opinion, or practised in Europe, so far as I know, outside the concentration camp (at least until very recently)." This is the kind of highly coloured and unscientific language which is best avoided in debating the factual merits of a case. The ethics of compulsion, of course, are always good for heated argument, as is shown by the whole history of advance in public health; in the present instance, I should like to make it clear that no alternative to public water supplies as a vehicle for fluorides can at present be advocated on technical grounds or on those of safety.

It seems scarcely necessary to point out that fluorides will not be "administered indiscriminately by medically unqualified persons." The word "indiscriminately" ill describes a process which will be conducted with strict administrative, mechanical, and chemical controls, and supervision will, of course, include that of the medical officer of health. Variations in the amounts of fluoridated water ingested by individual consumers are known to be without significance for health, within the very wide range of climates in the North American continent. Variations of consumption are

almost certainly less in this country, and the question of individual intakes of fluorides has been closely examined. There is no risk that, in the unprecedented event of fluoridation causing damage to health, this will occur "without anyone's being the wiser." The arrangements in Anglesey and other areas where the water is about to be fluoridated will be subject to regular scrutiny by doctors and dentists who know the signs of fluorosis. It is not surprising that Dr. Dobbs's medical friends are a little hazy about this condition, and about fluoridation generally; fluorosis is a rarity, and all of us would have to plead incomplete acquaintance with much of the recent medical literature.

Finally, lest judgment be clouded by charges of "mass-medication" or by dark hints about undiscovered but imminent hazards to health, it is well to reflect that in fluoridation we have a public health measure which has been studied and documented with unusual care and completeness; and that we in Britain have previously hesitated unwisely—for example, in relation to diphtheria immunization.—I am, etc.,

Aberdeen.

Early Diagnosis of Spinal Tumours

SIR,—Drs. H. J. G. Bloom, H. Ellis, and W. B. Jennett (*Journal*, January 1, p. 10) have made a useful contribution to this important condition, which can often be so tragic if the diagnosis is not early. As they clearly indicate, their material is selected, all the cases being Service personnel. Thus the incidence of various tumour types is different to most published figures. They rightly state that this accounts for the absence of meningiomas in their series. But one cannot agree with them that spinal meningiomas are only twice as common in women as men—they quote Learmonth.¹ Elsberg² pointed out that nearly all spinal meningiomas occur in women, and in my series³ of 59 cases 85% were in women and over 90% were seen in patients over 35 years of age.

They give little credit to the part played by radiology in the diagnosis of spinal tumours. While they say that the plain x rays of 44% of their cases showed appearances suggestive of spinal tumour, they make no mention of the fact that a specific diagnosis can often be made. This applies particularly to neurofibromas, the most important spinal tumours (apart from meningiomas), in that removal so often effects a complete cure. In my series of 53 spinal neurofibromas, no less than 45% showed plain x-ray changes enabling a specific diagnosis to be made. The most important sign is, of course, widening of the exit foramen. Bloom, Ellis, and Jennett had 15 neurofibromas, of which 7 are listed as having plain x-ray changes (47%). This correlates well with my figures, but the important point is that a specific diagnosis of neurofibroma can so often be made. The significance of normal plain x rays in a case of spinal neurofibroma is readily appreciated by considering the anatomical conditions. If the tumour has not invaded the exit foramen and is therefore probably entirely intradural, then the plain x rays are likely to be negative, since the tumour normally produces signs of cord compression before it is large enough to splay the pedicles. The differentiation from meningioma can then only be made statistically by considering the age and sex of the patient, although a very high C.S.F. protein will favour neurofibroma.

Again, myelography gets little credit. They say, "Although myelography is by no means always necessary for the detection of a spinal tumour, it is invaluable in accurate localization, and may be the only way in which a neoplasm can be excluded in suspicious cases. . . . The myelogram may also suggest whether the neoplasm is intramedullary or extramedullary. . . ." No one will disagree with these remarks, but what an understatement. One should be able to differentiate extramedullary-intradural lesions from those which are extradural. Such differentiation often takes one

much nearer to the pathological diagnosis. Furthermore, the surgeon wants to know the relation of an intradural-extramedullary tumour to the cord—right or left, behind or in front, the last situation being the most unpleasant. Four angiomas are included in the series. How were they diagnosed? Myelography is the only certain method short of surgery or necropsy. The myelographic picture is absolutely characteristic, and should save the patient an operation which never causes improvement and sometimes initiates deterioration.—I am, etc.,

Tuberculous Patients in General Hospitals

SIR,—Dr. Peter Stradling (*Journal*, December 18, 1954, p. 1483) has completely "missed the boat" about my whole letter (*Journal*, November 20, 1954, p. 1227). He overlooks the elementary principle that, generally speaking, before any campaign is carried out it is invariably preceded by intensive detailed and careful planning. He also wants to know "where is the money to build such sanatoria?" The answer is simple—from the very same sources which have unlimited supplies of money for war and the fearful destruction and devastation that accompanies it. It is amazing when it comes to the health and well-being of the nation how every obstacle is put in its way.

If Dr. J. Robertson Sinton (*Journal*, December 11, 1954, p. 1418) had read my letter carefully he would have appreciated that, because of my sincere and earnest desire that human beings should be treated like human beings and not like cattle, I want fully equipped sanatoria to be built throughout the country. Complacency and lack of enthusiasm have no place in dealing with such a serious malady. It has been proved in the Scandinavian countries that where there is adequate sanatorium accommodation and mass immunization with B.C.G. the number of tuberculosis patients has been greatly reduced. In my opinion, this is an example which Great Britain might well follow.

In answer to Dr. R. Lester Black, we must take a long-term policy in so far as the tuberculosis patient is concerned, and face up to the realization that, despite chemotherapy, etc., and provision of a couple of wards in general hospitals, the actual number of notified tuberculosis patients has in point of fact increased. In my view the dominant criterion of tuberculosis is not the death rate but the numbers of tuberculosis patients. In any case, as general practitioners know only too well, is not there a big enough waiting-list in general hospitals without taking away a further two wards?

May I conclude by saying that tuberculosis is a subject in which there has always been ample room for argument, but one fact is beyond dispute: without the tubercle bacillus there is no tuberculosis, and for medical men to have the temerity to state that the way things are at present there is no real danger of infection to the nursing staff, etc., through constant contact with tuberculosis patients is fanciful rather than factual. If I have set some of my professional colleagues thinking, then that could be the first real step in Britain's resurgence on the whole question of tuberculosis.—I am, etc.,

Glasgow, S.W.3.

ARNOLD B. COWAN.

Negative Tuberculin Test and Positive X-ray

SIR,—In 1949 all schoolchildren in Lewis were tuberculin tested and non-reactors had B.C.G. (if desired). A very high positivity rate was found. The local chest physician kindly x-rayed several hundred reactors and reported on them, and in many instances there was radiological evidence of definite intra-thoracic tuberculosis and bed rest was ordered.

A re-survey of all schoolchildren in 1954 yielded some interesting information: (1) A very considerable proportion of those showing radiological signs were now non-reactors. Had all positive reactors been x-rayed more such

evidence of reversal might have been available. Some scholars were followed from a decided positive reaction through diminishing sensitivity to negative and then B.C.G. vaccinated. (2) In a few instances (more might have been revealed if all had been x-rayed) it has been discovered that children who had had B.C.G. vaccination in 1950 had actually suffered from tuberculous lesions before vaccination. This naturally follows on point 1 if B.C.G. is administered automatically to non-reactors to tuberculin. (3) Consequent upon findings 1 and 2 it seems essential to x-ray all children—non-reactors as well as reactors—so that, in the event of a non-reactor having B.C.G. vaccination carried out and later developing intra-thoracic tuberculosis, one will be able to say whether the disease has started for the first time or is the result of a breakdown of a previous lesion. Only in this way will it be possible to evaluate B.C.G. as a preventive measure. (4) Following B.C.G. vaccination the local vaccination reaction and the subsequent allergic reaction vary from person to person. This variation has been considered as due to differences in the technique—even in the case of the same vaccination. It seems to me that an explanation of these variations might be found in points 1 and 2. For example, if a child has at some time had a primary lesion visible on x-ray and yielding a positive Mantoux, but in the course of a year or two the allergy but not the x-ray evidence disappears and B.C.G. is administered, will the local reaction and subsequent allergic reaction not be more marked than they would have been had infection never been experienced?

X-ray facilities are necessary to enable more investigation to be carried out.—I am, etc.,

Stornoway.

R. STEVENSON DOIG.

Trichomonal Vaginitis

SIR,—When Drs. S. R. M. Bushby, R. D. Catterall, and Mary Williamson (*Journal*, January 8, p. 78) found that a new drug, amido-nitrothiazole, exerted a killing power over *T. vaginalis* a hundred times greater than that of acetarsol I am sure that they believed—and naturally—that they might at last have discovered a permanent cure for this harassing disease. But, most disappointingly, they found that nitrothiazole was no more effective in preventing relapse than acetarsol. The large number of drugs which have been used for the treatment of trichomonal infestation of the vagina is evidence of a clinical defeat which is due to causes other than the failure of a specific drug. The cure of vaginitis will not arrive by the discovery of any new drug, however lethal to trichomonas.

All of the many drugs I have used, except absolute alcohol, will eradicate the organism for a few days, as judged by vaginal smear examination and usually the complete disappearance of vulval pain and pruritus. The immediate lethal power of the drugs in ordinary use is sufficient; the real problem is to prevent relapse. The causes of relapse are that the vagina has not been completely disinfested, by failure to pack the whole of the vault around the cervix with the pessaries, or that the organism hides away in the urethral and Bartholin's glands or in the vaginal epithelium. Re-infestation after treatment may also be by coitus, but most improbably due to lavatory seats, as the trichomonas dies by drying, and, though females of all ages use lavatory seats, infestation is rare in children, virgins, and after the menopause. The search for yet more lethal drugs presupposes that *T. vaginalis* is the actual cause of vaginitis, but of this there must be some doubt. For example, it is often found in a normal vaginal smear, while, on the other hand, a smear taken from a severe case may show only an occasional organism or even none at all. The intensity of the inflammatory reaction of the vaginal mucosa is by no means always related to the number of trichomonads found in the smear.

We already have all the anti-trichomonal drugs we need. The essential is the correct application of the one we choose. Self-treatment is entirely useless, for no woman can place pessaries so as to pack the fornices. They must be placed

visually through a speculum, under anaesthesia if the vulva is too tender for the passage of a speculum, and kept in place by a light pack of gauze which may be pulled out in twenty-four hours. If the present attack is a relapse the treatment should be repeated during the last days of menstruation for at least three months. Meanwhile the patient should remain celibate. Despite, however, the most careful and thorough treatment a few women will relapse at intervals, perhaps for years. Trichomonas is not the whole answer to the problem of vaginitis. It may be caused by associated bacteria or even a virus.—I am, etc.,

London, W.1.

ALECK BOURNE.

Mepacrine and Malaria in Children

SIR,—Dr. S. B. Dimson in his paper, "Congenital Malaria in England" (*Journal*, November 6, 1954, p. 1083), mentions the toxic effects of intramuscular injections of mepacrine reported by me¹ in small children in a paper published four years ago. Your readers might be interested in another, more recent case of immediate effects and serious sequelae of an intramuscular administration of mepacrine to an infant.

A well-developed European baby, 6 months of age, on suppressive quinine regimen from birth, had an onset of fever without any obvious clinical symptoms. In spite of repeatedly negative blood examinations for malaria parasites the infant was given an intramuscular injection of 50 mg. of mepacrine musonate. Within 20 minutes after the injection it stiffened, started rolling its eyes, lost consciousness, developed tonic and clonic convulsions, became deeply cyanosed, and collapsed. It was given nikethamide, artificial respiration, and was rushed to the hospital, where it received a large dose of chloral, oxygen, and cardiac stimulants. A lumbar puncture showed the cerebrospinal fluid under slightly increased pressure but otherwise normal. The temperature rose to 104° F. (40° C.). As the clonic convulsions kept reappearing the child was kept on chloral and oxygen for several days. Under this treatment and with excellent nursing the temperature slowly decreased, the convulsive status abated within a week, but occasional twitchings of arms and legs were still present and there were bouts of general muscular rigidity. The skin was yellow and mepacrine was excreted in urine for several days.

On discharge from the hospital the child showed an impairment of head control, hypotonia of the trunk and of one arm. Two months later the child received a good deal of expert attention at one of the London hospitals, where no major abnormality was found, apart from poor head control, failure to make any attempt to sit, and a feeble grasp. The cerebrospinal fluid showed a slightly raised protein content. To-day, after nearly a year, the child shows an improvement of the tone of its neck muscles, but it has a partial paralysis of one arm, shows now symptoms of spastic paraplegia of legs, and appears to have a retarded mental development.

Admittedly, cases of such severe encephalopathy due to mepacrine are uncommon, but it seems that they could be avoided by more critical intramuscular administration of this drug to infants and small children or, at any rate, by the use of chloroquine, which, apart from being an excellent antimalarial, is also much better tolerated by all age groups.—I am, etc.,

Encephalitis after Yellow Fever Vaccination

SIR,—The *Journal* of November 20, 1954, has just reached me, and I was interested to read Dr. Leonard Roodyn's letter (p. 1226) on encephalitis following yellow fever vaccination. I am prompted to write to you, as I have just had under my care an infant suffering from this condition; this is the fourth to be reported in recent weeks. A male child, aged 3 months, was vaccinated in the United Kingdom against smallpox on October 30 and against yellow fever on November 22. The parents arrived at Kano by air on November 30. On December 3 the child was admitted to hospital, as he would not take his feeds. On December 4

the rectal temperature was 103° F. (39.5° C.). He developed a Jacksonian attack involving the left limbs; this was accompanied by a left facial palsy and deviation of the eyes to the left. Direct questioning of the mother produced the story given above. The information about the yellow fever vaccination had not been given previously, as, quite naturally, the parents had not realized the significance of this point. The child did well and now appears to be normal.

From the experience of this case, and that recorded by Dr. L. G. Scott (*Journal*, November 6, 1954, p. 1108), it would appear that cases of encephalitis following yellow fever inoculation may occur when recently vaccinated children are many hundreds of miles from the centre where the inoculations were given. In this way hospitals in the United Kingdom may not be aware of the accident even if the correct diagnosis is made. Parents who travel with young children should be advised not to leave the United Kingdom for at least three weeks after receiving yellow fever vaccination in case encephalitis should follow, although this must be an infrequent complication.

With regard to the vaccination of young babies who travel from an endemic area to the United Kingdom, without stopping in a receptive area, it might be advisable to recommend that vaccination against yellow fever is withheld, as injections in these cases are given not so much to protect the individual as to prevent the spread of yellow fever in Britain, a possibility so remote that it can be ignored.—I am, etc.,

Kano, Nigeria.

E. A. BEET.

Tests of Hearing

SIR,—While agreeing with most of the remarks made by Professor A. W. G. Ewing in his statement on sweep frequency-screening tests of hearing (*Journal*, January 1, p. 41), it would appear desirable to point out that partial deafness of the severity necessitating special educational treatment should be detected before the age of 5 years if it is of congenital origin. Such deafness should be detected preferably before the age of 1 to 2 years so that the child may receive auditory training during the period of normal physiological speech development. If acquired deafness should occur, rehabilitation should start straight away, as soon as the child is well enough. It would be unfortunate if the impression were given that it is satisfactory to defer tests of hearing until the routine group tests are done at the age of 5. The search for deafness at an earlier age is long overdue. The post-natal clinic would seem an ideal place for increasing the mother's awareness of the possibility and implications of partial deafness.—I am, etc.,

London, W.1.

EDITH WHETNALL.

Medical Aspects of Amateur Boxing

SIR,—I was interested to read the article on amateur boxing by Drs. J. L. Blonstein and Edwin Clarke (*Journal*, December 25, 1954, p. 1523). As medical officer I attend weekly tournaments of one of the premier amateur boxing clubs in Glasgow. I must have attended over 200 tournaments and seen over 2,000 bouts. I disagree with the conclusion of the article in question. Far from being a useful and justifiable sport, amateur boxing is a dangerous, and often brutal, happening. Firearms, swords, daggers, razors, broken bottles, and coshes produce appalling injuries—I would say that boxing comes next on the danger list. Perhaps all-in wrestling is a "wee shade" more dangerous. Virtually, each boxer steps into the ring with the intention of injuring his opponent, especially his opponent's cranium and its contents.

Concussion produces an oedema of the brain, and this pathological condition does not clear up quickly. Though a boxer regains consciousness by the count of ten, is able to bathe, dress himself, and have a light meal, he is not recovered. I have known of a young man being off work for many months following a knock-out (by concussion). Much is made of medical control in the article. No such control exists here. Recently a boxer was knocked out on a Saturday and again on the following Monday. Boxers

here are examined before a contest only if it is an international or a championship match. The only difference between professional and amateur boxing, from my point of view, is the distance of rounds. I know of two severe eye injuries, one, at least, involving the retina. I note that the London article makes no mention of solar plexus blows, the effects of which are very distressing not only to the recipient but also to the spectators, and, not least, to the medical officer.

As a nation, are we in a position to afford this type of disability production? I admit that, after many years, "boxing" grows upon one—an innate sadistic admiration for "guts."—I am, etc.,

Newton Mearns.

JAS. C. LAURIE.

Cardiac Asthma

SIR,—Although rare, acute pulmonary oedema is probably one of the most alarming emergencies encountered in general practice. As Dr. J. G. M. Hamilton (*Journal*, January 1, p. 39) says, morphine is an effective drug for the relief of such attacks, but it is not without potential danger, particularly when administered intravenously. In a condition in which there is already extreme respiratory embarrassment, the depressant action of morphine upon the respiratory centre should be avoided if there is an alternative drug which can be used. Dr. Hamilton explains the effect of morphine by a multiplicity of actions, most of which could be achieved with alternative hypnotic and analgesic drugs. But, in fact, such other drugs are ineffective.

I believe that morphine relieves this condition by virtue of its peripheral vasodilator action. Its effect is therefore analogous to that of tolazoline¹ and other vasodilator drugs,² but these have the advantage of creating no respiratory depression. In hypertensive left ventricular failure, peripheral vasoconstriction is the precipitating factor in initiating and maintaining the attack of acute pulmonary oedema. My most recent case was a woman of 63 with a basal hypertension in the region of 220/120. She suffered an extremely severe attack of acute pulmonary oedema in the night and, when I reached her, was extremely distressed and practically unconscious. The blood pressure had risen to 285/150 and she exhibited the usual signs of intense peripheral vasoconstriction. Tolazoline hydrochloride, 25 mg., was injected intravenously, and one minute later the blood pressure had fallen to 225/100, with subsequent resolution of the attack. The use of vasodilator drugs carries with it none of the dangers of hypotensive agents, such as the methonium compounds, for the production of peripheral vasodilatation merely returns the blood pressure to its previous basal value and there is no danger of irreversible hypotension. In mitral stenosis and type II nephritis, a similar mechanism may play a part in producing attacks of acute pulmonary oedema, for I have relieved such attacks in these two conditions with vasodilator drugs and observed similar blood pressure changes. On the other hand, in myocardial infarction the use of any drug which lowers blood pressure may be an extremely hazardous procedure.

The general practitioner has a unique opportunity for studying and treating this condition. By the time the patient reaches hospital the attack may be in its later stages, and often subsiding, or the patient may be dead. In the prevention of subsequent attacks in hypertensive cases, I think more can be done than was suggested in Dr. Hamilton's article. I doubt whether general practitioners will be content to sit back and watch their patients leading a "digitalis life," with all its accoutrements of semi-invalidism, when more active measures are available. Surely it is preferable to reduce the patients' blood pressure, with consequent decrease in cardiac enlargement and prevention of further acute episodes of failure.³

It is usually possible to control most cases of hypertension with a combination of hypotensive agents, the composition of which may have to be varied from case to case. Probably the most useful combination in general practice is reserpine with hexamethonium or pentolinium by mouth. Thus in the case already quoted there were three severe episodes of acute pulmonary oedema in the first fortnight, before the blood pressure was controlled with these two drugs. In the following four months the blood pressure has been kept in the region of 150/100, a lower value than this producing postural faintness, and there have been no further attacks of left ventricular failure. It might be argued that

such treatment does not maintain a low blood pressure value and that hypertensive peaks occur as the effect of each dose wears off. Whether this is so or not, the clinical improvement in this case is striking and is associated with almost complete reversal of the cardiographic appearances of left ventricular strain and diminution in heart size on x ray. I have observed similar effects in a number of other cases of hypertension treated in like manner. I believe that it used to be said that once a patient suffered more than one attack of acute pulmonary oedema the prognosis was poor. With our present therapeutic armamentarium, there is no longer any need for such a pessimistic outlook.—I am, etc.,

Twickenham, Middx.

SIR.—In his excellent refresher course on "Cardiac Asthma" (*Journal*, January 1, p. 39) Dr. J. G. M. Hamilton points out that rapid venesection may be usefully employed. In 1924 I published a paper¹ in which I showed that a significant hydraemia occurred in such a patient in a few hours after a venesection (300 ml.), and I have since successfully treated many cases of acute pulmonary oedema and of chronic stasis of the lungs with venesection and, of course, with morphine in the acute stage. I consider venesection (300 ml. is sufficient) as the treatment of choice in these cases. I quite agree with Dr. Hamilton on the long-term management of these cases.—I am, etc.,

Aalborg, Denmark.

Dyspareunia

SIR.—I was interested to read in Mr. R. Christie-Brown's letter (*Journal*, January 8, p. 106) of the existence of a clinic for the exclusive purpose of treating dyspareunia. I wonder if it is generally realized that this complaint is often due to pathological processes in the urethra—sometimes resulting in vegetations. Whatever the changes, they are readily detected by urethroscopy and are generally amenable to the appropriate treatment. I have had a number of such cases where fertility has replaced infertility.—I am, etc.,

London, W.1.

H. P. WINSBURY-WHITE.

SIR.—I was interested to read that my friend Mr. Christie Brown (*Journal*, January 8, p. 106) "has become increasingly aware of the large part which dyspareunia plays" in the causation of infertility. It is possible that he will find that a high percentage of women attending an ordinary gynaecological out-patient department also suffer from the same troublesome complaint. If he would try cauterizing the internal os uteri with a stick of silver nitrate, I think he would find that he would cure most cases of dyspareunia provoked by deep penetration of the penis and that his new clinic might prove unnecessary.

The same treatment, provided women with gross pelvic pathology were excluded, would also cure most cases of lower sacral backache, frequency and urgency of micturition, stress incontinence of urine, and lower abdominal pain, including right iliac fossa pain, for which so many normal appendices and not a few ovaries are needlessly sacrificed.—I am, etc.,

Bradford.

G. W. THEOBALD.

SIR.—I was interested in Mr. R. Christie Brown's letter (*Journal*, January 8, p. 106) drawing attention to the existence of a "dyspareunia clinic." This condition is a sadly neglected complaint and one far more common than is generally realized. I am prepared to accept that many patients seek advice for a variety of symptoms (of which infertility is one) when the basic trouble is their inability to participate in a normal married life, but surely only

introital dyspareunia is likely to be associated with infertility as cause and effect. In such cases levator spasm is sufficient to prevent penetration.

I agree that general practitioners cannot be expected to deal with these cases, but I beg to suggest that these patients can often be treated successfully in an out-patient clinic by simple instruction and the use of vaginal dilators. Only the most refractory would I refer for a psychiatrist's assistance.

These cases are a challenge to the patience and ingenuity of the non-surgical aspect of our specialty. Is there not too much tendency nowadays to split up gynaecology into various component clinics: contraception, infertility, hormone, and now dyspareunia?—I am, etc.,

Cambridge.

OSWALD LLOYD.

Changes in the Mental Health Services

SIR.—In reply to Sir David Henderson (*Journal*, January 8, p. 104), I must apologize for my injustice to Scotland (*Journal*, December 18, 1954, p. 1484). I wrote with first-hand knowledge of Edinburgh only, and made the unwarranted assumption that the conditions obtaining here were those of the Scottish mental health service as a whole. I am well aware of the existence of Jordanburn Hospital and the nursing-homes, which I visit frequently, but these establishments have nothing to offer the type of patient under discussion. If a patient is so disturbed by his illness that he refuses to accept treatment, his admission to these places cannot be effected. If he accepts the need for treatment, then he can equally well go as a voluntary patient to a mental hospital, though the nursing-homes have the merit of being without the mental hospital.

I am also aware of the existence of an observation ward at the Royal Infirmary of Edinburgh, but am equally aware of the categories of patients who may be admitted there. They are (1) disturbed patients in other wards of the Infirmary, (2) patients from corrective establishments, and (3) cases of attempted suicide. They do not admit acute psychoses from the Edinburgh area in general. These facts I have confirmed from the Superintendent's office before writing. Despite, therefore, the sympathetic attitude of the Board of Control for Scotland in 1906, the facts in Edinburgh in 1955 are that there is no alternative but to certify an acutely disturbed patient who declines to go willingly to a suitable establishment.—I am, etc.,

Edinburgh, 5.

JOHN MARSHALL.

Crying in Infants and Children

SIR.—It was with great interest that I read the article by Professor R. S. Illingworth on infant crying (*Journal*, January 8, p. 75). In a hospital for mental defectives in this town it is noticeable that genuine crying with tear formation is extremely rare among the low-grade patients. Crying is more common among the females than the males, and among the females it is much more common in the higher-grade than in the lower-grade patients.

It would be instructive to learn why crying should cease while other childish behaviour patterns, thumb sucking, rocking, and head banging remain. Perhaps there is some explanation depending upon maturation of the central nervous system.—I am, etc.,

Chipping Norton.

F. E. JAMES.

SIR.—Professor R. S. Illingworth, in his article on "Crying in Infants and Children" (*Journal*, January 8, p. 75), refers to the obscurity of the mechanism of vomiting in small children who have been crying more than a quarter to half an hour. May I mention the following observation which may throw light on this mechanism?

On reviewing some discarded chest radiographs of young children and infants, there were a few radiographs where the lung fields were almost completely obscured by an opacity continuous with the heart and mediastinal shadow. I was informed (and it is probably common knowledge to our

x-ray colleagues) that it frequently happened that in a crying young subject (and it need not be vociferous crying) such radiographs were obtained; pacification allowed unobscured radiographic views of the lung fields. If every case of crying is indeed accompanied by this hyperaemia, and if it is maintained for long periods, then it may lead to mucus exudation in unusual amount from the bronchial epithelium which would gather in the bronchial lumen. Such mucus stimulating the oropharynx leads to reflex vomiting (in severe pneumonias in children and whooping-cough, cough followed or accompanied by vomiting is a frequent occurrence). A subsidiary factor may be stimulation of the medullary vomiting centre by hypoxia of the blood in the cerebral blood vessels resulting from pulmonary-bed pooling.—I am, etc.,

Romford, Essex.

B. SKLAN.

Obstruction from Orange Pith

SIR.—May I add a further case of acute intestinal obstruction caused by swallowing an unmaasticated piece of orange (*Journal*, December 18, 1954 p. 1484)?

A man aged about 45 years was seen by me in the casualty department complaining of colicky abdominal pain and vomiting for a duration of six hours. This was on a Sunday during the football season. Examination revealed this to be an early case of small bowel obstruction. The patient had a polya type of partial gastrectomy performed at the same hospital five years previously. A provisional diagnosis of obstruction due to post-operative adhesions was made. Laparotomy revealed small bowel obstruction caused by a foreign body impacted in the lumen of the gut two feet proximal to the ileo-caecal valve. Removal of the foreign body relieved the obstruction. Examination revealed it to be an intact unmaasticated "quarter" of a fair-sized orange. On taxing the patient's memory the following day, he recalled having a similar piece of orange in his mouth at a most inopportune moment during the course of a football match on Saturday. During the excitement that followed a victorious goal the orange had disappeared from mouth and mind.

Looking back on the case, I do not believe that such a large bolus could have gone through a normal pylorus. That this is one of the lesser known hazards of gastrectomy should be borne in mind. Whether it can be classed as one of the hazards of football, I shall leave to your readers' imagination.

I wish to thank Mr. R. Cunliffe-Shaw for allowing me to mention this case.—I am, etc.,

London, S.W.1.

N. H. ANTIA.

What is Health?

SIR.—I have read with great interest the report of the Kent Paediatric Society¹ and your annotation (*Journal*, December 11, 1954, p. 1409) under the above heading. A similar study of an older age group composed of university students has been carried out over the last eight years in the University of Aberdeen, where the approach to the problem has been different in many respects, chiefly in regard to the assessment of health. Following initial trials so effort is now made in this department to assess health on a mathematical basis. I would hesitate to accept a series of physical and intellectual scores as providing accurate measurement. Some of the conditions on the Society's marking form do not seem to me to warrant degrading, and I do not think it is yet clear as to what extent intelligence and the possession of personality assist the individual to adapt harmoniously either within himself or in relation to things without, which is what fundamentally constitutes health. It may be that an intelligent, highly reactive personality does not adapt so harmoniously to environmental agents as a more placid individual.

The procedure here is as follows: Each student coming for first examination has a careful interview of about an hour's duration followed by a physical examination. On completion the individual is placed, on a purely arbitrary

assessment, into one of four categories. The first is composed of those whose all-round qualities are outstanding, the third of those who are quite obviously unfit, whilst in between is placed the largest section, constituting the average. The latter is again divided into high and low, so that the groups are labelled 1, 2a, 2b, and 3 respectively. The student's progress at University is followed up, and each receives at least one re-examination, whilst those who stay over three years receive two or more reassessments. By means of a punch file record system the factors concerned with each group can be correlated. It is realized that assessments of this nature can only be of value if carried out in respect of adequate numbers and over sufficient length of time. A ten-year survey is in progress and it is hoped to publish the results in another two years.

This method of approach obviously lacks the precision of a more exact numerical measurement, but it is felt that to attempt to apply scientific accuracy to so ill-defined a subject as health may result in a less accurate impression than a more arbitrary assessment of what we all understand and appreciate, but which we find so difficult to define and measure. In spite of any criticism which these remarks may seem to convey I would like to congratulate the Kent Paediatric Society on its very fine pioneer survey.—I am, etc.,

Aberdeen.

A. H. MACKLIN.

Sudden Death in Labour

SIR.—From the incomplete evidence submitted it would seem that the death reported by Dr. Patricia E. Campbell (*Journal*, January 8, p. 87) was probably due to massive amniotic emboli due to uterine contractions, and not to the penicillin administered over an hour before.—I am, etc.,

Oxford.

JOHN STALLWORTHY.

SIR.—I have read with interest Dr. Patricia E. Campbell's stimulating report of sudden death in labour following injection of penicillin (*Journal*, January 8, p. 87). Ascribing such a major catastrophe, however, to a penicillin injection, without any apparent proof, cannot be accepted easily, and with apologies to Dr. Campbell I feel obliged in the interests of obstetrics to criticize the diagnosis. Is it not rather untenable that hypersensitivity to penicillin should express itself in such manner and degree one hour and a quarter after injection without any prior warning or reaction? This would not be in keeping with the patterns of drug sensitivity.

The unexpected onset in normal labour of vomiting, cyanosis, and sudden death with the morbid findings of pulmonary petechiae and incoagulable blood primarily suggests a diagnosis of liquor amnii embolism and a further definitive search for evidence of extrauterine amniotic content is then warranted. It is only 14 years since Steiner and Lushbaugh¹ first brought this pathological entity to our notice, and to date there are only about 50 cases on record. It is not surprising then that many as yet are unaware of the condition. In the reported case of Dr. Campbell's it is not stated whether there was a histological search for epithelial squames in the lung and, in their absence, if any special staining was used to outrule the presence of liquor amnii fat in the pulmonary blood vessels or whether there was any rent or tear in the amnion explaining the mode of occurrence of embolism.

"Obstetric shock," one time accepted as idiopathic in nature, has more recently become clearer in its aetiology, mainly through a more comprehensive approach to morbid anatomy. In such unknown estate no doubt drug anaphylaxis is entitled to a dwelling, but in Dr. Campbell's case I feel that another housing applicant should primarily be proved less deserving.—I am, etc.,

Galway.

DONAL O'SULLIVAN.

REFERENCE

- ¹ *J. Amer. med. Ass.*, 1941, 117, 1245.

SIR,—I was interested to read the report by Dr. Patricia E. Campbell of a case of sudden death in labour following a penicillin injection (*Journal*, January 8, p. 87). There are several features about it, however, which make the diagnosis of anaphylaxis seem unsatisfactory.

These are as follows: (1) The time interval of one hour between the injection and collapse of the patient is rather long for intravenous injection of the drug—probably the cause of the majority of sudden deaths after penicillin injection—to have been responsible. (2) Reporting the use of massive doses of penicillin, McLean¹ records sudden death of three patients, and says, "As death occurred in all cases within twelve hours of the initial dose, it seems unlikely that anaphylaxis was responsible." (3) The case clinically appears to present all the features of amniotic fluid embolism described originally by Steiner and Lushbaugh,² and subsequently by Reid *et al.*,³ in the United States of America, and by Shotton and Taylor⁴ in this country, and the necropsy findings are not inconsistent with this condition. Dr. Campbell does not state whether or not the lungs were examined histologically.—I am, etc.,

Glasgow, S.1.

Appendectomy in Chronic Appendicitis

SIR,—In common no doubt with the majority of your readers, I have been very interested in the correspondence on appendectomy for "chronic" appendicitis which followed the publication of the paper by Messrs. I. McLennan and J. K. Watt (*Journal*, September 25, 1954, p. 736). I was particularly impressed by the letter from Professor J. Chassar Moir (*Journal*, December 11, p. 1415) in which he pointed out the fact—shown in their paper—that "chronic" appendicitis appears to be much commoner in females of menstrual age and that, in his opinion, this is usually attributable to disordered ovarian function.

I am in the process of preparing a paper which lends much support to this hypothesis. In an analysis of all cases with pain in the right iliac fossa, as the presenting symptom seen at one particular surgical out-patient clinic at a provincial teaching hospital during the course of 12 months, the following figures were obtained: females 52; males 11; total 63. Thirty-seven of the females were between 14 and 30 years of age, the majority being either in the late teens or early twenties. These girls were nearly always complaining of intermittent "stabbing" or "niggling" pain in the right iliac fossa (and frequently in the left iliac fossa if specifically asked) which usually lasted anything from a few minutes to several hours, with little or no constitutional upset and usually no abnormal physical signs at the time of examination, although deep tenderness in the right iliac fossa had often been found by their own doctors during or shortly after an attack. In 33 out of the 52 females a diagnosis of ovulation pain was made and the patient reassured. Of the remaining 19 females, of whom the majority were between 40 and 50, one had acute appendicitis and three were thought to be recovering from a recent acute attack, whilst in the remainder a variety of disorders was found, including constipation, renal, gall-bladder, and frank gynaecological disease, plus one pregnancy. Among the 11 males, 6 had a history and/or signs consistent with recent acute or recurrent appendicitis, whilst two were found to be suffering from severe constipation. A right basal lung cyst, a large para-umbilical hernia, and right myofascial lumbar strain completed the list of males. During the same 12 months, 10 females between the ages of 15 and 30 were operated on for "apoplectic" ovary (ruptured lutein cyst) and 8 treated conservatively in the beds of this unit. It is believed that this condition, particularly in a minor form, is by far the commonest cause of recurrent pain in the right iliac fossa in young women.

Appendicular colic, characterized by recurrent central abdominal pain generally lasting only a few minutes at a time and often associated with slight deep tenderness over the appendix but without local rigidity, is a much more plausible explanation for the symptoms relieved by appendectomy particularly in childhood. In such cases, the appendix is nearly always normal to the eye of the sur-

geon and to the unbiased pathologist. It may be kinked and usually contains inspissated faecal matter, but it is rarely chronically inflamed. In so far as constipation appears to be the basic cause of appendicular colic, the condition tends to cure itself in time, but this may extend over many years. For such cases, appendectomy is probably a justifiable but certainly not an essential procedure. While chronic appendicitis undoubtedly exists as a pathological entity, and probably as the sequel to acute or recurrent attacks, it is, I think, a comparative rarity, if for no better reason than the vigilance of the average G.P. in referring all suspicious cases of acute or subacute appendicitis to hospital for emergency admission. Clinically, chronic appendicitis is either silent or declares itself only during acute exacerbations. Following the resolution of an appendix abscess, the appendix is histologically chronically inflamed, yet the patient is symptom free unless there is a recurrence of acute inflammation.

My conclusions, for what they are worth, are: (1) Chronic appendicitis is relatively rare and is a sequel to acute inflammation. (2) Chronic appendicitis *per se* is symptomless. (3) Appendicular colic is common, particularly in children, and is due to inspissation of faecal matter in perhaps a kinked but not usually a chronically inflamed organ. (4) Appendicular colic can be produced only if the wall of the appendix is capable of actively contracting, and this function is inevitably inhibited by fibrosis. (5) Acute-on-chronic (or recurrent) appendicitis is characterized more by persistent pain in the right iliac fossa (lasting continuously for several hours or days) and less by initial central colic. (6) Recurrent attacks of pain localized to the right iliac fossa and lasting only short periods (minutes to perhaps an hour) are rarely due to appendicitis. (7) Recurrent niggling pain in the right iliac fossa of young women is generally due to disordered ovarian function.—I am, etc.,

London, W.C.1.

