It would be unreasonable to suggest that mental ill-health and personal distress are the main factors in academic failure. But where good selection procedures are enforced, and only those students who have passed appropriate preliminary examinations at school are admitted, it seems unlikely that intellectual inadequacy can be the most significant cause. It was the feeling of the conference that a substantial proportion of the drop-out rate under those circumstances must be due to the effects of personal distress, and to the moodiness and the transient emotional instability which is so common as almost to be natural in this age group. But about these matters we still know very little; the need for methodical and well-organized research is great.

It is sometimes suggested that a better knowledge of the problems of mental instability could improve the selection procedure so as to lessen the number of unstable people admitted. While this might be true, it was felt to be an argument containing the seeds of some danger. Often great intellect, certainly genius itself, is housed in an unstable personality. A university, if it wants great men, must take selection risks or sink to the even tenor of the second-rate. Quite apart from the universities, these unstable personalities do not cease to exist in society simply because they are refused admission. It may be that they, as individuals, have the greatest need of the advantages of university education. Whether desirable or not, selection on grounds of emotional stability is not technically easy, for where instability is a transient result of the vicissitudes of maturation it may be essentially unpredictable at the time the student is accepted. All in all, the conference felt the most fruitful line of approach to the high drop-out rate was to offer help to cases of mental disturbance as they arose, with the aim of enabling them to continue their studies with the least possible interruption.

Preventive Measures

In many parts of the world considerable services for helping the disturbed student already exist. They range from the highly structured systems of counselling in many American universities to the intimate and informal help that can be given by individual members of the teaching staff in the older colleges. Student health services, which now exist in most parts of the world, are also coming to do more and more of this sort of work; the emphasis here is not primarily medical in the sense of dealing with psychiatric disease, but social in the sense of advising. If, as seems reasonable, these services taken all together can result in even a marginal reduction of the present unsatisfactory drop-out rates, they can pay their costs off many times over.

Ideally prevention is better than cure, and the conference was sharply aware of the much greater potential importance of preventive measures. This was felt particularly to be the case here, where the troubles encountered are not properly to be regarded as disease but as being precipitated by the more or less normal turbulence of growing up. But to translate precept into practice is far from easy, for there is as yet little knowledge of and less agreement on what techniques, if any, are effective in this field. The conference was emphatic that in this field of preventive mental health in the universities there is a need for much experiment. Simple didactic lecturing of set courses in "mental hygiene" was possible, but its value, though real, was limited. Its particular application was to medical students and to the sociological studies. Discussion groups, perhaps organized through the extension of counselling arrangements, were also worthy of trial. One problem that was open to immediate practical alleviation was that of the lonely student. There is ample evidence that loneliness, not "joining in," not only predisposes to distress, but is also a significant factor in academic failure. The provision of residential facilities is most helpful here, but there is ample opportunity also for experimenting with modified methods of university teaching, particularly with group-teaching projects, which involve a student with his colleagues in much the same way as does "pairing" in practical laboratory work. The universities, it was felt, should also experiment with modified techniques

to give more latitude to those students whose maturation is not proceeding as smoothly as is normal. There is a tendency to expect everyone to go through university in much the same way and at much the same speed and at much the same age, without full account being taken of individual differences. Ultimately, the conference felt, the most important contribution to prevention must be in modifications in university methods. And there was some evidence that the universities were already coming to realize that they must consider all the personal ingredients and the welfare of their students if they were to give the best in education.

The most important and consistent finding of the conference was that all these problems come back to the same fundamental—the need for more knowledge. Yet still very little is being done to augment it and almost nothing is being spent on active research. The conference felt this might well be penny-wise and pound-foolish.

WELSH NATIONAL SCHOOL OF MEDICINE 25th ANNIVERSARY OF CHARTER

On October 12 and 13 the Welsh National School of Medicine, University of Wales, celebrated at Cardiff the twenty-fifth anniversary of the granting of the school's charter. The opening address of the session was given by Professor JETHRO GOUGH—the first old student of the school to be appointed to a chair in the University of Wales—on the afternoon of Friday, October 12, and this was followed by a dinner the same evening in the City Hall which nearly 500 old students attended. Among the speakers at the dinner were the Vice-Chancellor of the University of Wales (Principal Anthony Steel), Sir Clement Price Thomas, Sir Tudor Thomas, Professor H. Scarborough, and the Provost of the school. On the Saturday afternoon a reception was held at University College, Cardiff. During these two days the departments of the school were open to visitors, and many old students took the opportunity to visit the various exhibitions and demonstrations which had been arranged. The original charter of the school was on view in the library, together with a number of historical books and documents.

Professor Gough's Address

Professor GOUGH began by reminding his audience that, although the school was celebrating the twenty-fifth anniversary of its charter, it was not celebrating its birthday. The school had been formed in 1893 by the University College of South Wales and Monmouthshire. Many famous medical men had been students of the college, but had gone elsewhere for their hospital training; these included the late Sir Thomas Lewis, Sir Clement Price Thomas, Sir Tudor Thomas, Sir Alun Rowlands, and Dr. Ernest Jones; but of the younger generation of consultants and specialists many had done the hospital as well as the college part of their course in Cardiff. The Welsh National School of Medicine, said Professor Gough, provided a basic training which enabled a man or woman to become a competent doctor and even to rise to the topmost heights of the profession.

The earlier teachers of the school had been mainly Scotsmen or men who had had their medical training in Scotland. The tradition of bedside teaching had come to Scotland from Leyden, in the Netherlands, and the Scots brought this tradition to Wales. The wheel had now turned full circle, for to-day there was a teacher from the medical school of Leyden in Cardiff learning the newer techniques of examining lungs. The past twenty-five years had seen great improvements in the school, particularly the provision of the new library and the formation of new departments, such as that of anaesthetics, which was now a full professorial department. Hospital facilities had also expanded. Llandough Hospital was now used for teaching, and the new maternity hospital, started by the Cardiff Royal Infirmary and continued under the National Health Service, had been completed. The Government had promised to build a new medical teaching centre, but so far there was no sign of this being

begun, and in any case it would be many years before it would be ready for use. The policy of the school, therefore, was to continue development in its present locality and to improve further the facilities for teaching and research. When the school obtained its charter, said Professor Gough in conclusion, there was great industrial depression in Wales, and the help from commerce and industry which is often given to university institutions was not forthcoming. But, now that Wales was more prosperous, the school might expect to get help from these quarters.

THE MOTOR SHOW

[FROM A SPECIAL CORRESPONDENT]

For the first time for many years there is a refreshing breeze of competition blowing through the Motor Show, which opened at Earl's Court on October 17 and remains open until October 27. This is, all to the benefit of the customer, and the prospective purchaser of even the most modest car—modest, that is, in size—receives the respect that is his due. The motor trade, too, is the first to admit that the stimulus of harder times is more healthy for the industry.