A. HENRY MILLARD.

Distribution of R.M.B.F. Christmas Gifts

SIR,—I am sure that your readers will be pleased to learn that the contributions to provide Christmas gifts for the beneficiaries of the Royal Medical Benevolent Fund amounted to £2,775. We were able to distribute £8 to each of them.

The warmth of gratitude expressed in letters of thanks would have gladdened the hearts of the contributors, and of yourself, Sir, for giving space so generously for the publication of the appeal.—I am, etc.,

WEBB-JOHNSON,

President,
Royal Medical Benevolent Fund.

London, S.W.15.

POINTS FROM LETTERS

Fixation of Blood Smears

Mr. N. V. GURJAR (Bombay) writes: I have been using successfully a 7% solution of sulphosalicylic acid as a fixative for blood smears. More than 3,000 smears of blood and marrow have been fixed by this method for a couple of seconds and then stained with different haematological stains. The results have been excellent. The cytological morphology is better as compared with alcohol fixation. Another advantage is that smears so fixed can remain (unstained) for any length of time without any fungus growth, which is a common feature of alcohol fixation. Recently I have also fixed some tissues for histological section with 10% solution of sulphosalicylic acid for 24 hours, and this has shown less shrinkage in cell cytology. This might prove a bit expensive in comparison to formol-saline or Bouin's fixative, but the advantage of getting better morphology could be a consideration particularly when dealing with small biopsies.

The Future of Surgery

Dr. E. F. BLUMBERG (London, S.W.3) writes: With reference to Sir Heneage Ogilvie's statement (*Journal*, December 18, 1954, p. 1435) that "the contributions of Germany to surgical advance in the last 50 years have been pathetic," for the years since 1933 your author is obviously correct. The first 25 years, however, produced a vast number of great names. I am including a small collection—Kocher, Trendelenburg, Lexer, Israel, Enderlen, Czerny, Bier (lumbar anaesthesia), Kehrer, Koerte, Garré, Sauerbruch.

Obituary

R. J. WILLAN, C.B.E., M.V.O., M.S., F.R.C.S.

Professor R. J. Willan, who died in London on January 12 at the age of 77, was for many years an outstanding surgeon in the north of England, and his reputation was high throughout the surgical world. Although a general surgeon, he was particularly well known for his genito-urinary work. He gave devoted service to his hospital, the Royal Victoria Infirmary, Newcastle-upon-Tyne, and to his university; he reached flag rank in the R.N.V.R. and was surgical adviser to the Ministry of Health; and he was a valued counsellor in the affairs

[Dorothy Willing]

of the Royal College of Surgeons of England and of the British Medical Association.

Robert Joseph Willan was born on January 10, 1878, the second son of John Willan, J.P., of Durham. From Durham School he went on to the University of Durham, graduating M.B., B.S., with honours, in 1906. He won the Gibb scholarship in pathology in 1904, the Charlton scholarship in the principles and practice of medicine in 1905, and the

Stephen Scott scholarship in 1908. Later, in 1920, he was awarded the Heath scholarship, which is awarded, also by Durham University, for an essay or paper based on personal investigations. He took the F.R.C.S. in 1908, and in the following year proceeded to the M.S., with first-class honours. After graduation Willan was house-surgeon and surgical registrar at the Royal Victoria Infirmary and senior house-surgeon at St. Peter's Hospital, London. In 1914 he was elected to the honorary staff of the Royal Victoria Infirmary as assistant surgeon, becoming full surgeon in 1922, and his skill, resolution, and hard work quickly gained him a wide reputation and an extensive practice. In due course he became senior honorary surgeon to the Infirmary, and then consulting surgeon when he retired in 1938, and for some time he was chairman of the honorary medical and surgical staff committee. An appointment of which he was particularly proud was that of honorary life governor of the Infirmary made soon after his retirement. He also served as honorary surgeon to the Ingham Infirmary, South Shields, to the Newcastle-upon-Tyne Dental Hospital, and to the Whickham and District Cottage Hospital. When the late Professor G. Grey Turner came south to become professor of surgery at the British Postgraduate Medical School at Hammersmith in 1935 Willan succeeded him in the chair of surgery in Durham University, a post which he filled with distinction until his retirement in 1942. He was then appointed emeritus professor. He was a past-president of the Durham University Medical Society and of the Newcastle upon Tyne and Northern Counties Medical Society.

At an early stage in his career Willan joined the Volunteers, being attached to the Durham Light Infantry. Later he transferred to the Royal Naval Volunteer

Reserve, retiring in 1933 with the rank of surgeon-captain after many years' service. During the first world war he served with the Grand Fleet and was for a time medical adviser to Prince Albert (later King George VI), and he also treated and gained the friendship of Admiral Jellicoe. He was awarded the Volunteer Decoration in 1919; and he was Honorary Surgeon to King George V from 1930 to 1933.

In the second world war he again served the Royal Navy as consultant in surgery for Scotland, with the rank of surgeon rear-admiral, and he was also surgical adviser to No. 1 Region of the Ministry of Health. He was appointed M.V.O. in 1915, O.B.E. in 1919, and C.B.E. in 1946.

From his early days in Newcastle Willan took a great interest in the work of the British Medical Association. Beginning as honorary secretary of the Newcastle-upon-Tyne Division in 1912, he was scientific secretary of the North of England Branch from 1915 to 1922, and his merits in these posts gained him the position of chairman of the Division in 1924-5 and president of the Branch in 1929-30. Much of the success of the Association's Annual Meeting held at Newcastle in 1921 was due to his organizing ability as honorary local secretary of the meeting. He served as a vice-president of the Section of Surgery at the Glasgow Meeting of the B.M.A. in 1922, was a representative to the Centenary Meeting held in London in 1932, and a member of the Council for a year (1931-2). He worked on a number of committees of the Association, and was particularly interested in the Science Committee, of which he was a member for nearly 30 years. He was chairman of its library subcommittee from 1946 until his death and was closely concerned with the move of the library to its present home in the garden-court wing of B.M.A. House.

Willan wrote a large number of articles for the various medical journals, articles chiefly concerned with subjects relating to the genito-urinary organs. All his writings were characterized by sound and practical common sense. In 1939 the seal of their approval was given to Willan by his surgical *confrères* when he was elected to the council of the Royal College of Surgeons of England, and he remained on the council for eight eventful years.

Of medium height and sturdy in build, Willan had the misfortune to lose the sight of one eye through an accident in later life, but he was never heard to complain of this infirmity. Good-natured in temperament, quiet in demeanour, rather reticent in giving his opinion, he could always be relied on to speak to the point. After his retirement from hospital and private practice he moved to London, where he regularly attended the Savoy Chapel, for he was very proud of his Membership of the Royal Victorian Order and he loved the quiet and the atmosphere of that religious oasis. After coming to London Professor Willan interested himself in medical charity. He was a member for some years of the council of Epsom College, where he was for two years chairman of the Special Committee: after that he was chairman of the Conjoint Committee for one year, but in 1954 had to decline nomination for re-election owing to the state of his health. He was also for a few years on the committee of management of the Medical Insurance Agency.

Professor Willan's wife, formerly Miss Dorothy E. Shawyer, died in 1949, after they had been married 39 years. There were one son and two daughters of the marriage.

G. McC. writes: No medical officer who has served on the permanent list of the Royal Naval Volunteer Reserve will have failed to have noted with regret the death of Robert Joseph Willan, for, although he was a surgeon and teacher of repute, it was his connexion with, and career in, the Royal Navy of which he was most ready to talk in his later years. As a very young man he joined the Royal Naval Volunteer Reserve shortly after its foundation. Serving in the years immediately prior to the first world war, he took an active part in training and preparing the Tyne Division for the part this Division was to take and for which he himself was mobilized in August, 1914. During his four and a half years of active service he wrote what became a minor classical publication entitled, *Clinical Notes for Surgeon Probationers*, which became the medical Bible for all those unqualified medical students who had medical charge of destroyers and other small ships. His place as a member of the R.N.V.R. in the Royal Navy became established when, as surgeon in the Hospital Ship *Plessey*, he was called upon to operate, in an emergency, on the Duke of York, who was later to become King George VI.

After the war he continued as a senior medical officer, attaining the maximum rank allowed in the Reserve, of surgeon captain, and in that rank holding the position of King's Honorary Surgeon. Retiring on the age limit in 1935, he kept close touch with his old Division and with Naval medical thought, and in 1939, on the outbreak of the last war, it was a great grief to him that he was considered too old to serve. Later he was re-employed as a surgeon captain (retd.), R.N.V.R., and was finally promoted to the rank of acting surgeon rear-admiral, R.N., which was a source of pride to himself and of satisfaction to those who knew him and had worked with him, and was interpreted as a tribute to the permanent Royal Naval Volunteer Reserve Medical Branch. After the war he kept up his connexion with the Tyne Division, and liked nothing better than to come North from his retirement to talk over old times with other "old salts."

J. B. MILLER, M.D., LL.D., D.P.H.

Dr. J. B. Miller, of Bishopbriggs, whose death at home on January 14 we record with deep regret, was chairman of the Representative Body from 1946 to 1948, and one of the most popular and respected figures for many years in the central affairs of the British Medical Association. He seasoned its assemblies with his humour and wit, but behind the drollery was a keen intellect, practical wisdom, and a notable capacity for friendship. He was 77 at the time of his death.

In the Association, after filling many positions in Scotland, including the chairmanship of the Scottish Committee, and also undertaking much useful work at the London headquarters, Dr. Miller was unanimously called to the chairmanship of the Representative Body, the first Scottish practitioner to hold that office. It is an office which demands, not so much skill in the shaping of policy or the conduct of negotiations, as exceptional qualities of chairmanship—firmness, impartiality, politeness; the ability to prick a pretentious bubble, to relieve a strained situation, to rebuke the rude or restive and prod the bored or indifferent; and a detailed knowledge of the business of the meeting. Miller's personality was such that he could display all these qualities and capacities during his three years of chairmanship, among the most difficult years the Representative Body has ever passed through.

James Blakely Miller was born on April 9, 1877, at Kirkintilloch in Dunbartonshire, the son of the Rev. Andrew Miller. He was educated at Glasgow High School and at the University, where he became secretary of the Medico-Chirurgical Society. After graduating M.B., Ch.B. (with commendation) in 1898, J. B. Miller

held the post of senior assistant at Town's Hospital, Glasgow, and then settled in general practice on the Lanarkshire border, in the valley of the Clyde. Bishopbriggs—its name coming down from pre-Reformation days—is only 15 minutes by bus from Glasgow Cross, but it is the centre of the mining and agricultural community among whom Miller found his lifework. In 1909 he proceeded to the M.D., again with commendation, and he also took the D.P.H. Besides being a general practitioner he was also a medical officer of health—for his native burgh of Kirkintilloch and for Kilsyth in Stirlingshire, both of them only a short distance from Bishopbriggs. He always took his public health duties seriously, and some years ago he wrote a useful article about the importance of the general practitioner as a health educator. A leading figure in the district in which he lived and worked, Dr. Miller was a justice of the peace for the County of Lanark, a past chairman of the Bishopbriggs District Ratepayers' Association, chairman of the local Horticultural Society, a trustee of the Cadder and District Miners' and Community Welfare, and one of the oldest members of the Cadder parish church, being father of the kirk session. He was a district medical officer for the county of Lanark, medical officer to the Post Office, Admiralty surgeon and agent, and medical referee to the Department of Health. During the first world war he was medical officer in charge of the auxiliary Red Cross hospital in his own parish of Cadder. In course of time he found wider fields for his energies as chairman of the Scottish Colliery Surgeons Committee, chairman of the Lanarkshire Local Medical and Panel Committee, and member of the Central Midwives Board for Scotland. In 1951 Dr. Miller completed fifty years of practice in and around Bishopbriggs, and his friends and patients marked the occasion by making a presentation to him at a public gathering in Cadder Parish Church Hall. Last year, at the Annual Meeting of the B.M.A. in Glasgow, Dr. Miller's own university conferred on him the honorary degree of doctor of laws. Professor Stanley Alstead, presenting him for the degree, described him as "a master of this difficult art of general practice," and as "a physician who personifies those virtues which have made the Scots doctor a revered figure throughout the world."

Dr. Miller first became a representative when the British Medical Association held its Annual Meeting at Glasgow in 1922, and in 1929 he was elected a member of the Council. Then began a round of central committee work of which he took his full share, although for him every meeting entailed two nights or two days in the train. He was chairman of the Health Services Committee which preceded the Medical Planning Com-

mission, and on that Commission itself he did excellent service as chairman of the Co-ordination Committee, a task which exactly suited his abilities. He was also, at various times, a member of the Public Health Committee (for a quarter of a century), the Parliamentary Elections Committee, and an earlier General Medical Services Committee which shaped the Association's proposals for a general medical service for the nation. Again, particularly on questions of industrial practice, workmen's compensation, and national health insurance, his experience and counsel were often of service. His knowledge of both the general practice and the public health fields made him a useful member of the liaison committee which ensures co-operation between the Association and the Society of Medical Officers of Health.

In 1945 he was elected by the Representative Meeting in London as its chairman for 1946. His election took place on the very day that Mr. Attlee's Government came into power, and the three years which followed were the most strenuous in the Association's history. They saw the introduction of the National Health Service Act, the mobilization of the profession against some of its provisions, the plebiscites, the resumed negotiations, and the conditional agreement to enter the Service subject to an amending Bill. His term of office ended within a week of the measure coming into operation. During those three years seven Representative Meetings were held, four of them devoted entirely, and the other largely, to the question of the National Health Service. In a similar crisis a generation earlier, when National Insurance was introduced, there were nine meetings of the Representative Body in the course of twenty months, and the two men who filled the chair during that period, Sir Ewen Maclean and Sir Jenner Verrall, had a stormy passage. But the conflict was perhaps sharper in 1946-8. The Association was by this time twice as large, its Divisions were better organized, it was politically more alive, and the demand for leadership was more acute. As chairman of the Representative Body Miller was faced with agenda containing hundreds of motions from Divisions, many of them similar in purpose but with differences of phrase which might be important, at all events in the eyes of the Division which had sent them forward. To assign priority and to make rulings as to how far one motion might be held to cover others was both an arduous and a delicate task, calling all the time for the utmost alertness and power of analysis, the blending of authority with tolerance, and the exercise of good humour to dispel any rankling sense of injustice.

Miller's Scottish humour, which was not artificial or forced but an idiom that was natural to him, never failed him. Not once in that long period was he outwardly perturbed. If he had occasion to utter a rebuke it was done in so whimsical a way that the lesson remained but not the sting. He was always scrupulously fair. In spite of his own obvious desire to get through the tide of words to the rock of decision, he resisted importunate calls that the question be now put or that the meeting proceed to the next business if he thought the matter had not been sufficiently debated. He never failed to give the proposer of a motion the right of reply, while hinting to him either that there was nothing to reply to in the arguments against him, or else that the arguments were so overwhelming that he could not possibly have any reply to them. He once remarked that the business of the Representative Meetings was got through thanks to a core of experienced representatives who never

appeared on the platform and who had made up their minds uninfluenced by eloquence of any sort. Dr. Miller underwent a serious operation in 1948, but in a surprisingly short time he was back again at Headquarters, looking rather more frail, but with mental energies unimpaired and a wit as sharp as ever. His recreations were golf and curling, gardening and field botany, and archaeology, for which last there is plentiful material in north-west Lanarkshire. Dr. Miller married Margaret Vaughan, daughter of the Rev. I. B. A. Watt, and he is survived by his widow, one son, and two daughters. Brownswood, Bishopbriggs, was a very happy home, and Dr. Andrew Blakely Miller and Dr. Marjory Buchan Miller, both of the Glasgow medical school, helped to carry on their father's practice there.

The CHAIRMAN OF COUNCIL, Dr. E. A. Gregg, writes: With the death of "J.B." a familiar and much-loved figure passed away—one of the old guard. He was a man of inflexible principle and great integrity and held in very high regard by all of us. His common sense and realistic approach to all problems was characteristic of all his contributions to debate, whether in Council or committee. His humorous asides and interjections during his chairmanship of the Representative Meetings were a delight and often a great help at a difficult moment.

Dr. J. B. Miller found the life of a family doctor a satisfying and good one, and he had no use for moaners and grumblers. There must be a great number who found in him a friend and helper in their troubles and illnesses, whose kindly ministrations will long be remembered. All his friends rejoiced with him when his old university conferred upon him the honorary degree of LL.D. during our meeting in Glasgow. He loved to recall his early days as a student, and his speech—a special one of his—when he described the old "bone" room and many of the incidents of those days was a sheer delight to us all. We can ill afford to lose men such as "J.B." His memory and his influence on B.M.A. affairs will continue for a long time to come.

The CHAIRMAN OF THE REPRESENTATIVE BODY, Dr. I. D. Grant, writes: By the death of James Blakely Miller the West of Scotland has lost an outstanding personality. "J.B." as he was known affectionately to his innumerable friends, was essentially a B.M.A. man. During a long and happy life he had cultivated many interests and hobbies, and the demands of a busy practice were not easily satisfied. But, despite all these activities, the welfare of the B.M.A. was always his first consideration. He occupied almost every high office of the Association in Scotland, and when in 1954 his Alma Mater conferred upon him the degree of LL.D. his colleagues, even more, I think, than himself, were gratified at the honour which was given to a most erudite and greatly loved general practitioner.

As chairman of the Representative Body, even though his health was failing a little, he made the long journey to London gladly and unsparingly. He played his full part in all the committees of the Association, and his charm of manner and pawky humour quickly won him the affection as well as the regard of his colleagues in the south. I well remember the first occasion on which he took the chair. Some representatives at an early stage of a bleak and foggy morning were just a little intolerant of the rather boring speaker. "J.B." appealed to the meeting: "You might perhaps allow him to go on. We are rather anxious to fill in the time anyhow, as the Birmingham train is an hour late."

He served on the Medical Planning Commission in 1940 and was largely responsible for many of the constructive suggestions made by that body for an improved medical service, but which, unfortunately, were not implemented by the politicians who eventually introduced the National Health Service. Like so many of his generation, he did

not take kindly to nationalized medicine, and was happy to live in semi-retirement after the inception of the National Health Service.

As an after-dinner speaker he was unsurpassed, and the flights of fancy on which he embarked on these occasions will long remain a pleasing memory to those of us who were privileged to hear him speak. However, the most outstanding service he rendered to the Association was one of which he himself was quite unconscious—that was his influence over his younger colleagues and his ability to arouse in them a desire to take part in B.M.A. work. By precept and example he showed us how much one man could do in the service of his fellows. He had a genius for friendship, and I do not think he had a single enemy. We know that the salutation which awaits him is, "Well done, thou good and faithful servant."

Dr. GUY DAIN writes: A Scot with so many of the good qualities of his race, J. B. Miller was not easily provoked to speech, but when he spoke it was with both wisdom and wit. He could, and frequently did, provide the short, snappy, and completely appropriate comment in the course of a discussion, and not infrequently when in the chair of the Representative Body. His speech proposing the health of the chairman of the R.B., then Sir Henry Brackenbury, was a masterpiece of humour and sly fun. But then he was to the B.M.A. over a long spell of years a wise counsellor and leader whose advice was always the result of careful thought and balanced judgment. For those of us who for so long have been associated with him in the work at Headquarters, his cheerful friendship and always helpful advice will be a great loss.

H. W. BARBER, M.B., F.R.C.P.

British dermatology was bereft of two eminent figures on the same day, January 13—Dr. H. W. Barber, of Guy's, and Dr. W. J. O'Donovan, of the London Hospital, to whom an obituary tribute appears on the next page. Both men were born in the same year. The careers of both in their first hospital appointments were interrupted by service in the first world war. Both gained a high reputation in dermatology and made contributions to its literature. Both were in consulting practice in the Harley Street area, within a couple of hundred yards of each other. Both became presidents of the Section of Dermatology of the Royal Society of Medicine. Dr. Barber, unlike Dr. O'Donovan, confined his activities to his profession and did not enter public life, but among his dermatological colleagues he was recognized as one who spoke with authority and out of wide experience. In the Dermatological Section, which every month holds a clinical discussion on a series of cases, Dr. Barber was a constant contributor, bringing forward unusual cases of his own and commenting in his thoughtful and often provocative way on the cases of others.

Harold Wordsworth Barber, the son of a Nottingham solicitor, was born on May 13, 1886. He was educated at Repton, and from there went on with a scholarship to Clare College, Cambridge, obtaining first-class honours in the Natural Sciences Tripos in 1908. His medical training was taken at Guy's, with which hospital he was associated until the end of his life. He graduated M.B., B.Ch. Cambridge, in 1911. In the following year he obtained the Arthur Durham Travelling Scholarship of Guy's, which enabled him to study dermatology in Paris and also at Hamburg, where he learned from the celebrated dermatologist, Professor Unna. He returned to be medical registrar at Guy's from 1913 to 1915, and took the M.R.C.P. at this time. In the first world war

he joined the R.A.M.C. for service in India, Mesopotamia, German East Africa, and France. After the war he returned to his registrarship at Guy's and in 1919 was appointed physician to the skin department. From this time onwards he quickly made his reputation in the specialty he had chosen. He remained on the active staff of his hospital until 1951, when he became consultant to the department. He was also consulting dermatologist to the Royal Navy, and served at various times on the honorary staffs of the Prince of Wales and the Evelina Hospitals. A past-president of the British Association of Dermatology, he was a corresponding member of the French, German, and Vienna Dermatological Societies. He became Fellow of the Royal College of Physicians in 1922. His Lettsomian lectures to the Medical Society of London in 1929 were on the subject of "Dermatology in Relation to other Branches of Medicine" and were published in a shortened version in this *Journal*. At the Annual Meeting of the B.M.A. in 1932 Barber was president of the Section of Dermatology and Venereal Diseases. He contributed to the journal's numerous papers on dermatological and more general medical subjects, and was responsible for the section on diseases of the skin in Taylor and Poulton's *Medicine*. In 1952 he gave the Prosser White Oration.

He married Juliette Louise, daughter of Madame Veuve Champrenand, of Paris; they had no family.

We are indebted to Dr. L. FORMAN for the following appreciation: The passing of Dr. H. W. Barber will give deep sorrow to his friends, his colleagues, and to the large number of patients who were grateful for his skill and sympathetic understanding. He was one of the best known of British dermatologists at home and abroad. Visiting dermatologists to this country would always be found at some time or another in Dr. Barber's clinic at Guy's, and they had great respect and affection for him. Indeed, he was a worthy representative of the medical profession. Impressive and handsome of appearance, he kept his youthful figure and carriage to the last. He was fluent in conversation, and his intellectual quality and capacity were soon apparent.

His interests were wide, and in all of them a tenacious memory and an active interest enabled him to discourse on literature, the theatre, racing, cricket, and other sports. On all these subjects his views were original, occasionally iconoclastic, and revealed the consideration of a contemplative man on the trends and achievements of this century.

Dr. Barber began his postgraduate career as a general physician, and was a most successful medical registrar at Guy's at a time when there were only two registrars in the medical wards; all those who were in the wards at that time testify to his ability and the facility with which he could impart his knowledge. It was with this background of general medical knowledge and training that he approached dermatology, and it gave him the ability to excite the interest of students and postgraduates in the specialty. His careful and minute study of the skin lesion was integrated with his assessment of the patients' personality and medical status in a way that can rarely have been equalled. His

opinion was an excellent one, based on a wide reading in medicine, and his management of the case was a model in the art of therapy.

Dr. Barber wrote fluently and well. He anticipated and stimulated much of the work indicating the importance of disorders of metabolism, endocrine changes, psychological disorders, and chronic infection in the genesis of skin reactions. Of his numerous writings two give the measure of his comprehensive approach and grasp of the problems of medicine and well repay frequent reading. The first is the Lettsomian Lectures, already referred to, and the second, his Prosser White Oration, "What is Truth?" published in the *Transactions of the St. John's Hospital Dermatological Society* in 1953.

Those of us who were trained by Dr. Barber will be ever grateful for the experience. He could make one see and understand. His knowledge of the fundamentals of medicine and of dermatology enabled him to present every case in a manner that provoked interest and thought and a determination to enlarge one's knowledge and experience. To his juniors he was kindness itself, and took the greatest pleasure in their progress and success. He never condescended, and was eager to refer to the observations and publications for which they were responsible. Dr. Barber's contributions to medicine will not be ignored, and in our hearts he will live. To his widow we extend our deepest sympathy.

A. E. S. writes: When I first went into the wards at Guy's H. W. Barber was a medical registrar. He was a quiet, charming personality. In many rounds with him, one in particular is remembered. He talked about agnosia, alexia, etc. He said that in reading up any subject it was well to read it in as many books as possible. I have seen him on many occasions since and have been his patient. He was admired and respected by all.

W. J. O'DONOVAN, O.B.E., M.D., M.R.C.P.

The death was announced on January 13 of Dr. W. J. O'Donovan, who was for a quarter of a century physician in charge of the skin and phototherapy departments of the London Hospital and lecturer on diseases of the skin and on syphilis at the Medical College. Dr. O'Donovan was well known in many spheres—medical, political, and religious—and in all of them his ebullient personality, his wit and repartee, and his good-humoured zeal in controversy made a marked impression.

William James O'Donovan was born in Kent in 1886, but his family was from County Cork. He was a student at London University, entering the London Hospital Medical College in 1905 and qualifying in 1909. He graduated M.B., B.S. in 1911, proceeded M.D. in 1913, and took the M.R.C.P. in 1914. After qualification he held for over a year the post of pathological assistant at his hospital and at a later period he was for some time junior assistant director at the pathological institute there. During the first world war he was chief medical officer to the Ministry of Munitions, and for his services was made O.B.E. in 1920. He went on to widen his experience in general medicine and surgery and then returned to the London as first assistant in the skin and light department. In his early days as physician he had charge of the syphilis block and later of the syphilis out-patient clinic until a separate venereal diseases clinic was established under the authority of the London County Council in 1930. After a quarter of a century at first as assistant physician and then as physician he retired in 1952.

A well-known dermatologist, O'Donovan combined with his dermatology an interest in pathology, in order, as he said, to prevent himself from becoming what his

chief, J. H. Sequeira, once described as a "pimple doctor." At one time he was coroner's pathologist for London. Perhaps his most outstanding contribution to dermatology was his exposition of emotional factors in skin disease. This aspect was much neglected by physicians thirty years ago when he wrote his *Dermatological Neuroses*. A considerable textbook of his on *Diseases of the Hair* was written in a fortnight. He made contributions on a wide range of subjects, including industrial dermatitis and cancer and T.N.T. poisoning (he was a member of the Government T.N.T. Committee). For a time he assisted in the editorship of the *British Journal of Dermatology*. He was consulting physician to the skin department of Queen Mary's Hospital, Stratford, and to a number of other hospitals; consulting dermatologist to Dr. Barnardo's Homes; and lecturer at the London Institute of Dermatology, St. John's Hospital. In the second world war he served

(Elliott and Fry)

in the R.A.M.C. from 1939 to 1945, when he was released with the rank of lieutenant-colonel. He held the appointment of adviser in dermatology to the Middle East Forces in Egypt and Palestine. He was an assistant examiner in medicine in the University of London, and in 1952 he was elected a representative of the Faculty of Medicine on the standing committee of convocation of the University.

For seven years Dr. O'Donovan was honorary secretary of the Marylebone Division of the British Medical Association, for two further years its chairman, and for four years he represented it in the Representative Body. In 1933 at the Annual Meeting at Dublin he was president of the Section of Dermatology, and in 1939-41 president of that section of the Royal Society of Medicine.

During the general strike of 1926, when the electricity supply to the London Hospital was cut off, his energetic and public protest brought him with a bound into national politics, and in 1931 he was returned to Parliament as Conservative member for the Mile End division of Stepney, in which the London Hospital stands. His reversal of a 6,000 Labour majority was a tribute to his personality rather than an endorsement of his politics; he failed to hold the seat at the General Election in 1935, and was similarly unsuccessful in 1950 in opposing Dr. Edith Summerskill in West Fulham. He did not fit very well into Parliament. He was not able, as the members of the old Nationalist party were, to adapt his Irish exuberance to the constraints of Parliamentary procedure, but on the political platform, especially with an antagonistic audience, he was in his element. He occupied various positions of prominence in the Conservative Party, and was president of the University of London Conservative Association.

Dr. O'Donovan was a devout Catholic, and never hesitated to introduce Catholic doctrine into medical or political discussions. For more than 30 years he was honorary secretary of the Guild of St. Luke, SS. Cosmas and Damian. In 1951 he received from the Pope the

honour of the Knighthood of St. Gregory the Great. Just before the second world war he was appointed by the Cardinal Archbishop of Westminster the leader of Catholic Action in England.

He married Ethel K. Smith, who was a great help to him in his professional and public life, and they had one son and two daughters.

We are indebted to Dr. BRIAN RUSSELL for the following appreciation: Dr. O'Donovan succeeded Dr. Sequeira as physician to the skin department at the London Hospital in 1926 and held the post for 26 years. The esteem in which he was held was indicated by a following of 70 students and doctors on his last teaching round. He had an extensive training in general medicine and pathology before taking up dermatology, and he always maintained a practical interest in morbid anatomy, holding that the post-mortem table was as conducive to right thinking and the pursuit of truth as laboratory work at a teak bench. During the second world war he served in the Middle East, and those who trained with him at Tidworth will never forget the zest with which he applied himself to adjustment from civilian to military habits.

Dr. O'Donovan will be remembered as one of the great personalities of the medical profession during the first half of the twentieth century. He had an ebullient mind with ready wit and unfailing repartee suitable for every occasion. He was more interested in sick people with their skin affections than in hair-splitting arguments over individual spots and pimples: he believed in the importance of emotional factors in the genesis of many common dermatoses, and wrote a short monograph, *Dermatological Neuroses*, in 1927 which was the prototype of much writing on dermatology from its psychiatric aspects.

Those who were fortunate enough to attend his political meetings will never forget his oratory and ability to cope with hecklers, which soon earned him the right to sit in Westminster. Hearing him giving evidence in court made one think that he might have made just as successful a career in the legal profession as in medicine. Always cheerful in adversity, he could joke about his own illness even after the first of the three episodes which progressively struck him down. All those who have enjoyed his quips and sallies, and who have thus found the acquisition of knowledge less tedious, owe a debt of gratitude to this irrepressible and irreplaceable personality for having observed when he first came to the London Hospital the inscription over the Medical College doorway, *Amara lento tempera risu*, which may be very freely translated, "Temper the bitter things of life with a smile."

Dr. PATRICK HALL-SMITH writes: I should like to pay tribute to the late Dr. W. J. O'Donovan, with whom I was closely associated, first in the Army, and then as his senior registrar at the London Hospital. In the difficult years just after the war no young dermatologist could have served a more stimulating or considerate chief, and many besides myself owe their careers to his championship and guidance. "O'D," as he was popularly known, had a great presence and a truly sparkling personality; he was a gifted and original speaker, possessing a lively forensic skill in argument. Always an individualist, he wore a scarlet-lined cloak during his Army service, and discomfited a series of inspecting generals who imagined they were conversant with military law. Hecklers at West Fulham in the 1950 election also found the contest unequal. His learning and intellect were apparent, but those who knew him well recognized too a man of strong faith and courage. Generations of old-Londoners will recall him as an exceptional clinician and teacher, and as one who was never dull; his colleagues in dermatology mourn a unique and lovable personality whose provocative statements enlivened many a dreary meeting. He will not be forgotten, and his writings will live on as an important contribution to British dermatology.

G. V. ANREP, M.D., D.Sc., M.Sc., F.R.S.

Dr. G. V. Anrep, professor of physiology in Fouad I University, Cairo, died in Cairo on January 9, aged 63.

Gleb V. Anrep was born in St. Petersburg, the son of Basil von Anrep, who studied the action of cocaine and in 1880 suggested its use as a local anaesthetic. From the University of Dorpat he went on to study medicine in St. Petersburg. Before qualifying in medicine in 1914 he worked for a time as demonstrator of physiology in the Military Medical Academy at St. Petersburg, and he had also visited London and worked in the physiology department of University College. During the war he served as a medical officer in the Russian Army until 1917 and then returned to St. Petersburg as senior assistant in physiology at the Institute of Experimental Medicine in that city. He joined the forces of General Denikine, who fought against the Bolsheviks, and not long afterwards he had to leave Russia. Settling in London, he was first appointed assistant, then in 1923 senior assistant, and finally in 1926 reader in physiology at University College. He obtained the D.Sc. degree in physiology in 1923 and was awarded the Schäfer Prize and William Julius Mickle Fellowship two years later. He became a naturalized British citizen in 1925. Before going to Cairo as professor of physiology in 1931 he was for a time a lecturer in physiology at Cambridge, and also Cooper-Lane lecturer at Stanford University, San Francisco. He was elected F.R.S. in 1928.

Most of Anrep's studies were on the circulation, and he published numerous articles in the *Journal of Physiology*, the *Proceedings of the Royal Society*, and other journals. His Lane Medical Lectures were published in book form in 1936 under the title *Studies in Cardiovascular Regulation*. Anrep was a former pupil and collaborator of Professor Pavlov, and in 1927 he translated and edited Pavlov's book, *Conditioned Reflexes*, which had been published in Russian in the previous year. This was a most important piece of work, for it was the first time that a full account of Pavlov's researches had appeared in the English language. Apart from the ordinary difficulties of translation, Anrep had to cope with an entire new terminology. The result was remarkably successful.

G. H. G. writes: G. V. Anrep was a pupil of Pavlov and played an important part in making conditioned reflexes known outside Russia. He had paid a short visit to University College, London, before the first world war, and came back there in 1918 owing to political events in Russia. He thus came under the influence of Starling, and soon showed that he was a skilful experimenter who could make heart-lung preparations more rapidly than other people. He published a series of papers on the metabolism of the salivary glands and on the regulation of the circulation. With Starling, and with other people, he carried out elaborate experiments such as the perfusion of the head and neck by means of a heart-lung preparation, and worked out details of the reflexes controlling the circulation. He was elected F.R.S. in 1928 at the early age of 37. At about this time he added much to our knowledge of the coronary circulation and the circulation in voluntary muscles, proving that the actual contraction of the muscles caused a stoppage of the flow, and recording the reactive hyperaemia which followed even when the flow was stopped for a fraction of a second. This work is summarized in the Lane Medical Lectures which he gave at Stanford University in 1936.

In Egypt Anrep became interested in histamine, and published a series of papers with G. S. Barsoum and others

on the physiology of this substance. He was the first to show that normal urine contains not only free histamine but also inactive conjugated histamine, and that this comes from the intestine. He discovered the first histamine-releaser, tubocurarine.

He was proud of his British nationality, but this cannot have helped him when, a few years ago, his career was again interrupted by political events and he had to give up work in the laboratory. He was an energetic and enterprising person with many interests. He learned Arabic well enough for intelligent discussion of the world's affairs. He drove an old Ford car on expeditions across the desert which more cautious people regarded as foolhardy. He was an enthusiastic philatelist who had an arrangement with postmasters in Cairo which led to the discovery of what he called "the Anrep variations." He was very good company and fond of telling dramatic tales about himself; it is sad that we shall hear him no more.

Sir ARTHUR KEITH, M.D., LL.D., D.Sc.
F.R.C.S., F.R.S.

Dr. F. PARKES WEBER writes: Everyone knows of Sir Arthur Keith's enthusiasm in regard to the collection of skulls when he was conservator of the Museum of the Royal College of Surgeons, London. He was not contented with one specimen of the skulls of any particular class of natives, but preferred to have a considerable number for purposes of comparison. Shortly before the first world war a cousin of mine, who was somewhat of an amateur anthropologist, lived in a flat close to the British Museum. He possessed a small collection of skulls of the aborigines of a small island in Oceania. As he was going to be married he wished to get rid of these skulls in deference to the wish of his fiancée. He thought of presenting them to the collection of Sir Arthur Keith. The latter invited my cousin to dinner with him at a Holborn restaurant, in order to discuss the matter. After the meal Sir Arthur said to my cousin: "If you don't give me those skulls I'll have yours." This so tickled the fancy of my cousin that, if he had not already made up his mind, he decided to present the collection to the Royal College of Surgeons. Subsequently, after my cousin had returned from Salonika, where he had served during the war, I saw a good deal of him and he told me the above story.

A memorial service for the late Sir ALFRED B. HOWITT, C.V.O., M.D., will be held in the chapel of St. Thomas's Hospital, London, S.E.1, at 12.15 p.m. on Thursday, January 27.

Medico-Legal

BABY'S DEATH FROM BORON POISONING

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On November 23, 1954, the inquest was concluded at Ealing before Mr. H. G. Broadbridge, coroner for West Middlesex, on a 3-months-old baby boy called Tony Smith, who died on September 28, 1954, from boron poisoning.

The baby had been a little sore about the buttocks and between the legs. His mother asked in a chemist's shop for a boracic powder and told the chemist what she wanted to use it for. She was sold some powder in a little cardboard drum. The powder had no smell and the child's grandmother thought that the drum was labelled "boracic acid powder."

After the powder had been used for about a week the baby seemed ill, and on September 19 he was admitted to Hillingdon Hospital suffering with severe vomiting and diarrhoea. He also had a ruptured navel. Three days later

Dr. H. V. L. Finlay, the paediatrician at Hillingdon Hospital, diagnosed poisoning by boracic acid, and the whole skin, including that inside the nose and mouth, began to peel. The boron content of the urine was found to be 28.7 mg. per 100 ml. Six days later the baby died.

In evidence Dr. Finlay said that the raw condition of the baby's napkin area on admission to hospital was ideal for the absorption of boric acid. He had never seen any harmful effects from the use of boric acid preparations, but emphasized the danger of using pure boracic acid in powder form, and thought it should not be sold indiscriminately over the counter.

Dr. Donald Teare, who made the post-mortem examination, found the boric acid content of the brain to be 13 mg. per 100 g., of the lung to be 28 mg. per 100 g., and of the kidney to be 33 mg. per 100 g., which together with the amount in the urine previously estimated was within the range in which boron poisoning occurs. Dr. Teare said that ordinary powders sold for babies usually contained 5 to 10% of boric acid, and that of the 37,000 necropsies he had made this was the first occasion on which he had found boric acid poisoning. He thought that what had happened was that the baby's mother had been sold neat boric acid as a powder.

A verdict of death by misadventure was recorded.

Vital Statistics

Influenza

A few more outbreaks of virus-B influenza had been reported up to January 17, and the increases in the weekly claims on the Ministry of Pensions and National Insurance suggest a greater prevalence among adults. In London reports of sickness indicate the probable presence of influenza, and in the environs the situation is much the same. In the northern half of the country and in Wales the disease is waning; in the southern half it is still advancing here and there, particularly in the eastern region, but progress is slow. Clinically the infection is usually mild. Laboratory reports continue to confirm most of the outbreaks as being due to virus B, but two patients in the midlands have been proved to be suffering from a virus-A infection. No spread from either has been traced.

Smallpox in France

A message from the French Ministry of Public Health and Population, dated January 8, reports the number of cases of smallpox in the Vannes area as 25, including two deaths, though a press report from Paris dated January 12 gives the number of cases as 40, including 4 deaths. The first case occurred at the beginning of December, 1954, in an unvaccinated child aged 1 year. The child's father had returned 10 days previously from military duties in Indo-China, where he had been in a hospital in which cases of smallpox were being treated.

Causes of Death in June Quarter

In England and Wales in the June quarter deaths from respiratory tuberculosis (1,657) were 9% fewer than in the corresponding period of 1953. Cancer deaths were slightly more—21,826 as compared with 21,451; but deaths from cancer of the uterus (888) were 12% below those in the second quarter of 1953. Accidental deaths rose to 3,633 (3,272 in June quarter, 1953). This was mainly accounted for by increases in accidental poisoning (243 deaths compared with 177 a year earlier), falls (1,249 compared with 969), and burns (166 compared with 146). The number of suicides (1,415) was the highest since the June quarter, 1939.

England and Wales Population

The home population of England and Wales has increased by over 500,000 since census day (April 8, 1951), according to the Registrar-General's estimates published in the Return for the September Quarter, 1954. It is given as 44,480,000 (21,492,000 males and 22,988,000 females).

Week Ending January 8

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 463, whooping-cough 1,791, diphtheria 13, measles 9,385, acute pneumonia 1,135, meningococcal infection 42, acute poliomyelitis 25, dysentery 346, paratyphoid fever 4, and typhoid fever 4.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

A rise occurred in the incidence of infectious diseases in England and Wales during the week ending January 1. The increases in the number of notifications included 2,480 for measles, from 5,840 to 8,320, 466 for whooping-cough, from 1,256 to 1,722, 352 for acute pneumonia, from 756 to 1,108, and 34 for scarlet fever, from 673 to 707.

The largest increases in the incidence of measles were 598 in Lancashire, from 1,912 to 2,510, 438 in London, from 550 to 988, 228 in Essex, from 341 to 569, 159 in Derbyshire, from 69 to 228, 155 in Warwickshire, from 172 to 327, 145 in Yorkshire West Riding, from 558 to 703, and 122 in Durham, from 306 to 428. The largest rises in the number of notifications of whooping-cough were 56 in Lancashire, from 127 to 183, and 50 in Durham, from 85 to 135. Only small variations were reported in the local trends of scarlet fever. 13 cases of diphtheria were notified, being 2 fewer than in the preceding week. The areas with multiple cases of diphtheria were Lancashire, Liverpool C.B. 4, Warwickshire, Birmingham C.B. 3, Surrey, Epsom and Ewell M.B. 2.

23 cases of acute poliomyelitis were notified; these were 13 more for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were London 5 and Middlesex 3.

340 cases of dysentery were notified—the same total as in the two preceding weeks. The chief centres of infection were London 57 (Hackney 17, St. Marylebone 11), Norfolk 57 (Norwich C.B. 41), Lancashire 56 (Oldham C.B. 14, Liverpool C.B. 13), Yorkshire West Riding 24, Warwickshire 18 (Birmingham C.B. 17), Lincolnshire 18 (Scunthorpe M.B. 18).

82 deaths were attributed to influenza in the great towns, a rise of 26. The largest totals were Manchester C.B. 8, Birmingham C.B. 7, Nottingham C.B. 6, Wolverhampton C.B. 5.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 1, 1955 (No. 52), and corresponding week 1953-4.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 166 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrar-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1954-5					1953-4

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Association of British Pharmaceutical Industry.—The Association of the British Pharmaceutical Industry celebrated its 25th anniversary last week by publishing a booklet describing the history and work of the association and by holding a reception which was attended by the Minister of Health, Mr. IAIN MACLEOD, and his Parliamentary Secretary, Miss PAT HORNSBY-SMITH. Mr. J. F. BOUCHER, the president of the A.B.P.I., made a short speech at the reception, introducing the Minister. Mr. MACLEOD said that when he heard that the A.B.P.I. was holding its reception in the Great Hall of B.M.A. House he thought of his own position as being rather like Daniel accepting an invitation to be chief guest in the lions' den. Referring to the resentment which some people felt about Treasury control and investigations, Mr. Macleod said that such investigations were inseparable from a national health service. An industry of the importance and with the achievements of the British pharmaceutical industry had no need to fear these investigations. He himself was very conscious of the contribution the industry made to the life and health of the nation.

Ceremony at Nuffield Orthopaedic Centre.—On January 4 portraits of Lord Nuffield and the late Mr. G. R. Girdlestone, F.R.C.S., were unveiled at the Nuffield Orthopaedic Centre, Oxford, by the Vice-Chancellor of the University, Mr. A. H. SMITH, and Professor J. TRUETA (in the absence of Lord Nuffield). Speaking at the ceremony, Sir ROBERT MCCARRISON said that, not long after qualifying, Mr. Girdlestone had injured himself in a motor-cycle accident, and after this he decided to devote his life to the care of cripples. His work extended steadily, but by 1930 the huts of the orthopaedic centre were beginning to deteriorate. Lord Nuffield had then provided money to rebuild the hospital, and it was reopened in 1933 as the Wingfield-Morris Orthopaedic Hospital. Mr. Girdlestone always had a feeling of mission in life; he had not only got the hospital going but had imprinted on it his own spirit of service, friendliness, and happiness. Professor TRUETA said that Lord Nuffield and Mr. Girdlestone had met early in their lives. Although different in temperament and ideals, between them they had been able to make the hospital what it was to-day. The portrait of Lord Nuffield, by John Whalley, was presented by Lady Nuffield. Mr. Girdlestone's portrait, painted from a photograph by Frank Eastman, was subscribed for by patients and friends.

E.B.S. at Work.—The Emergency Bed Service invites all hospital admission officers in the Greater London area to visit the service's operations room at Fielden House, 28, London Bridge Street, London, S.E.1, to study its work. An appointment should be made by telephone (HOP 7181).

Sir Allen Daley has been elected chairman of the National Association for Maternal and Child Welfare.

COMING EVENTS

Liverpool Medical Dinner.—The annual dinner for past and present medical students of Liverpool University will be held on February 3 at the Bluecoat Hall, Bluecoat Chambers, at 7.30 for 8 p.m. Mr. A. A. GEMMELL, P.R.C.O.G., will be the guest of honour. Tickets (21s.) from H. DINNICK, Medical School, Liverpool.

Hunterian Oration.—Sir CECIL WAKELEY, Bt., will deliver the Hunterian Oration at 4 p.m. on February 14 at the Royal College of Surgeons, Lincoln's Inn Fields. He will speak on "Hunter and Surgical Research."

Fourteenth International Congress of Pure and Applied Chemistry.—The congress, which covers organic chemistry, will be held in Zurich from July 21 to 27. All those wishing to participate are asked to notify the secretary-general, XIVth International Congress of Pure and Applied Chemistry, Zurich, 1, Switzerland, not later than February 15.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, January 22
INSTITUTE OF ORTHOPAEDICS.—10 a.m., clinical demonstration by Mr. D. Trevor.

Monday, January 24
INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: Lecture-demonstration.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Mr. D. MacG. Jackson and Dr. W. M. Levitt: Burns and their Treatment.

Tuesday, January 25
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. Janet Vaughan: Radiation Effects on Bone.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: Lupus Erythematosus.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. J. D. S. Flew: Induction of Labour.

Wednesday, January 26
BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. M. S. Jones: Concept of a Therapeutic Community.
HARVEIAN SOCIETY OF LONDON.—8.15 p.m., annual general meeting. Presidential Address by Dr. R. Cove-Smith: Fitness, Facts and Fallacies.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Pathology of Lupus Erythematosus.
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—5.30 p.m., Professor F. C. Ormerod: Types of Deafness.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. C. E. Dukes: Pathology of Calculous Disease.
NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—8.30 p.m., Mr. J. H. Kellgren: Rheumatism.
SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP.—At Chemical Society, Burlington House, W., 6.30 p.m., meeting of Nutrition Panel. Mr. E. M. Learmonth, M.Sc., F.R.I.C.: Soya in the Field of Nutrition.

Thursday, January 27
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor C. H. Gray: Chemistry of the Porphyrins.
GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7 p.m., Debate with Royal Medical Society.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. A. S. Woodcock: Diagnosis of Gynaecological Conditions by the Examination of Smears; Dr. D. G. Miller: Diagnosis of Carcinoma of the Lung by Examination of the Sputum; Dr. J. H. Pettit: Histological Study of "Leucoplakia Vulvae."
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. Macdonald Critchley: The Body Image.
RENAL ASSOCIATION.—At the Ciba Foundation, 4.30 p.m., Mr. D. Innes Williams and Dr. R. Pugh: Renal Hypoplasias; Dr. S. W. Stanbury and Dr. M. D. Milne: Base Losing Nephritis.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Mr. H. B. Stallard: Retinoblastoma Treated by Radon Seeds and Radium Disks.
ROYAL MEDICAL SOCIETY, Edinburgh.—At Glasgow, 8 p.m., debate with Glasgow University Medico-Chirurgical Society. Motion: That the Resident is the Cinderella of the National Health Service.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. J. W. Smith: Postural Mechanism of Joints.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: neurology demonstration.
SOCIETY FOR ANALYTICAL CHEMISTRY: WESTERN SECTION.—At Bristol University, 7 p.m., Dr. E. Windle Taylor: Recent Advances in the Bacteriological Examination of Water.

Friday, January 28
●INSTITUTES OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. S. C. Gold: Lupus Erythematosus.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Mr. V. C. Thompson: Tumours of the Lung I.
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—5.30 p.m., Mr. Maxwell P. Ellis: Ulcers of the Mouth and Pharynx.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. B. McN. Truscott: Carcinoma of the Female Breast. (2) 4 p.m., Dr. H. S. Banks: Question and Answer on Common Infectious Diseases.
●ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. E. McC. McGirr: Radioactive Isotopes.
ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dissertation by Mr. A. A. Russell: Medicine and Atomic Warfare.
ROYAL MICROSCOPICAL SOCIETY.—At King's College, Newcastle-upon-Tyne, 6 p.m., Dr. Geoffrey Bourne, D.Phil.: The Living Cell.

Saturday, January 29
●UNITED NATIONS STUDENT ASSOCIATION.—At London School of Hygiene and Tropical Medicine, 2 to 7 p.m., conference on World Health.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS
Lawler.—On January 6, 1955, to Sylvia D. Lawler, M.D., wife of L. J. Lawler, 34, Wolsey Road, London, N., a son—Anthony John.
Sachett-Kaye.—On December 29, 1954, to Dr. Beryl (formerly White), wife of A. I. Sachett-Kaye, M.D., M.R.C.P., a son—Richard St. John Clarence.
Tucker.—On January 5, 1955, at the Rubislaw Nursing Home, Aberdeen, to Helen (formerly Rennie), wife of Dr. Hugh M. Tucker, Urquhart Villa, Lossiemouth, Morayshire, a sister for Malcolm, Gillie, and Mandy—Sally Ann Richardson.
Warren Browne.—On January 8, 1955, at King's College Hospital, London, S.E., to Muriel, M.B., Ch.B. (formerly James), wife of Dr. D. Warren Browne, of Cowes, Isle of Wight, a daughter.

DEATHS
Devitt.—On December 26, 1954, at Hermanus, Natal, South Africa, Denis Christian Devitt, M.R.C.S., L.R.C.P., F.F.A.R.C.S., formerly of Northwood, and Rustip, Middlesex, aged 48.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

How Much Sleep for Young Children?

Q.—I should like to know what is the consensus of medical opinion regarding the number of hours of sleep which a healthy, extremely active child of 3 years should have. Also, whether it is considered advisable that such a child should have a mid-day sleep or rest.

A.—Perhaps more important than the consensus of medical opinion is the individuality of the child. Many notably active children are especially so at the age mentioned, thrive satisfactorily although sleeping less than might be expected, and by the time of their fourth birthday sleep heavily in the way characteristic of the older child. Allowing that individual requirements vary considerably, a child of 3 can be said to require about 12 hours' sleep in the 24 hours. A mid-day sleep is not essential and should not be insisted upon if it results in too little sleep or in prolonged delay in going to sleep at night. On the other hand, a mid-day rest is desirable, as the relaxation will conserve the physical reserves of the very active child.

Lack of Sexual Desire at Menopause

Q.—I have a patient who is 45 years old, with five children. She is now at the menopause and has no desire for sexual intercourse. Could you advise an aphrodisiac drug which could be used with safety?

A.—Although it is natural for sex drive to weaken with advancing years, the menopause itself should not result in loss of desire unless the woman concerned expects it to do so. Many women tend to regard the change of life as the end of life so far as sex function is concerned, and it is this attitude rather than any hormone change which may cause frigidity. In fact, women with a proper outlook may continue to desire and enjoy coitus after the menopause; some even go through a phase of increased desire. In the case cited there may be other factors concerned as well—fear of pregnancy, for example, which so many women experience as they approach the menopause. But, whatever form they take, the factors are likely to be psychological rather than endocrinological.

There are no aphrodisiac drugs of real value, and, even if it would help, oestrogen therapy is not indicated because of possible undesirable side-effects. It is claimed that androgens in small doses can increase libido in women, but the evidence is not very convincing, and inert tablets sometimes have an equally good effect.

Antibiotics in Tetanus

Q.—What antibiotics are the best to use in the treatment of tetanus? How effective are they?

A.—Two possible effects of antibiotics in tetanus must be distinguished, that on the primary disease and that on complications, particularly pneumonia.

Cl. tetani is moderately sensitive to penicillin (inhibited by about 0.1 unit/ml.), and an effect on the multiplication of this organism in the body can therefore be expected. Clinical evidence of the usefulness of penicillin in modifying the course of the disease is contradictory. Buxton and Kurman¹ used it as an adjuvant to treatment with antitoxin and sedatives in two cases; Diaz-Rivera *et al.*² used it in 10 cases out of a series of 59: in each of these papers it is concluded that penicillin is of value, but the findings have no statistical significance. Altmeier³ used penicillin in 13 out of a series of 16 cases, and regarded it as of no

value; the dose used was small by present-day standards. Perhaps the main argument against the efficacy of antibiotics in tetanus is the fact that complete excision of the wound often fails to save life. If total removal of the focus of infection—often a simple procedure, since a small punctured wound is a frequent cause—is ineffective, what can be expected of chemotherapy? It has to be concluded that toxin already formed and fixed in the central nervous system can cause death despite all measures to prevent its further formation.

The prevention of pneumonia is a legitimate indication for the use of antibiotics in tetanus, and penicillin is commonly used for this purpose. There is no information on which to decide whether any of the broad-spectrum antibiotics would be more effective. This aspect of the problem differs little from that of preventing autogenous descending infections of the bronchi and lungs under other circumstances.

Myokymia

Q.—A man aged 43 years suffers from fibrillary movements all over the body. About nine months ago he had an attack of bacillary dysentery in South Africa, and the condition developed after that. He has been under my observation for the past five months, and the fibrillation appears spasmodically over the muscles of all four limbs, abdomen, and trunk, but no wasting has occurred. There is no loss of power, and both deep and superficial reflexes are normal. There is no pain, no loss of weight, or elevation of the temperature. What investigations are indicated? What are the treatment and prognosis?

A.—Widespread fibrillation or fasciculation in the muscles may occur without atrophy in persons who are without other symptoms, though it is sometimes associated either with an abnormal liability to muscular cramp, increased sweating, or both. This condition, known as myokymia, is quite harmless. Though the fasciculation, resembling as it does that of motor neuron disease, may at first give rise to anxiety, there is no development of weakness, atrophy, or signs of pyramidal disease. Nothing is known of the cause of this form of myokymia, but the writer has seen it in one instance follow an attack of dysentery. The myokymia may persist indefinitely, but does not as a rule trouble the patient when anxiety has been relieved. There is no treatment known to the writer which is effective.

Transfusion in Head Injuries

Q.—How should the principles of early transfusion in severe injuries be applied to the treatment of head injuries? Is not the maintenance of a good blood supply to vital centres, depressed by both local trauma and systemic shock, more important than the traditionally taught danger of increasing intracranial haemorrhage by raising the blood pressure?

A.—If a patient who has sustained a head injury has also lost a quantity of blood from a wound elsewhere and shows clinical evidence of this blood loss, it should be made good by transfusion. Should raising of the blood pressure give rise to further intracranial bleeding this must be recognized and treated, as it should be had there been no indication for blood transfusion.

On the other hand, a head injury alone, without external bleeding, would provide no indication for a blood transfusion. The state of cerebral concussion which immediately follows a head injury is recovered from rapidly and spontaneously in the great majority of cases. The pallor, low blood pressure, and shallow respiration which characterize this state are therefore not to be regarded as evidence of surgical shock. In more severe head injuries with contusion and laceration of the brain the clinical picture is not one of shock, and the pulse is slow with the blood pressure often

elevated. Though in the most severe injuries with brain-stem haemorrhages the pulse and respirations will be rapid, there is nothing to indicate transfusion in therapy. Of essential importance in cases of brain injury is the avoidance of cerebral anoxia by maintaining a clear airway. This can usually be effected by gentle suction through the mouth, but when this is inadequate tracheotomy is a life-saving measure.

Inhalation Therapy

Q.—What is the place of inhalations in modern therapy?

A.—The use of inhalations in modern therapy is very limited. Apart from the volatile anaesthetics, inhalations for nasal catarrh, and amyl and octyl nitrite, certain non-volatile substances can be thus administered. They may be in solution as adrenaline for asthma, or in fine suspension as penicillin for certain respiratory infections, although the employment of penicillin in this way is on the wane.

Although a great variety of drugs could be given by inhalation, there is no special virtue in this route apart from the rapid effect due to quick absorption. The amount absorbed cannot be controlled with any accuracy, and a danger of local irritation, as from the stramonium fumes of asthma cigarettes, must be borne in mind.

Aphthous Ulcers

Q.—A girl of 7 has for several years suffered from small painful ulcers of the mouth. Otherwise she is quite fit. She is about to start orthodontic treatment, and her dental surgeon insists that the ulcers should be dealt with before appliances are fitted. Can you suggest any investigations and treatment that may be profitably carried out? Vitamins A and B have been given and alkaline mouth-washes, with no improvement.

A.—Unfortunately the aetiology of aphthous or so-called dyspeptic ulcers still remains obscure in spite of the considerable amount of work done on the subject. They are now in fact thought to have no connexion with dyspepsia and are seen more frequently in females than in males. The ulcers are formed as a result of the breaking down of vesicles resulting from intra-epithelial oedema of the stratum granulosum of the oral mucosa.

Local antibiotics have been tried and some success has been claimed, but they are unlikely to prevent the formation of vesicles, although they may diminish the secondary infection when the vesicles break down. There is some evidence that the ulcers may be allergic in origin, and on this basis antihistaminics have been employed and success has again been reported. The formation of vesicles has also suggested the possibility of virus infection, and on this basis virus vaccines have been employed; again a small amount of success has been claimed. Vitamins A, B, and C have all had their adherents, but no sustained success has been reported. Local demulcent mouth-washes are of value, but the treatment often advocated—of painting the ulcers with a caustic—cannot be recommended, since this usually merely prolongs the healing process and does not prevent the formation of further ulcers.

NOTES AND COMMENTS

Home-made Anti-freeze.—Dr. G. W. FLEMING (Gosport, Hants) writes: Referring to the answer given to this question ("Any Questions?" December 11, 1954, p. 1434), what is wrong with industrial methylated spirit? I have used it for 40 years with complete success in a ratio of 1 to 7 parts of water. Have I just been lucky, and is not this mixture as reliable as I think it is? It is certainly cheap (3s. to 4s.) compared with other anti-freeze mixtures. It could boil off, I suppose, but I just keep my radiator topped up with 1 in 7 methylated spirit and water and have never had a freeze-up. I put an old Army blanket over my radiator at night as well, but my garage is unheated and without doors—just an open shed.

Dr. W. H. DICKINSON PRIEST (London, W.1) writes: I was more than somewhat shaken by your expert's statement that glycerin has a corrosive action, especially as I was just about to treat my car to its annual dose of one part in sixteen, as I

have done all my motoring life with nearly all my other cars. With great respect, may one inquire the basis for this statement? That it (and proprietaries) stir and scour up rusty sludge is admitted, but is not this a good thing for the next drain-out? If the proprietaries contained an anti-rust chemical, which I believe is general now in the U.S.A., one would not resent their expense so much, but so far as I know this has not reached this country yet. I am not aware of having suffered any ill effects ever from glycerin. I may add that I have asked several garage proprietors with whom I deal and they profess ignorance of the alleged corrosive action. I would be grateful for further information.

OUR EXPERT writes: The general position regarding the anti-freezes for car cooling systems can be briefly summarized as follows: There are a number of substances which, when added to the cooling water in the radiator, lower its freezing point sufficiently to prevent it from freezing in winter, without at the same time reducing the cooling capacity of the system. Unless inhibited by means of appropriate additives, however, every one of these anti-freeze solutions causes corrosion of the cooling system components, the intensity of attack depending to a large extent not only on the anti-freeze used but also on the combinations of metals found in the particular cooling system, type of car operation, etc. With ethylene glycol, methanol, and ethanol (as well as methylated spirit), which form the basis of most commercial anti-freezes, this attack is usually relatively mild, its intensity being of the order of that of ordinary water. The addition of special corrosion inhibitors greatly reduces this attack. It should perhaps be stressed at this point that such bodies as the Society of Automotive Engineers in America and the U.S. National Bureau of Standards consider the corrosive action of ordinary water in the radiator excessive for satisfactory operation of the cooling system, and recommend the use of corrosive inhibitors in cooling water in summer. With uninhibited glycol or alcohol in the radiator, it is improbable that any serious defects in the cooling system would become obvious in the first two or three years of operation, and, under favourable conditions, perhaps during the whole life of the car. The corrosive action of glycerin has been reported by the U.S. National Bureau of Standards in its Circular No. 506 of November, 1952. Also, the Swiss Society for the Study of Motor Fuels at Berne observed that the attack by glycerin, while generally low, assumed the particularly dangerous form of localized pitting of iron and solder metal. The composition of proprietary anti-freezes is not normally disclosed by the makers, but there is no doubt that most, if not all, of them do in fact contain corrosion inhibitors. In the formula recommended by the Chemical Research Laboratory, quoted in the *British Medical Journal* of December 11, 1954 (p. 1434), sodium benzoate and sodium nitrite perform this function. Finally, I should like to draw Dr. Dickinson Priest's attention to the fact that his one-in-sixteen solution of glycerin protects his cooling system against only 2 to 3° F. (1.1 to 1.7° C.) of frost. A one-in-seven solution of methylated spirit and the anti-freeze of the Chemical Research Laboratory give protection against about 7 and about 18° F. (3.9 and 10° C.) of frost respectively.

Skin Ink.—Dr. N. S. FINZI (Cobham, Surrey) writes: As the originator of the formula¹ given in reply to a question on skin ink ("Any Questions?" January 1, p. 55) I should like to add a few words of advice as to its use. It oxidizes readily and is then of no use for skin marking. To avoid this it should be made up in small quantities only, in small well-corked or stoppered bottles. In order to diminish the rate of oxidation, I use 0.2 ml. of sulphurous acid instead of the hydrochloric acid. It is not permissible to use it in radiotherapy patients in any part exposed to radiations, on account of secondary radiation from the iron: a solution of fuchsin is used for these, but it is not so permanent, if washed.

OBSERVATIONS ON THE TREATMENT OF PULMONARY TUBERCULOSIS AT THE PRESENT TIME*

BY

JAMES L. LIVINGSTONE, M.D., F.R.C.P.

Physician, King's College Hospital and Brompton Hospital, London

[WITH SPECIAL PLATE]

In previous Mitchell Lectures the emphasis has usually been on some aspect of tuberculosis as seen through the eyes of a physician engaged in clinical practice. In selecting a subject I was aware that the late Dr. F. G. Candler talked on the diagnosis and treatment of pulmonary tuberculosis in 1940, but so much has changed in the intervening 14 years with the advent of specific antibacterial therapy and the advances thereby made possible in thoracic surgery that I felt my observations on the present state of therapy in this disease might not be out of place. I shall deal with my own clinical material and with work in this country of which I have at least some slight personal knowledge.

We all admit that preventive medicine does far more in the eradication of tuberculosis than the puny efforts of the clinician in dealing with the sick; in Scandinavia, certain provinces of Canada, and some parts of the United States it would appear that clinical tuberculosis will disappear in the near future, as smallpox and diphtheria have in Great Britain.

The mortality from respiratory tuberculosis has shown a steady decline for the past century, save for the two world wars, but the fall since 1948 has been striking. From 1931 to 1939 the average total annual death rate for England and Wales was about 25,000; from 1940 to 1944 the figure was approximately 22,000, but in 1945 it was 20,000, and by 1953 it was just under 8,000. Whether this abrupt fall is related to antibacterial therapy is for the statistician to decide. The notification of new cases remains high—in the neighbourhood of 50,000 per annum since 1947—but has dropped from about 48,000 in 1952 to 41,000 in 1953. The number of non-notified deaths from respiratory tuberculosis is still high, even though it has fallen from 3,530 in 1937 to 2,239 in 1952 and 1,751 in 1953. Papworth has shown us that in the known case simple hygiene to prevent spread of infection is highly efficacious; it is the undiagnosed positive case which is the danger.

With mass radiography and improvement in the standard of chest clinics, the type of case seen at a London chest hospital has altered appreciably of late years, but the management of the symptomless case remains a real problem. Apart from cases found by mass radiography,

*Based on the Mitchell Lecture delivered before the Royal College of Physicians, London, June 18, 1954.

pulmonary tuberculosis seems to be changing its character, and we know that over 45% of probationer nurses and first-year medical students are Mantoux-negative when they first attend hospital.

Bed Rest

In recent years one of the greatest advances has been the Medical Research Council's trials of chemotherapy, with simultaneous clinical and scientific observations on large numbers of patients with similar types of disease, using control cases, and with a panel examining results dispassionately. For this we owe much to the late Dr. Marc Daniels. In the first streptomycin trials in 1947-8 the control cases were given six months' proper bed rest, and the improvement in a proportion of these was impressive. Dr. Wallace Fox, in a personal communication, has told me that 17 of the original 52 control (acute bilateral) patients are still alive after five years; most of these were not given chemotherapy for the first two years, although many had collapse measures.

In my experience, in the newly diagnosed case the incidence of "extension" of disease during the period of a few weeks while the patient is awaiting admission to hospital is alarming. Explicit and simple instructions on the details of bed rest at home must be given to the patient. My directions are that he must have the foot of the bed raised on two bricks and use no more than two pillows; he is allowed up once a day only, for toilet purposes and to wash and shave, otherwise he must lie in bed throughout the twenty-four hours, including meal-times, save for using a chamber for emptying the bladder.

In cavitated disease, postural retention as practised extensively by Dillwyn Thomas at Sully Hospital, Glamorgan (Thompson, Savage, and Rosser, 1954), with the patient lying in a simple plaster cast and with the foot of the bed raised, at the correct inclination for six to twelve weeks, is a real advance in treatment, especially when combined with chemotherapy. Although cavities rarely close permanently, they usually decrease markedly in size and the surrounding exudative disease becomes more proliferative. Cough and sputum disappear quickly as a rule. The lung is then in a better state for further treatment and less extensive surgical measures are required.

Antibacterial Therapy

The discovery of streptomycin by Waksman and his colleagues (Schatz, Bugie, and Waksman, 1944) and the experimental work and clinical trials of Hinshaw and his co-workers (1944, 1945, 1946) have revolutionized the treatment

of pulmonary tuberculosis, not only as regards medical treatment, but by allowing more extensive surgical measures by collapse or resection with a greatly diminished risk of broncho-pleural fistula and dissemination of the disease. Another advance was the discovery that the combination of *p*-aminosalicylic acid (P.A.S.) with streptomycin materially decreased the incidence of resistant strains of bacteria to both drugs. In 1951 isonicotinic acid hydrazide (isoniazid) was discovered. This powerful, cheap, and relatively simple drug can be taken by mouth, and again the incidence of resistant organisms is diminished when it is combined with either of the other drugs.

Obviously new and possibly more efficient drugs will be produced; the clinician tends to become confused with the rapid changes taking place these days. The principle of testing under scientific control the value and dangers of new therapeutic agents is of the greatest value, and it behoves us not to discard a well-tried combination of drugs until there is good evidence that a new combination is more efficient and less toxic.

On looking back over the milestones in therapy during the past 30 years—insulin, liver extract, sulphapyridine, penicillin, and cortisone in Addisonian crisis—I still treasure the moment of doubting amazement when I saw the results of streptomycin treatment in the group of young patients with acute exudative disease who were in the Brompton Hospital during the Medical Research Council's trials from 1947 to 1953. The following is an example of such a case.

Case A.—A girl aged 18 years was admitted to the Brompton Hospital in January, 1949, with four months' history of cough, night sweats, and loss of weight. She was acutely ill with tuberculous bronchopneumonia: temperature, 103° F. (39.4° C.); pulse, 120; respirations, 30. She was given streptomycin, 1 g. daily, with P.A.S., 15 g. daily for 14 weeks. In January, 1950, a left pleuropneumectomy was performed, and she was subsequently sent to a sanatorium for six months. She is well and working four years later. (Plate, Figs. 1-3.)

When participating in the treatment of this girl I was thrilled by the vista of what might be accomplished in the future treatment of pulmonary tuberculosis. Such a prospect, coupled with the advent of lobar and segmental resection after chemotherapy, may have blinded us to the value of the older and tried forms of treatment, however. There is a tendency in some countries to accept the view that the proper treatment of pulmonary tuberculosis is a prolonged course of rest with chemotherapy followed by the resection of the remaining areas of nodular caseous disease. The rather scathing term "pimplyotomy" has been used by some clinicians who feel that the pendulum of resection has swung too far.

Thoracic surgery has had an immense influence in giving us knowledge of pathological processes in the lungs at an earlier stage than is seen at necropsy. As a class, thoracic surgeons are highly trained and very able; they handle the lungs in life and can correlate the x-ray appearances with the actual lesions found. It is therefore not surprising that the thoracic surgeon should have great influence in advising in and organizing the treatment of pulmonary tuberculosis. Perhaps it is not untimely to suggest that we physicians, in publishing the results of medical treatment, should use the same factual presentation as our surgical colleagues.

In the treatment of pulmonary tuberculosis we have three main weapons in addition to the long-established principles of rest, diet, fresh air, and graded exercise: (a) antibacterial drugs without collapse therapy; (b) collapse treatment, either medical or surgical, in which the diseased lung remains in the body and possibly acts as a stimulus to antibody formation; and (c) resection of the diseased part, which may act as a reservoir of subsequent infection. Any of these three may be used singly or in combination. We must be clear as to our aims in treatment, which are: (1) permanent healing of the lesions; (2) minimal loss of respiratory function; and (3) the attainment of these in the shortest time. The treatment of tuberculosis is long in any case, and un-

necessary months of idleness may have serious effects on morale and on domestic happiness.

Artificial Pneumothorax Therapy

I want to review our results by medical collapse measures alone, before antibacterial therapy was introduced, so as to have a base-line for the comparison of treatment to-day. The true value of artificial pneumothorax therapy is difficult to assess from the voluminous literature, because of variations in the classification of the extent of disease and an often inadequate follow-up. A paper by Foster-Carter, Myers, Goddard, Young, and Benjamin (1952) on cases in the Frimley Sanatorium furnishes some sort of yardstick. The paper covers the five-year period 1937-42 and 1,153 patients, of whom 955 had cavitated disease, and approximately 99% were followed up for at least eight years. Classification was according to the number of zones in the postero-anterior radiograph on admission: this was shown by Hartley, Wingfield, and Burrows (1935), on their experience of 2,759 cases at Frimley, to be probably the most reliable classification on which to base prognosis. It is as follows: Class I, not more than one zone involved; Class II, unilateral or bilateral disease not involving more than three zones; and Class III, four or more zones involved.

The average period of stay in the Brompton Hospital was 40 days and in Frimley Sanatorium 140 days, amounting to about seven months' institutional treatment in all. No doubt the criticism could be made that these cases are a selected group, as Frimley did not take bed-rest cases, and that Class III (advanced) cases diagnosed radiologically were not really so "advanced" as those transferred to other sanatoria where bed-rest patients were accepted. Obviously a ten-year follow-up would have been better than one of eight years. Be that as it may, the figures show a fair proportion of Class III cases. A further point is that these patients were under the control of different physicians at the Brompton Hospital, whose opinions varied widely as to the use of collapse measures, division or not of adhesions, and duration of treatment. This paper is, however, impressive in that the numbers are sufficient, with nearly 99% of cases followed up for eight years, and the results statistically significant. I am grateful to the authors for allowing me to quote from it.

Of 256 patients with cavitated disease, who had no collapse therapy at any time, 113 (44%) survived eight years; 93 (82%) of these were working and 62 were known to have a negative sputum. Of 83 patients in Classes I and II, 74% survived eight years, and of 173 in Class III, 33% were alive after that period. Thus it is clear that the extent of the original disease is of more importance than the size of the cavities. Of the 616 cases of cavitated disease reported in the much-quoted paper by Barnes and Barnes (1928), 130 were followed up for five years; of these, 79% were in Class III and 85% had large cavities; the five-year survival rate was only 10%. The Frimley figures give a less gloomy picture: of 104 Class III patients with large cavities 33% survived five years and 23% eight years.

In non-cavitated disease artificial pneumothorax treatment appears to be of little benefit. Of 130 patients treated without collapse therapy 88.9% survived eight years, although 24 (18%) required collapse therapy later. Of 62 patients treated by unilateral pneumothorax, 87% survived eight years and 35% needed further collapse. It is possible that the physician selected the less favourable cases for collapse therapy. The point I want to emphasize is the relatively good prognosis in non-cavitated disease without antibacterial therapy.

Of 457 patients with cavitated disease treated by unilateral artificial pneumothorax 316 (69%) survived eight years; 423 (93%) of these cases came into Classes II and III. An eight-year survival rate of 82% was obtained in 240 cases in Class II, and in 48% of 183 cases in Class III.

The striking finding of the Frimley investigation—in my view a most unexpected one—is the good result attained by

what I would call "contra-selective collapse." The authors define three grades of collapse resulting from artificial pneumothorax: (a) "satisfactory," with disappearance of the cavity; and (b) "adherent satisfactory," in which the cavity fails to close within one year. A further surprising fact is that extension of disease to the opposite lung occurred in 25% of the "satisfactory" group, 23% of the "adherent satisfactory" group, and only 11% of the "adherent satisfactory" group. This might be just a chance happening and is difficult to explain on other grounds.

Empyema occurred in 17% of the whole series, with 14% in the "satisfactory" group, 9% in the "adherent satisfactory" group, and 36% in the "adherent unsatisfactory" group, which again shows the danger of maintaining treatment when the cavity fails to close. The results eight years after termination of the pneumothorax show that 64% of the "satisfactory," 60% of the "adherent satisfactory," and about 28% of the "adherent unsatisfactory" group were well and working.

The deductions I draw from this important paper are as follows: (1) The grading according to zones in the radiograph gives a good indication of prognosis. (2) A satisfactory collapse in which the cavity closes gives much better results than are obtained without collapse therapy. (3) An artificial pneumothorax which fails to close a cavity in a reasonable time is dangerous. (4) The incidence of empyema is 17%, which is too high; it occurs particularly in the group with persistent cavities.