The outstanding feature of this year's show is the introduction of two-pedal control systems for the less expensive cars. One well-known 10-horse-power car has this system in its basic specification. For others it is an optional extra. Two-pedal control is dependent upon vacuum action for declutching during gear changes, and the necessary servo and control gear is said to have been brought to a fine pitch of perfection. Full automatic transmission is now a feature in a number of cars of the more expensive kind.

Doctors especially will look for reliability, safety, comfort, and economy in running cost, and these virtues are to be found in the standard ranges offered by the big manufacturing groups. So many of them are sisters under the bonnet that points of difference have to be looked for in other directions. The buyer's final choice may well be made on personal likes and dislikes of not so essential but nevertheless important matters of detail—for instance, ease of getting in and out of the driving seat.

The finish of all models is much improved, and one hopes that with a smaller output there will be a closer inspection in the factory than has lately been the rule before delivery to the buyer. There have been too many complaints of minor faults which a keener eye would not have passed, and this irritation need not be an inherent evil of mass production. One also wishes that some day some manufacturer will make it really possible for the owner to oil and grease his car himself without having to run the risk of slipping a disk. One manufacturing group is showing a car with safety belts fixed to each passenger seat. These are an extra at £3 10s. each, but it is a step in the right direction. Nearly all makers are now fitting tubeless tyres to all their models, and this also should make for greater safety. Except on some of the expensive sports cars, disk brakes have not yet arrived, but generally speaking the modern hydraulic type of brake gives sure service.

In a short visit to a show where it would occupy much time to form a proper appreciation of each exhibit alone it would be invidious, even if it were possible, to pick out any cars for particular appraisal. Two, however, might perhaps be mentioned as being out of the common run. One is an inexpensive (£575, purchase tax included) sports car with a resin-bonded moulded fibre-glass body. The total weight of 5½ cwt. allows the air-cooled twin-cylinder two-stroke engine to propel the car at a speed which is claimed to be in excess of 70 m.p.h., with a petrol consumption of 55–60 m.p.g. The other interesting feature—more in the shape of things to come—is the Rover gas turbine car. No date has been put for its production yet, and many technical problems have to be overcome before it will be generally available. In appearance it is a beautiful car, and it attracts the eyes of many for whom its engineering features are a hidden mystery.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

B.C.G. and Vole Bacillus Vaccines

SIR,—In his letter (*Journal*, October 6, p. 826), Dr. E. F. James asks for clarification of certain parts of the Medical Research Council's report on B.C.G. and vole bacillus vaccines in the prevention of tuberculosis in adolescents (*Journal*, February 25, p. 413).

In the first place, he considers that insufficient weight has been given to complications of vaccination in concluding that the procedure is beneficial. In particular, he draws attention to the two cases of erythema nodosum attributed to B.C.G., and to three cases of regional tuberculous adenitis following vole-bacillus vaccination, as well as to the 22 cases of lupus requiring treatment that also occurred among the 6,400 participants receiving the latter vaccine. He rightly points out that these complications were excluded from the calculations from which the incidence of tuberculosis in the vaccinated children was assessed, and suggests that the true morbidity in this group should be taken as the total incidence of tuberculous lesions, whether caused by infection with the human tubercle bacillus or by vaccination. Presumably Dr. James would set some limit to this procedure, since every vaccinated person who shows a normal skin reaction at the site of inoculation has a tuberculous lesion, deliberately produced. If, however, the procedure recommended be restricted to the lesions mentioned above, the addition of the two cases of erythema nodosum to the 13 cases of tuberculosis occurring in 14,100 participants given B.C.G. (table IV of the report) would merely raise the average annual incidence of tuberculosis in this group from 0.37 to 0.43 per thousand, as against 1.94 in the comparable unvaccinated group. There is nothing in these figures to substantiate Dr. James's own claim that "B.C.G. is the most dangerous substance which has ever taken shelter behind the principle of protective inoculation." On the other hand, the development of lupus in the vole-bacillus vaccinated is given prominence in the section of the report which discusses how far the complications attributable to vaccination should weigh against the efficacy of the method in preventing tuberculosis. Although the lesions were localized and were mostly discovered only on routine examination, their occurrence certainly contradicts the present routine use of this vaccine. The report, however, mentions the possibility that an intracutaneous method of administration (instead of multiple puncture) might not produce this sequel.

Secondly, Dr. James criticizes the reliance placed on methods other than the periodic radiograph for the discovery of tuberculosis in the participants. In fact, 55% of the 165 cases of definite tuberculosis were first found by these other means. All suspected cases, however they came to notice, were fully investigated by radiography. Dr. James further points out that a quarter of the participants did not have our routine radiograph during the follow-up period covered in the report; but this proportion was approximately equal in the vaccinated and unvaccinated groups, and, because of the initial random allocation, there is no reason to believe that this omission has affected the ratio of the incidence of tuberculosis in the vaccinated to that in the unvaccinated group. Moreover, the high yield of cases from other sources indicates that lesions developing in the participants not attending for the periodic radiograph could be expected to be discovered by these other means if clinically important; it is thus probable that very few cases of clinically important tuberculosis escaped notice.

In answer to the third question, for reasons of space the report did not include an analysis of the protective effects of

the vaccines in London, Birmingham, and Manchester separately. In fact, protection was approximately equal in all three areas.

Finally, Dr. James's concluding remark links his present criticisms with those which were made in 1927 by the Editor of the *British Medical Journal*¹ and by the late Professor M. Greenwood in your correspondence columns,² with reference to the original statistics of Calmette and Biraud on tuberculosis in B.C.G.-vaccinated children, and which "exposed Calmette's fallacious claims for B.C.G." These earlier criticisms were concentrated almost entirely upon the lack of adequate unvaccinated controls in the early studies. In designing the present trial, the Committee responsible was determined to avoid just these faults, and made a special point of arranging for random allocation of the tuberculin-negative volunteers into vaccinated and unvaccinated, but otherwise similar, groups, which have been followed with similar intensity; furthermore, the cases of tuberculosis have been assessed by an independent assessor.—I am, etc.,

P. D'ARCY HART,

Chairman,
Medical Research Council's
Tuberculosis Vaccines Clinical Trials Committee.

London, N.W.3.

- 3 Greenwood, M., *British Medical Journal*, 1927, 1, 896 and 1082.

SIR,—If editors possess functioning blush reflexes you must have blushed to the roots of your editorial hair when reminded by Dr. E. F. James (*Journal*, October 6, p. 826) that in 1927 you "exposed Calmette's fallacious claims for B.C.G.," especially since it is such a short time since you described the report of the Tuberculosis Vaccines Clinical Trials Committee of the Medical Research Council as showing "beyond doubt the benefit of B.C.G. vaccination" and presenting evidence that seemed sufficient to convince the most critical (*Journal*, February 25, p. 443).

A few months later (*Journal*, June 30, p. 1534), when you must have had ample time to consider the matter fully, you wrote: "Doubts about the length of time protection lasts are not as important as the fact that vaccination has now been proved to prevent tuberculosis." It can therefore only be concluded that you are one of those who have accepted the Committee's findings with that lack of critical examination which has astonished Dr. James.

I have consulted the 1927 volume of the *Journal* to read the terms of your "exposure" of Calmette, but I find that all you did was to point out that, in the absence of compulsory notification, Calmette's estimate of the infantile mortality from tuberculosis in France required careful examination, and his claim for the efficacy of B.C.G. vaccination based on it was not valid. You quoted similar criticism by Danish workers, and concluded by proposing the terms of an ideal experiment for testing Calmette's claims. I could detect nothing resembling an "exposure" in the article. A postscript may be added that Calmette's oral method of vaccination was replaced by intracutaneous vaccination in Denmark in 1930–1, and began to be used extensively in 1940.

Dr. James must know that vole bacillus vaccine is not being used in the Ministry of Health's scheme of vaccination against tuberculosis in Great Britain, and that it has never been used in Ireland, but nevertheless he makes use of the occurrence of lupus vulgaris after vaccination with the vole bacillus by multiple puncture to discredit vaccination against tuberculosis generally. He omits any mention of the suggestion in the report that the lupus could have been due to the method of vaccination. The only recorded complications after B.C.G. vaccination were two cases of erythema nodosum, and even if Dr. James adds these to the cases of tuberculosis which occurred in the B.C.G.-vaccinated group the resulting incidence of "tuberculosis" is still only a fraction of that in the control group. He could, however, have gone further and classified every child vaccinated with B.C.G. as having "tuberculosis," in so far as a primary "tuber-

culous" lesion of the skin accompanied by regional adenitis occurs in every successful vaccination, but perhaps he does not really believe that tuberculous meningitis and B.C.G. adenitis are equal in the sight of the child's parents or his doctor.

His second criticism is of the validity of the follow-up. I do not possess the necessary knowledge of statistical methods to discuss that question, and I leave it to the statisticians on the Trials Committee.

Dr. James's third point—i.e., the geographical distribution of the cases of tuberculosis—is not likely to have escaped the authors of the trial, and it is presumable that they were aware of "accidental environmental factors . . . [which] might easily account for an apparent protective effect of the vaccination." As for his point about different diagnostic criteria possibly vitiating the results—the report states that every case of definite or suspected tuberculosis was examined in due course by one of the physicians of the Tuberculosis Research Unit of the Medical Research Council, and the records were kept centrally so that cases could eventually be assessed and classified by an independent assessor.—I am, etc.,

H. G. CALWELL.

Whitehead, Co. Antrim.

SIR,—Many more experienced and competent people will doubtless answer Dr. E. F. James's criticisms (*Journal*, October 6, p. 826). May I make just two points? (1) Cases of lupus only occurred after the use of the vole bacillus and never after B.C.G.; so to condemn B.C.G. vaccine on this score seems somewhat illogical. (2) At the Hospital for Sick Children we have occasional cases of regional adenitis (20 in 2,400 children vaccinated). We would not consider it reasonable to say these children are "suffering" from tuberculosis, and in only one case in five and a half years has there been constitutional upset with the adenitis. The rest have had no upset at all; the local lesion is painless, and clears up with one or at the most two expressions, usually without any anaesthetic. Constitutional upset sometimes follows diphtheria or "polio" immunization, but we do not describe these children as "suffering" from these diseases.—I am, etc.,

Diesel Fumes

SIR,—The report by Mr. B. T. Commins, Mr. R. E. Waller, and Dr. P. J. Lawther (*Journal*, September 29, p. 753) on smoke in a London diesel bus garage has been widely publicized in the popular press as proving that diesel exhausts are not responsible for the increase in lung cancer. The London Transport Executive has gone further, in announcing to the press that "the best medical advice available indicated that the diesel engine, when well maintained, did not emit any harmful amount of substances liable to be injurious to health, and that the exhaust emission of London buses contained little if any carcinogenic hydrocarbons" (*The Times*, September 29).

It would seem necessary, therefore, to emphasize that neither Commins, Waller, and Lawther nor any other investigators have ever stated that 3:4-benzpyrene is the only substance present in diesel exhausts which could be carcinogenic. Commins, Waller, and Lawther show that the concentration of smoke in the garage, when certain of the engines were running, was from two to six times as great as in the air outside. Since diesel smoke has been shown by Kotin, Falk, and Thomas¹ to be carcinogenic, it would be necessary to repeat the biological studies of the latter, using extracts of exhaust solely from "well maintained" diesel engines, before being able to suggest that these are not carcinogenic.

Moreover, it is questionable whether conditions in a garage truly represent those in a busy city street. It is stated in the report by Commins, Waller, and Lawther that movement of buses in the garage involved "several short bursts of acceleration with idling in between." Movement of buses in a busy

street involves very frequent acceleration and deceleration, and Elliott, Nebel, and Rounds² in an investigation of diesel buses in Chicago showed that the output of hydrocarbons per hour was as follows: idling 0.376 lb. (170 g.); accelerating 0.683 lb. (311 g.); cruising 0.300 lb. (141 g.); decelerating 0.960 lb. (426 g.). Thus the output is twice as great when accelerating and three times as great when decelerating as when idling. Kotin, Falk, and Thomas³ showed that the output of hydrocarbons from a diesel engine increases markedly with load (about 20% of the increase occurring between 25% and 50% load, 25% of the increase between 50% and 75% load, and 50% of the increase between 75% and full load). Buses in a garage are empty and are moving across a level floor; hence the load is negligible compared with that in a street. This probably also explains the fact that, although "London Transport derate all their engines by 10% in order to reduce the possibility of heavy smoke emission," nevertheless considerable smoke emission is not infrequently seen in London.

Quite apart from the question of lung cancer, it is known that the diesel engine produces large quantities of oxides of nitrogen. The maximum permissible concentration of these oxides for exposures of not more than eight hours is given by the American Conference of Government Industrial Hygienists (1954) as 5 parts per million. For technical reasons these gases are not easy to estimate, but calculation from the known relative exhaust content of nitrogen oxides and carbon monoxide from diesel and petrol engines, and the known concentration of carbon monoxide in London streets,³ suggests that the concentration of nitrogen oxides in London street air is 0.7 to 1.5 p.p.m. However, no allowance has been made in these calculations for the fact that the exhaust volume of the diesel engine is from two to seven times as great as that of a comparable petrol engine (the nitrogen oxide output being up to ten times as great), and that, since it is the larger vehicles which have diesel engines, the total horsepower of diesel engines in a busy street is much greater than that of the petrol engines. With these factors allowed for the concentration of nitrogen oxides reaches 6 to 8 p.p.m.

It would seem therefore that the onus lies upon the London Transport Executive and other authorities contemplating replacement of electric vehicles to obtain further proof that the diesel engine is entirely harmless to health before embarking upon replacement of vehicles which emit no fumes whatsoever.—I am, etc.,

Purpose of Medical Education

SIR,—I have only recently received your issue of August 4. As a recently qualified practitioner doing his National Service I find the correspondence (p. 298) interesting. The eminent gentlemen have overlooked giving the answer to this important question: What sort of doctors do we want? Those who can safely be employed anywhere in the world, often with the minimum of facilities, or those whose basic training is so narrow that they will be a danger to their patients anywhere except in Great Britain, where the magnificent specialist services are within easy reach?