I have analysed a series of my own cases, 62 in all. So far as I am aware this includes every case admitted to the Brompton Hospital under my care in which I recommended pneumothorax treatment during the six years 1942-7 inclusive; these cases are therefore not included in the Frimley report. The series is too small to be of any statistical value, and in addition seven patients have not been traced.

The results, which are analysed in Table I, were good in 36 and bad in 11, and there were 10 deaths. I believe in attaining an anatomically perfect collapse where possible, and adhesion section was performed in 35 out of 47 cases,

TABLE I.—Results of Artificial Pneumothorax in Cases Admitted to the Brompton Hospital During 1942-7

	Non-cavitated, Sputum Negative	Class I	Class II	Class III	Total
Failed A.P.	—	—	5 (1 died)	2 (1 died)	7 (2 died)
Lost touch	—	1	5	1	7
A.P. maintained	—	1	—	—	1
Result good	7	11	11	7	36
Treatment failed	—	—	6 (5 died)	3 (3 died)	11 (8 died)
Total	7	13	27	15	62 (10 died)

Years after termination of A.P.	Good Results				
Over 4	7	6	6	5	24
3 to 4	—	2	4	1	7
1½ to 3	—	3	1	1	5
Total	7	11	11	7	36

yet empyema occurred in only 2 of the 47 patients, who were all followed up for at least eighteen months after termination of the pneumothorax. In both cases a suspended cavity was obvious and the pneumothorax should have been terminated within a few weeks. I can also endorse the observation by F. H. Young (1949) that cases under the care of one physician throughout do better than those under multiple control.

Phrenic Paralysis with Pneumoperitoneum Treatment

Banyai (1946) introduced this treatment about 1934 and is enthusiastic as to its value. Many papers on its applica-

tion have been published, but in this country at any rate it is employed chiefly as a preliminary treatment for acute exudative disease, to give some rest to the lung before more definite collapse measures are undertaken. I have used it in a limited number of (generally advanced) cases since 1942, and feel that its value, particularly when it is combined with chemotherapy, is perhaps not sufficiently appreciated. I have had no experience with pneumoperitoneum without phrenic paralysis.

As in pneumoperitoneum the pleural surfaces are not separated, the complications seen with artificial pneumothorax—such as fluid, empyema, haemothorax, and frozen lung—do not occur. Serious complications are rare—less than 5%. As with pneumothorax treatment, a certain amount of skilled supervision is required to attain the objective aimed at—relaxation and rest of the lung selected for phrenic paralysis. This entails a careful search for an accessory phrenic nerve at the time of the phrenic crush and suitable refills to keep the paralysed diaphragm high in the chest, to the level of the third rib or intercostal space in front as seen in the ordinary postero-anterior radiograph; also recrushing the nerve if the hemidiaphragm recovers too early. Careful assessment is needed at a suitable time, usually between six and nine months, to ascertain whether the aims of treatment, especially cavity closure, have been attained; if not, further treatment should be instituted. Lateral radiographs and also tomographs are necessary to decide the progress of the lesion, as pneumoperitoneum affects mainly the posterior part of the lung.

All but two of my 68 patients who have undergone this procedure at the Brompton Hospital have been followed up to date. Apart from four cases in which the pneumoperitoneum was induced by other physicians but supervised by me, the treatment has been given on my recommendation in all cases. Treatment has been abandoned for at least eighteen months, and no patients have been given chemotherapy as part of their treatment. My registrars, Dr. K. J. Gurling and Dr. W. H. Helm, have reviewed the case sheets and original radiographs with me, so as to obtain an unbiased assessment of the extent of the original disease and the results of treatment. When the original films were not available, owing to the fire at the Brompton Hospital in 1950, we have taken the radiologist's report or my own notes on the original films.

Table II gives the over-all results obtained in the 68 cases, divided into Classes I, II, and III and "lower-lobe cavities." In 32 the results were classified as "good," in 20 as "failed,"

TABLE II.—Over-all Results in 68 Cases Treated by Phrenic Paralysis and Pneumoperitoneum

Class	No. of Patients	Results of Treatment				Final State			
		Good	Failed	Non-proven	Lost	Received Other Treatment	Well and Working	Disease Progressive	Died
I	6	3	1	2	—	3	6	—	—
II	24	10	9	4	1	7	18	1	4
III	26	10	7	8	1	12	16	2	7
Lower-lobe cavities	12	9	3	—	—	3	9	—	1 (non-tb)
Total	68	32	20	14	2	25	49	5	12

and in 14 as "non-proven"; 2 have been untraced for one and a half years. With further treatment in 25, 49 of the patients are well and working and have negative sputum. Table III gives a detailed analysis of 65 cases.

The 6 cases in Class I need little comment. In Case 1 the patient, a business man, had to travel by air, and a thoracoplasty was therefore performed. In Case 4 an artificial pneumothorax was induced because the physician did not believe in pneumoperitoneum treatment. In Case 6 a

pleural effusion occurred before treatment, with the formation of a thick-walled apical cavity. In Class I the results were: 3 good, 2 non-proven, and 1 failed.

The 21 cases in Class II were treated with the aim of cure without further treatment. The results were: good, 9; failed, 7; non-proven, 4; and untraced, 1. The final state is more cheerful in that after treatment 17 patients are well and working, 3 have died, and the other is untraced. The remaining 3 cases of the 24 in Class II were treated in preparation for surgical treatment on the same side, and are therefore not included in Table III. The first patient had a left plombage in 1951 and is now well; the second, a diabetic girl of 27 years with extensive bilateral cavitation, has had a left extrapleural pneumothorax and a right plombage, but is going downhill. The history of the third case is as follows:

Case B.—The patient, a woman of 39 with chronic unilateral cavitated disease, developed a tuberculous bronchopneumonia following a large haemoptysis and the left lung was virtually destroyed. Streptomycin treatment had to be stopped after a fortnight owing to the development of severe toxic reactions to the drug. With a left phrenic crush and pneumoperitoneum the diaphragm was kept high and the disease controlled. Owing to the presence of disease on the right side it was necessary to wait for eighteen months before a left pneumonectomy could be performed, but during most of this time she was free of cough and sputum and doing her housework, and by the end of the period she had regained her normal weight. Unfortunately, when on holiday she was given a refill at a strange clinic, where she had a syncopal attack. This was thought to be due to an air embolism, and the refills were abandoned forthwith without any consultation. The patient died three months later with enormous cavities on both sides. Diagrams of the radiographs are shown below.

The above case illustrates the dangers of dual control, and, moreover, shows the importance, when surgical treatment

successful, the treated lung standing up to surgical collapse of the contralateral side; the other 5 were failures. In Group C, of 10 cases, 4 were classed as successful; 2 of these patients recovered without further treatment. There were 4 non-proven cases and 2 failed. Three cases required thoracoplasty. As in all of the 68 cases the pneumoperitoneum has been abandoned for eighteen months or longer there are no cases in Group D.

An example of the few cases in which a permanent pneumoperitoneum has been maintained is described below. (See Plate, Figs. 4-6.)

Case C.—A man aged 28 years with severe diabetes, Kimmelstiel-Wilson syndrome, and gross hypertension. The extent of the disease and subsequent progress are shown in the radiographs. He has never had antibacterial therapy. For some four years he has been clinically well, without cough or sputum, and is earning his living. I have refused the repeated requests of his chest physician to subject this patient to a thoracoplasty to close the cavity on the left side.

The last part of Table III shows the results in 12 patients with lower-lobe cavities, which are notoriously difficult to close; 3 of these had had unsuccessful pneumothorax therapy previously. Results were successful in 9. In Case 7 the patient died of acute enteritis four years after a lobectomy, performed because haemoptysis persisted in spite of pneumoperitoneum treatment. The resected specimen showed that the original cavity had closed and the bleeding had been caused by an area of bronchiectasis.

The patient in Case 2, a girl of 20, had a large cavity which became "blocked": she remained well and free of sputum for four years with the pneumoperitoneum, but then "spread" occurred near the cavity and a left lower lobectomy was performed. Five years later she is well and working, having had two children in this time. This case taught me that when a cavity becomes "blocked" but does not progressively decrease in size, resection should be carried out, say after a year.

In Case 5, a male aged 27, the pneumoperitoneum had been abandoned too soon, as clinical and radiological examination indicated that healing was taking place. Subsequently the patient went through a whole series of surgical operations.

Plombage

The late Dr. F. G. Chandler (1940) has said that the thoracoplasty is "a terrific and mutilating operation, one that offends the aesthetic sense and craftsmanship of the surgeon." With the modern thoracoplasty few would now subscribe to this view, particularly as most surgeons use general rather than local anaesthesia, which was not the rule some years ago. The mortality

is now less than 5% with experienced surgeons, but the immediate post-operative pain and the common complications, such as atelectasis of the lower lobe and fluid formation, call for fortitude from the most courageous patient. The waiting period for the second stage, and occasionally the third, calls for even more courage. In my experience thoracoplasty still gives most reliable and lasting results, and patients may be seen attending for an annual check, year after year, in good health, in full work, and with minimal deformity. In spite of these good results, however, one feels at times that one is using a sledgehammer to crack a nut.

Like Chandler I had hoped that some form of plombage with a non-irritant substance would be devised, and that—although it contravenes a principle of surgery by leaving a foreign body in the tissues—something better than the old wax plomb would be found.

Wilson in 1948 showed in animals that "lucite" spheres caused little irritation or reaction in the tissues. Trent, Moody, and Hiatt in 1949 published a damning report on

Diagrams of radiographs in Case B. (a) Condition before treatment (October 20, 1950): grossly diseased cavitated left lung. (b) During treatment (May 4, 1951): left diaphragm up to level of second rib; patient without symptoms, doing full day's housework. (c) Condition on day of death (October 21, 1952), three months after treatment had been abandoned: "destroyed" left lung; gross cavitated disease in right.

has been decided upon, not to abandon the pneumoperitoneum until the patient is actually in a surgical bed.

In Class III, the advanced cases, there are 26 patients who offer a challenge to the clinician for any form of therapy. The aim in these cases was to see how many can be salvaged rather than successfully treated. With chemotherapy, of course, the outlook is better, but these patients did not have this help. I divided them into four groups, as a bald statement of success or failure does not give a fair picture of what may be done: Group A—with the aim of cure without other treatment; Group B—with the aim of curing one side preparatory to collapse or resection on the opposite side; Group C—with the aim of temporary treatment preparatory to collapse or resection on the same side; and Group D—the pneumoperitoneum is maintained indefinitely, as the condition of the patient or the extent of the disease does not allow of major surgery.

In Group A there are 8 cases: 3 were successful, 3 failed, and 2 were non-proven. After further treatment all patients are well and working. In Group B 3 of the 8 cases were

51 cases in which lucite spheres were introduced into the extrapleural space. Woods, Walker, and Schmidt (1950) in the United States, and Lucas and Cleland (1950) in this country, have reported favourably on the use of extrapleural stripping as for a Semb thoracoplasty and then introducing lucite balls (at first hollow, but now solid and sterilizable by boiling), of which they have had considerable experience.

Mr. W. P. Cleland, who has carried out the plombage in most of my cases, has kindly let me have his results to date in 186 of his own cases treated three or more years ago, starting about 1948. Of these only about 56% were good risks and some 12% were designated as "scrapheap" cases. His figures are as follows:

	No. of Cases
Good results without further treatment	104
Unsatisfactory:	30 (72%)
Persistent cavitation	8
Active disease	3
Sinuses, etc.	4
Untraced	18
Died (from unrelated causes, 8)	19
Total	186

There were 13 cases with space infection. Of these, 2 were pyogenic; one had a thoracoplasty and the other was treated by general and local chemotherapy; both patients are now well. The other 11 cases had late tuberculous infection, the majority with sterile pus; of these, 2 died from conditions unrelated to their infection, 3 had sinuses, and 6 are well.

Table IV gives details of the 27 cases for which I recommended lucite plombage. The results were good in 20 and moderate in 2, and there were 5 failures. Of the 3 deaths, one patient (Case 7) died from an anaesthetic preliminary to a pneumonectomy, one (Case 22) from epilepsy when cured of her tuberculosis, and the other (Case 23) from carcinoma of the bronchus. Complications were not serious.

It is still early, the longest period since operation being five years, to be sure that the foreign body in the chest will not give trouble, but I am hopeful. From the patient's point of view the advantages of this operation are three-

fold: (1) it is a one-stage procedure; (2) it is not followed by chest deformity; and (3) it has a relatively low complication rate with absence of post-operative shock and severe pain in the majority. From the point of view of the physician there is a fourth advantage—the patient can have the operation in a "medical" ward and so avoid the wait of six to twelve months for a surgical bed.

Resection

In some countries, particularly the United States, resection has become the accepted form of treatment after a long course of antibacterial therapy, varying from six months to two or even three years. Its use may be considered broadly under two headings: (a) *direct* therapy, in which the diseased and usually functionless portion of lung, which has previously caused symptoms, is removed, thus eliminating a reservoir of future infection; and (b) *prophylactic* therapy, by which I mean removal of parts of damaged lung not at the time causing symptoms but which are considered to be potential sources of infection at a later date. Certain discrete round foci or bronchiectatic segments of the upper lobes are examples. In regard to direct therapy, the older school argue, from previous experience of collapse therapy, that the diseased lung left in the chest acts as a stimulus to specific immunity, while the younger school have greater regard for the theory of removing "the factory." Controversy over prophylactic resection of apparently benign lesions still continues.

From my own impressions as opposed to factual data I regard bronchiectasis in the upper lobe, collapsed by disease or therapeutic procedures, as a benign condition in all but a small minority of cases, and bronchography shows that it is very common. According to Clegg (1953) discrete round foci may be of three types: (a) small areas of tuberculous pneumonia; (b) cold abscesses within the bronchi; and (c) blocked cavities.

In this country Ronald Edwards (Bickford *et al.*, 1952), of Liverpool, who published his first 200 results in 1950, and later Dillwyn Thomas (Thompson *et al.*, 1954) of Sully

Hospital in Wales, with their assistants have performed a large series of resections, although most thoracic surgeons are undertaking a greater or less number according to their views on the pathogenesis and progress of tuberculosis of the lungs. The tendency now is that with lobectomy or resection of more than one segment of a lobe it is probably wise to prevent over-inflation and possible "reactivation" in the remaining lung by some operation to reduce the size of the hemithorax. This may be done at the time of the original resection or at a later date; in either case it adds something to a simple thoracotomy.

Mr. Edwards has kindly allowed me to quote these figures of his results. Of 1,023 patients, 20 died within three months of operation, an immediate mortality of 1.95%. In a four-year follow-up of 112 cases there are 61 pneumonectomies with 4 deaths and 4 with late exacerbations of disease: 49 lobectomies with one post-operative death and 5 exacerbations; and 2 segmental resections with 1 exacerbation. After four years 95% of the 112 patients are well and working.

By 1952 the percentage of segmental resections performed had increased to approximately 66% of all resections. Up to March, 1952, after 259 segmental resections, only one post-operative death and two empyemata had occurred.

Thompson and Savage, working with Dillwyn Thomas at Sully Hospital, report for the five-year period to June, 1953, 266 cases of resection of various types with an operative mortality of 1.88% and "apparently arrested" disease in about 97%. It is too early yet to assess final results.

For what it is worth I present my own small series of resections. By nature I am conservative, and while welcoming advances in treatment I am inclined to wait and see the results of innovations in the cases of more enterprising physicians. Of 11 pneumonectomies, mostly with "destroyed" lung, results were good in 9. There were 2 deaths, one from acute bronchitis 2½ years after, the other from epilepsy one year after; the latter has already been referred to under "Plombage." Of 21 lobectomies, results were good in 18 and poor in 2; there was one failure. Only 4 had post-operative collapse to decrease the size of the hemithorax. Of 8 segmental resections, results were good in 6 and bad in 2.

Conclusion

In this paper I have given certain figures, which I believe to be reliable, concerning artificial pneumothorax and pneumoperitoneum treatment without antibacterial therapy. Now that antibacterial therapy is available the results of surgical intervention are much better, as also are those of medical collapse. With medical collapse and chemotherapy, in my experience, many patients with minimal or moderate disease can safely return to their homes and occupations within eight to twelve months.

In the Frimley series from 1937 to 1942 quoted above the incidence of empyema was 17%—an appalling figure. If this is the true risk at the present time, then it is no wonder that artificial pneumothorax is much less used than in the past. The results in suitable cases five years after refills have been discontinued are very good, however. Of my own series of 62 patients treated with artificial pneumothorax from 1942 to 1947 it is possible, but I think unlikely, that in each of the seven untraced cases an empyema developed. Of 47 cases followed up for at least eighteen months after the pneumothorax was abandoned, only in two did empyema develop; both of these were badly selected cases in which treatment should have been abandoned forthwith.

I now teach my students that the indications for artificial pneumothorax are very limited and that the treatment should be used only in the following circumstances: (1) when the clinical duration of disease is at least four months and chemotherapy has been given for a further four weeks; (2) when cavities are less than 4 cm. in diameter; (3) when there is no clinical or radiological evidence of endobronchial

disease; and (4) when it is estimated that after the lung has healed it will fill the hemithorax without risk of over-inflation or displacement of the mediastinum. I further impress upon them that they should not hesitate to abandon an artificial pneumothorax that has been started if conditions are unfavourable.

We physicians unfortunately often deal with advanced cases quite unsuitable for pneumothorax or surgical treatment at that stage. In these cases the use of chemotherapy with postural retention for two to three months, followed by phrenic crush and pneumoperitoneum, will give an idea of future possibilities. A plombage on the worse side at the appropriate time may in some of these rather hopeless cases enable the patient to get back to a useful life within twelve to eighteen months. It is perhaps not sufficiently appreciated at the present time that pneumoperitoneum with phrenic paralysis added to antibacterial therapy has real value.

The following is a typical case (see Plate, Figs. 7-9).

Case D.—An officer in the Merchant Navy aged 27 years had been a contact of his brother and sister, both of whom had cavitated disease. In June, 1950, radiological examination showed bilateral disease with cavitation. The patient was admitted to a sanatorium, where he was given bed rest with streptomycin, 54 g., and P.A.S.; a right artificial pneumothorax was attempted and abandoned. In June, 1951, he was sent home. From December, 1951, to April, 1952, he was in the Brompton Hospital with a positive sputum. He was treated by postural retention for six weeks and then had a left phrenic crush with pneumoperitoneum; during this time he received streptomycin, 87 g., with P.A.S. He returned to a sanatorium for five months and was then readmitted to the Brompton Hospital on September 1, remaining there till November 5. His sputum was still positive on culture. Tomography revealed a small cavity at the right apex. On October 1 a right lucite plombage was performed, after which he was dyspnoeic for some days. Sputum disappeared soon after this, and he has been doing part-time work since December, 1953. Pneumoperitoneum treatment continues. The total dose of streptomycin received by this patient was 182 g.

Bacteriologists and morbid anatomists in this and other countries are investigating the finding in many resected specimens that large numbers of bacilli are present in some lesions and none in others; only a small proportion of these bacteria will grow on the artificial media now in common use, and may fail to infect or kill laboratory animals.

Dubos (1953), in his summing up of a discussion on the subject at the twelfth Conference on the Chemotherapy of Tuberculosis held in February, 1953, in the United States, comments on these facts. Bacilli are found more often in cavitated lesions than in closed necrotic foci; these bacilli may be dormant and not necessarily dead. A low-oxygen, high carbon-dioxide content is known to inhibit the growth of tubercle bacilli *in vitro*, and these are just the conditions found in closed necrotic lesions. Breakdown products of necrotic tissue such as spermine and spermidine, and enzymes such as lysozyme, also inhibit bacterial growth *in vitro*. Bacilli may, however, persist in the tissue-cells and lymph nodes of men and animals in spite of prolonged chemotherapy.

Further research is required both by laboratory workers and by clinicians who will make accurate observations on the anatomy, pathology, and bacteriology of these pulmonary lesions, follow up the patients, and publish their findings.

There is no doubt that in the right type of disease resection is a fundamental treatment which has come to stay—and rightly so. At present I am uneasy about the policy of some surgeons in removing apparently "benign" lesions on the supposition that these may break down at some future date.

When one ponders over the problem of pulmonary tuberculosis one is always brought back to the question of immunity. Why should the rat be immune and not the guinea-pig? Recently I have been studying sections of lung

taken at biopsy from patients with miliary shadows in the lungs. Some of these cases are diagnosed on all available evidence as "sarcoidosis," and others as benign chronic miliary tuberculosis; a small group seems to be "on the fence" between the two. I have a feeling that further experimental study of the syndrome called "sarcoidosis" may provide a clue to the problem of immunity in tuberculosis.

Summary

The treatment of pulmonary tuberculosis is reviewed in the light of recent advances.

The aims of treatment are: (1) permanent healing of the lesions; (2) minimal loss of respiratory function; and (3) the attainment of these in the shortest time.

In addition to the long-established principles of rest, diet, fresh air, and graded exercises there are three main therapeutic weapons: (1) antibacterial drugs without collapse therapy; (2) collapse therapy, either medical or surgical; and (3) resection of the diseased portion of lung.

The value of the various forms of treatment is assessed on the basis of results obtained by the author and by other workers in Great Britain.

The finding that large numbers of tubercle bacilli are present in some lesions and none in others is referred to, and the need for further research into this question is stressed.

Further experimental study of the syndrome called "sarcoidosis" may provide a clue to the problem of immunity in tuberculosis.

My grateful thanks are due to my registrars, Dr. J. K. Gurling and Dr. W. H. Helm, for their valuable assistance in reviewing the records of my cases; also to my secretary, Miss Hope Daniel, for her persevering efforts in following up the patients.

In his Report for 1953, Dr. Stuart Laidlaw, Medical Officer of Health for the City of Glasgow, writes: "One can readily imagine the public outcry had diphtheria immunization been available only to the well-to-do. But it is little encouragement to those protagonists of free preventive measures that so few avail themselves of the opportunities offered. Public apathy is not restricted to diphtheria immunization alone. Only 17% take advantage of free infant vaccination, though Glasgow is a seaport town with an air terminal. Many contacts of open cases of tuberculosis decline to be x-rayed. Many parents ignore the opportunity of B.C.G. protection for children of school-leaving age. There is also the unsatisfactory response by expectant mothers to the offers of free dental treatment and supplementary vitamins despite the fact that these provide additional safeguards to themselves and the unborn child."

CURRENT THERAPY IN PULMONARY TUBERCULOSIS IN THE UNITED STATES*

BY

HAROLD GUYON TRIMBLE, M.D.

Associate Professor of Clinical Medicine, Stanford University, California

[WITH SPECIAL PLATE]

The study forming the subject of this lecture was carried out under the auspices of the Committee on Non-Surgical Collapse Therapy of the American College of Chest Physicians to determine the kind of therapy advised as the initial treatment in different cases of pulmonary tuberculosis by physicians who are recognized experts in this disease. Ten representative cases were selected. They were of ordinary forms of tuberculosis that might be seen any day in such a physician's office. They differed as regards age, race, sex, and type of disease, but had no unusual or bizarre complications. All had positive sputum. They could be grouped, according to the classification of the National Tuberculosis Association, into minimal, moderately advanced, and far advanced. These patients had been known to us for a long time. It was endeavoured to make the initial problem as simple as possible. A similar study was carried out on these same ten cases in 1948.

The method of investigation was as follows. A brief case history with a single chest radiograph of each case was sent, with an accompanying questionnaire, to the one hundred physicians selected as representative of the top clinical thinking in their respective areas throughout the United States. The questions asked were: (1) Would you use bed rest alone as therapy for this type of case? (2) Would you add drug therapy? (3) Would you use collapse therapy? (4) Would you use surgery? (5) With the therapy indicated above, how long would you keep this patient on complete bed rest and in a sanatorium? In general, complete bed rest is interpreted as strict rest in bed with no bathroom privileges; the patient is not allowed out of bed at all for any reason. Modified bed rest is indicated as such.

In what follows the replies to the above questionnaire are analysed.

Drug Therapy

Drug therapy will be discussed for all of the cases together, because the same practitioners recommend practically the same dosages throughout the ten cases and most of them say they would start chemotherapy immediately. The length of time chemotherapy would be continued varied considerably, however, for the different patients.

Antimicrobial therapy is now generally accepted by the vast majority of chest physicians as part of the routine treatment of pulmonary tuberculosis, whatever the extent of the disease. Such therapy would be used as part of the basic treatment by 97%, with variation, according to the extent of the disease, only from 93% for minimal disease to 99.5% for far advanced disease. The drugs of choice were limited to streptomycin, para-aminosalicylic acid (P.A.S.), and isonicotinic acid hydrazide (isoniazid). Practically all the physicians would use combined and continuous therapy, with a marked preference for streptomycin plus P.A.S. A majority favoured the intermittent use of streptomycin in a dosage of 1 g. twice weekly, with P.A.S. by mouth to tolerance—about

*Based on the Fourth Varrier-Jones Memorial Lecture, given at Manson House, London, on May 14, 1954.

J. L. LIVINGSTONE: OBSERVATIONS ON THE TREATMENT OF PULMONARY TUBERCULOSIS AT THE PRESENT TIME

12 g. daily. There was less agreement about the dosage of isoniazid, which varied from 3 mg. per kg. of body weight to 10 mg. per kg. with a majority using 3 to 5 mg. per kg. In the more acute far advanced cases there was a definite leaning toward combining all three drugs.

In the United States there is a strong trend toward standardization in the use of antimicrobial therapy. This is probably greatly influenced by what is called the Annual Conference on Chemotherapy of Tuberculosis under the auspices of our Veterans Administration, which acts as a forum for the presentation of various studies on the subject.

When the views on the length of time such therapy should be continued are studied no pattern evolves. There were recommendations for courses of from one month all the way to continuous therapy for three years. In minimal and moderately advanced disease a majority thought in terms of one year or less, with a considerable number favouring less than eight months; while in far advanced disease a majority would continue giving the drugs for one to two years. However, in both instances there were many recommendations that these broad generalizations would not cover.

As a corollary to the above it is interesting to note that there are now very few who use bed rest alone in the treatment of pulmonary tuberculosis—only 1%, in fact, of the total reporting. However, when we consider the use of antimicrobial therapy plus bed rest we find that 37% of the group as a whole favoured this as the treatment of choice. This percentage was made up very largely from the answers on the treatment of minimal disease, in which nearly three-quarters of the group favoured antimicrobial therapy plus bed rest.

Since 1948 the use of bed rest plus drugs and without collapse therapy has tremendously increased, at the expense of collapse therapy.

Treatment Recommended in Five Sample Cases

I will not discuss each of the ten cases separately, but will use as examples one minimal, two moderately advanced, and two far advanced cases (minimal, Case III; moderately advanced, Cases VIII and IX; and far advanced, Cases II and X).

Case III: Minimal pulmonary tuberculosis, bilateral, productive, with pleural effusion on the right, in a 43-year-old white female. Chest radiograph (Plate, Fig. 1) revealed a homogeneous density in the right pleural cavity (pleural effusion) and infiltration at both apices—more marked on the right.

The graph for this case (Graph 1) shows that in 1953 practically no one would treat this pleural effusion in association with minimal bilateral tuberculosis by bed rest alone, in contrast to 37% in 1948. However, approximately three-fourths would use bed rest plus chemotherapy. As many as 98% would use chemotherapy plus other methods, with a marked decrease in the use of collapse therapy since 1948.

GRAPH 1.—Case III: Comparison of recommendations for treatment in 1953 with those in 1948. Chemotherapy alone with bed rest was prescribed by 74% in 1953, as against 14% in 1948 (indicated by vertical dividing line).

largely at the expense of pneumothorax, which fell from 37% to 1%. A very few would think surgery advisable for this patient.

Case VIII: Moderately advanced pulmonary tuberculosis, unilateral, with a solitary 3-cm. cavity at the right apex, in a 34-year-old white male (Plate, Fig. 2).

Most physicians would now use chemotherapy. One-third would initiate a prompt reversible collapse, about half of these using pneumoperitoneum and the other half a right pneumothorax. Two-thirds would, however, prefer surgery after the lesion had shown some stabilization by bed rest plus drugs. The large majority would expect maximum response to drug treatment and relatively stabilized lesions within three to six months. Fifty-two physicians would prefer resection and eleven a thoracoplasty.

If the treatment prescribed now is compared with that recommended in 1948 (Graph 2) it will be seen that in the case of this 34-year-old man with moderately advanced

GRAPH 2.—Case VIII: Comparison of 1953 with 1948. Chemotherapy alone with bed rest prescribed by 10% in 1953 and by none in 1948.

disease and a unilateral cavity nearly all would use chemotherapy, with a definite reduction in the use of reversible collapse therapy from 68% in 1948 to 31% at the present time. It is noteworthy that there has been a marked drop in the use of pneumothorax in favour of pneumoperitoneum since 1948. It is interesting, however, that 18% would still try pneumothorax, and continue it for three to five years in most instances if the collapse promptly became adequate. But surgery was the treatment of choice for this patient.

Case IX: Moderately advanced pulmonary tuberculosis, acute, bilateral, more extensive on the left, in a 34-year-old white female. Chest radiograph (Plate, Fig. 3) revealed a soft mottled infiltration in both upper lung fields, more extensive on the left.

Practically all the physicians would use chemotherapy in this case, and six out of every ten would favour reversible

GRAPH 3.—Case IX: Comparison of 1953 with 1948. Chemotherapy alone with bed rest prescribed by 37% in 1953, as against 26% in 1948.

collapse, only a very few advising resection. The collapse therapy recommended was pneumoperitoneum. No one at the present time would treat this moderately advanced, acute bilateral disease in a 34-year-old woman with bed rest alone, as compared with 28% in 1948 (Graph 3). However, 37% would use only bed rest plus chemotherapy. There has been some increase since 1948 in the number who would use reversible collapse therapy, 57% favouring pneumoperitoneum, while only 2% would use pneumothorax, in contrast to the 29% who recommended pneumothorax in 1948. Four would now advise surgery as the primary procedure, advocating resection.

Case II: Far advanced tuberculous pneumonia in a 31-year-old white female. Chest radiograph (Plate, Fig. 4) showed a diffuse homogeneous density occupying the upper half of the right lung field and containing a cavity.

All the physicians would use drugs in this case, 42% prescribing streptomycin and P.A.S., 30% streptomycin, P.A.S., and isoniazid, while 28% would use a combination of any two of these drugs. Thirty-two physicians would use pneumoperitoneum and eight would try to establish a right pneumothorax. Forty-nine would expect to do a resection after a period of bed rest and drug treatment lasting from five to ten months. Three would prefer thoracoplasty.

In this far advanced case of tuberculous pneumonia in a 31-year-old woman no one would treat the patient with bed rest alone, and there was complete agreement as to the use of combined antimicrobial drug therapy. There was a tendency to use all three drugs in this case and to give streptomycin daily at the beginning. The majority would use the drugs for from twelve to twenty-four months.

The use of collapse therapy has fallen from 58% in 1948 to 40% now (Graph 4), largely at the expense of pneumothorax, with a correspondingly large increase in the use of

GRAPH 4.—Case II: Comparison of 1953 with 1948. Chemotherapy alone with bed rest prescribed by 15% in 1953, as against 23% in 1948.

pneumoperitoneum. Three years seemed to be the recognized time for pneumothorax to be continued. There was much disagreement as to how long to continue pneumoperitoneum, the largest group favouring five years, but substantial numbers indicated three or four years and a few suggested shorter periods. Note the definite increase in the use of resection at the expense of thoracoplasty and collapse therapy. Physicians who favoured resection tended to recommend a longer stay in a sanatorium than those who preferred collapse therapy.

Case X: Far advanced pulmonary tuberculosis, fibrocaceous lesions in the upper half of both lungs, with cavity on the left, in a 57-year-old white male. Chest radiograph (Plate, Fig. 5) showed old calcified lesions at the right apex, multiple scattered nodules, little fibrosis, but soft infiltration throughout the right lung in the upper two-thirds. In the left lung there was a soft mottling throughout the upper third, with a 1.5-cm. cavity in the first interspace.

In this case of far advanced pulmonary tuberculosis with cavitation and bilateral fibrocaceous disease in a 57-year-old man no one would now use bed rest alone, but 35% would use only bed rest plus chemotherapy. More would use rever-

GRAPH 5.—Case X: Comparison of 1953 with 1948. Chemotherapy alone with bed rest prescribed by 35% in 1953, as against 23% in 1948.

sible collapse therapy now than in 1948—almost two-thirds, compared with 44% in 1948 (Graph 5). There is a marked shift toward the use of pneumoperitoneum. All would now use chemotherapy. Very few considered this a case for surgery.

Summary of Recommendations

The recommendations for treatment can best be summarized by grouping the ten cases according to the three degrees of severity referred to earlier.

For the minimal group few would use bed rest alone. 72% would use bed rest plus chemotherapy. About 20% more would add various forms of collapse, mostly pneumoperitoneum, but a few pneumothorax. Even in the minimal cases a small percentage would recommend surgery, mostly resection.

In moderately advanced disease a very few would recommend bed rest alone. Less than 40% would use chemotherapy alone with bed rest, a larger number—60%—adding collapse or surgery. Three-fourths of those advising collapse would use pneumoperitoneum, the other one-fourth pneumothorax. Resection was recommended by 20%.

In far advanced disease no one recommended bed rest alone. A small number would use chemotherapy plus bed rest. About 80% recommended collapse therapy or surgery with chemotherapy and bed rest. Almost 60% would use pneumoperitoneum; 21% would perform resection.

Concluding Remarks

Just a personal word in closing. We have found this study very interesting. We actually treated these patients somewhat differently. Our own therapy would be complete bed rest until the sputum disappeared or became negative on examination by the concentration method. All of these patients would receive drugs, usually a combination of all three and for a period of approximately eighteen months. We use much reversible collapse therapy, with pneumoperitoneum as the method of choice and as the initial treatment in most cases. We review our results in three months, and if cavities that are not well on the way to closing are present we may then consider pneumothorax. However, all patients are examined bronchoscopically before being subjected to this procedure. Actual tracheo-bronchial disease is a contra-indication to pneumothorax, though it is not to pneumoperitoneum. We may then turn to surgical procedures. With some patients we feel from the beginning that surgery will eventually be necessary. We use bed rest plus drugs plus pneumoperitoneum as a

damping-down method for the acute exudative lesions, expecting the surgeon to remove the cavity-bearing area at a later date.

Tracheo-bronchial disease is still a problem. Many patients in whom tuberculous disease of the walls of the bronchi can be visualized through the bronchoscope are not permanently cured by drugs. If such tracheo-bronchial disease is removable, we feel that localized segmental resection is eventually indicated.

We have termed these methods a "dynamic approach" to the problem of tuberculosis. With prompt diagnosis and adequate treatment more patients with pulmonary tuberculosis are now getting well than ever could have done so previously.

Summary

The trend of treatment of pulmonary tuberculosis in the United States is discussed on the basis of a questionnaire sent in 1953 to one hundred physicians in that country. Recommendations were sought as to the treatment of ten selected cases of the disease. The replies are analysed and compared with those received in answer to a similar inquiry in 1948 concerning the same ten cases.

The investigation has shown that since 1948 the use of bed rest plus drugs and without collapse therapy has enormously increased. Collapse therapy is, however, still favoured in cases of more advanced disease, but pneumoperitoneum seems to have largely replaced pneumothorax as the procedure of choice.

A CASE OF GIANT-CELL POLYPHLEBITIS

BY

AMAL CHAKRAVARTI, M.D.

AND

GANEN CHAKRAVARTI, M.B.

Burdwan, West Bengal, India

[WITH SPECIAL PLATE]

Since 1941 attempts have been made to bring under a single heading such apparently diverse clinical conditions as polyarteritis nodosa, lupus erythematosus, scleroderma, and dermatomyositis. Banks (1941) has suggested that there is a common denominator in these diseases. Klemperer, Pollack, and Bachr (1942) proposed grouping them under the term "collagen diseases," fibrinoid degeneration of collagen having been found to form the basis of all of them. Claims have also been advanced for including in the group such diseases as rheumatic fever, Buerger's disease, and even serum sickness and the calcinosis. In spite of attempts at generalization, however, the "collagen group" of diseases remains an assortment of heterogeneous clinical varieties, and the specific conditions which should be included or excluded continue to be a matter for speculation.

Polyarteritis nodosa is predominantly a vascular collagen disease. Recognized as early as 1866 (Kussmaul and Maier), it has received widespread recognition only in recent years. Though an appreciable number of cases have been reported in the world literature, so far only three cases occurring in India are on record, the first of which was reported by one of us (Chakravarti, 1951). It must be appreciated, however, that polyarteritis nodosa has hitherto been recognized as an entity only

on the basis of the clinical findings; that it has any relationship to infection, hypersensitivity, or allergy is far from being established, and experimental attempts to arrive at its aetiology have been without success. But, unless the aetiology of such diseases as this is established beyond doubt, cases of arteritis presenting aberrant manifestations differing from the recognized clinical picture will raise problems of identification and lead to claims for the discovery of new entities. Thus a variety of arteritis with a different age incidence, vascular distribution, and prognosis was described in 1932 by Horton, Magath, and Brown. They gave it the name of "temporal arteritis." Giant cells formed the distinctive feature in its pathology, and, though it was claimed that giant-cell arteritis and polyarteritis are identical, this view was not supported by Harrison (1948).

In the light of the above considerations we describe below a case in which the clinical picture resembled in some respects that of polyarteritis nodosa, yet differed from it in a number of essential features. Clinically it was considered to be an example of polyphlebitis rather than of polyarteritis, but histological examination of the vascular lesions revealed the presence of giant cells, so long considered almost characteristic of temporal arteritis. The case would therefore appear to be of a hitherto unrecognized type of arteritis.

Case Report

A married woman aged 28 years; mother of four children, the last of which was born six years ago. No history of miscarriage. Past history of colitis, lasting three months, seven years ago. Streaks of blood in sputum during a febrile bout lasting one week three years ago. Husband's two brothers died of pulmonary tuberculosis, six and three years ago respectively.

Present Illness

The patient had suffered from a low-grade, irregular fever and malaise for the past year. One year previously slightly painful, tender spots had appeared on the medial aspects of the thighs, followed by a similar spot on the anterior aspect of the right forearm. For six months there had been persistent and gradually progressive anorexia and asthenia. A constant dull pain in the left hypochondrium, with exacerbations when the patient lay on her left side and on walking, had been noticed for the past three weeks. Since the last attack of colitis seven years ago there had been frequent bouts of diarrhoea. There were no cardiac complaints, no subjective urinary symptoms or respiratory trouble, and no signs of mental disturbance.

Clinical Examination

On examination the patient was found to be sickly, of asthenic build, pale, and anaemic. In the left eye there was phlyctenular conjunctivitis. Temperature 99° F. (37.2° C.); pulse rate 128 and respirations 32 per minute. The fingers were not clubbed. There was no enlargement of cervical or axillary lymph nodes, but the inguinal nodes showed discrete enlargement; these were neither painful nor tender. The spleen was palpable three fingerbreadths below the costal margin; it was soft and acutely tender, but there was no evidence of perisplenitis. The liver was palpable two fingerbreadths below the costal arch; it was rather soft, but peritoneal or paravertebral tenderness was absent. No abnormality was detectable in the colonic or renal area or in the lungs. There was no obvious dilatation of the heart; a harsh systolic murmur was audible all over the praecordium, with maximum intensity in the left third space, in the parasternal line, conducted well out to the posterior axillary line, but no thrill or associated diastolic murmur; the pulmonary second sound was accentuated. Blood pressure 108/64 mm. Hg.

On the medial side of the right arm, just above the elbow-joint, a thick subcutaneous tender lump containing a non-pulsatile cord-like structure could be felt. Similar non-pulsatile cord-like structures containing tender nodules were present on the front of the right forearm and the medial aspects of the thighs; these were the painful, tender spots complained of by the patient. A nodule was also present in the course of the cephalic vein on the right arm. The superficial arteries felt normal and had pulsations in them, except the left radial and brachial arteries, which could not be felt. This was probably a congenital abnormality with adequate compensation by way of collateral channels, since the nutrition of the limb was well maintained. There was no subjective or objective evidence of peripheral vascular disturbance.

Laboratory Investigations

Blood: R.B.C., 3,750,000 per c.mm.; Hb, 60%; W.B.C., 11,000 per c.mm. (polymorphs 75%, lymphocytes 18%, monocytes 2%, eosinophils 5%); E.S.R., 144 mm. in 1 hour (Westergren); coagulation time, 2 minutes; bleeding time, 3½ minutes; blood culture (repeated after two weeks), no growth; blood urea, 24 mg. per 100 ml.; Wassermann reaction negative. Urine: albumin, trace; pus cells, few; red blood cells, occasional; culture, *Alcaligenes faecalis*; no acid-fast bacilli seen by concentration method (examined thrice at intervals of two weeks). Stool: few degenerated pus cells; occasional red blood cells; no protozoa; no acid-fast bacilli seen by concentration method (examined twice at intervals of two weeks). Sputum: no acid-fast bacilli demonstrated by concentration method (examined twice at intervals of two weeks). Peripheral blood tested for "L.E. cells" found to be negative. Tuberculin test just positive with 1 in 1,000 dilution.

Special Investigations

Skiagrams of chest (taken at intervals of two months) showed no evidence of any parenchymatous lung infiltration. No evidence of calcified lymph nodes could be seen in a flat radiograph of the abdomen. Radiological examination of bones and joints distal to the affected vessel in the forearm showed no detectable abnormality. Ophthalmoscopic appearances were normal. An electrocardiogram gave evidence of sinus tachycardia with a normal sinus rhythm and normal auriculo-ventricular conduction; there was no evidence of coronary disease or of ventricular enlargement.

Histological Examination

Subcutaneous Forearm Vein.—The vein was thickened, cord-like, and thrombosed. On section the outer coat showed haemorrhage and many new, thin-walled blood vessels throughout its thickness. In some areas there was fibrinoid degeneration, patchy in distribution. Infiltration by round cells, of which the principal cells were lymphocytes together with a few plasma cells and monocytes, was of almost uniform distribution. At the junction of the outer and middle coats there were multinucleate giant cells surrounding the whole circumference like a ring. The middle coat showed interruption by granulation tissue. The muscle fibres were separated from one another by vascular connective tissue and lymphocytes. Minute patchy areas of degeneration were also seen in the middle coat. The intima was thickened by cellular connective tissue, in which a few capillaries were also seen. The lumen was greatly narrowed, but no thrombus was present, and the appearance was suggestive of organization and recanalization of a previous thrombus. (See Special Plate.)

Cephalic Vein.—A small area of thickening was felt, but the vein appeared otherwise normal. On section the outer coat showed a few areas of focal collections of lymphocytes in which could be seen a few multinucleate giant cells; there were also small areas of haemorrhage and degeneration. In the middle coat the findings were the same as in the specimen from the forearm. The inner coat was more or less normal.

Inguinal Lymph Node.—There were patchy areas of fibrinoid degeneration, but no giant cells were seen. The follicular structure was unaltered and the capsule intact.

A small arteriole from the right forearm adjacent to the affected vein also showed no abnormality.

Discussion

In arriving at a diagnosis in this case there would, in the first place, seem to be little difficulty in excluding other known forms of acute phlebitis. Thrombophlebitis migrans, for example, is of short duration and is characterized by a polymorphonuclear leucocytosis. "Tropical primary phlebitis," which was described by Fisher, Fisher, and Lendrum in 1947, runs a self-limiting course, and recurrence is uncommon. Histologically the granulation tissue interrupting the vessel wall is composed of new capillaries, polymorphs, and polyblasts, some of the last-named containing phloxinophil inclusion bodies. Again, in thromboangiitis obliterans there may be an associated phlebitis, but the disease is afebrile and characterized by arterial obstruction in the limbs; moreover, giant cells are found only in the region of organizing blood-clot. Secondly, although the family history, together with the clinical course, might suggest chronic miliary tuberculosis, absence of positive evidence of tuberculosis and the fact that the lesions were limited to the systemic veins would rule out such a possibility.

It seems certain that the case belongs to the group of vascular collagen diseases. Of these, the conditions that seem worth considering in the differential diagnosis are: (1) lupus erythematosus, (2) giant-cell arteritis, and (3) polyarteritis nodosa. (1) In acute disseminated lupus erythematosus skin lesions may be absent, but, in addition to endocarditis, involvement of serous membranes and joints is an important feature. Moreover, this is rather a visceral involvement than a surface vascular manifestation. Clinical diagnosis is dependent on the demonstration of L.E. cells. (2) Giant-cell arteritis usually affects the aged, the lesions being chiefly confined to the scalp and cranial arteries; the veins are never affected. (3) Polyarteritis nodosa is essentially a condition of primary arteritis usually affecting males. Hypertension and kidney involvement form an essential part of the clinical picture, and leucocytosis is common. Histologically, giant cells are seldom encountered.

Our case, therefore, though most closely resembling polyarteritis nodosa in the widespread distribution of the vascular lesions, has definite points of difference. Thus there was no hypertension or renal failure even twelve months after the onset of the illness; leucocytosis was absent; lesions were limited to widely scattered veins; and, finally, giant cells were present. These would appear to be grounds for regarding the case as at least a variant form of the collagen group of diseases which has not hitherto been described.

The histological slides were sent to Professor J. H. Dible, of the Department of Pathology, Postgraduate Medical School of London, for his opinion, and he makes the following comments: "I have examined the tissues and have also discussed them with Dr. Harrison. He points out that giant-cell arteritis, so far as is known, never affects veins, and, moreover, it is essentially a disease of advanced years. I don't think either the history or the histology of the lesion fits in with syphilis. . . . I have never seen tuberculosis attack veins in this way. . . . The disease which seems most worth considering is polyarteritis nodosa. The limiting of lesions to the veins and the peculiar picture of giant cells are certainly unusual, but, then, so is the whole case. I don't think this disease, either clinically or histologically, is the same as those reported by Fisher, Fisher, and Lendrum (1947)."

Summary

A case is reported of a protracted febrile illness in a young married woman in which polyphlebitis, inguinal lymphadenopathy, disproportionate tachycardia, and a high erythrocyte sedimentation rate were notable

features. The condition in many respects resembled polyarteritis nodosa, but differed from it in that the vascular lesions were limited to the veins and in the presence of giant cells.

A full account of the clinical and laboratory findings is given and the differential diagnosis discussed.

The patient is alive and is being followed up.

We are most grateful to Professor Dible for his valuable opinion on the tissue slides. Our thanks are also due to Dr. C. V. Harrison, Reader in Morbid Anatomy, University of London, for his views on giant-cell arteritis, and to Drs. S. N. De and A. Mukherjee, of the Departments of Pathology at the Sir Nalratn Sarkar Medical College and School of Tropical Medicine, Calcutta, respectively, for their help and co-operation.

SPONTANEOUS MYXOEDEMA DEVELOPING AFTER THYROTOXICOSIS

BY

RUSSELL FRASER, M.D., F.R.C.P.

AND

B. E. C. NORDIN, M.D., M.R.C.P.

(From the Department of Medicine, Postgraduate Medical School of London, W.12)

Primary adult myxoedema most commonly occurs from idiopathic primary atrophy, but may also follow thyroidectomy, excessive radio-iodine dosage, or destructive thyroid disease such as lymphadenoid goitre (Hashimoto's thyroiditis). It is also frequently stated in textbooks that adult myxoedema may arise in patients who have previously had frank thyrotoxicosis ("burned out toxic goitre"), but it is exceedingly hard to discover records of such cases. Crotti (1938) describes one, but gives the impression that he has seen many more: he intimates that the progression from hyperthyroidism to hypothyroidism takes many years. McGavack (1951) describes the case of a patient who received only iodine treatment for his thyrotoxicosis but developed myxoedema some four years later. In view of the paucity of cases recorded, we are reporting one which was first treated for thyrotoxicosis with antithyroid drugs for 21 months; an active thyroid gland was still present at the end of this time. Twelve months later the patient was definitely myxoedematous.

Case Report

A married man aged 40 first presented in November, 1950, with an 18-months history of increasing fatigue, intolerance of hot weather, and 3 st. (19 kg.) loss of weight. He also complained of some dyspnoea on exertion and of some prominence of the eyes in the past two months. His appetite was very good. On examination at that time he was a thin, flushed, and anxious man (Fig. 1 A) with a fine tremor of the fingers, an increased peripheral circulation, and a slightly enlarged soft thyroid gland with a bruit. There was no true exophthalmos, lid retraction, or lid lag, but a definite "stare." There were no other physical signs. Investigation confirmed the diagnosis of hyperthyroidism (Fig. 2). The basal metabolic rate ranged from 140 to

160% of normal according to the Boothby standards (52 to 60 cal./square m./hr.). A radio-iodine test yielded only 10.7% excretion in 48 hours ("T" index of thyroid uptake = 105 compared with the normal of 3-13) (see Fraser *et al.*, 1953).

After a short course of an anti-thyroxine drug (butyl-4-hydroxy-3:5-diiodobenzoate) (Fraser and MacLagan, 1953), and after an episode of pyrexia which was found to be due to otitis media, the patient was discharged on methyl-thiouracil, 600 mg., and thyroid, 1 gr. (65 mg.), daily. He responded rapidly to treatment, gained weight, and remained well controlled on diminishing doses of thiouracil from January, 1951, to October, 1952. Antithyroid drug treatment was then stopped, and a radio-iodine test done a few days later showed that the gland was still active in that the 48-hour excretion was 16.7% (T=62). He was then given a short course of potassium iodide and re-tested in February, 1953, when the 48-hour radio-iodine excretion had risen to 77% (T=2.6). This was attributed to excessive ingestion of iodides as the patient appeared

Fig. 2.—Results of investigation.

euthyroid, but when the test was repeated three months later it yielded a similar result, and when he was seen again in October, 1953, he had all the features of myxoedema—full puffy facies, husky voice, and dry skin—and his weight had risen to 13 st. (82.5 kg.) (Fig. 1 B). On admission for reinvestigation it was found that his blood cholesterol had risen to 391 mg. per 100 ml., his basal metabolic rate had fallen to -28 to -33% (25-28 cal./square m./hr.), his protein-bound iodine was 2.8 µg. per 100 ml., and he had

electrocardiographic evidence of myxoedema. There was no evidence of pituitary failure: he had a normal 17-keto-steroid excretion, and a normal diuresis in response to a standard water load.

Conclusion

Our data indicate that this patient had Graves's disease in 1950; that his thyroid gland was still functioning at the end of 1952, after treatment with thiouracil; and yet that one year later he had advanced primary myxoedema, which has since responded to thyroxine. We have been unable to find a record of any other case of myxoedema developing spontaneously so soon after thyrotoxicosis.

SEZARY'S SYNDROME

BY

W. E. ALDERSON, B.M.

Consultant Dermatologist, Bradford Royal Infirmary

GEORGE I. BARROW, M.B.

Late Registrar, Department of Dermatology, Bradford Royal Infirmary

AND

ROBERT L. TURNER, M.B.

Late Registrar, Department of Pathology, St. Luke's Hospital, Bradford

Disturbances of the reticulo-endothelial system associated with generalized erythrodermia are well known, and form a diverse group, from which Sézary and Bouvraïn (1938) first described a distinct syndrome. This is characterized clinically by bizarre features, and pathologically by the appearance of peculiar monocytoid cells in the blood. Sézary (1949) reviewed all the four published cases (Sézary and Bouvraïn, 1938; Sézary, Horowitz, and Maschas, 1938; Baccaredda, 1939; and Sézary and Bolgert, 1942), to which Wilson and Fielding (1953) have added one more—the first reported in Britain.

The purpose of this paper is to draw attention to this syndrome by recording the clinical and pathological features of two further cases, and to discuss their relation to the reticuloses.

Case 1

The patient, a widow aged 77, previously led an active, healthy life. She had had smallpox at the age of 11 years and pneumonia at 73. Seven sons were alive and well; one premature infant was stillborn. About eight years ago she first suffered from attacks of extensive erythrodermia "just like measles," with varying degrees of exfoliation, and intense pruritus, starting in the feet and spreading over the limbs and trunk. These attacks were transient initially and were preceded by malaise. Later all her skin assumed a mottled appearance. Her palms were occasionally affected so severely that she was unable to do her housework. The mucous membranes were not affected, nor was there any history of excessive sweating, although she felt the cold intensely.

Some twelve months ago she became aware of "hot aches" and stiffness of the fingers, with distortion and looseness of the nails—so much so that she was unable to relieve the intense pruritus by "having a good scratch." Her skin also showed scattered patches of both leucodermia and brown pigmentation. Alopecia was complete apart from

occasional tufts on the scalp. Recently oedema of the legs occurred, and infected excoriations have resulted in whitelows, and superficial ulcers on the ankles and elbows.

When first seen in 1950 she showed extensive erythema, fine desquamation, telangiectasia, and superficial lymphadenopathy. Various diagnoses were then considered, including parakeratosis variegata, pityriasis rubra pilaris, poikiloderma vasculare atrophicum, and lymphosarcoma. Skin and blood examinations at that time were equivocal. The presence of atypical white cells in the blood was noted, but their significance was not realized.

Clinical examination showed an elderly woman whose bizarre appearance is well illustrated by Fig. 1. The skin

showed a generalized mottled erythrodermia with fine scaling and interspersed areas of slaty-brown pigmentation and leucodermia of varying sizes and indefinite distribution. Petechiae were maximal over the sternum and shins, the latter also showing erythema ab igne. The hair was absent apart from residual tufts on the scalp and a few remaining

FIG. 1.—Face and hands of Case 1.

hairs on the pubes. The eyelids showed chronic blepharitis and ectropion of the lower lids. The nose was shrunken and the nares were widened. The joints of the wrists and knees showed arthritic changes. There were oedema, ulnar deviation, and flexural contractures of the digits of both hands: full extension, active or passive, of the fingers of the right hand was impossible. The nails and terminal phalanges of the left hand were almost entirely absent; the thumb was normal. The changes were less marked in the right hand, although all fingers showed some degree of deformity. The lymph nodes in the axillae and groins were all enlarged, firm, rubbery, and discrete. There was one similar lymph node in the right cervical area. The mucous membranes were normal.

No significant lesion has been revealed in any other system. The spleen was not felt. The liver edge was palpable just below the costal margin. There was slight oedema of the legs. B.P. 170/80. Weight 7 st. 12 lb. (49.9 kg.). The temperature and pulse were normal. X-ray films of the skull, spine, pelvis, and chest were essentially normal. The mental condition was that of a well-adjusted euphoric elderly woman.

Case 2

The patient, a married woman aged 40, had suffered from eczema as a child. Her appendix had been removed at the

age of 17 years. In 1948 she developed a patchy eczema whilst in hospital for recurrent erysipelas of the face. She has one daughter, aged 19 years.

About four years previously she first complained of pruritus starting on the trunk, followed by erythema of the arms, thickening of the skin, and generalized scaling. This started six months after laparotomy, at which the left tube and ovary—with a benign necrotic fibroma—were removed. "Drenching" night sweats followed by rigors were frequent. They ceased six months ago, since when she has felt the cold intensely.

During 1952 superficial lymphadenopathy occurred whilst she was under treatment elsewhere for generalized exfoliation. A provisional diagnosis of lipomelanotic reticulosis was made and A.C.T.H. therapy instituted. Considerable improvement ensued, but A.C.T.H. was stopped after pigmentation and staphylococcal pyoderma supervened.

In January, 1953, she was admitted to hospital under our care with the same provisional diagnosis, the clinical features being those of intense pruritus, generalized erythrodermia,

mild desquamation, pigmentation, and superficial lymphadenopathy. She continued to develop occasional pyodermic nodules, which have healed normally, although some required drainage.

Clinical examination showed a pathetic woman, whose appearance is shown in Fig. 2.

The skin showed generalized erythrodermia, fine scaling, and "mottling," which was more confluent on the lower parts. Generalized brown pigmentation was maximal on the face and trunk. Leucodermia was absent. The arms were lichenified and there was some eczematization of the lower legs. Two right linear abdominal scars were present. At the time of writing there was one small pyodermic nodule on the right wrist. The hair was absent. The eyelids were normal, but the lower eyelashes were absent. The nose, joints, nails, and mucous membranes were normal. The lymph nodes in the neck, axillae, and groins were all enlarged, firm, rubbery, and discrete.

No significant lesion has been revealed in any other system. The spleen was not felt. The liver was palpable two fingerbreadths below the costal margin. There was slight oedema of the feet. B.P. 110/65. Weight 6 st. 5 lb. (40.4 kg.). The temperature and pulse have occasionally been slightly raised. X-ray films of the skull, spine, pelvis, and chest were normal. The mental condition was that of an anxious woman whose intellectual level is well below average.

Pathological Features

Skin.—Biopsy material from the axilla (Case 1) and from the neck (Case 2) both show similar histological appearances. The main feature is uniform infiltration of the epidermis and corium with monocytoid cells (Fig. 3). The distribution is perivascular in the corium and focal in arrangement in the epidermis. The predominant cells are distinguished by large irregular convoluted nuclei with dense chromatin and scanty feebly acidophilic cytoplasm. Allowing for structural alteration during fixation and staining,

these cells are almost identical with those in the blood. The remainder are mainly round cells. The epidermis shows marked parakeratosis, some acanthosis, vesicle formation, and prominent rete pegs. The corium is oedematous and the smaller blood vessels show endarteritis. Sweat glands are present, but hair follicles are conspicuously absent.

Lymph Nodes.—Lymph nodes from the axilla (Case 1) and from the neck (Case 2) are similar in histological appearance (Fig. 4). The capsule is intact, is thickened, and shows no infiltration. The cortex is remarkably broad, slightly lobulated, and paler than normal when stained with haematoxylin and eosin. The cortical follicles are atrophic and compressed, some still showing Flemming's centres. The pallor is due to sheets of cells with large pleomorphic nuclei, often seen in mitosis. Their scanty cytoplasm is faintly acidophilic.

Among these cells are small numbers of lymphocytes, eosinophils, and small deposits of melanin. Stained preparations reveal few reticulum fibres in the cortex. Medullary sinus catarrh is marked. The appearances are similar to those of lipomelanotic reticulosis ("dermatopathic lymphadenitis"), described by Jarrett and Kellett (1951), although nuclear mitosis and pleomorphism are more marked in the cortical cells of our cases. Jarrett and Kellett thought that the cortical cells of their cases were reticulum cells of histiocyte type. In appearance, though not in depth of staining, their nuclei resemble those of the Sézary cells in the blood of our patients. The variation in staining is probably due to differences in fixation. This view is supported by the presence of large numbers of these cells in lymph-node-puncture smears stained by Jenner-Giemsa technique.

Blood Picture.—During observation both patients have shown an unresponsive secondary normochromic anaemia, the Hb varying from 9 to 12 g. and the M.C.H.C. from 30 to 34%. No nucleated red cells were seen. The platelets appeared normal, ranging from 300,000 to 400,000 per c.mm. At times both patients have shown a slight leucocytosis which never exceeded 16,000 per c.mm., with a varying eosinophilia. The dominant feature, however, was the invariable presence of the *cellules monstres* of Sézary. At one time these abnormal cells constituted 35% of the total white-cell count; at others their numbers were so reduced that special search was necessary to detect their presence (Table I).

24.2.54	12,800	60	13	2	16	0	9

Sézary cells in air-dried Romanovski films (Fig. 5) are approximately twice the size of normal polymorphs. They are peroxidase-negative. The scanty, feebly basophilic cytoplasm resembles that of normal monocytes and occasionally shows fine dusty granules or pseudopodia. The nucleus occupies about four-fifths of the cell and varies considerably in shape,

(a)

(b)

FIG. 5.—Peripheral blood: (a) Sézary cell in mitosis with adjacent normal polymorphs; (b) characteristic mature Sézary cell.

sometimes being round, convoluted, reniform, or bilobed. Binucleate and trinucleate forms have been seen. They simulate mature lymphocytes only in chromatin arrangement and depth of staining. Nucleoli are usually absent or indistinct. These cells were occasionally seen in mitosis in Case 1.

Sternal Marrow.—Marrow smears from both cases show no distinctive features (Table II). Sézary cells are present, but no more than would be expected by dilution with the blood.

TABLE II.—Myelograms

Cells	Case 1	Case 2
Blasts	1.0	1.0
Early normoblasts	3.0	4.0
Intermediate normoblasts	10.5	8.0
Late normoblasts	10.5	6.0
Reticulum cells	1.5	0.5
Sézary cells	1.0	3.0
Myeloblasts	0.5	2.0
Promyelocytes	1.5	3.5
Myelocytes	15.5	25.0
Metamyelocytes	20.0	22.0
Granulocytes	25.0	15.0
Lymphocytes	7.0	4.0
Monocytes	1.5	2.0
Plasma cells	0.5	3.0
Megakaryocytes	2.0	1.0

Laboratory Investigations.—The laboratory investigations are summarized in Table III. They have been repeated on several occasions, and the results have invariably been within normal limits, except the E.S.R. (Wintrobe), which is raised slightly in both patients. Hess's test for capillary wall fragility was unsatisfactory because of the state of the skin.

TABLE III.—Laboratory Investigations

Investigation	Case 1	Case 2

Diagnosis

The features of Sézary's syndrome are intense pruritus, generalized erythrodermia, pigmentation, and superficial lymphadenopathy, associated with the presence of unusual monocytoid cells in the blood.

In general this description might apply to many of the reticuloses, of which "lipomelanotic reticulosis," Hodgkin's disease, the leukaemias, and mycosis fungoides are of importance.

Lipomelanotic reticulosis often starts as a localized dermatosis, before generalized erythrodermia, intense pruritus, and superficial lymphadenopathy develop. Varying degrees of exfoliation, lichenification, pigmentation, excoriation, and low-grade sepsis occur. Attacks of profuse sweating are almost invariable. Eosinophilia is usually present. It may be difficult to differentiate this condition from Sézary's syndrome without careful haematological examination.

Hodgkin's disease frequently presents with lymphadenomatous masses, and less often with cutaneous manifestations. When it affects the skin pruritus may be marked, but erythrodermia is unusual. Prurigo papules or scratch marks may be the only visible signs.

The leukaemias should always be suspected. The cutaneous manifestations may take the form of intense pruritus, erythrodermia and exfoliation, although nodules and areas of infiltration occur. The hair and nails may shed. Purpura often occurs in the acute phase, the patient usually having an irregular pyrexia. Erythrodermia in the form of glazed or weeping areas may give the classical picture of "l'homme rouge." Both lymphadenopathy and hepatosplenomegaly may be present. The characteristic blood and marrow pictures indicate the diagnosis.

Mycosis fungoides is usually substantiated only when tumour formation has occurred. The earlier lesions are often red scaly patches, transient at first, eventually becoming fixed and infiltrated. Involution may occur, leaving pigmented areas, but persistence is usual. They usually precede the development of cutaneous tumours by a long interval.

Parapsoriasis embraces an ill-defined group of conditions, of which parakeratosis variegata may possibly cause confusion. Although generalized retiform hyperaemia and scaling are present, subjective sensations and lymphadenopathy are absent, and the blood picture is normal.

In cases of generalized erythrodermia with lymphadenopathy, chest x-ray and haematological examination, including marrow puncture, and biopsy of the skin and lymph nodes should be done. If doubtful, these examinations should be repeated at intervals.

Discussion

We have known of this syndrome now for two years. Despite the study of likely patients, only two cases have been seen, and the literature contains only five other confirmed cases. The condition therefore appears to be of some rarity. This is perhaps due to failure to recognize

TABLE IV.—Clinical Features of Published Cases

the syndrome. The case reported by MacCormac and Whitby (1935) as leukaemic erythrodermia was possibly an example of this condition. Hodgkin's disease with cutaneous manifestations and circulating Reed-Sternberg cells (Simmers, 1924; Miller, 1928; Wigley, 1937; Combes and Bluetarb, 1941) has perhaps been confused with Sézary's syndrome because of the superficial similarity of Reed-Sternberg cells to the *cellules monstreuses*.

Review of the clinical features of the five published cases and the two reported here shows that this condition seems to occur mainly in elderly females (Table IV). Some patients given a history of skin trouble, such as transient rashes, occurring some time before the onset of pruritus, which was the presenting symptom in all cases. Pruritus was intense, eventually generalized, and later associated with exfoliative erythrodermia, pigmentation, purpura, and "mottling," which in one patient (Case 1) took the form of a retiform telangiectasia.

Cutaneous thickening and oedema give a strange facies, which may be accentuated by ectropion, patchy loss of hair, or even total alopecia. Other features noted include dystrophy of the nails, arthropathy, frictional eczema, excoriation, and pyoderma. In all cases superficial lymphadenopathy was marked. Chest x-ray examination revealed no evidence of mediastinal glandular enlargement.

The general condition of one of our patients (Case 1) has consistently remained good, although the local condition has varied; the other patient has been in poor health for some time. At intervals, both patients have had short courses of A.C.T.H. and cortisone with temporary improvement, but relapse has invariably occurred. At present both are improving spontaneously, and further A.C.T.H. is therefore being withheld. Pigmentation, erythrodermia, and scaling are becoming less marked, and there is associated diminution of the superficial lymph nodes. The eyebrows and eyelashes are regrowing. The mental outlook of both patients has improved.

The number of cases reported is inadequate to assess the prognosis. It is possibly significant that all except one case have been elderly. Sézary does not state the actual cause of death in his cases. In Baccaredda's case deterioration and death were unexpected, and due to pyelonephritis; Wilson and Fielding's patient died from cardiac disease. At present the general condition of our cases appears satisfactory and early death is not anticipated. Apparent clinical improvement in our cases whilst in hospital may not indicate that the condition is any the less malignant, as spontaneous remissions occur in all reticuloses.

The clinical and laboratory features of the present cases and of those reviewed by Sézary (1949) indicate that they form part of the reticuloses. Although Sézary described the condition as a "nouvelle reticulose cutanée," the cytological appearances are similar to those of the reticulum-cell reticuloses (Israëls, 1951) although affecting different structures.

One of us (R. L. T.) has had the opportunity of examining blood and marrow smears from the cases described by Israëls (1951) and classified by him as reticulum-cell reticulosis. In some of these cases the abnormal cells closely resemble the *cellules monstreuses* of Sézary. The difference between these series appears largely clinical, possibly depending on the anatomical site where the disease begins.

In general, the present classification of the reticuloses is unsatisfactory. It comprises a large group of conditions, varying from the lipid storage diseases to disturbances characterized by progressive proliferation of all or part of the reticulo-endothelial tissues. In the British literature two classifications, depending respectively on the histology (Robb-Smith, 1938) and the clinico-pathological features (Israëls, 1953) are recognized. Israëls suggests that in his classification many of the subgroups delineated by histological examination alone may be but phases in the ultimate evolution of the same disease process.

With this in view, and because of the similarity of the lymph-node histology of our cases to that of lipomelanotic reticulosis, we have reviewed the series reported by Jarrett and Kellett (1951) from this hospital in order to see if those surviving showed Sézary cells in the blood, or other evidence of malignant reticulosis. Of their 16 patients (13 men and 3 women), who were observed for 3½ years, 5 have since died, and one could not be traced. Of the remainder, one is still affected and 9 are clinically clear. Sézary cells were not found in any of these cases, nor were other manifestations of reticulosis. In no case was the certified cause of death related to the reticuloses.

Sézary provisionally classified the *cellules monstreuses* as aberrant reticulum cells originating from the reticulum tissue in the skin. This view is probably correct, although we are less certain of the site of origin, as they resemble the proliferating reticulum cells of lymph nodes—smears from which in the present cases show a high proportion of these cells. Their similarity to the proliferating cells seen in the blood and marrow of Israëls's reticulum-cell reticulosis is again emphasized.

Histologically, this appears to place Sézary's syndrome as a transitional phase between lipomelanotic reticulosis and reticulum-cell reticulosis.

The apparent benign clinical course of lipomelanotic reticulosis (Pautrier and Woring, 1937; Jarrett and Kellett, 1951) contrasts sharply with the typical fulminating course of reticulum-cell reticulosis. The review of Jarrett and Kellett's lipomelanotic series indicates that nine patients have recovered—so much so that this diagnosis would not now be entertained.

Clinically, therefore, the present cases appear to lie between these extremes, having run a chronic course for several years. Although at present showing some spontaneous remission, it is possibly significant that Case 1 has slowly deteriorated since first seen.

Wilson and Fielding (1953) were hesitant about applying the term "reticulosis" to Sézary's syndrome. They suggest that it is similar to lipomelanotic reticulosis in that it represents a non-specific response to cutaneous disturbance which "is not, at least to begin with, malignant in character." We consider that Sézary's syndrome is more than simple reactive hyperplasia. It is an early phase of malignant reticulosis primarily affecting the skin and superficial lymph nodes. Involvement of the deeper structures is probable provided death does not occur from intercurrent disease.

The ultimate aetiology of this syndrome, as of all reticuloses, remains obscure. Careful study of prolonged conditions such as this, linking reactive states to irreversible malignancy, may possibly contribute to knowledge of the latter.

Summary

Two further cases of Sézary's syndrome are described and the five previous cases reviewed.

It is thought to be a local reticulosis intermediate in phase between benign reaction and frank malignancy.

The chronicity is possibly due partly to its "pre-malignant" character and partly to the organ affected—the skin and superficial lymph nodes.

We are grateful to Dr. S. Varadi, of Sheffield, and Dr. M. C. G. Israëls, of Manchester, for advice and encouragement; to Mr. L. Sutcliffe, of Bradford, and Mr. C. Howe, of Manchester, for the photographs; and to Miss M. E. Whyte for technical assistance.

Speaking at a graduation ceremony for medical students at St. Andrews University on January 14, Principal T. M. Knox, vice-chancellor of the University, uttered a warning against the modern tendency to divert professional men from the practice of their profession into administration. "It used to be said in scorn about teachers," he said, "that they taught only because they could not do. One might perhaps have expected an equally scornful remark about administrators." But administration now presented itself in such an attractive guise that many professional men were lured away from the exercise of their professional skill into an office chair. "I am not sure that this is a sign of health in the body politic." "In fact," Principal Knox went on, "administration is just a necessary evil, not an end in itself, but a means to the freedom and progress of professional work, and, whatever the difficulties of administration may be, it is a great deal easier than the exercise of professional skill."—*Scotsman*.

INCIDENCE OF DENTAL CARIES IN CHILDREN UNDER 5 YEARS OLD

BY

GEOFFREY L. SLACK, O.B.E., T.D., D.D.S.
F.D.S. R.C.S.Eng., Dipl. Bact.

Senior Lecturer in Preventive Dentistry, School of Dental Surgery, University of Liverpool

Amongst the few surveys of the incidence of dental caries in children under 5 years old that have been published in this country are those of Knowles (1948) and Jackson (1952). Frequent reports have been made on the dental condition of children aged 5 and over, in particular the studies of Mellanby and Coumoulos (1944, 1946) and Mellanby and Mellanby (1948, 1950, and 1951).

In 1948 it was decided to carry out a series of surveys of the dental condition of the children in the city of Liverpool day nurseries. Four static surveys were completed during the period 1948–52, and the findings are presented in this paper.

The primary aim of these surveys was to determine the incidence of dental caries in children under 5 years old, before they passed into the regular care of the school dental service. A high caries attack rate would, without doubt, prejudice the chances of maintaining the dental fitness of these children by adding to the already heavy burden of dental work now being undertaken. Further, it would be possible to estimate on the basis of the results the number of dentists required to maintain a satisfactory treatment service.

As the second aim, it was desired to ascertain whether any variation in incidence of dental caries would occur over a period of years and to speculate upon possible causes of such variations. For example, a poor state of dental health might be attributed to the possibility of dietary errors during pregnancy and lactation affecting the resistance of tooth structure to caries attack. Alternatively, or in addition, post-natal dietary errors might create in the child environmental conditions in the mouth which would favour the carious process.

Children under 5 provide a useful measure of pre- and post-natal influences. The deciduous teeth begin to be mineralized *in utero* during the eighth week. The completion of the mineralization of the deciduous dentition occurs after birth, during the third year. At about 6 years of age the first permanent molar teeth erupt in a position distal to the deciduous second molar. This is followed shortly afterwards by the shedding of the deciduous incisors. Thus, by confining the investigation to children under 5 the complications of mixed (deciduous and permanent) dentitions are avoided.

Materials and Method

Liverpool Day Nurseries.—These are administered by the maternity and child welfare department under the city medical officer of health. In 1950 the number of day nurseries was increased from 13 to 15, and in 1953 it was reduced to 14. The nurseries are located in widely separated areas, which vary from the poorer districts to the more salubrious parts of the city. The number of children accommodated on a daily basis varies from 40 to 70. The eligibility of children for places in the day nurseries depends on the circumstances of the applying parent. The object is to provide daytime nursery facilities which will enable the parent to go out to work. At one time children who had been accepted could remain at the day nursery until school age, but this policy

was changed in 1951. It is now the intention that accommodation should be available for restricted periods of time until the parents can make other arrangements. The estimated annual turnover is about 15%. The nurseries open at 6.30 a.m. for the admission of children and close at approximately 6.30 p.m. after the children have been collected by the parents. At present the daily charge is three shillings.

Feeding Arrangements.—The children are given three meals at the nursery. Breakfast and tea are prepared and cooked at the individual nurseries. However, the midday meal is prepared, cooked, and then delivered in insulated containers from central kitchens by the school meal service. The vegetables are cooked at the nurseries. In addition, the children receive cod-liver oil, orange juice, and one pint (570 ml.) of milk daily. There are no between-meal snacks whilst the children are at the day nursery. The only exception is that sweets of the dolly mixture type are given after inoculations. Incidentally, many of the children arrive eating sweets, buns, or cakes, and often are given some form of confection by the parents on leaving the nursery at the end of the day. Knowles (1948) reports a similar practice in the London area nurseries. The reason for this may be the desire of the parents to establish or re-establish themselves in the affections of these very young children after long daily separations. It is known, too, that many of the children are similarly indulged at the week-ends.