In my opinion it is a retrograde step to narrow the curriculum. Weed it or prune it of excrescences. Teach about the common things. Pathology, basic principles applicable to all medicine and surgery, basic clinical techniques, and a knowledge of what never to do—on these any intelligent person can build, using as bricks the knowledge of diseases he has seen or read about. Produce a man who uses his brain, his knowledge, and his common sense, who has the skill to give a safe anaesthetic or remove an appendix if he has to. I am biased, as I am serving afloat and most of the time I have no laboratory services available.—I am, etc.,

R. J. KNIGHT.

Medical Education

SIR,—In view of your recent number on medical education (September 1), I should like to add a word on one aspect that has been discussed in your columns previously.

Recently a responsible medical journal in one of its articles allowed the phrase "He was then laparotomized." This statement, which is gaining popularity, offends the ears even of one young in the profession and not trained in "the classics." It was written, moreover, by one who is responsible for postgraduate training in an important London hospital.

More and more such words are creeping into the medical vocabulary, and perhaps with attention again focused on medical education all professional journals might collaborate in refusing to print such monstrous expressions.—I am, etc.,
London, S.W.1.

H. STEWART MOORE.

Fluorohydrocortisone

SIR,—In the *Journal* of October 13 (p. 872) you state of fluorohydrocortisone "its effect on the excretion of sodium and potassium is so marked that it is doubtful whether systemic administration is ever likely to be indicated." In the past two years we have used this substance extensively in small amounts in combination with cortisone acetate in Addison's disease and after adrenalectomy. It has proved so useful in checking sodium loss in many of these patients that it is shortly being made available for hospital use at the request of several of us working in this field. In our hands, with experience of 150 adrenalectomized subjects, it has largely replaced deoxycortone, having the great advantage of being rapidly effective when taken by mouth in a fraction of the dose.

We feel that your rejection of this preparation is too sweeping, for it overlooks its great value in the special field of Addison's disease and after adrenalectomy.—I am, etc.,

London, S.W.1.

F. DUDLEY HART.

Enzyme Tests for Glycosuria

SIR,—It was with interest that I read Dr. Stuart Carne's letter (*Journal*, October 6, p. 827) concerning enzyme tests for glucose. I have been using "tes-tape" for some months for my midwifery and other general practice cases. There is no doubt that, as Professor Gray and his colleagues (*Journal*, September 8, p. 586) have pointed out, the test should be carried out with strict attention to cleanliness. Where patients are concerned such manoeuvres as "wiping off the excess of urine" will contaminate and invalidate "clintix" or tes-tape in equal degree. The remedy is to persuade patients to carry out the test properly.

For qualitative screening I use $\frac{1}{4}$ in. (6 mm.) of tes-tape dropped into the urine. I thereby avoid any need to play spillikins with small sticks, and a number of urines can be tested with a speed and efficiency not equalled by any other procedure. Tes-tape is put up in a light-proof container, and this seems to me an advantage over clintix, as the enzymes concerned deteriorate on exposure to light. For quantitative analysis I still prefer the Benedict's test, which for its proper operation requires eight drops of urine in 1 in. (2.5 cm.) of Benedict's solution, and not the inverse proportions, as inferred by your correspondent.—I am, etc.,

Hanworth, Middlesex.

Composting of Household Waste

SIR,—Now that the role of organic matter in the soil is becoming more widely understood, it was surprising to find the fallacies in the Zuckerman report¹ repeated in your otherwise most informative leading article on composting of town refuse (*Journal*, September 29, p. 758).

The primary and most important function of organic matter in the soil is to provide food for the soil organisms whose activities bring into solution the minerals which are present in abundant quantities in the rock particles in nearly all soils, thus making these substances available to plant

life. This effect of the presence of organic matter in soil has recently been demonstrated in a startling manner at the Haughley Research Station, where it has been shown that in soils which contain a high proportion of organic matter the content of available minerals, especially phosphates, rises steeply during the summer months even though no mineral fertilizers have been used; but that this rise does not occur in soils low in organic matter even though large quantities of mineral fertilizers have been applied.

The available minerals that any organic compost may contain should be regarded as a free bonus, rather than as a criterion of their value as a manure. In the Zuckerman report no attempt whatever was made to assess the value of municipal composts as a source of food for that most voracious, and at the same time most essential, section of the world population—namely, the soil organisms. In effect, its assessment of the value of such composts was equivalent to assessing the value of a packet of soap-flakes on the gift coupon that it happened to contain.—I am, etc.,
T. T. STAMM.

London, S.E.1.

REFERENCE

- Natural Resources (Technical) Committee, *The Use of Town's Wastes in Agriculture*, 1954. H.M.S.O., London.

SIR,—I have read with considerable interest your leading article on composting of household waste (*Journal*, September 29, p. 758). This, as you have pointed out, is neglected by the authorities here in Britain and leads to the waste of organic fertilizer material which must amount to many thousands of pounds annually.

In November, 1955, the Leonard Hill Technical Group published an article in *World Crops* entitled "A New Fertilizing Process for the Improvement of Unproductive Soil," by M. André Birre. This deals *inter alia* with a compost process developed by an American, Dr. Earp Thomas. After he had succeeded in isolating suitable types of bacteria and blending them so that they would transform waste organic matter into humus-like material, further research led him to build an apparatus to facilitate the transformation more rapidly. He was granted patent rights for the method, which makes use of his "continuous-flow digester."

This apparatus consists of a vertical cylinder divided into eight sections or floors and fitted internally with rotating booms. The organic household waste, after having been milled to a pulp-like consistency, is introduced into the top section of the digester and is treated there with the inoculum. The rotating booms stir the mass continually and convey it slowly towards an aperture that allows the material to fall on to the floor below; here the rotating booms continue to stir it and convey it to another aperture through which it again falls into the next section. The same process is repeated eight times before the material leaves the digester. The material takes 24 hours to reach the final opening before leaving the digester, and in this period it is completely transformed into fine, granular, humus-like material. It has the appearance and smell of mould and is ready for spreading on to the soil.

The first practical installation for this process in Europe was constructed in France, and after a period of experimental operation in Paris it has now commenced production on a commercial scale. M. Birre notes that La Direction Technique de la Voirie Parisienne is interested in installing similar plants in all their refuse dumps.—I am, etc.,

J. EDWARD THOMAS.

Twopenny-halfpenny Advertising

SIR,—About a year ago I began to receive letters from a seaside resort, addressed in what appeared to be feminine handwriting and bearing twopenny-halfpenny stamps. These envelopes contained advertising material from a drug firm of transatlantic origin and presumably "advanced" methods of sales promotion. This method of gaining my attention to their products appeals to me about as much as "queue-jumping," so I now apply sanctions. These consist of throwing all this firm's literature straight into the waste-paper

basket and as far as possible avoiding the use of any of its drugs. I propose to continue to do this until a representative of this firm calls on me in person and hears from me what I think of his employers. Recently the post brought me a letter-card, sealed, hand-addressed, and containing a mimeographed advertisement for a product of another transatlantic drug firm. So I now have two names on my sanctions list.