Dental Standards.—All examinations were carried out by me, using mirror and probe in a good light. New Ash's Clinic No. 17 probes were used, being discarded after 15 to 20 examinations. The probe is fairly coarse, with a short taper to its point. I recorded findings on a simple chart. Caries was recorded, showing the surface(s) of the tooth involved, and graded as follows: Grade 1: cavities which would definitely admit the point of the probe; doubtful cavities were not included. Grade 2: cavities involving up to one-third of the crown of the tooth. Grade 3: cavities involving more than one-third of the crown; missing teeth due to extraction were placed in this category. Fillings were recorded as caries and scored accordingly. The condition of the gums was also recorded, and the severity of gingivitis was graded 1, 2, and 3. Co-operation was enhanced if the examinations were carried out in the presence of as many children as possible. The older children were usually examined first; the younger and doubting children usually followed without demur. Only four toddlers resisted all manner of coaxing to allow examination during the five-year period. Much of this success was due to the kind yet firm handling of the children by the matrons and their excellent staffs. A simple method was used to examine the babies. I sat facing the nurse and the baby was placed on our knees with its head towards me. This inversion of the baby proved an easy method of obtaining a view of the upper teeth.

Numbers Examined.—The number of children examined is given in Table I. In the first two examinations only those children were examined who were likely to stay a reasonable length of time. This accounts

TABLE I.—Children Examined

Age	Dec., 1948	May, 1949	June, 1951	May, 1952	Total
Under 2	33	21	151	152	357
" 3	146	136	153	197	632
" 4	117	149	134	148	548
" 5	28	52	156	136	372
Total	324	358	594	633	1,909

for the low figures in the 4–5 age groups in the 1948 and 1949 examinations. When the longer stay policy was abandoned a progressive survey was no longer possible. Thereafter all children were examined.

Results

The results of the series of four examinations are presented by age groups (Table II). The percentage of caries-free children in the series of examinations shows a similar trend for all age groups. There was a definite drop in the percentage in May, 1949, followed by a rise in June, 1951, to a higher level than in December, 1948.

The average D.E.F. (decayed, extracted, and filled) teeth per child has been calculated. The trend of caries attack is similar.

The effect of a small number of children each having a large number of decayed teeth would be to raise the overall average of D.E.F. and perhaps show a false position. This effect can be minimized by expressing the findings in terms of D.E.F. per 100 teeth. However, the trend is again similar.

The susceptibility to decay of individual teeth varies. The results of all four examinations have been pooled, and are presented by age groups (see Chart). There is a steady rise, though at different rates, in the susceptibility of all teeth with the increase in the age of the children. The pattern of the results approximates the findings of Knowles (1948). The high susceptibility of the deciduous molars, especially the second

TABLE II.—Results of Four Surveys

Date Examined:	Dec., 1948				May, 1949				June, 1951				May, 1952			
Age:	-2	-3	-4	-5	-2	-3	-4	-5	-2	-3	-4	-5	-2	-3	-4	-5

D.E.F.—Decayed, extracted, or filled teeth.

molars, is particularly striking when considered in terms of the length of time these teeth are exposed to the oral environment. It is generally accepted that the eruption times of the deciduous dentition are: incisors, 6-10 months; canines, 16-20 months; first molars, 12-16 months; and second molars, 20-30 months (Kronfeld, 1939). Occasionally eruption times fall outside these dates. It is possible that enamel formed at about the time of birth is less resistant to caries. Rushton (1933) has shown that the disturbance of birth causes a change in the enamel. Histological sections show a line of demarcation between the pre-natal and post-natal enamel. It is an appalling thought that 7% of the second deciduous molars are decayed before the children are 2 years old, and that, even worse, over 45% are decayed before the children reach 5 years. Comment is made below on this point.

The severity of caries was assessed in accordance with the grades referred to above. The results of the four examinations for all age groups have been pooled. Of the 876 decayed first molars, 28% were grade 1, 46% grade 2, and 26% grade 3. Of the 1,808 decayed second molars, 43.5% were grade 1, 38.5% grade 2, and 18% grade 3.

Finally, only 11 children out of the total number of 1,909 had any fillings present. The gum condition of the children was generally good, and less than 2% suffered from clinically detectable disturbances.

Discussion

The primary object of the survey, which was to ascertain the incidence of caries, has been achieved. It is reasonable to comment on these findings relative to all children, for it has not been shown that dental caries is any less prevalent at either end of the social or financial scale. The only exception is that children fully resident the year round in orphanages, institutions, and the like have a much lower incidence of decay (Hewat, 1931, 1932). These latter children constitute only a very small fraction of the child population of the United Kingdom.

It is a sad reflection that all children who enter school have, on an average, five decayed teeth each. Thus the school dental service is faced with a considerable problem.

The live-birth rate in Liverpool over the past ten years averages approximately 16,500 a year (A. B. Semple, 1953, personal communication). This provides a basis for the calculation of the number of dentists required. Thus, $16,500 \times 5$ decayed teeth = 82,500 teeth requiring treatment in the 4-5-year-old children alone. It is possible for one full-time school dentist to complete, say, 3,168 fillings a year. Assuming one simple filling per tooth, 26 dentists would be required to deal only with this 4-5-year-old age group each year. Certain factors would affect this figure, such as extractions, root fillings, multiple fillings, difficult children, refusals, attendances to private dentists, etc. Even if allowance be made for these factors, the situation is impossible. In Liverpool the establishment of dental surgeons in the school service is 24, to deal with the whole school population and such pre-school children who do attend.

No doubt much the same situation exists in the majority of other similar communities. As a result multiple extractions of the deciduous teeth have to be carried out so that time may be devoted to the preservation of the permanent teeth of the older schoolchildren. The consequence is that large numbers of children become dental cripples with impaired mastication and malocclusion of the permanent teeth due to the early loss of the deciduous teeth. The deciduous molars should be retained until 9-10 years old, when the permanent premolar teeth which follow them are due to erupt. It is little wonder that the demand for the treatment for these irregularities far outstrips the supply of trained orthodontists. Nor is it surprising that full dentures are required by adults at an early age.

The increase of dental man-power, though essential to a certain level, does not provide a satisfactory solution to this

problem. The real solution lies in more dental research into the aetiology of dental caries, and, in the meantime, the application of every known measure which may bring about a reduction in decay.

The second object of these surveys was the examination of the trend of caries attack during the five years. The result is interesting (see Table II).

It is reasonable to assume that the influential factor responsible for this trend was not of pre-natal origin affecting tooth structure during formation. A common pre-natal factor would not have caused similar variations in all the age groups at the same time. Hence it is reasonable to examine the possible local or environmental factors which might be concerned.

Diet.—There were no significant changes in the main nutritional parts of the diet during the period. Some improvement in quality was introduced during 1951. No correlation is possible.

Supplements.—The prescribed amounts and quality of the vitamin supplements were maintained. At the nurseries the daily pint of milk was given regularly. Changes in the supplying contractors precluded any basis for correlation.

Sugar and Sweets.—The variations in the ration between 1942 and 1953 were examined. This is discussed below in detail.

Oral Hygiene.—No changes in the oral hygiene routine at the nurseries were made during the period.

Extraction Rate of Flour.—No correlation.

Availability of Fruit and Vegetables.—Usual seasonal variation; comment is made below on this point.

The presence of easily fermentable carbohydrate in the mouth has for some time been thought to be an important factor, and must be considered. Stones *et al.* (1954) completed a two-year study in 1951 on the effect of administering 22 oz. (620 g.) of sugar in addition to the ration. The extra sugar was given at meal-times only. There was no significant difference in the incidence of dental caries between the children receiving the extra sugar and those in the control group. On the other hand, the recent comprehensive studies carried out at the Lund Research Station at Vipeholm Hospital in Sweden are important, for the between-meal carbohydrate has been shown to be one of the most important factors in causing dental caries (Gustafsson *et al.*, 1952).

It is tempting, therefore, to speculate regarding the effect of the United Kingdom rationing of sugar and sweets during the period of the four surveys.

The May, 1949, examination, which revealed a drop in the percentage of caries-free children, took place about two to three weeks after the derationing of sweets on April 24, 1949. It may be remembered that there was such a wave of buying that plenty soon became a famine after a few weeks, and rationing was reimposed on August 14, 1949. Thereafter the size of the ration varied until derationing on February 5, 1953. It is interesting to consider whether the quantities of sweets obtained by these children during this period were sufficient to produce changes in the oral environment which hastened the carious process.

Little is known about the rate of development of carious lesions. It is a common clinical experience to find fresh carious lesions within a three-months period after children have been made dentally fit. In this case two weeks seems a short time for the development of lesions; nevertheless, speculation is provoked. Dental surveys of large numbers of children need to be undertaken every two to three weeks over a period of at least two years. Two problems may then be solved—the rate of development of clinically detectable caries, and the possible seasonal variations in the caries attack rate.

Careful study of the former must necessarily precede that of the latter. In the United States of America the greatest incidence of caries appears to occur in the autumn and winter, and the lowest incidence in the summer and spring (Price, 1930; McBeath and Zucker, 1938; Lathrop, 1941, 1943). This finding is not in agreement with the present study, and may be due to local differences between this country and America.

The seasonal variation, if it occurs, could be due to the variations in the composition of diet such as increased consumption of sweets during the periods when there is less inclination to eat fruit and vegetables or when supplies of the latter are restricted by supply or price. If the cause of such variation could be found, a real advance would have been made in dental research.

Conclusions

Children under 5 years suffer severely from dental caries and are in need of dental care. With any foreseeable available dental man-power in the next few years, the task is too great to be dealt with on a reparative basis, so that every possible preventive measure needs to be applied.

At the present date two measures are of proved value in reducing the caries attack rate. The fluoridation of domestic water supplies in the United States is so effective that the United Kingdom Mission of the Ministry of Health (1953) has recommended the inauguration of studies in this country.

The second measure, the plain water rinse after all food and drink, is of individual application. Thus to make this measure effective the education of all those having children in their care is essential. The medical profession is in a unique position in this respect. For it is to the medical practitioner that parents, teachers, and heads of institutions turn for guidance concerning the care of very young children.

The habit of drinking plain water after eating, whatever it may be, must be established in children before the first teeth erupt. As soon as possible they must be taught to rinse and to swallow the water. Experience has shown that children learn this procedure more quickly than when expectorating the water. In any case, the former method is the more socially acceptable. Three rinses should be carried out, forcing the water between the teeth to dislodge the food debris. This routine must never be varied. It must continue throughout the school terms and holidays alike, immediately after all meals, mid-morning or afternoon snacks, sweets, chocolates, and so on. Fibrous foods, such as apples, at the end of meals enhance the procedure. When possible the rinsing should be followed by tooth-brushing, but it must always be done after the last food or drink is taken at night.

I have prepared an instructional pamphlet (United Liverpool Hospitals, 1953). It is written in the simplest terms with deliberate repetition, and is designed to introduce this procedure of preventive dentistry to the mothers of very young children. Actually, the instructions apply to children of all age groups. The method provides, short of a return to primitive diets (Price, 1939), a logical means of reducing the caries attack rate, by the removal of the carbohydrate substance which is so essential to the existence of the organisms associated with the caries process. The regime is simple and clear enough for all to understand.

Summary

The findings of four surveys, during the period 1948-52, of the incidence of dental caries in children under 5 years old are presented.

These children suffer considerably from dental caries. Children on reaching school age have an average of five decayed teeth.

The school dental service faces an impossible task in maintaining a reparative service with the present numbers.

The results show that the trend of dental caries incidence follows a similar pattern in all age groups under 5 years. There was a drop in the percentage of caries-free children in 1949 compared with 1948, 1951, and 1952. An attempt is made to speculate on the cause of this drop.

In the conclusions that are drawn two preventive measures of proved value are mentioned. The fluoridation of domestic water supplies in the United States has been of such value that the United Kingdom Mission has recommended the initiation of fluoridation studies in this country. The second measure recommended is the plain water rinsing of the mouth after eating or drinking anything whatsoever. It should be taught to children before teeth erupt. The technique is described.

The education in dental health of all those who have children under their care is a primary need, whether they be the parents, teachers, or heads of institutions. The medical practitioner is in a unique position, for it is from him that guidance is sought initially in the dental care of these young children.

I wish to express my thanks and gratitude to Professor W. M. Frazer, late medical officer of health for the City of Liverpool, and Dr. Ruby M. Bell, late assistant medical officer of health in charge of the maternity and child welfare department, who kindly gave me facilities to carry out these surveys. Also to their successors, Professor A. B. Semple and Dr. V. J. M. Stark for their continuing interest. I wish to thank the supervising matron and all the matrons and staffs of the individual day nurseries who have helped so much in carrying out the work, Mr. W. Lee for photographing the chart, and Miss I. Rayner, who carried out the tedious task of collating the data for analysis. I am indebted to the Ministry of Food, Liverpool, who kindly supplied the sugar and sweet ration figures from which some data were obtained. Finally, I express my appreciation to Professor H. H. Stones, Director of Dental Education, School of Dental Surgery, University of Liverpool, for his help and encouragement.

The PRINCESS ROYAL unveiled a plaque at No. 10, South Street, Park Lane, London, on January 21 to commemorate the residence in a house on that site of Miss Florence Nightingale. She lived there from 1865 until her death at the age of 90 in 1910. The proposal to erect the plaque was made to the London County Council's planning committee by the Florence Nightingale Hospital, the National Council of Nurses, and the Western Heritable Investment Co., Ltd., the occupiers of the present building. The Princess Royal, who is Patroness of the Florence Nightingale Hospital, was received by Sir CULLUM WELCH, chairman of the hospital, and by Lady WELCH and Mrs. A. C. E. KIMBER, joint chairmen of the hospital's appeal committee. A link with Miss Nightingale herself was provided by the presence at the ceremony of Mrs. ALICE CRAWLEY, who as Miss Cochrane was her secretary for some years. Also present were the chairman of the board of governors, St. Thomas's Hospital, and members of the executive and appeals committees of the Florence Nightingale Hospital, representatives of the National Council of Nurses of Great Britain and Northern Ireland, and the chairman of the London County Council.

A CASE OF BILATERAL FATIGUE FRACTURE OF THE FIBULA

BY

DAVID A. RICHMOND, B.Sc., F.R.C.S.
Orthopaedic Surgeon

AND

J. SHAFAR, M.D., M.R.C.P., D.P.H.
Physician

From the Burnley Group of Hospitals

Fracture of a bone may result from ordinary functional activity in the absence of any obvious injury or violence. Such fractures are referred to as fatigue or stress fractures, and occur spontaneously in apparently normal bone as a consequence of the summation of stresses which singly are insufficient to produce fracture (Burrows, 1948). The incidence of this condition rose sharply during the second world war, but since then, as judged by published cases, it would appear to be an infrequent finding. By far the commonest site of this form of fracture is in one of the metatarsal bones; the tibia is involved five or six times less frequently, and the fibula forty times less frequently (Hartley, 1943). The series of 32 fatigue fractures analysed by Richmond, 1945, showed the following locations: metatarsals, 25; upper third of tibia, 5, and lower third of fibula, 2.

The case reported below is an example of fatigue fractures involving the lower third of both fibulae in a middle-aged housewife.

Case History

A married woman aged 45 was referred to one of us in a general medical clinic as a case of "arthritis of ankles." She complained of pain and swelling in both ankles. The pain had been noticed before the onset of the swelling, and had gradually become very severe—so much so that walking had become difficult. She lives in an upstairs flat and runs up and downstairs to and from a shop many times a day. The only unusual exercise undertaken recently has been that involved in using a treadle sewing-machine employing her right foot only. In addition she runs the flat for herself and her husband.

On examination there was a visible swelling $1\frac{1}{2}$ in. (3.8 cm.) above the tip of the lateral malleolus on the right side. There was a tender bony thickening at this level on both sides. Pain could be elicited at these sites by everting or rotating the calcaneus in the ankle mortise. Similar pain was produced by fully dorsiflexing the foot at the ankle-joint. Both heels showed eversion when standing. Radiographs showed fractures of both fibulae $1\frac{1}{2}$ in. (3.8 cm.) above the malleolar tips, slightly oblique in direction as seen in the antero-posterior views. The lateral views showed little of the fractures. Callus was visible on both sides (see Figs.). No osteoporosis was evident in these films or in films of the hands.

Stirrup strapping was applied to both ankles and the patient was advised to curtail her activities as much as possible. Her signs and symptoms gradually improved, and four months later her pain had almost disappeared, and only slight bony thickening was apparent clinically.

Comment

The diagnosis of fatigue fracture rests on a consideration of the clinical features and radiological findings. Pain is the usual presenting symptom, and may be of acute onset or of gradually increasing severity. There is little in the

patient's history to indicate the nature of the condition: since no record of injury or violence or of a sensation of snap is forthcoming, the possibility of fracture may well not arise.

The local signs are those of localized swelling and tenderness. Burrows (1948) has described three cases of fatigue fracture of the fibula in which tenderness was absent and five in which swelling was not evident. Oedema over the area of the dorsum of the foot may be present and local redness and increased temperature are other occasional findings. In unilateral examples limp does not appear to be a significant sign, but it was certainly a prominent feature in our case. Movement of the ankle-joint is unimpaired, but passive eversion of this articulation produces severe pain over the site of the fracture. Similar pain is produced by any movement which causes widening of the ankle mortise, such as full dorsiflexion of the foot.

Radiograph showing fracture and callus formation of both fibulae.

Watson-Jones (1952) emphasizes that radiographs may show no abnormalities until the fissure is widened by reactionary osteoporosis, or until bone is laid down beneath the periosteum. Burrows states that a fracture line may be evident in some instances only at the end of the third week, and that even then it may be recognized only with the aid of a lens; a dense band is often the earliest change in the x-ray picture, and may be the last abnormality to clear. At a later date callus appears, and may consolidate and persist for many months as a bony buttress across the concavity or "stressed" aspect of the bone.

From his review of the literature and his own personal series of cases Burrows was able to segregate two groups in which fatigue fractures of the lowest third of the fibula occur. The first group comprises young athletes, such as runners and skaters. It is not difficult to understand the mechanism of production of the fracture or fractures in such activities. The second group, to which our own case belongs, is made up of women of middle age or over who are much on their feet in the course of the day. The aetiological factors in this second group are probably several. Burrows refutes the suggestion of Hartley (1943) that osteoporosis plays any significant part in its causation.

The site of the fractures would seem to offer an explanation of the mode of production; in our case they were situated $1\frac{1}{2}$ in. (3.8 cm.) above the tip of the lateral malleolus, and a similar level was noted by Burrows. Here the bone is largely cancellous in type and the fracture line is just below the interosseus ligament. Continued eversion of the feet, particularly in overweight females, will throw a strain on the lateral aspect of the fibula. The pull of the interosseous ligament medially and the forcing of the lower portion of the fibula in an outward direction will determine a focus of stress concentration at a point immediately below the ligament. It may well be, therefore, that at this focus deformation occurs which is at first elastic, and so reversible, but which later becomes permanent. As a consequence of

the localized molecular disruption there results a gradual spread towards the centre. The analogy to fatigue fractures in metals presents itself and would repay further study. It would be interesting to note whether the characters of the fractures in both types are similar. In those of metals the fracture is comparatively smooth at its outer zones where the surfaces have been rubbed together on innumerable occasions prior to the sudden spread of the fracture transversely, this suddenly fractured zone showing relative coarseness. Difficulty remains in affording an explanation for the predominance of this group of fatigue fractures of the fibula in females.

Summary

A case of bilateral fatigue fractures of the fibula in a middle-aged woman is reported.

Point tenderness, and pain at the same site when the ankle mortise was widened by everting the heels or dorsiflexing the foot, were features of the clinical findings.

The site of the fractures was identical with that described by Burrows (1948) in women of middle age.

Treatment advised was stirrup strapping and rest.

INTUSSUSCEPTION OF VERMIFORM APPENDIX IN ALLERGIC CHILDREN

BY

R. G. MITCHELL, M.D., M.R.C.P.E.d., D.C.H.

Lecturer in Child Health, University of St. Andrews; lately
Medical Registrar, the Royal Hospital for
Sick Children, Edinburgh

Chronic intussusception is relatively rare in childhood and the symptoms are often ill defined, especially when the appendix is the site of intussusception. The following two cases are of interest because the presence of allergic disease caused difficulty in diagnosis. The age of the second patient makes her case additionally interesting, because this is only the second report of intussusception of the appendix in a child under 2½ years of age, the first being that of a boy aged 10 months (Forshall, 1953).

Case 1

A boy of 3 years was sent to the Royal Hospital for Sick Children because of attacks of diarrhoea with blood in the stools. A tentative diagnosis of gastro-intestinal allergy had been made because there was a history of infantile eczema.

After spontaneous delivery at term the child was breast-fed for three weeks and then put on to cow's milk, following which he developed eczema. He had bronchitis at 6 months and measles at 1 year. There was no family history of allergic diseases. The patient was well until seventeen days before admission, when he passed a small quantity of bright red blood per rectum. Two days later he had a little diarrhoea and again passed blood. Treatment with a chalk mixture was prescribed and no further bleeding occurred for ten days. Five days before admission he passed several loose stools containing a larger amount of blood; he looked pale but not ill. On the day of admission he had an attack of abdominal pain and passed more blood in the stool.

Examination on admission showed a poorly nourished child with rough dry skin. A soft systolic murmur was

heard at the apex of the heart, otherwise physical examination was negative. Blood examination revealed a moderate hypochromic anaemia.

On the day following admission he passed a dark stool, and a small, smooth, mobile mass was felt in the right iliac fossa which disappeared and reappeared at intervals during the next two days. He passed no further stools, but complained on one occasion of abdominal pain lasting for a few minutes. On the fourth day a tumour was felt extending from the right iliac fossa to the right hypochondrium, and at operation (Miss R. M. Mackay) a mass was found consisting of the caecum, into which the appendix had completely intussuscepted. There was no obvious impairment of the blood supply, but all layers were so oedematous that reduction was impossible. The caecum was opened, and the completely inverted and very swollen appendix was seen inside; the tip was just becoming gangrenous, but the rest was only congested. The appendix was removed and the caecum closed. Following blood transfusion, recovery was uneventful.

Case 2

A girl, aged 16 months at the first admission, was born spontaneously at term and was fed on dried milk. At the age of 6 weeks she developed infantile eczema, and at 6 months the introduction of egg into her diet resulted in vomiting and urticaria, which recurred whenever eggs were given. She had no other illnesses until 14 months, and there was no family history of allergy.

At 14 months she began to have attacks of abdominal pain and vomiting, lasting for a day or two at a time, and her appetite became poor. She passed normal stools between and during the attacks. On admission to Maryfield Hospital, Dundee, at 16 months of age, she was found to be a well-nourished child with extensive eczema, involving principally the shoulders, chest, and knees. No other abnormality was found and no mass was palpable in the abdomen. The haemoglobin was 11 g.%, the leucocyte count 12,000 per c.mm., and the erythrocyte sedimentation rate was 40 mm. in the first hour (Westergren). The urine was normal. There was mucus and a little red blood in the stools, culture of which showed no pathogenic organisms. The Mantoux test was positive, but x-ray examination of the chest showed only increased broncho-vascular markings.

While in the ward she was inadvertently given an egg custard and had an immediate reaction consisting of generalized urticaria, vomiting, and abdominal pain, which promptly subsided on treatment with an antihistaminic drug.

A provisional diagnosis of gastro-intestinal allergy was made, but a barium enema examination was carried out to exclude any other condition in the bowel. There was a temporary hold-up of the barium in the ascending colon, but eventually normal filling was obtained. The possibility of an intussusception which had been reduced by the enema was considered, but as the symptoms had subsided she was allowed to go home.

She had no more trouble until two months later, when she was readmitted because of further attacks of abdominal discomfort followed by the passage of blood in the stools. Apart from extensive eczema, no abnormality was found on physical examination. A second barium enema showed good filling of the colon but defective filling of the caecum. Gastro-intestinal allergy was still thought to be the most likely cause of her symptoms, and as she was thriving she was discharged from hospital.

One month later she had three more attacks of abdominal colic with blood in the stools, and this time a horizontal thickening was palpable in the upper abdomen. At laparotomy (Mr. W. G. Campbell) a basal appendicular intussusception was found which had further intussuscepted into the colon. The intussusception was easily reduced except for the part formed by the base of the appendix, and the fundus of the caecum with the appendix was removed. Microscopical examination showed diffuse post-inflammatory fibrosis in the subserosa of the appendix, while the mucosa

and submucosa of the caecum showed diffuse and heavy infiltration with eosinophil leucocytes. Post-operative progress was satisfactory, and one year later she was very well, although the eczema was still present.

Discussion

The outstanding symptom of intussusception of the appendix is intermittent abdominal pain, often accompanied by nausea and vomiting, and the stools are usually normal (McSwain, 1941). Many symptoms have been attributed to gastro-intestinal allergy, but intermittent abdominal pain and vomiting are those most commonly mentioned. Blood in the stools is often described as a feature of gastro-intestinal allergy, especially in infants, while it is usually scanty or absent in chronic intussusception (Gaymer Jones, 1924). The difficulties of proving that gastro-intestinal symptoms are allergic have been discussed by Ingelfinger, Lowell, and Franklin (1949), who concluded that absolute confirmation is virtually impossible. They considered such a diagnosis reasonable "if gastro-intestinal symptoms invariably follow contact with a normally inactive substance, and if other causes such as psychic effects and mechanical irritation are excluded." The history of sensitivity to egg of the second patient, and the vomiting and urticaria produced by its administration, favoured the diagnosis of gastro-intestinal allergy, and it seemed reasonable, in the absence of other demonstrable cause, to ascribe the abdominal pain and blood in the stools to allergy as well. Beaven (1929) reported a somewhat similar case, his patient being a girl of 3 years who had florid eczema, and who developed urticaria if she ate eggs. The child had had peri-umbilical pain for one month before laparotomy was carried out. In this child, however, an intussusception was found involving a Meckel diverticulum.

In the present Case 1 there was less justification for attributing the symptoms to allergy, but the history of eczema, the absence of abnormal signs in the abdomen, and the duration of symptoms were misleading. The initial diagnosis was not sustained after admission and the true cause became apparent when the abdominal mass was felt.

Intussusception of the appendix was first recorded in a boy aged 7 (McKidd, 1859), and the majority of cases since reported have occurred in the first decade of life (Forshall, 1953). The condition is usually chronic, the average duration of symptoms before operation being eight months in the 77 cases reviewed by McSwain (1941). Although all cases may not arise in the same way, it is thought that the condition is usually due to peristaltic contractions of the appendix, initiated by attempts to expel a foreign body or by a local thickening of the appendix itself (Fraser, 1943).

It seems possible that in the present cases increased peristalsis resulting from allergic reactions facilitated the occurrence of intussusception, although the eosinophilia in the caecal wall in the second case cannot be adduced as evidence, because the significance of such infiltration is not clearly understood. Moreover, since neither McSwain (1941) nor Fraser (1943) mentions allergy in reviewing the literature on intussusception of the appendix, it appears unlikely to be a common cause, and the association may have been fortuitous.

Summary

Two cases of chronic intussusception of the appendix in young children are reported.

The symptoms were at first attributed to allergic reactions because of a history of infantile eczema in the first child and the presence of infantile eczema and gastro-intestinal allergy in the second.

I am grateful to Professor J. L. Henderson for permission to report these cases, and to Dr. Kenneth Rhaney for the pathological report.

SURGERY IN OCTOGENARIANS

BY

RONALD W. RAVEN, O.B.E., F.R.C.S.

Surgeon, Westminster (Gordon) Hospital; Surgeon,
the Royal Marsden Hospital

The problems caused by lesions in aged patients which constitute either an immediate or a delayed threat to life require careful consideration if an adequate solution of them is to be found. It is recognized that the number of these patients in this country is gradually increasing, and these matters will assume greater proportions in the years to come. A study of a personal series of 34 octogenarians who underwent surgical operation demonstrates that much can be done to help these aged patients even though they are afflicted with the worst forms of malignant disease. The patients were divided into two groups: with malignant and with non-malignant lesions. Their details are set out in Tables I and II.

There were 24 patients with malignant disease; for the majority a major operation was required, and four died. The follow-up of the survivors is shown and six patients were still alive up to twenty-nine months after the operation. Three patients died of non-malignant causes 3 years, 4½ years, and 4 years 5 months later. Of those who died of cancer four lived for a minimum period of two years.

Distribution and Management of the Lesions

In 15 patients a carcinoma of the alimentary tract was present, and in 9 it was situated in the colon or rectum. One patient suddenly developed a perforation of the pelvic colon proximal to an annular constricting carcinoma. Another suffered from complete intestinal occlusion caused by carcinoma of the pelvic colon.

For an aged patient with an obstructing carcinoma of the transverse or pelvic colon Paul's operation is a satisfactory procedure, provided any involved regional lymph nodes can be removed at the same time. When the affected loop of bowel cannot be exteriorized—for example, in the lower part of the pelvic colon, or at the recto-sigmoid junction—Hartman's operation is useful. For non-obstructing lesions of the transverse or distal colon a partial colectomy with an end-to-end anastomosis is usually radical enough rather than a more extensive left hemicolectomy. When the carcinoma affects the right half of the colon a right hemicolectomy in one stage is advisable if there is no obstruction.

In one patient a large pelvic abscess complicated a carcinoma of the pelvic colon and caused severe toxæmia. A series of staged operations were performed, including drainage of the abscess, the institution of a defunctioning transverse colostomy, partial colectomy, and closure of the colostomy later. The timing of these staged operations is important, so that the patient's general condition is at its optimum when the next stage is performed. By this means many aged patients, even when seriously ill, can be brought through safely. It is worth noting that a palliative colostomy for a carcinoma of the rectum in two patients was followed by survival periods of 2½ and 3½ years. Another patient lived 4½ years after a perineal excision of the

rectum and died of another cause at the age of 87. In some aged patients the application of coagulation diathermy to an obstructing carcinoma of the rectum is a useful method of treatment; one patient lived 2 1/12 years.

TABLE I.—Octogenarians with Malignant Lesions Treated Surgically

Age of Patient	Disease	Operation	Immediate Result	Late Result
85	Carcinoma rectum	Left inguinal colostomy	Recovered	Died 2½ years later
88	"	"	"	Died 3½ years later
83	"	Left inguinal colostomy and perineal excision of rectum	"	Died 4½ years later of another cause
90	"	Diathermy to growth	"	Died 2 1/12 years later
83	Carcinoma colon, perforated. Enlarged prostate; retention of urine	Partial colectomy; later prostatectomy	"	Died 1 year after first operation
83	Carcinoma colon, complete intestinal occlusion	Partial colectomy, Paul's operation	"	Alive 2 years later
82	Carcinoma pelvic colon	Partial colectomy, Hartman's operation	Died	—
81	Carcinoma pelvic colon with pelvic abscess	Drainage of abscess, defunctioning transverse colostomy, partial colectomy, closure of colostomy	Recovered	Alive 9 months later
86	Carcinoma transverse colon	Partial colectomy	"	Alive 1 year later
81	Carcinoma caecum	Right hemicolectomy	"	Alive 9 months later
80	" stomach	Subtotal gastrectomy	"	Died 7 months later
80	"	Gastro-jejunoscopy	"	Died 8 months later
81	Carcinoma oesophagus	Partial oesophago-gastrectomy	Died 7 weeks after operation	—
80	"	"	Recovered	Died 22 mths later
81	Sarcoma breast	Irradiation and radical mastectomy	"	Died 3 months later
82	Carcinoma breast	Irradiation and mastectomy	"	Died some months later
80	"	"	"	Died 3 years later
81	Carcinoma tongue (recurrent)	Partial glossectomy	"	Alive 7 months later
89	Carcinoma floor of mouth and mandible	Partial excision of floor of mouth and mandible. Partial block dissection of neck	"	Alive 2 5/12 years later
82	Carcinoma prostate. Diabetes mellitus	Suprapubic cystostomy	Died	—
87	Carcinoma pinna	Excision	Recovered	Died 3 years later of another cause
81	Rodent ulcer of face	"	"	Lost sight of later
82	Rodent ulcer of orbit	Exenteration of orbit	"	Died 4 5/12 years later of another cause
83	Vesical calculus and carcinoma of prostate with retention of urine	Lithotripsy and transurethral resection of prostate	Died	—

TABLE II.—Octogenarians with Non-malignant Lesions Treated Surgically

Age of Patient	Disease	Operation	Immediate Result
86	Rectal prolapse	Thiersch's operation	Recovered
83	"	"	"
80	Enlarged prostate	Prostatectomy	"
84	"	"	"
80	Crohn's disease of ileum	Enterostomy	"
80	Chronic cholecystitis	Cholecystectomy	"
85	Strangulated femoral hernia	Herniotomy	"
81	Ulcerated angioma of breast	Mastectomy	"
80	Senile tuberculosis of shoulder-joint	Sequestrectomy	"
84	Necrotic ulcer of pinna	Excision of pinna	"

The re-establishment of normal micturition in aged patients who have undergone an operation for carcinoma of the pelvic colon or rectum is often a difficult problem to solve. In males this is often caused by a benign enlargement of the prostate, and surgical treatment is necessary. When the prostate is small and fibrous a transurethral resection is satisfactory, but if the gland is large and fleshy it is probably better to enucleate it, provided the patient will stand the operation. Retention of urine in females can be very troublesome, and regular catheterization is required until normal micturition is re-established. This was necessary for several weeks in the case of the patient with the pelvic abscess complicating a carcinoma of the pelvic colon.

Two patients with a carcinoma of the oesophagus underwent a partial oesophago-gastrectomy; one died in hospital seven weeks later, the other lived for twenty-two months. The problems of each patient with a carcinoma of the oesophagus must be considered carefully, and if possible normal deglutition should be restored. When radical surgical treatment is contraindicated, the insertion of a Souttar tube or a course of high-voltage x-radiation often helps. A palliative gastrostomy is an unsatisfactory procedure.

One patient with a recurrent carcinoma of the tongue had a partial glossectomy and was well seven months later; the original lesion had been treated by a partial glossectomy and block dissection of the neck seven years previously. Another patient had a large carcinoma involving the floor of the mouth, mandible, and regional lymph nodes, and complete surgical excision gave a good result; the patient was well 29 months later. In these cases no attempt is made to reconstruct the mandible, since it is better to accept the deformity rather than submit the patient to a further operation and thus prolong his stay in hospital.

Ten patients with non-malignant lesions underwent operations, and all recovered (Table II).

Rectal prolapse is frequent in aged patients, and causes much suffering. Thiersch's operation is valuable because it is simple and usually provides complete control of the prolapse. For example, the patient who was aged 86 when operated on was at the time of writing 90 and never ceased to be grateful. In some patients the silver wire breaks after a time, but it can be easily removed and a new one inserted. Prostatic obstruction is another common condition in aged patients; each must be carefully considered and the appropriate treatment carried out. Two patients underwent prostatectomy with uneventful recovery.

General Considerations Regarding Surgery in the Aged

The health of these patients varies greatly, and it is necessary to assess their biological rather than their chronological years. Some tissues age more quickly than others, and the processes of repair may be retarded considerably in certain parts of the body. Repair is, of course, slower and less complete in old than it is in young tissues, and this fact should be remembered in this branch of surgery. Degenerative changes in vital organs are frequent and cause complications after operations; the most serious and frequent are those of the cardiovascular and renal systems. As a principle it is advisable to perform the simplest operation designed to cure the particular condition causing symptoms. In aged patients nutritional defects are common owing to an inadequate dietary intake, errors in food assimilation, derangement of water and electrolyte balance, and vitamin lack. These factors combine to interfere with wound-healing, lower the resistance of tissues to infection, and generally decrease the patient's power to withstand a major surgical operation.

It is advantageous to have a clear picture of the changes often present in many organs in aged patients, and reference is made to the work of Howell and Piggot (1951) regarding the morbid anatomy of various systems of the body. Important findings included the following: considerable atheroma was present in the aorta in 68% of patients, in the coronary arteries in 36%, and in the cerebral arteries

in 25%. Changes in the heart were patchy myocardial fibrosis in 44%, old coronary infarcts in 12%, fatty myocardial changes in 12%, and brown atrophy in 20%. Amongst the changes in the respiratory system were atrophic emphysema in 64%, hypertrophic emphysema in 28%, pulmonary oedema in 68%, bronchopneumonia in 32%, pleural effusion in 12%, and chronic bronchitis in 32%. Normal kidneys were found in only 12% of patients; the pathological changes in others included coarse scarring, granular surface, narrow cortex, thickened vessels, and excess fat.

The common post-operative complications according to their frequency and potential threat to the patient's life are the following. Bronchopneumonia is frequent and serious and often diffuse, with few demonstrable chest signs. Thus cough is slight but there is fever, and radiological changes in the chest are common. Cardiac complications are frequent and include congestive heart failure, coronary occlusion, and various arrhythmias. Pulmonary oedema is a frequent accompaniment of heart complications. Peritonitis is an important complication of various intra-abdominal lesions and operations; this is not tolerated well by aged patients. Attention is called to the frequency of infections in the urinary system which may be serious, and therefore early recognition and treatment is essential. Post-operative thrombosis and embolism often occur, and fatal embolism may be an accompaniment of impairment of the heart's action. Mental disorientation is worthy of special mention; the strength of the patient's mentality to withstand a major operation must always be assessed beforehand.

Special Points Regarding Treatment

Provided intelligent management is instituted many aged patients are brought safely through major surgical operations. Obviously emergency surgery is more risky than elective surgery, and according to Carp (1951) the former carries a mortality rate about two and a quarter times greater than for the latter. An adequate time is allotted for pre-operative treatment when elective surgery is contemplated, and nutritional defects are rectified as much as possible by routine methods. Oral feeding is preferable to other routes whenever this can be done, and a high calorie diet rich in vitamins is given. Any disturbance in the water and electrolyte balance is rectified, and when parenteral fluids are necessary they are selected carefully and administered according to the patient's exact requirements, controlled by laboratory investigations. Physiotherapy is given routinely, and the importance of the correct psychological approach is mentioned because aged patients require tactful and kindly handling in an optimistic atmosphere.

During the Operation.—Attention is given to the usual details of operative technique. Exaggerated positions on the table and rapid changes in the position of the patient are avoided. Any undue exposure of tissues is eliminated and careful haemostasis is essential. The circulatory system must not be overloaded with intravenous fluids, including blood, and the amount given of the latter is assessed by measuring the blood loss during the operation.

Anaesthesia

Premedication is minimal in amount and controlled carefully, because respiratory depression is easily induced. Therefore small doses of "omnopen," $\frac{1}{4}$ to $\frac{1}{2}$ gr. (10 to 20 mg.), or pethidine, 100 mg. or less, are given; the exact dose chosen is related to the body weight, general condition, and the results of the liver- and renal-function tests. Anaesthetic induction is smooth and adequate oxygenation is essential. It is necessary to avoid deep anaesthesia and marked fluctuations in the blood pressure. For the usual abdominal operations the following is a satisfactory method. The patient is anaesthetized with intravenous thiopentone sodium and not more than 0.5 g. is given. An endotracheal tube is passed and anaesthesia is continued with pethidine, given intravenously (dose 50 mg.); this is repeated if necessary, but not more than 25 mg. is given. For abdominal

relaxation tubarine up to 15 mg. is sufficient. A clear airway must be maintained, and bronchial aspiration may be required during and after the operation.

Post-operative Care

Routine methods are employed and emphasis is placed on certain aspects. Fluid, including blood, and electrolyte requirements are assessed and provided carefully. The manifestations of potassium deficiency, acidosis, or alkalosis are recognized early in their development and treated. Oral feeding is resumed as soon as possible. For post-operative sedation barbiturates are avoided and reliance is placed upon small doses of the morphine derivatives; chloral and bromides are also useful. Physiotherapy is given routinely, and early ambulation is required unless contraindications are present.

Summary

A series of 34 octogenarians who underwent surgical operation is reported. They are divided into two categories—those with malignant and those with non-malignant lesions—and the end-results are given. Certain principles in their treatment are stressed, and it is shown that many of them can be brought safely through major surgical operations.

Medical Memoranda

Recovery after Overdosage with Methylpentynol

Methylpentynol is now being prescribed fairly widely as a hypnotic and as a means of allaying apprehension, but there are relatively few reports of the results of overdosage. The following case report describes recovery after ingestion of approximately 10 g. of methylpentynol in the form of a proprietary elixir ("oblivon"), and this appears to be the largest recorded overdosage followed by recovery.

CASE REPORT

A woman aged 39, weight 7 st. 8 lb. (48.3 kg.), was admitted to hospital on October 29, 1954, having taken approximately 5 oz. (150 ml.) of a proprietary elixir containing 250 mg. of methylpentynol per drachm (70 mg. per ml.). There was a history of previous mental illness, necessitating admission on a voluntary basis to a mental hospital in July, 1954, for a period of ten days. Since that time the patient had been depressed at intervals and had threatened to commit suicide.

About mid-morning on October 29 she drank 5 oz. (150 ml.) of methylpentynol elixir and was admitted to hospital at 3.30 p.m. She was then deeply asleep, but responded faintly to pressure on the supraorbital nerve. Her general condition was good: respirations 20, pulse 72, blood pressure 130/80. Her pupils were normal in size and reacted briskly to light.

On the assumption that absorption was probably complete, stomach lavage was not carried out. General supportive treatment was instituted, and methylamphetamine hydrochloride, 30 mg., was given intravenously every half-hour. At 6.30 p.m. she was less deeply asleep, and half opened her eyes when spoken to. Her general condition was good: respirations 21, pulse 72. By 8.30 p.m. she was half awake and making attempts to speak. At 10 p.m. she was able to speak and to answer questions, although still drowsy. At this point the methylamphetamine hydrochloride was discontinued.

During the next day she was somewhat drowsy, but rational and capable of answering questions. By the morning of October 31 she was fully recovered and later consented to have further mental hospital treatment as a voluntary patient.

Animal experiments conducted by Margolin *et al.* (1951) showed that the dose that killed 50% of test rodents (LD₅₀) varied from 600 to 900 mg. per kg. Recoveries in adult humans have been reported after ingestion of 6.25 g. (Bourne, 1954) and 8.75 g. (Lemere, 1952), but the single fatality on record is thought to have followed the ingestion of 4.5 to 6 g. (Cares *et al.*, 1953).

Case of Fallot's Tetralogy with Multiple Congenital Abnormalities

The past decade has shown rapid advances in the understanding of congenital heart disease. The work of Blalock and Taussig (1945), Taussig (1948), and others has resulted in major progress in the surgical treatment of the three main conditions: pulmonary stenosis, patent ductus arteriosus, and coarctation of the aorta. An increasing number of other congenital conditions associated with morbus caeruleus are coming gradually to light. Thus, Campbell and Deuchar (1953), in a series of 200 cases of morbus caeruleus, found two cases of dextrocardia with complete situs inversus, one with isolated dextrocardia, and three with laevo-cardia plus transposition of abdominal viscera.

CASE REPORT

On February 10, 1953, an Indian boy aged 8 was brought to hospital. A typical history of a "blue baby" who had survived repeated attacks of endocarditis was elicited from his father. He had always been delicate and easily got dyspnoeic on moderate exertion. He was, however, able to attend school, where he had a good record. He could not take part in any games. He suffered frequently from attacks of cough, associated with high fever, and had some difficulty in swallowing. His appetite was poor. He had also suffered from abdominal discomfort associated with constipation. His present history was that of fever, cough, and severe dyspnoea, lasting for three days.

Clinical Findings.—He was rather thin and proportionally built, but somewhat small for his age. He walked into the examination room unaided with some effort. There were cyanosis of moderate degree and marked clubbing of fingers and toes; temperature 102° F. (38.9° C.), pulse 124, respirations 36; marked dyspnoea; multiple bilateral rhonchi in lungs. Heart: forceful, visible apex beat in fifth left interspace; a loud diffuse systolic murmur was heard along the left sternal border, maximal over the third and fourth left interspace, but audible also over a wide area on the front and back of the chest. Abdomen: soft, not tender, some fullness below umbilicus; spleen and liver not palpable. Rectal examination: hard faecal masses in ampulla.

A provisional diagnosis of pulmonary stenosis, probably a Fallot's tetralogy, complicated by infective endocarditis, was made. The father of the boy refused to have him admitted. Blood cultures could not be taken during the acute phase of the illness. Treatment and subsequent investigations had to be carried out in the out-patient department.

The acute symptoms subsided after a week of massive penicillin therapy and rest, making the following investigation possible.

X-ray films of the chest revealed a boot-shaped heart of normal size; replacement of aortic knuckle and pulmonary convexity on left upper cardiac margin by a concavity; dextroposition of aorta, being visible in two distinct cones within shadow of superior vena cava; marked passive pulmonary hyperaemia.

Blood picture: Polycythaemia, with Hb 108%; erythrocytes, 6,910,000; leucocytes, 9,400 (polymorphs 48%, lymphocytes 44%, monocytes 1%, eosinophils 7%).

Barium swallow examination was done to ascertain the relationship of the oesophagus to the great vessels (see Fig.).

Diagnosis.—These clinical, radiological, and haematological findings strongly suggested a diagnosis of Fallot's tetralogy—that is, pulmonary stenosis; dextroposition of aorta with widening, dextra-septal deviation, causing aorta to override septum; high ventricular septal defect resulting in a persistent venous-arterial shunt; right ventricular hypertrophy (Boyd, 1947). According to Mercer (1950), this dextroposition of the aorta is present in 25% of all cases of Fallot's tetralogy.

In view of the dextrocardia, a complete radiological investigation of the gastro-intestinal tract was then carried out. Barium meal examination revealed a situs partialis inversus: dextrocardia; inversion of duodenum; position of duodeno-jejunal flexure not clearly seen; terminal ileum, caecum, appendix, and colon appear again in normal position. The appendix seems to have a rather wide lumen. In the left half of the transverse colon an area of early diverticulosis was discovered, extending as far as the splenic flexure. The affected segment showed fine spastic notching on the summits of the haustral bulges, described first by Spriggs (1929) to be characteristic of early diverticulosis. Barium-filled diverticula could be seen in the same segment after partial evacuation and after complete evacuation of the barium meal. The latter, as well as a subsequent barium enema, showed a megarectum. Sigmoid and rest of colon were of normal calibre.

Lastly, congenital absence of the left twelfth rib was found as a curious skeletal abnormality.

COMMENT

The pulmonary stenosis in this case may not be very marked, as cyanosis was moderate and the degree of exercise-tolerance fair, even after several previous attacks of infective endocarditis. The abnormal findings in the gastro-intestinal tract may well explain the abdominal symptoms of this patient, bearing in mind that children with morbus caeruleus often suffer from digestive disturbances and put on weight rather slowly.

It may serve as a good example that in congenital heart disease multiple extracardiac congenital abnormalities can be expected, particularly within the thorax and abdomen.

Barium swallow examination in Fallot's tetralogy: boot-shaped cardiac silhouette with concavity (C) at left upper margin; dextroposition of aorta seen in two cones (A); upper oesophagus lying to left of great vessels, being indented markedly on right margin by aorta (B); lower oesophagus deviating to right, indicating dextrocardia.

A deliberate search for such abnormalities is advisable before operative measures, such as creation of an artificial ductus arteriosus or pulmonary valvulotomy, are considered, as it has been found (Campbell and Deuchar, 1953) that the mortality in cases with complex lesions is rather high.

I wish to thank the Director of Medical Services, Federation of Malaya, for permission to publish this case. I am also indebted to the staff of the x-ray department of the Malacca General Hospital for the radiograph, and to Dr. M. Rajathurai, of the pathology department, for the blood studies.

Nervous Manifestations of Infectious Hepatitis

Neurological complications of infectious hepatitis are rare (Cameron, 1943). The incidence is varied—for example, 2 in 170 cases (Harries and Mitman, 1951), 3% (Lucké and Mallory, 1946), and 32 in 151 (Hardy and Feemster, 1946).

CASE 1

A girl of 6 years vomited once on January 7, 1954, but was well until the 11th, when vomiting recurred with lethargy.

She was admitted to hospital on the 12th with severe lethargy and general hypotonia. X-ray films of chest and skull were normal. The next day there was rapid deterioration. She was grey, limp, and incontinent of urine, and fluids were regurgitated through the nose. Light coma; fundi normal. She was given an intragastric drip and postural drainage with suction. In the evening there was generalized spasticity.

Laboratory Findings.—C.S.F. normal. Blood urea, 40 mg./100 ml.; blood sugar, 60 mg./100 ml.; alkali reserve, 59.5 vols. CO₂/100 vols.; W.B.C., 13,000 c.mm. (polys. 84%, lymphs. 9%, monos. 7%). Serum protein: total 7 g./100 ml. (albumin 4.4 g., globulin 2.6 g.). Serum alkaline phosphatase, 16 units; thymol turbidity, 5 units; thymol flocculation, ++. Serum did not appear jaundiced.

On January 14 there were frequent vomits of altered blood; marked dehydration; slight scleral icterus. T. 102.8° F. (39.3° C.); P. 144; R. 40. I.V. infusion started. Crystalline penicillin, ½ mega unit i.m. 6-hourly. Vitamins K and B complex. Deep coma; no paralysis; spastic limbs. Extensor plantar and absent abdominal reflexes. Second lumbar puncture still normal, but pressure 200 mm. Trace of bilirubinuria. January 15: Still intense coma; vomiting altered blood; cyanosed; noisy bubbling respiration; flaccid quadriplegia and extensor plantar response. January 16: Rational; jaundiced; liver not enlarged. January 18: Still incontinent of urine and faeces. I.V. drip discontinued. W.B.C., 23,000 per c.mm. (polys. 93%, lymphs. 4%, monos. 3%). January 23: Jaundice fading. January 29: C.N.S., normal; no icterus; liver normal size. Virus studies and leptospiral agglutination: negative. March 10: Discharged from hospital. June 8, 1954: Child physically fit, but irritable, with no sequelae. Liver function tests, including the zinc sulphate turbidity for γ -globulin (6 units), were all normal.

CASE 2

A girl of 9 years was admitted to hospital on April 5, 1953, with a week's history of vomiting, headache, and severe lethargy. Three siblings had jaundice. She was very drowsy, with slight scleral icterus; liver tender and enlarged three fingerbreadths. Temp. 96° F. (35.6° C.), later 100.4° F.

(38° C.). Dehydrated. Given adequate i.v. fluids with vitamin K i.m. Retention of urine until April 7, when she had severe lethargy and bilirubinuria. April 8: Conscious; well jaundiced, with liver enlarged. I.V. fluids discontinued.

Laboratory Findings.—Blood urea, 34 mg. per 100 ml.; W.B.C., 7,400/c.mm. (polys. 54%, lymphs. 42%, monos. 3%, basos. 1%). Alkaline phosphatase, 22.5 units; thymol turbidity, 14 units; thymol flocculation ++++. Total serum protein, 5.5 g./ml. (albumin 3.0, globulin 2.5). Some degree of liver dysfunction present.

The patient was discharged from hospital on May 29. When seen on June 8 she was symptom-free, having no nervous sequelae except slight irritability. Liver palpable one fingerbreadth. Liver function tests normal, except zinc sulphate turbidity for γ -globulin (11.6 units), the local normal range being 2.8 to 10.4 units.

PATHOLOGY AND PATHOGENESIS

Briefly, there is an acute non-specific degeneration of ganglion cells with some oedema of the brain without demyelination and, in 15% of fatal cases, a mild meningo-encephalitis (Lucké, 1944). Apart from any direct action of virus upon the central nervous system, loss of the detoxifying function of the liver may account for the nervous manifestations.

Walsh (1951, 1953) suggests that hepatic coma may be due to inability of the brain cell to combine glutamic acid with ammonia to form glutamine (Weil-Malherbe, 1950), whilst Riddell and McDermott (1954) postulate the coma in chronic liver disease as due to ammonia intoxication.

DIAGNOSIS

Nervous manifestations may take the form of encephalomyeloradiculitis, with both motor and sensory involvement (Zimmerman and Lowry, 1947). On the other hand, the signs may be encephalitic with or without motor paralysis or post-infectious sequelae. Clinically, the case may resemble uraemic or diabetic coma. Coma caused by other infections and narcotic or toxic poisoning must be considered; so must psychic states.

TREATMENT

There is no specific remedy. Davidson and his colleagues (Gabuzda *et al.*, 1952; Phillips *et al.*, 1952) note the potential danger of a high-protein diet and of ammonium-containing compounds in decompensated liver disease, but stress the therapeutic value of protein in compensated liver disease. Glutamic acid therapy in hepatic coma is not yet of proved value (Riddell and McDermott, 1954). Hypertonic glucose or double-strength plasma (i.v.) for cerebral oedema, paraldehyde for excitement, and antibiotics for secondary infection may all be helpful. Bed rest should be maintained until there is no bilirubinuria and the liver is no longer enlarged.

There are three points I would like to stress: (1) The nervous manifestations preceded the jaundice and cleared up as it became marked. (2) The course may be reversible, and recovery may occur after apparent hopelessness. (3) This infection may be the cause of some cases of idiopathic encephalitis or meningoencephalomyelitis.

Reviews

ANY QUESTIONS?

Any Questions? A Selection of Questions and Answers published in the *British Medical Journal*. Third series. (Pp. 227 + xv. 7s. 6d.) London: British Medical Association, 1954.

The third series of *Any Questions?* is as informative and as entertaining as ever, and there seems no end to the usefulness of this feature of the *Journal*. One of the advantages or disadvantages of being a medical don is that one is so often asked at high table the sort of question the answer to which is not provided in the medicine one teaches to students, and one therefore sympathizes with the inquiries which have given rise to these books. Bizarre questions of this type in the present volume include, "Will a wig stop hair growing?" (answered by the single word, "No"), and the results of intermarriage of white and black, answered at much greater length and with the aid of a funny story. A second group of questions concerns new knowledge which has not yet reached the textbooks, as, for example, the best treatment of amoebiasis, the danger of vaccination in pregnancy, and the carpal tunnel syndrome. Then come questions which are off the normal beat of the practitioner—sanitation and hygiene, the sound-proofing of surgeries, and the prevention of scale in sterilizers. Finally, there are the marital, sexual, and psychological problems, which begin to shade into the world of Dorothy Dix. The answers are fair game for the medical sharpshooter. I should strongly disagree with the view that alcohol is not a diuretic, which is contrary to the experience of William Shakespeare (*Macbeth*, Act II, Scene III, line 27) and the experiments of Maurice B. St. auss.

This third volume is provided with a cumulative index which makes it more than ever apparent that a series of this kind gains strength by growth in size and that it will eventually become a valuable encyclopaedia of medicine.

L. J. WITTS.

BIOCHEMISTRY FOR THE CLINICIAN

Biochemical Investigations in Diagnosis and Treatment. By John D. N. Nabarro, M.D., M.R.C.P. (Pp. 299 + ix. 25s.) London: H. K. Lewis and Co., Ltd. 1954.

Dr. Nabarro has covered a wide field in these 300 pages and is to be congratulated on providing a very readable account of the subject. He has avoided all matters of technique, and has not devoted much space to the underlying biochemical mechanisms. The book, therefore, is mainly a guide to the clinician on what tests may usefully be carried out on patients with metabolic diseases and on how he should interpret the results. The author's purpose is much enhanced by the rather original index, which is in two parts: "Index of Investigations" and "Index of Conditions, Diseases, and Treatment." This will be a great help to those using the book. The actual arrangement of chapters is a compromise between the two, some being devoted mainly to diseases, and others mainly to tests or types of biochemical derangement.

The text is well written, up-to-date, and remarkably condensed. It is inevitable from its size that certain sections should appear to be rather too brief; for example, the sections on renal tubular acidosis and on hypoglycaemia could be expanded with advantage. The arrangement of references is somewhat puzzling. A few key references are found at the end of certain chapters, and in addition 91 more are given at the end of the volume, but the subject to which each of them refers is not indicated. The usual table of normal values at the end is comprehensive and valuable. This book will undoubtedly be useful to the busy clinician who wants a quick reference to possible biochemical disturbances in his patients, and equally to the laboratory worker faced with an unusual type of biochemical disturbance.

N. F. MACLAGAN.

ANAESTHESIA IN GERMANY

Die Narkose, Ein Lehr- und Handbuch. By Professor Dr. H. Killian and Professor Dr. H. Weese. (Pp. 1,003 + xxviii; illustrated. D.M. 170.) Stuttgart: Georg Thieme, 1954.

The massive, all-inclusive tome, of which this is an impressive example, is becoming increasingly rare among medical books. Few men feel able to write with authority on more than one or two facets of their work. Most are specialists even within their specialties. When teaching they must be careful not to assume either that the other man's field is easier than their own, and thus treat it superficially, or that it is specially difficult and so ignore it altogether or labour too painfully to expound it. Both these mistakes are made in this book. The title suggests that the clinical administration of anaesthesia would form the book's backbone. The authors, however, are not anaesthetists themselves, and though some (but only some) of the appropriate sections have been rightly delegated to their anaesthetic colleagues Drs. Irmer and Koss, the general balance of subject-matter does not seem correct. The sections dealing with the administration of anaesthesia are too short and the rest are too long. In a textbook of anaesthetics detailed accounts of pharmacology, pathology, physiology, and so forth are acceptable in their proper proportions and when relevant to the main subject-matter. The impression given here is that they are almost ends in themselves.

It is doubtful whether this book will help in a practical way the young anaesthetists in training in Germany. They need something more akin to our own *Essentials of General Anaesthesia* by Macintosh and Bannister. They might conceivably get the impression that a detailed theoretical knowledge of such related sciences as pharmacology, physiology, pathology, and haematology would compensate for their inability to pass a tracheal tube or to distinguish between respiratory obstruction and overdose, or for their lack of long experience in the operating theatre. Teachers and experienced anaesthetists in general, however, will regard the book differently: they will appreciate the enormous field from which the material has been collected and admire the herculean labours of compiling it. They will, if their knowledge of German is good, find this massive book valuable as a means of reference to practically everything connected with anaesthesia, even if sometimes only distantly related.

The publishers have done an expert job, and the volume is a pleasure to handle and to look at. Lavish reference lists are given at the end of each subject and an adequate index is included. A sad note is struck by an obituary notice of Professor H. Weese, one of the co-authors, who did not live to see the book in print.

THE FIRST ELIZABETH'S HEALTH

Elizabeth Tudor: The Lonely Queen. By Sir Arthur Salusbury MacNalty, K.C.B., M.A., M.D. (Oxon), F.R.C.P., F.R.C.S. (Pp. 272. 18s.) London: Christopher Johnson, 1954.

Much has been written about the fatal illnesses of monarchs, but their general health has not so often been the subject of comment. Sir Arthur MacNalty, who has made a special study of the Tudor period and two years ago published an interesting study of "Henry the Eighth, a Difficult Patient," has now turned his attention to Henry's talented daughter, Queen Elizabeth the First, and has written an account of this remarkable woman with special reference to her ailments and illnesses. The book is meant for the general reader, who will here find in small compass a readable account of this exciting period of English history. Medical readers will turn with special interest to Chapter XV, where is discussed "The Queen's Medical Case-book."

Queen Elizabeth was for the most part a strong woman, both physically and mentally, and we find it difficult to accept the view that she was hysterical. She successfully overcame such serious diseases as smallpox and nephritis, and continued hunting and dancing up to the last year, the seventieth, of her life. She appreciated the advice of her

physicians, but did not always follow it, for when on one occasion she was ill of what was thought to be food-poisoning she held another opinion of her illness: she thought it was due to the "fact that for three or four years she had found herself so well that she had disregarded all the strict discipline which her physicians formerly had been accustomed to impose upon her by purging her and drawing a lot of her blood from time to time."

In two appendices we are given a list of Elizabeth's suitors and a brief account of her physicians. We wish that space had permitted a fuller account of the latter.

This book is a definite contribution on new lines towards the understanding of a great, complex, and interesting personality, and we believe it will deservedly attract widespread attention.

ZACHARY COPE.

OPERATIVE SURGERY

Textbook of Operative Surgery. By Eric L. Farquharson, M.D., F.R.C.S. Ed., F.R.C.S. Eng. (Pp. 853+viii; illustrated. 75s.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

Books on operative surgery range from the concise one-volume textbook designed to cover the standard operations for the benefit of a student working for examinations to the large encyclopaedia in several volumes. The first seldom gives enough detail to help the practising surgeon; the second is usually a syndicated work and reflects its multiple authorship in a certain unevenness of standard.

Mr. Farquharson's book is in some ways unusual. First, though in a single volume, it is a large work containing 850 pages; secondly, the whole of it is written by himself, so that it has a uniformity of style and of outlook that makes it easy to read; and, thirdly, it is written with a particular aim and adheres to it throughout. That aim is to afford practical advice to the young general surgeon working for the first time on his own responsibility and unable to call on more expert help.

In pursuing his intention Mr. Farquharson precedes each section with a brief review of the anatomy of the part and of the principles on which operation is based, adding in some sections an account of the use of special instruments such as the cystoscope and the sigmoidoscope. He describes the important and commonly performed operations in considerable detail, with excellent and helpful illustrations, the majority of which are by Miss McLarty. The rarer procedures, or those whose value is more in doubt, he discusses less fully, but in most cases gives references indicating where detailed information can be obtained.

For the purpose for which it is intended this is a really good book, one that should find a permanent place in any surgical library. A London surgeon, even though he be a Scotsman, cannot be expected to agree with all the views of one trained in Edinburgh, but the criticisms that can be offered are of detail only, with one exception. The example of parenteral fluid administration given on page 566—9 litres in 24 hours—is dangerous and should be amended in the next edition.

Messrs. Livingstone have done their job as publishers with their usual craftsmanship.

HENEAGE OGILVIE.

ORTHOPAEDICS OF CHILDHOOD

Kinderorthopädie. By Rupprecht Bernbeck. Introduction by Professor Dr. Med. Georg Hohmann. (Pp. 234; 174 illustrations. D.M. 39.) Stuttgart: Georg Thieme. 1954.

It is inevitable that any volume embracing all the orthopaedics of childhood will be a little uneven. This volume presents the author's personal experience from the German viewpoint. After a general introduction, which is much the best portion of the book, there follow a series of special sections, the largest being devoted to clubfoot and congenital dislocation of the hip. This includes a clear description of the pathological varieties of clubfoot. The treatment is not so clearly described; for example, whereas

Kite's plasters are mentioned, there is no reference to the use of Denis Browne's splints. In contrast to these full discussions, the section on slipped femoral epiphysis is short and incomplete, and other sections, on torticollis, osteomyelitis, and the dyschondroplasias, are merely résumés.

The book is well illustrated with radiographs in series, and is worth perusal for these alone. The volume as a whole will appeal to the children's physician, and the fuller sections to the specialist. The book unfortunately evidences the isolation of German medical thought during the past 15 years, from which in other fields, such as virology, it is slowly escaping. In the literature quoted there are surprisingly few references to English and American authors (2 out of 52), and French and Italian authors are given equally scant treatment.

J. G. BONNIN.

THE VITAMINS

The Vitamins: Chemistry, Physiology, Pathology. Volumes I and II. Edited by W. H. Sebrell, jun., and Robert S. Harris. (Volume I: pp. 676+xiii; Volume II: pp. 766+xiii; illustrated. \$16.50 each vol.) New York: Academic Press Inc. 1954.

This is an encyclopaedic work on vitamins which is to appear in three volumes, the first two having already been published in the second half of 1954. The treatment is essentially biochemical, although, as the subtitle indicates, chemical, physiological, and pathological aspects are also included. It is not, and is not intended to be, a guide for the general practitioner, or even for the clinical specialist. The manifestations of vitamin deficiency and their therapy are not dealt with in any detail, since, as the authors themselves say, such information is available in other publications. For the same reason methods of vitamin assay are referred to but briefly. The approach is not historical, but rather that of a detailed systematization of existing knowledge in those fields of vitaminology that border on biochemistry. As such it is an invaluable reference work for the laboratory investigator; and the bibliography, which is unusually extensive (although sometimes too exclusively American), will prove extremely helpful.

It is not too much to say that "Sebrell and Harris" immediately becomes an indispensable work of reference for all serious research workers concerned with vitamin science.

LESLIE J. HARRIS.

CLINICAL NEUROLOGY

The Basis of Clinical Neurology. By Samuel Brock, M.D. Third edition. (Pp. 510+xii; illustrated. 54s.) London: Baillière, Tindall and Cox, Ltd. 1953.

In this detailed account of the anatomy and physiology of the nervous system Dr. Brock has been at pains to exclude material not of direct value to the clinical worker. All the same it has taken over five hundred pages, not all lightened by his excellent line diagrams, to say what seems essential. Syndromes are described, but not disease; anatomical dysfunction, and not pathology; so that the student of anatomy will find as much of interest as will the clinical worker. The way function is married to structure makes clinical syndromes easy to understand. For instance, the spinal cord is considered in seven short chapters in which, its anatomy and blood supply having been dealt with, its structure is related to movement, to sensation, and to visceral function; and then it is considered as a conducting and a segmental organ.

Some of the most interesting sections to the reviewer are in small type—which shows the author's discretion—and the arrangement of material enables the student to select with ease. He should not, however, miss the last clinical chapter, on posture, for this is a delightful essay in which the systematic integration of dull facts brings them to life. The closing chapters on the cerebrospinal fluid, radiology, and electromyography are unnecessary in a text of this sort, and do not maintain the standard of the earlier dynamic clinical sections.

DENIS WILLIAMS.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 29 1955

TREATMENT OF PULMONARY TUBERCULOSIS

The introduction of effective antibacterial drugs has revolutionized the treatment of pulmonary tuberculosis. Whereas in the past the physician treating this disease has had to rely upon the natural resistance of the patient aided by bed rest and by the indirect effect of collapse therapy, he now has available methods of direct attack upon the tubercle bacillus; and the surgeon, previously restrained in the application of some of his more radical methods by the fear of complications, has now much greater freedom of action. These striking changes in the practical management of pulmonary tuberculosis have tended to distract attention from important epidemiological changes which have been occurring more gradually but which may be of greater ultimate importance. As Dr. J. L. Livingstone points out in his Mitchell Lecture, published in the opening pages of this *Journal*, preventive medicine does more to eradicate tuberculosis than the efforts of the clinician in dealing with the sick. This, like most generalizations, needs qualification. It is true without reservation in relation to underdeveloped communities where the pool of infectious cases is too great to be much diminished by the provision of treatment on any practicable scale. But in communities in which good progress has already been made in the control of the disease it seems clear that rigorous clinical measures can make a significant and perhaps decisive contribution towards the removal of the last remaining sources of infection. Dr. Livingstone's main purpose in his lecture was to give an account of his own experience in the management of pulmonary tuberculosis, with special reference to collapse therapy. The measures which he uses include artificial pneumothorax, phrenic paralysis with pneumoperitoneum, and extrafascial apicolysis with "lucite" plombage of the type described by Cleland.¹

Dr. H. C. Trimble's paper, also published in this issue (p. 250), provides an interesting companion to Dr. Livingstone's. Its approach is entirely different. It describes the analysis of the answers given by one hundred physicians in 1953 to a number of questions about the treatment they would use for ten representative cases of pulmonary tuberculosis which were presented to them in the form of brief case histories

and radiographs. The answers are compared with the answers given to the same questions about the same patients in 1948. It is perhaps a valid criticism that the method of presentation of the cases to the physicians was of necessity artificial. It is to be hoped that no physician would seriously give advice about the treatment of a patient on the basis simply of a case history and inspection of a radiograph. Nevertheless Dr. Trimble's analysis gives some indication of change in opinion. It also shows very wide variation in present-day practice. Similar differences of opinion would probably be found in the answers to corresponding questionnaires relating to the treatment of a number of other illnesses, especially those where both medical and surgical methods are in use—for instance, peptic ulcer. The most important trend among the American physicians was the greatly increased use of antibacterial treatment. In the far advanced cases every physician would use such treatment, and even in minimal infections only very few would use bed rest without antibacterial treatment. As compared with 1948, artificial pneumothorax showed a remarkable diminution in popularity, while pneumoperitoneum showed a corresponding increase. Dr. Trimble does not state how often the physicians whom he questioned would combine phrenic nerve paralysis with pneumoperitoneum. Dr. Livingstone states that he regards pneumoperitoneum as an adjunct to phrenic paralysis, and that he has never used pneumoperitoneum without phrenic paralysis. This seems to be the logical consequence of the view that collapse therapy must be selective if it is to be effective.

Among the American physicians there has been an increase in the proportion of patients for whom surgical treatment would be advised; and resection has become far more popular than thoracoplasty. Some of the recommendations for resection are surprising; for instance, a few physicians stated that they would advise resection in a case of bilateral acute pulmonary tuberculosis rather more extensive on the left side. Dr. Livingstone makes a useful distinction between resection performed as direct therapy, removing diseased and usually functionless portions of lung which have caused symptoms, and resection performed prophylactically, in which damaged lung not known to have caused symptoms is removed on the ground that it is a potential source of danger at a later date. He adds that in some countries resection after a long course of antibacterial therapy has become the accepted form of treatment. The justification for "prophylactic" resection depends upon the view that residual encapsulated caseous foci

¹ *Thorax*, 1950, 5, 248.

² American Trudeau Society, *Amer. Rev. Tuberc.*, 1953, 68, 477.

³ Goodwin, R. A., *Ann. Intern. Med.*, 1954, 41, 328.

⁴ Foster-Carter, A. F., *et al.*, *Brompton Hosp. Rep.*, 1952, 21, 1.

are dangerous; but no agreed opinion about how dangerous they are has yet been reached.²

One of the most remarkable changes which has occurred since the advent of antibacterial treatment has been the great diminution in the popularity of artificial pneumothorax. Some physicians have ceased to use this form of collapse therapy.³ Dr. Livingstone believes that there are still some indications for artificial pneumothorax, and points out that the figures derived from the Frimley follow-up of 1,153 cases, each for a minimum period of eight years, show that even before antibacterial drugs were available a pneumothorax which resulted in closure of the cavity improved the prognosis.⁴ The real drawback of artificial pneumothorax treatment was the high incidence of pleural complications. There is, however, reason to believe that the combination of antibacterial drugs with artificial pneumothorax will result in a lower incidence of such complications. No comparably extensive series of cases treated with artificial pneumothorax since the advent of antibacterial drugs has yet been studied. It is to be hoped that Dr. Livingstone and others who continue to use artificial pneumothorax in selected cases will publish their results in due course. It is difficult to believe that a method of treatment which was so widely and successfully used for so long by so many physicians can really have no useful part to play in the future.

In pulmonary tuberculosis to-day the multiplicity of possible therapeutic measures in several fundamentally different categories tends to cause confusion, and the formal assessment of all possible combinations of them is not feasible. But the disease presents such a variety of anatomical and immunological features that it would be surprising if procedures which have proved successful in the past were not found still to be useful in selected cases in combination with antibacterial treatment. In the more usual types of case the physician may hope eventually to have precise data indicating the superiority of one of the possible lines of treatment: in those not falling into a category which has been statistically investigated he will continue to have the responsibility of exercising judgment based upon experience.

HEPATIC FIBROSIS

The idea that nutritional deficiency is of great importance in the causation of liver disease springs mainly from the results of animal/experiments performed in the past 15 years.^{1,2} These experimental results seemed at first to show why human liver disease is more prevalent in Africa, Asia, and other countries where the standard of nutrition is well below that of

Western Europe and the U.S.A. The fatty liver of kwashiorkor in Uganda³ and of the "fatty liver disease in infants in the British West Indies"⁴ were strikingly similar to the fatty livers so readily produced in rats by dietary means and which so consistently caused cirrhosis if maintained for long enough. The failure, however, of methionine or choline to mobilize the fat from the livers of affected children, and the difference in the distribution of the lesions in the human liver from that in the experimental animal, suggested from the first that the direct application of the experimental results to man was altogether too simple. The recent observations of J. H. Walters and J. C. Waterlow⁵ on the incidence of hepatic disease in West African children give prominence again to these difficulties, but also help to dispel them.

The clinical material which formed the basis of this study in the Gambia consisted of four groups of children and adolescents up to 20 years of age—a control group of 15, a group of 17 patients with symptomless hepatomegaly, a group of 26 malnourished infants, and a group of 21 children with hepatomegaly associated with oedema and ascites. All cases were studied as hospital in-patients, and the investigations included one or more needle biopsies of the liver in every case. The fibrosis in these biopsy specimens was classified, in increasing order of severity, as normal, periportal quiescent, periportal active, and diffuse. The incidence and severity of the fibrosis in the children with symptomless hepatomegaly were about the same as in the control groups—namely, 50%—and almost entirely of the periportal quiescent type. Walters and Waterlow concluded from this that the hepatomegaly in these children could not be regarded as a precirrhotic state. In the group of malnourished infants, however, periportal fibrosis of an active type associated with cellular infiltration was the characteristic lesion, and present in most cases. In the patients with hepatomegaly and ascites or oedema the severest forms of fibrosis were most frequently found.

Having obtained a rough indication of the type and incidence of hepatic fibrosis in the community, the authors, in an attempt to throw light on the aetiology, directed their attention to the two outstanding environmental factors—namely, nutrition and parasitic infestation. What they reveal is both grim and startling. Owing to the inadequacy of the local

agriculture, food is never plentiful, and the daily food consumption per head of the population varies from 1,980 calories shortly after the rice harvest to 1,570 shortly before. Protein consumption, which does not exceed 50 g. per day at the best time of the year, is almost entirely of vegetable origin; cows' milk is scarcely consumed at all and fishing is despised. It is not surprising that evidence of severe malnutrition is present at all ages and especially between 6 months and 2 years, when the infant is gradually weaned from the breast and, not yet partaking of the communal food, receives supplementary feeds of sweetened vegetable paps. In addition to this "marginal state of nutrition interrupted by an annually recurring period of privation" the population is subject to an extraordinarily intense parasite infestation, malaria being outstanding. In the survey carried out by I. A. McGregor and D. A. Smith⁶ parasitaemia was found to rise from 62% in the first year of life to a peak of 97% from the third to the fifth years and then to fall steadily to about 20% in adult life. Microfilaria, trypanosomiasis, and schistosomiasis are all common, and "helminthic infestations approach malaria in frequency." Infective hepatitis is rare in the Gambia and only four cases were found in three years.