No doubt these are attempts to reach the doctor who automatically throws all his unsealed mail straight into the dustbin. Although I feel there are strong arguments in favour of this method of disposal, I have always managed at least to glance through all my mail. The "twopenny-halfpenny" technique can only serve to annoy my class of recipient, without reaching the other class.—I am, etc.,

Shipley.

A. E. PENN.

SIR,—The latest manifestation of advertising to which we are being subjected is appalling. One has recently received in the post from a drug firm a series of cards in sealed envelopes ostensibly addressed by hand and postmarked from various different towns. It is obviously the sender's hope that one will mistake these letters for private correspondence and so will not consign them unread to the waste-paper basket. When an advertiser sinks to such a level in order to establish contact with me I can have no faith whatsoever in the honesty of any claims for his products which he may make once that contact is established.—I am, etc.,

West Bromwich.

D. SAKLATVALA.

Tests for Drunkenness

SIR,—May I through your columns call attention to the matter of medical examinations for drunkenness when in charge of a motor vehicle? To be incapable of driving or properly caring for a motor vehicle because of the effects of alcohol is a serious crime and can be punished severely. The verdict of the courts in such cases is substantially influenced by the medical evidence. Since medical diagnosis of drunkenness carries such heavy legal responsibility, the quality of the medical examination on which such a diagnosis rests should be beyond all doubt. I would like to suggest that: (1) drivers suspected of drunkenness by the police should be taken to a hospital for examination and not to a police station; (2) the examination should be made by at least two, or preferably three, medical men of senior status.

The examinee would still be able to call his own general practitioner, and if he so wished he could ask for legal representation. The panel should prepare a detailed medical statement of the facts of the examination and their interpretation thereof. Whether or not a unanimous decision was arrived at should be made known. No doubt a properly constructed medical panel would soon be pressing for blood and urinary alcohol tests to help them in their deliberations. I would not like this plea to fall down on possible impracticabilities, but in any case I wish once again to call attention to this important matter.—I am, etc.,

Wylam, Northumberland.

G. F. ROWBOTHAM.

Longer Holidays

SIR,—I read with interest Dr. G. A. Powell-Tuck's letter on the subject of longer holidays (*Journal*, September 29, p. 769). This subject has occupied my thoughts for some years, working as a G.P. in an industrial area. I agree with him about the undoubted increase in psychosomatic disorders and frequently stress the importance of a holiday as opposed to the "tonic" which is in regular demand. I have expressed my desire to several leaders of industry to have holidays organized on a "one-week every three months" plan, or alternatively one week in the winter-spring period, two weeks in the spring-summer-autumn period, and one week in the autumn-winter period. If such holidays could be arranged in a staggered fashion I feel sure that many works and industrial plants would not require to close at all (unless for replacement of plant, which could probably be done gradually throughout the working period in any

case), and with the mental and physical refreshment of the workers production would probably increase. I feel certain that a falling off need not be feared.

In the Scottish industrial belt life for a large proportion of the population hinges on two events—the "fair" fortnight, usually in July, and two to three days at the New Year. A six months' interval between holidays—too long. The mass exodus at the "fair" fortnight means inadequate and crowded accommodation and transport at holiday resorts and the prices at their highest, and the New Year respite with its accompanying celebrations invariably produces a sharp rise in the sickness rate. The prospect of a week's leisure with pay at reasonable intervals must make a strong appeal to the majority and can do nothing but good.—I am, etc.,

Bo'ness.

A. MCWATT GREEN.

Brown Dog of University College

SIR,—While I was waiting in a corridor for my viva in midwifery in December, 1907, Sir William Osler—as presiding examiner—went into the room where the examination was taking place. One of the examiners was a Dublin man, noted for his bullying tactics. After a few minutes Osler came out and said to me: "The torture of the Brown Dog of Battersea isn't in it."—I am, etc.,

Painswick, Glos.

S. HARTILL.

SIR,—Mr. A. Clifford Morson's letter (*Journal*, October 6, p. 827) prompts me to add one further note on this subject. I was R.M.O. at U.C.H. at the time of the attack on the "Brown Dog" in Battersea Park. Dr. Baron (*Journal*, September 1, p. 547) says it was on November 19, 1907, but W. H. Lister said it was on Wednesday, November 20; I don't know which is right. I was rung up by Lister that evening and told that he and nine others were being held at Battersea Police Station and asked if I could get them bailed out. I thereupon got in touch with Mr. Sidney Spokes, then dental surgeon to U.C.H., who happened to be the only J.P. on the staff, and he readily agreed to go down and deal with the situation. He certainly bailed out the U.C.H. men, who made up eight out of the ten, and I always thought he had bailed them all, but apparently Mr. Morson must have dealt with at least one from his own hospital.

Some of the victims still flourish and could no doubt give an accurate account of what happened at the Battersea Police Station.—I am, etc.,

London, W.1.

ARCHIBALD GRAY.

Brown Induration of Lung

SIR,—In your excellent leading article "Brown Induration of Lung" (*Journal*, September 22, p. 703) you say that the pathogenesis is unknown, but most workers have stressed the possibility of a primary defect of the elastic tissue of the walls of the small blood vessels and alveoli. You state that the prognosis is bad.

Having worked for some years on this problem, I^{1,2} think that it is questionable whether hypoplasia of pulmonary elastic fibres should be truly regarded as a primary symptom, and whether it is a consequence of some structural defect in the lungs. Essential pulmonary haemosiderosis is considered to be an immuno-allergic disease caused by a still unknown sensitizing agent inducing the production of auto-antibodies. The antigen-antibody reaction causes in the lungs, as the shock organ, capillary dilatation, consequent stasis, diapedesis, rhexis, increased destruction of the injured red corpuscles and deposits of haemosiderin. The mechanism of its origin is closely related to those of acquired haemolytic anaemia and idiopathic thrombocytopenic purpura. Prognosis is not so bad as stated, because favourable results may be obtained by splenectomy. Independently of each other, Paterson³ in England, de Castro-Freire and Cordeiro⁴ and Cordeiro⁵ in Portugal, and Steiner in Hungary have attempted not only to check the progress of the disease but also to make it regress in three cases by means of splenectomy.

Diagnostic lung puncture was applied in some cases, but it involves a certain risk because of the nature of the disease. This is why exploratory thoracotomy with lung biopsy was preferred in our case. Early diagnosis must be aimed at, since in this way there is hope for complete restoration to health.—I am, etc.,

Budapest, Hungary.