Walters and Waterlow have attempted to identify the various causes of the high incidence of fibrosis, and it is hardly surprising that they cannot incriminate one in preference to another. From their histological and chemical analyses they are apparently justified in excluding prolonged and severe fatty infiltration as a major factor. On the other hand, the consensus of informed opinion is against regarding malaria as a cause of diffuse fibrosis of the kind and severity commonly found in this investigation. The authors therefore feel compelled to fall back on a hypothesis first postulated by the Gillmans in a somewhat different context. From their work on the induction of cirrhosis by repeated injections of Trypan blue,⁷ J. Gillman and T. Gillman⁸ suggested that two factors are required, one which causes a proliferation of reticulum cells and another which stimulates these cells to form reticulin and collagen fibres. They regard a depressed level of oxidation as this necessary second stimulus. The sequence of events in the Gambian children is then viewed as follows. Severe and recurrent malarial infestation causes the reticulum-cell response of the hepatic mesenchyme. The further progression to active diffuse fibrosis then follows as the result of the depressed level of oxidation due to the impairment of parenchymal-cell function consequent upon the state of malnutrition. In other words, as a result of chronic malaria the reactivity of the hepatic connective tissue to mild damage of hepatic parenchymal

cells is greatly enhanced: a degree of parenchymal damage which is usually without effect on the connective tissue now calls forth a progressive fibrogenetic response.

That diffuse hepatic fibrosis can occur in the malnourished in the absence of severe fatty infiltration must not be adduced as evidence that fatty infiltration does not or cannot induce fibrosis in man. The evidence collected by Waterlow¹ himself in the West Indies shows that it almost certainly can. The importance of this work in the Gambia is that it emphasizes that even lesser degrees of malnutrition, themselves incapable of producing chronic liver damage, can do so in subjects whose mesenchymal reactivity has in some way been enhanced. Is it perhaps possible that the frequency of keloidal scarring in certain communities is an indication of this mesenchymal hyperactivity and should be taken as a warning of their special nutritional vulnerability?

THE HAEMOPHILIAS

Until recently haemophilia seemed to be a well-defined disease. In the eighteenth century Consbruch reported that he had been called to see a boy who had cut his thumb and bled to death within two days. A brother of this boy and several brothers of his mother's had died similarly. The sex-linked inheritance of this liability to bleed to death was thus recognized early. The bleeding tendency has been found to be due to a coagulation defect, the absence of an antihæmophilic globulin necessary for the first stage of coagulation. Normal plasma, which contains this antihæmophilic globulin, restores coagulation when either added *in vitro* or transfused *in vivo*.

The coagulation of the blood has been conveniently divided into three stages, for the first of which the antihæmophilic globulin is necessary: (1) platelets are ruptured and active thromboplastin is formed; (2) active thromboplastin produces conversion of prothrombin into thrombin; (3) thrombin causes the soluble fibrinogen to form elongated crystal-like protein fibrils, which combine into fibres by lateral association. Calcium has long been known to be necessary for the formation of thrombin, and thus there were, besides the antihæmophilic globulin, factors I-IV: fibrinogen, prothrombin, thromboplastin, and calcium. In due course patients were found whose plasma contained all these four factors but who still lacked other agents necessary for coagulation and present in normal plasma. Addition of hæmophilic blood could restore coagulation; thus the missing component could not be the antihæmophilic globulin.

⁹ *Amer. J. Med.*, 1954, 17, 57.
¹⁰ *Blood*, 1954, 9, 258.

By comparing these patients' plasma with one another it became clear that there were at least two deficiencies, that of factor V (or V-VI), a labile protein which disappears on storage—hence the synonym labile factor—and of factor VII. Both are hereditary deficiencies, though they are not transmitted by the X chromosome. They are seen rarely, but the clinical importance of factor VII is that its activity is the first to be suppressed during treatment with dicoumarol and ethyl biscoumatate ("tromexan"). In the laboratory test, deficiency of factors V or VII differs from the classical haemophilia by causing a prolonged prothrombin time. The prothrombin time is also prolonged in hypoprothrombinaemia, usually due to liver disease or vitamin-K deficiency, more rarely congenital. However, when factor V or factor VII is deficient, addition of normal plasma from which prothrombin has been removed can restore the prothrombin time to normal; it will not do so if the plasma under investigation lacks prothrombin.

Among the various terms that have been attached to factor-V and factor-VII deficiency are parahaemophilia A and B, while the term haemophilia itself was reserved for the classical bleeding disorder transmitted with the X chromosome and reversed by transfusion of the anti-haemophilic globulin present in normal plasma but not in normal serum. New difficulties in nomenclature arose when it was found that there were differences among the supposedly true haemophilia patients themselves. Plasma from some haemophiles could counteract the clotting defect in others, and this effect was mutual. Thus, although the disease was clinically the same and was inherited with the X chromosome in these groups of patients, it must have been caused by different factors absent in one and present in the other. Whereas the classic antihaemophilic factor was a globulin contained in the fibrinogen fraction of the plasma, the second principle was found both in plasma and in serum. It was described in Britain by Biggs and others,¹ who named it Christmas factor, after the first patient in whom they diagnosed the new condition, and in the U.S.A. by Aggeler and his colleagues,² who called it plasma thromboplastin component (P.T.C.). The distinction between classical haemophilia and the new coagulation defect is of practical importance. While both will respond equally to treatment with normal plasma, the second will not be reversed by the therapeutic administration of purified antihaemophilic globulin. Even if normal plasma is transfused an important difference is observed. The classical antihaemophilic globulin disappears within a few days after a transfusion of 500 ml. of normal plasma, but the stability of the beta-globulin, which corrects the new condition, is such that a favourable influence on blood clotting can be observed as long as three weeks after the transfusion.³

P.T.C. deficiency and Christmas disease are almost certainly identical disorders, but few authors have as yet stated this with certainty.⁴ Some American workers have suggested that the classical haemophilia should be called haemophilia I (or A) and P.T.C. deficiency haemophilia II (or B). Others,⁵ who have named factor-V and factor-VII deficiencies haemophilioid states A and

B, want to retain for the classical condition the term haemophilia and to call the newly discovered P.T.C. deficiency haemophilioid state C. Aggeler and his group⁶ have now proposed the terms haemophilia and deuterohaemophilia, the missing coagulation factors to be called, instead of antihaemophilic globulin and P.T.C., plasma thromboplastin factors A and B (P.T.F.-A and P.T.F.-B). A third plasma thromboplastin factor has been described and was named plasma thromboplastin antecedent (P.T.A.).⁷ The new deficiency seems to be distinct from both classical haemophilia and Christmas disease. Its mode of inheritance has not yet been established, but it may not be a sex-linked disorder.

Some might argue that the term haemophilia should comprise all those disorders of coagulation in which there is a defective thromboplastin formation with a normal prothrombin time (to insist on sex linkage might exclude P.T.A. deficiency). It may after all only be a chance that the antihaemophilic globulin was discovered before the beta-globulin, which the American authors have named first P.T.C. and now P.T.F.-B, and which is almost certainly identical with the Christmas factor. Frick⁸ restudied fifty-five patients previously simply diagnosed as haemophiles and found that six were in fact cases of P.T.C. and four of P.T.A. deficiency. A similar distribution of the three deficiency states has been found in a survey of twenty-seven families carried out by Rosenthal.⁹ On the other hand, Macfarlane¹⁰ is of the opinion that variants of the term haemophilia are confusing and difficult to remember, that it would be best to avoid them, and when no established name like haemophilia is available to refer to deficiencies in terms of the missing factor—"As to the nomenclature of these factors some agreement will have to be reached, and soon, if inextricable confusion is to be avoided."

ADOPTION

Those whose responsibility it is to ensure that the adopted child is given the rights and security of a child in a normal family will find their work greatly assisted by many of the recommendations of the Hurst Committee on adoption.¹ The welfare of the child rather than the satisfaction of the adopters has been the aim of the committee, which has wisely refrained from making sweeping changes which, if interpreted into law, might set up a rigid code that would defeat its own end and increase the number of *de facto* adoptions. The committee recommends that the period of notice of placing should be increased from seven to fourteen days and also that the first six weeks of life should not be counted as part of the statutory probationary period. This, together with certain changes of procedure, would make it impossible for an adoption order to be granted before a child is 5 months old. Not everyone has agreed with the committee's insistence that a child should never be able to remember a time when he did not know the truth about his adoption, though psychological disturbance is not an unusual result of sudden or perhaps even harsh revelation to an adolescent that he or she is an adopted

child. The Standing Conference of Societies Registered for Adoption has just issued a useful leaflet for the guidance of adoptive parents entitled, "What Shall We Tell Our Adopted Child?", but if the advice given there is followed—namely, to let the child know "from the beginning" that he has been adopted—there still remains doubt, as Dr. W. J. Pinoff² has remarked, about a young child's capacity to understand the implications of the statement (however wrapped up it may be), "I am not your real mother." Dr. F. Charlotte Naish,³ who is well qualified to speak with authority on the subject, suggests that it would be as well to keep an open mind on this difficult question, while encouraging further research into the best method of telling children that they are adopted.

There is an interesting shift of emphasis in the committee's report from the health of the child to that of the adopters. The adoption of handicapped children need not be discouraged, but, on the other hand, a child should not be adopted by applicants whose good health and expectation of life are in doubt. The suggested compulsory medical examination of the prospective adopters by a doctor appointed by the court is an entirely new departure—which has the approval of the British Medical Association—but its value will be lessened if x-ray examination of the lungs is not made obligatory. The committee's desire to ensure that an adoption order is not refused for a handicapped child if the applicants have been informed and understand the implications is commendable. But unfortunately no machinery has been envisaged for simple explanation by the court doctor to the prospective adopters of any salient medical data relating to the child, and it may well be asked how the committee's view that "it is for the applicants to decide when they know the facts" is to be realized unless such facts are explained to them by a doctor.

The most controversial aspect of the report concerns third-party adoption. There has been a general dislike of this method, and the doctor acting as third party has not escaped criticism, in that his interests are often centred more on the psychological needs of the applicants or the welfare of the child's mother than on the best interests of the child himself. This has been given peculiar prominence by a quotation in the report from an unfortunately worded doctor's letter, which, although stated not to be typical of the attitude of the profession generally, has been widely publicized in the press. As the British Medical Association pointed out in the evidence submitted to the committee, the good results achieved in many cases by means of third-party adoption, as well as the impracticability of entirely abolishing direct or third-party placings, call for a realistic approach, and for the provision of safeguards to protect the child in all circumstances. The Hurst Committee's report has been framed on the basic assumption that the welfare of the child must come first. It is to be hoped that this spirit will be retained if the recommendations are embodied in formal legislation.

MUSCLE SPASM AND RHEUMATISM

It has sometimes been said that, since muscle spasm is partly responsible for the pain of many rheumatic conditions, antispasmodics should be administered. Physostigmine,^{1,2} curare,³ and, more recently, mephenesin,^{4,5} have all been suggested as suitable, but opinion remains divided on their value, if any, and it is perhaps worth while considering whether there is any sound theoretical basis for their use in rheumatism. It is a well-established clinical observation that in painful conditions of the spine or limb girdles there are local areas of muscle tenderness, often referred to as trigger areas, fibrositic nodules, or myalgic spots. The nature of these is sometimes a matter of diverting speculation, and the fact that local procaine injections are often followed by prolonged or even permanent relief has led to the development of the superficially attractive hypothesis that these are localized areas of muscle spasm which are of themselves responsible for the pain by setting up a vicious circle via a reflex path through the anterior horn cells. This view received some experimental support when Elliott and Kremer^{7,8} inserted needle electrodes into the muscles of patients with proved disk lesions and found evidence of spontaneous motor activity restricted to these points. While there was nothing particularly new in the recognition that muscle contraction is associated with referred pain, the emphasis had hitherto been largely on the hyperaesthesia and muscle spasm accompanying visceral lesions. This was the so-called visceromotor reflex studied by Mackenzie so long ago as 1892.⁹ Later Lewis and Kellgren^{10,11} in animals and Kellgren¹² in human volunteers observed the presence of muscle spasm and tenderness in response to painful lesions in deep somatic structures, and they concluded that this mechanism probably did not differ fundamentally from that of visceral pain mechanisms. To ascribe to muscle spasm an important part in the production of painful conditions, or at least in their perpetuation, is not, however, quite the same thing. Thus Wolff¹³ believed that some forms of headache were due to such a phenomenon, and Schlesinger and Stinchfield¹⁴ suggested that in some cases of acute lumbar disk lesion a vicious circle of pain and muscle spasm might produce a state of affairs which was something more than simple protective splinting. It has been only too easy to suggest that psychological tension leads to muscle tension, giving rise to so-called psychogenic pain. Reviewing these ideas recently Taverner¹⁵ has pointed out that, while an irritative lesion of a nerve root will give rise to spontaneous muscle activity, this is not necessarily associated with pain, and may be observed by the electromyograph in

pain-free muscles. By contrast, in the patient with acute lumbago at rest the muscles may be completely silent. The observations of Frykholm¹ on brachial neuralgia due to nerve root compression in the cervical region are of the greatest interest and throw some new light on this problem. He was able to demonstrate at operation in this type of case that stimulation of the ventral root gives rise to deep pain associated with muscle tenderness of the so-called myalgic type, while stimulation of the dorsal root gives rise to a more peripheral pain associated with paraesthesiae—that is to say, pain of a neuritic character. Perhaps muscle spasm therefore, at least in rheumatic conditions, is no more than a result of referred pain or of ventral root irritation.

OSTEOPOROSIS AND CORTISONE

Osteoporosis—a condition caused by loss of the proteinous matrix of bone—is a common finding in Cushing's syndrome, and F. Albright¹ has produced evidence that this is due to an excess of certain adrenocortical hormones, such as hydrocortisone, which have an anti-anabolic action whereby they prevent the building up of proteins from amino-acids. In sufficient dosage over a prolonged period of time cortisone or corticotrophin induces many of the changes found in Cushing's syndrome, and workers at the Mayo Clinic² have shown that in some patients a dose of cortisone exceeding 100 mg. daily causes a negative nitrogen and calcium balance. In patients with rheumatoid arthritis this undesirable side-effect of cortisone is often counteracted by an increase of appetite, which leads to enhanced protein intake and hence a positive rather than a negative protein balance. Nevertheless it was not unexpected that in some patients prolonged administration of cortisone should lead to osteoporosis, with pain in the back and collapse of vertebral bodies, and more than a dozen such cases have now been reported.³⁻⁷ In many instances it is difficult to be certain that the condition is attributable solely to the cortisone, because osteoporosis may occur as a complication of rheumatoid arthritis, during prolonged immobilization, and particularly in postmenopausal women. In some patients the symptoms of osteoporosis and pathological fractures have developed within a few months of the start of cortisone treatment, and possibly the increased sense of well-being produced by the drug has led patients with osteoporosis which before treatment was prevented by pain and muscle spasm. Recently osteoporosis and crush fractures of the vertebrae have been reported⁷ in four male patients receiving prolonged cortisone or corticotrophin—one of them being a boy aged 9—and there can be little doubt that the treatment caused the bone changes. This hazard should be kept in mind when cortisone treatment is prolonged and particularly when large doses are given to elderly patients or postmenopausal women; physiotherapy⁸ and testosterone² may help to avert it.

TETANUS IMMUNIZATION

Every year since the war about seventy people in England and Wales have died of tetanus, and probably at least as many more have recovered from the infection. The highest death rate was in boys aged 5-14 years, and most of the deaths were of people living in rural areas, particularly in East Anglia and the south-west. Some of these deaths might have been prevented by more extensive use of prophylactic antitoxin, but the experience of Cole¹ suggests that many probably had injuries so trivial that they were not even seen by a doctor. Every year many thousand injections of tetanus antitoxin are given and are followed inevitably by a number of serum reactions; occasionally one of them is fatal. Every day doctors are faced with the difficult task of weighing the risks of horse serum against those of tetanus.

There is strong though indirect evidence for the value of active immunization against tetanus. Only twelve cases occurred in the American Army during the last war, and only six of these had received the basic course of toxoid.² The American Army used no antitoxin, but relied entirely upon booster doses of toxoid after injury. Further suggestive evidence was obtained by Ipsen,³ who showed that there has been a marked decline in tetanus morbidity in Massachusetts in children under 5 years of age, most of whom are now actively immunized, and in young adults, a high proportion of whom were actively immunized in the armed Forces. Conybeare and Logan⁴ found a similar decline since the war in the tetanus death rate of young male adults in England and Wales.

Active immunization on a scale sufficient to produce an appreciable result would hardly be practicable were it not for the development of vaccines combining tetanus toxoid with other antigens already widely used. The immunization of all infants with a single vaccine effective against diphtheria, whooping-cough, and tetanus, with later boosting doses as required, would be ideal, but it is important that in combining antigens nothing should be lost. Barr and Llewellyn-Jones showed⁵ that the result obtained with a combined prophylactic depends to an extent not fully understood on the composition of the vaccine and the state of immunity of the inoculated. However, many studies have shown that it has been possible to produce satisfactory levels of antibody against the component parts of combined vaccines, so the problem should not be insuperable. Field trials are in progress at present to confirm that the protective effect of a whooping-cough vaccine is not diminished by combining it with a diphtheria antigen. A triple vaccine incorporating tetanus toxoid would require similar trial.

We record with regret the death on January 25 of Dr. Charles Herbert Hampshire, C.M.G., secretary of the British Pharmacopoeia Commission from 1929 to 1950.

EMERGENCIES IN GENERAL PRACTICE

THE MANAGEMENT OF ECLAMPSIA

BY

W. I. C. MORRIS, M.B., M.Sc., F.R.C.S.Ed., F.R.C.O.G.

Professor of Obstetrics and Gynaecology, University of Manchester; Obstetrician and Gynaecologist, St. Mary's Hospital, Manchester

Although eclampsia remains one of the most serious of obstetrical complications, the Australian workers have shown that in the practice of a first-class maternity hospital a determined effort to eliminate eclampsia may be completely successful.* The measures which succeeded at the Crown Street Hospital in Sydney were administrative as well as medical. They involved arrangements for antenatal out-patient care at the very highest standard, and the reallocation of beds so as to increase antenatal accommodation at the expense of lying-in beds. The latter allowed the admission of all patients who showed evidence of pre-eclamptic toxæmia, and also many of those patients who were believed to be likely to develop pre-eclampsia, on the basis of excessive weight gain observed at their frequent antenatal examinations. The most important obstacle to the application of such methods in this country occurs in areas where maternity hospital beds are insufficient to allow an adequate number to be set aside for antenatal patients. In hospitals in more favoured areas eclampsia is already rare, while a general practitioner carrying out alert antenatal care very seldom needs to treat an eclamptic patient at home. Although successful measures for the complete prevention of pre-eclamptic toxæmia have not yet been established, the prompt treatment of early cases of toxæmia is often successful and the immediate transfer to hospital of patients showing severe pre-eclampsia is enough in itself to make convulsive eclampsia a very great rarity in domiciliary practice.

Space does not permit of elaboration of the conservative treatment of pre-eclampsia. So far as general practice is concerned the most successful measure is to increase the time spent by the patient in bed to the maximum compatible with her domestic circumstances. Restriction of sodium intake in the form of cooking salt, table salt, and sodium-containing digestive medicaments is helpful but not always easy. A nocturnal barbiturate—for example, butobarbitone 0.18 g. (3 gr.)—is often advisable. It is most important to keep very clearly in mind the indications that a case of pre-eclampsia is becoming too severe to handle in the patient's home. Of these the most important are (a) oedema which persists in the lower limbs after a complete night's rest, or oedema which significantly affects the hands or face; (b) a blood pressure at or above the level of 150/100; (c) albuminuria confirmed in a catheter specimen of urine, no matter how small the quantity of albumin may be; and (d) finally the well-known prodromal symptoms of eclampsia itself, splitting headache, blurring of vision, severe epigastric pain, and reduction in output of urine.

General Principles of Management

The general practitioner will wish to undertake domiciliary treatment of eclampsia only in most isolated communities, the number of which has been greatly reduced by the availability of good ambulance services. According to Frew the

*Hamlin, R. H. T., *Lancet*, 1952, 1, 64.

eclamptic patient appears to travel well by air if under the action of a basal narcotic such as bromethol.

There is as yet no specific treatment for eclampsia. It is universally accepted that measures to limit the number of the fits offer the best hope of saving life. Along with these measures attention is required to the prevention or prompt treatment of such complications of eclampsia as inhalational pneumonia, cardiac embarrassment, or suppression of urine.

The sedative regime associated with the name of Stroganoff has been widely employed with varying success. Morphine and chloral were the drugs originally recommended, but other and more powerful narcotics have been introduced without modifying the essential principles. Of these later drugs the most valuable appear to be sodium thiopentone and bromethol. All are potential respiratory depressants, and the balance between the effective and the toxic dose is very delicately poised.

Certain drugs which reduce the elevated blood pressure are also effective in preventing convulsions. Of these, the extract of veratrum viride (a plant of the lily family) manufactured under the proprietary name of "veratrone" has always been popular in the Cincinnati school. In this country Stern and Burnett have authoritatively recommended it.†

Whichever type of drug is selected, the general nursing management of the patient is of the greatest importance. The maintenance of a clear airway is essential. Artificial dentures should be removed as soon as possible. The mouth must be kept clear of secretion, blood, or vomitus. The use of the semiprone position, changing from one side to the other at two-hourly intervals, is probably sound, but care must be taken to swab out the dependent cheek before moving the patient. Quiet, the avoidance of bright light, and the maintenance of an even temperature help to diminish the afferent stimuli which may precipitate convulsions. The eclamptic patient should not be overheated, and there is no reason to encourage sweating by the application of a harsh blanket. The vigorous perspiration often seen during recovery from eclampsia is the result of that recovery, and not its cause.

The possibility of inhalational pneumonia is diminished by good nursing. It is important to give neither solids nor liquids by mouth during the acute phase in order to prevent their inhalation during feeding or regurgitation. Penicillin may be given prophylactically in dosage of 300,000 units eight-hourly.*

The heart is most effectively supported by ensuring that anoxia is reduced by keeping the airway completely unobstructed in the intervals between fits. If available, oxygen should be administered immediately after each convulsion and continued so long as there is the slightest trace of cyanosis. Digoxin 1.5 mg. (1/40 gr.) may be given intravenously to a patient who has not been receiving any other form of digitalis. Venesection of 500 ml. may be useful in acute pulmonary oedema, which occasionally complicates cardiac failure in eclampsia.

Obstetrical intervention is generally restricted to the terminal second stage. There is no doubt that the patient who has an eclamptic convulsion when the head is on the perineum is often treated most effectively by an immediate forceps delivery. In other circumstances the better interests

†J. *Obstet. Gynaec. Brit. Emp.*, 1954, 61, 590.

of the patient are usually served by conservatism. In hospital practice there is a place for induction of labour in antepartum eclampsia, but usually such intervention is delayed until the fits are controlled by sedatives, by which time labour has often ensued spontaneously. Caesarean section is not to be regarded as a treatment of choice in any circumstances. It is inevitably associated with a high maternal mortality in eclampsia. There are occasional cases, however, where it may seem justified to a person with very great experience of the treatment of eclampsia.

Observation of the eclamptic patient must be close and uninterrupted. Changes in skin colour, the depth of coma or degree of restlessness, the temperature, pulse and respiration, the variations in blood pressure, the volume of urinary secretion, the activity of the uterus, all require watching. Too much disturbance of the patient is to be avoided, but a four-hourly report from the midwife is a great support in controlling treatment. There is little point in being scrupulous about the foetal heart sounds during the acute phase of the disease, for the foetus is always in grave danger in eclampsia and the detection of signs of foetal distress is unlikely to influence treatment greatly. Despite the old adage, intrauterine death of the foetus does not have much influence on the maternal prognosis.

First Aid

The fit of eclampsia is essentially similar to that of epilepsy except that there is no phenomenon strictly comparable to the aura of epilepsy. After slight facial twitching a tonic phase sets in, being followed by the onset of clonic spasms. The end of the fit is usually preceded by the coincidence of a clonic inspiratory effort with relaxation of the muscles controlling the glottis. Cyanosis at once diminishes. A moment or two later the jaw muscles relax completely and the fit may be said to have passed off. Coma of variable length and depth follows. In comparison with post-epileptic coma it is relatively brief.

The primary concern of first aid is the prevention of injury during the clonic phase. Gentle restraint for the writhing body will prevent the patient rolling out of bed or knocking her limbs against walls or furniture. Little more than this is possible. The advice to force a gag, a wedge of wood, or the handle of a spoon between the teeth is sound enough in theory, but usually the clenching of the jaws is much too firm to allow this to be done without the risk of loosening teeth or causing other damage. It is some comfort to recollect that if the tongue lies between the teeth at the moment of onset of the fit, nothing can save it, while if it is internal to the opposed jaws it is in any case safe. The time for insertion of a gag or dental prop is immediately after the fit, opportunity being taken to remove any artificial dentures and to swab out the mouth and pharynx if the tongue has been bitten or if there has been any regurgitation of gastric content.

The intravenous administration of sodium thiopentone in dosage of 0.25 to 0.5 g. is very sound as a first-aid procedure. It may be expected to arrest the fit at any stage, and by its prompt administration some lives may be saved which would otherwise be lost during a single unusually severe eclamptic convulsion. Unfortunately the preparation of the injection takes a little time, so that a first convulsion may have come and gone before it can be administered. If this is the case it is prudent to put down the syringe containing the injection in some safe but accessible position, so that it will be instantly available if there be a further attack.

At one time it was customary to endeavour to control the fits by the exhibition of prodigious quantities of chloroform. There is little doubt that the liver damage of eclampsia was often fatally aggravated by this additional insult. Inhalational anaesthetics are useless during the respiratory arrest of the convulsion. Their employment immediately after the convulsion is justifiable as a first-aid measure to delay the onset of further attacks where fits are following each other in very

rapid succession and thiopentone is for any reason unavailable. Chloroform on a Schimmelbusch mask at the rate of approximately 15 drops per minute for not more than 2-3 minutes may allow time for less damaging sedatives to take effect. Ether, theoretically preferable, is too apt to produce salivation, an added embarrassment to breathing.

The immediate management of the eclamptic patient includes certain examinations. It is most useful to obtain some idea (a) whether the patient is in labour or likely soon to be in labour, (b) whether there is any abnormality likely to give rise to mechanical difficulty, and (c) whether her urinary output is satisfactory. As the necessary examinations may well precipitate a convulsion in a restless semi-conscious patient, it is well to take the opportunity to carry them out in the period of coma immediately following a seizure, especially if thiopentone or chloroform has been given. The unconsciousness is then likely to be prolonged by a few additional minutes which will allow a quick abdominal and vaginal examination and the passage of a catheter. If a self-retaining catheter is available, its use should certainly be considered. A clip can be applied to it when the bladder has been emptied, and thereafter the release of the clip at four-hourly intervals enables the urinary output to be exactly measured without further disturbance of the patient.

Further Management

When "Flying-Squad" Service Available

If such a service operates in the practitioner's area and is willing to undertake treatment of the eclamptic prior to and during her movement to hospital, then the hospital should be contacted without delay. A joint scheme of treatment can be worked out in accordance with local policy.

No Flying-Squad Available but Removal to Hospital Possible

In city practice it is enough to move the patient as quickly as possible by ambulance from her home to the hospital of choice. The practitioner should accompany his patient. It is useful to take a gag and tongue forceps, a Schimmelbusch mask, and a bottle of chloroform. Where distances are greater it is wiser to begin sedative treatment in the home and to delay moving the patient until such sedatives have had time to take effect. A very useful drug for this purpose is bromethol, of which 5.5 ml. dissolved in 220 ml. of tap water at body temperature may be administered rectally. This acts within 20 minutes and the deep narcosis which follows renders the transport of the patient fairly safe. Unfortunately, the use of bromethol in general practice is limited by the fact that it is now rarely obtainable outside maternity hospitals, its vogue as a basal anaesthetic in general surgery having expired. It is an excellent "flying-squad" medicament, but the unaided general practitioner will often need to adopt other expedients. Of these morphine with all its faults as a respiratory depressant is the most useful and generally available. Its reinforcement with some other sedative (e.g., chloral or a barbiturate) is usually practised since it may then be possible to avoid very full doses of morphine. The following scheme of dosage is advised, the hour of commencing treatment being represented by the symbol "H." All drugs are administered intramuscularly.

Hour	Drug	Dose
H	Morphine	15 mg. (½ gr.)
	Sodium phenobarbitone	0.3 g. (5 gr.)
H+1	Morphine	10 mg. (1/6 gr.)
H+2	Depart by ambulance	

The second dose of morphine should be omitted in the unlikely event of any real respiratory depression (e.g., respirations 10 per minute or less), but if so an appropriately loaded syringe should be entrusted to the ambulance nurse to use if the patient has a further seizure during transit. It must be emphasized that the delay in moving the patient is justified only if the first injection produces some degree of control of her fits. If she continues to have fits some thirty minutes after starting treatment, no time should be lost in giving the second injection of morphine and dispatching her to hospital.

Removal to Hospital Impossible

Faced with the need to treat his patient entirely at home, the single-handed practitioner cannot hope to apply treatments which may tax the resources of a fully-staffed maternity hospital. Methods involving prolonged medical supervision can hardly be selected, and it is not practical to consider such treatments as the continuous intravenous thiopentone management of O'Donel Browne. The drugs readily available to the practitioner are likely to be limited to those of sedative type, and accordingly a Stroganoff type of management is likely to be forced on him. The aim should be to keep the patient deeply narcotized for at least 24 hours, and thereafter to prolong the sedation in lesser degree for a further 24 hours. Most patients are out of danger by that time. The following dosage scheme is suggested, the hour of commencing treatment being represented by the symbol "H", all drugs are administered intramuscularly.

Hour	Drug	Dose
H	Morphine	15 mg. (½ gr.)
	Sodium phenobarbitone	0.3 g. (5 gr.)
H+1	Morphine	10 mg. (1/6 gr.)
H+4	Morphine	15 mg. (½ gr.)
H+8	Morphine	15 mg. (½ gr.)
H+12	Sodium phenobarbitone	0.3 g. (5 gr.)
H+18	Morphine	15 mg. (½ gr.)
H+24	Sodium phenobarbitone	0.3 g. (5 gr.)
H+30	Morphine	15 mg. (½ gr.)
H+36	Sodium phenobarbitone	0.3 g. (5 gr.)

The recurrence of fits despite treatment might well justify the acceleration or increase of the doses of morphine. Indications to delay the next dose include undue respiratory depression (respirations 10 or fewer per minute), persistent cyanosis, and accumulation of bubbling secretion in the trachea and bronchi—usually an indication for full dosage of atropine (i.e., 1 mg.—1/60 gr.).

In addition to sedatives, some value is attached to the parenteral injection of hypertonic solutions of glucose or magnesium sulphate. These may have some effect in reducing cerebral oedema. Glucose is believed also to favour diuresis, while magnesium sulphate may reduce blood pressure slightly and appears to potentiate the anticonvulsant action of morphine. Glucose is given intravenously in daily dosage of 1,000 ml. of 20% aqueous solution. Magnesium sulphate is usually given intramuscularly in 50% aqueous solution, in dosage of 10 ml. repeated after each convulsion up to a total daily dose of 60 ml. The side-effect of paralysis of voluntary muscle must be kept in mind, and a total dose of 20 ml. should not be exceeded without making sure that the knee-jerks are present at the time each fresh injection is given.

Other useful drugs are: (a) *Sedatives*: Chloral hydrate, oral or rectal, 3 g. (45 gr.)—4 g. (60 gr.); paraldehyde, rectal, 40 ml. (1 fl. oz.), intramuscularly, 10–20 ml. (2–4 fl. dr.). (b) *Veratrine*, intramuscularly, 0.6 ml. (10 minims)—as initial dose. Further doses, if necessary, may be started after 30 minutes. They must be controlled by blood-pressure readings at 15-minute intervals. The aim is to secure an early reduction of systolic blood pressure to less than 120. Thereafter veratrine is withheld unless the systolic pressure rises above 150 mm. Hg. For details see Stern and Burnett's paper mentioned earlier in this article.

Next article on Emergencies in General Practice.—*"Acute Lumbago and Sciatica,"* by Mr. John Charnley.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

INTERNATIONAL FEDERATION OF GYNAECOLOGY AND OBSTETRICS

The constitution of the International Federation of Gynaecology and Obstetrics has now been adopted by 42 countries, including Great Britain, Canada, Eire, India, New Zealand, the United States, and Russia. The Federation was founded during the International Congress on Obstetrics and Gynaecology in Geneva last year, and has the following objects:

(a) To promote the development of science and assist in scientific research work relating to all the fields pertaining to gynaecology and obstetrics, to further the attainment, by all appropriate means, of a higher level of physical and mental health of women, mothers and their children, to develop and improve the exchange of information and ideas in the field of gynaecology and obstetrics, to contribute to the research of fresh knowledge in this field, to contribute to the improvement of teaching standards in the profession, to promote international co-operation and facilitate relationships between national medical bodies of the profession.

(b) To recommend a common policy in regard to these matters on the proposal of member societies.

(c) To represent member societies whenever joint scientific action can be pursued in such matters.

(d) To foster the initiation and development of all activities aiming at the attainment of the objects of the Federation as defined under (a) above.

(e) To organize international congresses, including all countries or certain groups of countries. Circumstances permitting, each international congress shall be held successively on a different continent. Members of national societies may attend all congresses.

The executive board of the Federation is composed as follows: *president*, Professor H. de Wetteville (Switzerland); *vice-presidents*, Professor L. Gérin-Lajoie (Canada) and Professor E. Cova (Italy); *secretary*, Professor R. Keller (France); *treasurer*, Dr. F. L. Adair (U.S.A.); *members*, Professor César A. Brea (Argentina), Professor O. Rodrigues Lima (Brazil), Professor H. Martius (Germany), Dr. V. B. Green-Armytage (Great Britain), Professor B. N. Purandare (India), Professor Hideo Yagi (Japan), Professor A. Bravo (Mexico), Dr. J. Harbutt (New Zealand), Dr. Howard C. Taylor, jun. (U.S.A.), and Professor A. Belochapko (U.S.S.R.); *executive secretary*, Dr. W. Geisendorf (Switzerland).

ORDER OF ST. JOHN OF JERUSALEM

The *London Gazette* has announced the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:

As Knights: Brigadier R. A. Hepple, C.B.E., M.C., M.B., and Dr. W. P. Warner, C.B.E., D.S.C. *As Commanders (Brothers)*: Surgeon Captain E. H. Lee, M.D., Brigadier K. A. Hunter, O.B.E., M.D., Lieutenant-Colonels G. N. Morris, M.B., F.R.C.S., and F. K. Mugford, M.B., Air Commodore A. A. G. Corbet, M.D., Mr. K. G. W. Saunders, O.B.E., F.R.C.S., and Drs. S. H. Keshen, A. P. Gorham, E. M. Dearn, R. A. P. Gray, and R. R. Trail, C.B.E., M.C. *As Officers (Brothers)*: Colonel G. A. Winfield, O.B.E., M.D., Lieutenant-Colonels S. Mackenzie, O.B.E., M.R.C.S., L.R.C.P., J. A. Melanson, M.B., and W. R. Everatt, T.D., M.B., Major M. J. Bett, M.D., Professor J. Galea, M.B.E., M.D., Messrs. J. S. Grant, M.D., F.R.C.S., J. A. White, M.B., F.R.C.S., V. C. J. Harris, F.R.C.S., A. L. Buchanan, M.B., F.R.C.S., R. H. Percival, F.R.C.S., and G. E. G. Peirce, M.B., F.R.C.S., and Drs. R. S. Reid, M.B.E., R. A. Dench, M.C., J. Morris, F. O'Daly, J. C. Moor, J. C. Cassaglia, G. D. E. Tullis, A. H. Penistan, E. F. Brown, E. L. Butler, M. Y. Paget, G. E. Mullins, R. Dick, R. M. B. MacKenna, H. G. Wiltshire, L. J. Haydon, T.D., H. E. Offord, J. R. Oddie, J. T. Watkins, J. H. Dixon, J. J. Kennedy, V. C. Meyer, J. McC. Caldwell, and H. E. W. Robertson. *As Associate Officers (Brothers)*: Drs. H. M. Jacobs, A. Rabinowitz, and E. B. Doany. *As Officer (Sister)*: Dr. Eily E. Gurr. *As Serving Brothers*: Surgeon Captain F. G. W. MacHattie, Surgeon Commander M. Wellman, Colonels J. E. Andrew, M.D., F.R.C.S., and E. E. Tieman, O.B.E., M.D.,

Wing Commander H. J. Bright, M.D., Squadron Leader D. O. Coons, M.D., Messrs. J. J. Coulthard, M.B., F.R.C.S., and M. H. Elliot-Smith, M.B., F.R.C.S., and Drs. O. J. Curl, K. O'L. Doherty, W. J. Boyd, T. E. Kirk, H. S. Sharpe, R. C. Wilson, P. de Bec Turtle, D. O. Dickie, J. S. Stuart, H. Leslie, L. D. M. Gavin, J. F. M. Milner, V.D., J. W. Dowzer, H. W. Taylor, R. E. Crockett, S. C. Pritchard, O.B.E., D. W. R. Richardson, V. St. C. Lucas, O. Thomas, D. T. Clark, J. W. McAllan, R. A. Lewis, A. Sandison, J. R. Martin, and R. W. Cunningham. *As Associate Serving Brothers:* Drs. A. Gordon and Kwan Kui Lun. *As Serving Sister:* Dr. Eleanor M. Whitehead.