Medical Evidence at Inquests

SIR,—My letter (*Journal*, September 29, p. 767) was not intended to cast any reflections, and I am sorry if it appeared to do so. The pathologist to whom I referred, a very well-known man, is dead, while the coroner retired some years ago. I am sure that neither of them would have felt hurt. The cases I quoted were used only to support Dr. F. M. Rose (*Journal*, August 11, p. 356), who said that the coroner might fail to get all the facts if he did not consult the family doctor.

Under a Home Office instruction the coroner now notifies the time and place of the necropsy to the doctor in charge of the case; but as this may be taken to apply only to the hospital staff the examination may take place before the family doctor knows even that the patient has died. Would it be too much to suggest that the hospitals might inform him whenever a necropsy is to be made on one of his patients?—I am, etc.,

Beckenham, Kent.

W. M. PENNY.

St. Luke's Day

SIR,—Once more October 18 comes round again, reminding us of the patron saint of our profession. On that day there will be again world-wide commemoration of his immortal work. It is, of course, as a writer rather than as a physician that he has become famous. Of his two great treatises the second, though less in honour than the first, is of very great value. It gives us all we know of the life-work of Paul, the foremost missionary to the gentile world. It shows us Luke as his fellow-worker and faithful friend and companion in the conversion of our gentile world to Christianity. His second work—the Acts of the Apostles—shows us the beginning of the first international society. We may well on St. Luke's day endeavour to realize our debt to Luke, not only as an evangelist, but also as the biographer of the foremost and greatest of missionaries to our gentile world, St. Paul.—I am, etc.,

Banstead, Surrey.

HERBERT CAIGER.

Selwyn College List

SIR,—New Zealand medical graduates who lived at Selwyn College, Dunedin, will be glad to hear that the *Selwyn College List* is now being printed. Besides short biographies of the ex-students, there is a history of the College and its foundation, full accounts of the former wardens, and the chronicle of the Students Association and its sporting activities. The list is illustrated and contains a fully coloured reproduction of the College coat of arms.

Those who have not already done so should order their copies immediately from the Business Manager, *Selwyn College List*, P.O. Box 620, Dunedin, New Zealand. Only a limited number of copies are being printed. The cost will be 25s. plus postage.—I am, etc.,

Dunedin, New Zealand.

W. R. MORRIS.

POINTS FROM LETTERS

Accident at Coughton

MESSRS. WHITELEY and PICKERING (Redditch) write: Will the doctor who rendered assistance at the scene of an accident at Coughton on the Birmingham-Alcester Road on June 13, 1956, when a boy was killed, please communicate with Whiteley and Pickering, solicitors, Redditch, Worcs.

Obituary

J. W. TREVAN, F.R.C.P., F.R.S.

Dr. J. W. Trevan, consultant to the Wellcome Foundation Ltd., and formerly director of the Wellcome Research Laboratories, Beckenham, died at his home at Addiscombe, Surrey, on October 13, aged 69.

John William Trevan was born at Bodmin on July 23, 1887. His family had roots in both Devon and Cornwall and he spent his boyhood in Plymouth, where he went to a local school and then to the Plymouth Technical School. With the aid of scholarships he was

able to become a medical student at St. Bartholomew's Hospital, where he soon made a name for himself, winning the Harvey, Foster, Walsham, and Burrows prizes. He was also awarded the Brackenbury scholarship in medicine. In 1908 he graduated B.Sc. with honours in physiology, and three years later he qualified in medicine, taking the degrees of M.B., B.S. After a resident post at Bart's he became a demonstrator of

physiology there while holding the Fishmongers' research scholarship. At this time his research work was mainly concerned with renal secretion and respiration. In 1914 he took the M.R.C.P. and during the first world war worked as casualty physician at St. Bartholomew's Hospital, except for two years' service in the R.A.M.C. as a pathologist in the Near East. In 1920 he joined the staff of the Wellcome Physiological Research Laboratories as pharmacologist when Sir Andrew Balfour was the director. At Beckenham he worked at first on local anaesthetics, the chemotherapy of tropical diseases, and the biological standardization of drugs. Existing methods were unsatisfactory, and, having a good mathematical brain, he examined the subject statistically, eventually evolving the method of determining toxicity by estimating the dose which is lethal for 50% of the test animals (LD50). After the discovery of insulin he turned his attention to solving the difficulties of standardizing preparations of that drug for use on patients. His well-known paper on the biological assay of drugs was published in the *Proceedings of the Royal Society* in 1927.

In 1940 Trevan succeeded Dr. R. A. O'Brien as director of the Wellcome Physiological Research Laboratories, and he held this post until 1953. He was also a director of the Wellcome Foundation Ltd., and for a short time before his retirement he acted as director-in-chief of the Wellcome Research Institution. Although he was best known for his work on the biological assay of drugs, he was concerned with research in many other fields, including veterinary medicine. During the second world war he played an important part in increasing the supplies of biological products needed by the armed Forces.

Trevan was a member of the Biological Standards Commission of the League of Nations and of the British Pharmacopoeia Commission. In 1937 he was elected

president of the Section of Therapeutics of the Royal Society of Medicine, and in the following year he was a vice-president of the Section of Pharmacology, Therapeutics, and Anaesthetics at the Annual Meeting of the B.M.A. He became a Fellow of the Royal College of Physicians in 1942 and of the Royal Society in 1946. At University College, London, he was an honorary lecturer, and was a member of the Board of Studies (Pharmacology) of the University of London.

Dr. Trevan's main hobby was music, and for many years he sang in the choir of St. Aubyn's Congregational Church, Upper Norwood, where he was also deacon.

He was twice married. His first wife, daughter of the Rev. J. L. Keys, died in 1937, and of this marriage there were three sons and two daughters. His second wife was the daughter of Sir Hubert Llewellyn Smith, at one time economic adviser to the Government, and there were a son and two daughters of this marriage.

We are indebted to Professor J. H. BURN for the following appreciation:

The sudden death of J. W. Trevan is a great shock to those who knew and respected him. He enjoyed the peculiar distinction of having made an outstanding contribution to pharmacology which resulted in the development of biological standardization as a discipline of its own. In the period before and after the first war the need for ensuring uniformity in the potency of digitalis and similar agents was realized, but no one knew how to achieve it. Pairs of frogs were injected with decreasing amounts of digitalis tincture to determine the minimum lethal dose. It was, however, impossible to find the minimal lethal dose, for often frogs receiving lower doses died, while those receiving higher doses survived. Then in 1927 came Trevan's paper showing that these results were the natural consequence of biological variation, and that lethal-dose measurements must be expressed in terms of the percentage of frogs killed, and that the most accurate estimate which could be obtained was of the dose lethal for 50% of animals, the LD50. Now Trevan would have rendered great service by pointing this out as an academic conclusion, but he applied it courageously in practice and taught us that in standardizing digitalis we must not be content to test a dose on two frogs but on thirty frogs. He stressed the necessity of using large numbers of animals, and as a consequence the necessity for using small animals. Faced with the problem of standardizing insulin, he developed the method, general throughout the world to-day, of using mice, in which after the injection of insulin the percentage of mice which convulsed was determined. In one of the early years 28,000 mice were used in his laboratory for this purpose, and the use of mice on this scale constituted a revolution.

His influence was not confined to pharmacology. In his paper on the error of determination of toxicity Trevan considered not only digitalis and insulin but also dysentery toxin and diphtheria toxin, and showed how his conclusions were equally applicable in the standardization of sera. In the field of chemotherapy, too, he and his colleagues described a method of measuring the effect of organic antimonials against trypanosome infections in mice by the mean survival times of the groups of mice treated; this was the first advance in the field after the work of Voegtlin and Homer Smith.

Trevan's scientific personality was well illustrated by his published papers, which were few in number but of the highest quality. He was beyond everything diffident about results until they were finally complete. This reluctance to publish was fully reflected in his modesty and in the serenity of his outlook, which was perhaps his most striking characteristic. He might appear at times gloomy and moody; this was entirely superficial, for just beneath was the humour which came flashing out to reveal how balanced and even he was. Ambition seemed to play no part, and he was satisfied with the performance of complex

daily tasks which were carried out in obscurity. Only those who had direct dealings with him knew the breadth of his knowledge, and how much thought he had given to the integration of the theory and practice of medicine. With his modesty and serenity he combined charity and charm.

A. Q. WELLS, M.A., D.M.

Dr. A. Q. Wells, who was on the scientific staff of the Medical Research Council and worked at the Sir William Dunn School of Pathology at Oxford, died suddenly at Inverness on October 9 while on holiday. He was 60 years of age.

Arthur Quinton Wells was born in London on June 22, 1896, the fifth son of Mr. A. P. L. Wells, who had been senior surgeon at the Central London Ophthalmic Hospital. He was educated at Peterborough Lodge School,

[David Peters, Witney, Oxon.]

University College School, and St. John's College, Oxford, going on for his clinical training to St. Bartholomew's Hospital, where many members of his family had previously qualified. During the first world war he served as a surgeon sub-lieutenant in the R.N.V.R., first in H.M.S. *Plassy* and then in H.M.S. *Ulysses*. After graduating B.M., B.Ch. in 1923 he went into general

practice for two years at Eyam, in Derbyshire, where he was honorary surgeon to the Bakewell and District War Memorial Hospital. In 1926 he was appointed research student in the department of pathology at Cambridge, and in 1928 he proceeded to the D.M. He moved to London in 1930 to become lecturer in bacteriology at St. Bartholomew's Hospital, and five years later he returned to Oxford as pathologist at the Bureau of Animal Population. At the beginning of the second world war he joined the Emergency Public Health Laboratory Service, and served as administrator of the laboratory at Oxford, which at that time was the headquarters of the service. After the war he returned to the study of tuberculosis at the Sir William Dunn School of Pathology. Wells's special interest in this subject had developed many years before, and he had published several papers on tuberculosis in wild voles and on murine tuberculosis, on which he was a leading authority and the author of a monograph published in the Medical Research Council Special Report Series in 1946. He developed the use of the vole bacillus vaccine and was a member of the Medical Research Council's Tuberculosis Vaccines Clinical Trials Committee, which reported earlier this year on the results of a large-scale trial of both B.C.G. and vole bacillus vaccine.

During his research activities Wells found time for a great deal of public service in an administrative capacity. He was a county councillor for Oxfordshire from 1938 to 1945 and was first chairman of the Oxford Regional Hospital Board. He gave up this latter appointment in 1950 because he found the work incompatible with his research work. He was also a trustee of the Nuffield Provincial Hospitals Trust and of the Oxford District Hospital Improvement and Development Fund. In 1953 he was High Sheriff of Oxfordshire, and with his tall stature and dignified appearance he was a magnificent

figure in court dress. A keen collector of alpine plants, he was chairman of the Curators of the University Botanic Gardens at Oxford.

Dr. Wells leaves a widow, four sons, and one daughter.

We are indebted to Dr. R. L. VOLLUM for the following appreciation:

Dr. A. Q. Wells discovered the mycobacterium now commonly known as the vole bacillus while investigating the cause of recurrent fluctuations in the population of voles for the Bureau of Animal Population. After prolonged investigation of the cultural characteristics and the limited pathogenic properties of this organism he saw the possibility of using it as a vaccine. He carried out extensive carefully controlled experiments in animals of various species, and when he was satisfied that it had useful antigenic properties combined with very low pathogenicity he carried out some experiments on humans. The results were promising, and the use of the vaccine was gradually extended, but always under carefully controlled conditions. The investigation of its value is still in progress in this country and in Africa. The indications at present are that it is at least as good as B.C.G., and that it probably produces a more enduring immunity. Recently he had been interested in the relationship between allergy and immunity in tuberculosis and had extensive experimental work in progress.

In spite of his multifarious activities he gave the impression of being a gentleman of leisure. He concealed his twentieth-century efficiency by gracious eighteenth-century living. At his beautiful home at Shipton Manor he had a very fine alpine garden—as well as an excellent market garden. He was a keen botanist. When I travelled with him in Africa he occasionally determined to take me for a long walk for much-needed exercise, but the walk was usually curtailed by his finding an unfamiliar plant or flower which had to be examined and photographed *in situ*. Indeed, on one occasion he and his camera were in danger of going over Victoria Falls when he found an interesting specimen on the edge of a precipice. He also enjoyed deer-stalking and shooting. During the pheasant season one did not expect to find him in his laboratory every day.

A. Q. was a colleague we could ill afford to lose. The final results of much of his work will not appear for some time, but he has laid a firm foundation for an enduring memorial. We will miss his quiet sense of humour and his shrewd comments on men and affairs. Our deep sympathy goes out to his wife and family.

C. L. DUNN, C.I.E., L.R.C.P.&S.Ed., D.P.H.

Lieutenant-Colonel C. L. Dunn, for many years director of public health in the United Provinces of India, died at Chislehurst, Kent, on October 10. He was 81 years of age.

Cuthbert Lindsay Dunn was born at Valparaiso on May 15, 1875, the son of Mr. Charles James Dunn, of Dunnfield, Co. Londonderry. He received his early education at Dollar Academy and studied medicine at Edinburgh University, taking the Scottish triple qualification in 1899. After service in the South African War, for which he was awarded the Queen's medal with four clasps, he entered the Indian Medical Service in 1902. Two years later he was awarded another medal and clasp for his work in the Tibet campaign. From 1910 to 1914 he held the appointment of deputy sanitary commissioner in the United Provinces, relinquishing the post to serve in the first world war. By this time he had determined on a career as a hygiene specialist, and had taken the D.P.H. In recognition of his distinguished services during the course of the campaign in Serbia he was awarded the Order of St. Sava (fourth class) by the

King of Serbia. Returning to India at the end of the war, he was appointed director of public health in the United Provinces in 1919, and occupied this post until he retired from the Indian Medical Service, with the rank of lieutenant-colonel, in 1932. He had been appointed C.I.E. in 1928. For some years after his return to England he served on the Indian Medical Services Committee of the B.M.A.

After his retirement from the I.M.S. Dunn joined the staff of the Ministry of Health and was much concerned with the plans for the Emergency Medical Service. In recent years he prepared, wrote, and edited the two volumes of the *Medical History of the Second World War* devoted to the Emergency Medical Services. The volumes were published in 1952 and 1953. He also wrote *Malaria in Ceylon* and was joint author of a book on *Indian Hygiene and Public Health*. Dunn was twice married. His first wife, formerly Miss Janet L. Dalgleish, died in 1941, and nine years later he married Miss Kathleen E. Knott. She survives him together with the two daughters of the first marriage.

We are indebted to Sir ARTHUR MACNALT for the following appreciation:

The *Official Medical History of the Second World War* has sustained a grievous loss in the sudden death of has sustained a grievous loss in the sudden death of the Lieutenant-Colonel C. L. Dunn, a medical officer of the Ministry of Health and an assistant editor of the *History*.

In his untiring work as director of public health in the United Provinces of India Dunn won the confidence and friendship of his colleagues and the people of India. Indian doctors, his former pupils, were his frequent visitors and correspondents in his later days. On retirement he lived at Fleet, in Hampshire, but the outbreak of the second world war called him once more to public service. He was appointed hospital officer of the Ministry of Health Eastern Region, Cambridge, where his experience and administrative gifts were exercised in a new field.

In 1941 Dunn became one of my assistant editors for the *Official Medical History of the War*. Up to 1945 he was chiefly employed in collecting material for the *History* of the Emergency Medical Services in the series. The first volume was published in 1952, the second in 1953. Both volumes were favourably received and were described as "a fascinating story of organization and achievement." By these Dunn will be especially remembered, as well as for his books on *Indian Hygiene and Public Health* and *Malaria in Ceylon*.

Up to the end Dunn's interest and work for the *Medical History* continued to be unremitting. He was a most painstaking editor, and no error or misprint escaped his eye. Of our many contributors a number have expressed their gratitude to Dunn for going through their manuscripts, making helpful suggestions and criticisms, and eliminating redundant and overlapping material. When Dunn appeared in my room with a cheerful smile, bearing a volume of typescript, and saying, "Now, Chief, I want you to write a foreword," I knew that my task of reading the book and approving its presentation had been lightened by his labours. On the morning of Dunn's death I received by post a critical and useful note from him concerning a contribution to our final volume.

Colonel Dunn was tall, clean-shaven, of fair complexion, and a typical Ulsterman. He carried his years lightly. In his Edinburgh University days he had been a friend of Sir Andrew Balfour, and like him was a noted athlete. Dunn played a good game of golf up to his 80th year, was an excellent raconteur, and interested in art and general literature. I miss a dear friend, a man of high integrity, a loyal servant of the Crown in peace and war, and an able medical historian. Our sympathy goes out to his wife and two daughters.

R. O. ADAMSON, M.D.

We record with regret the death on September 30 of Dr. Robert Oswald Adamson at the age of 91. For many years he was one of the best-known general practitioners in Glasgow. He retired to live at St. Andrews during the last war.

We are indebted to Sir ROBERT MUIR for the following appreciation:

Dr. Adamson was a man of striking personality and of unusual ability. He was born on January 9, 1865, and was the youngest son of Dr. John Adamson, of St. Andrews. The latter was a man of varied accomplishments and was a noted pioneer in the early days of photography, many of his photographs being preserved permanently in museums. He was noted still more for his services in connexion with public health during the cholera epidemic in the early days of the century. His work was of outstanding value, and he did much to improve the health and amenities of St. Andrews.

My associations with Robert Adamson were many and varied, but all were of the most pleasant kind. We entered the arts classes in Edinburgh University together in 1880, went through all the arts and medical classes together, and were also together as resident physicians in the Edinburgh Royal Infirmary. It is perhaps of note that ultimately we were nonagenarians for more than two years, he being slightly the junior. He took the degree of M.A. in 1884, and that was in the days of the compulsory seven subjects' curriculum. Later he graduated M.B., C.M., with first-class honours, in 1889, proceeding to the M.D. in 1901.

There was then a break in our intercourse till I was appointed to the chair of pathology in Glasgow, and at that time Adamson had established his position in medical practice and his reputation was steadily growing. He became our family physician and attended my sisters and myself through all our illnesses, some of them being of grave nature. He impressed me by his powers of accurate observation, wide knowledge, and decision in judgment, and I can say that in my opinion he was one of the ablest physicians that I have known. He had quite an unusual power of distinguishing trivial from serious cases, and in this way lives were saved by him. He had made the habit of making and storing full notes of all his cases, and this he considered an essential in his work. He himself was not a laboratory worker, but he was keenly alive to scientific methods so that he could view a case from all points of view. He often came to the pathology department to discuss problems and cases, and I was always impressed by his keen grasp of the practical use of our methods. I often thought that if there was such a thing as a chair of general practice Adamson would have made a grand professor.

Adamson was a hard worker and never spared himself in his professional work, but he had also recreations, and these meant much to him. He had a fine physique, and in his early days played Rugby football as a forward for the Edinburgh Academicals. Later he had his chief enjoyment from long walks and from nature studies, especially botanical; but golf, as to many others, was his chief enjoyment. I remember well the Wednesday half-day holidays at Killermont with him and various others, and from these he drew the greatest pleasure. He was a keen golfer and one hard to beat, but it was always good to have him as a companion whether as partner or foe. I remember also our golfing parties in places further afield. These were made up of men in various lines, and many were men of distinction, but Adamson was always a ruling spirit, and a common question when such an outing was contemplated was, "Is Adamson coming?"

Adamson was a wide reader, was always studying and trying to keep up to date. He took great pleasure in good literature, and Shakespeare was his favourite author. He was interested in the subject of his early days and always spoke with gratitude of his arts curriculum.

Adamson married Mary Ommaney, daughter of the late Commander Henry M. Ommaney, R.N. She died in 1953. They had two daughters and one son. Both daughters took up the subject of medicine and both gave distinguished services. The elder, Evelyn, after training in this country and obtaining the C.M.B. from Queen Charlotte's Hospital, went to Africa and there her life's work was carried out, most of the time in the service of the Universities' Mission. Her work was in medicine, especially midwifery, and even in the supervision of hospital construction, and was carried out in a devoted manner in the most adverse circumstances, sometimes in places without hospital or the bare essentials. The younger daughter, Estelle, entered the nursing profession and in it gained rapid promotion, being ultimately appointed as matron to the Western General Hospital in Edinburgh. Recently she was appointed to a travelling fellowship for three months, for the purpose of studying hospital administration in various countries on the Continent; she is at present engaged in this work.

Adamson's last illness was a long and wearisome one. There was prostatic trouble with chronic uraemia, but there was also general failing of powers, especially of memory. He was well aware of the latter failing, and this gave him much distress.

He was a man of strong personality and definite opinions, but he could always gain the affectionate regard of those who differed from him. Looking back now, I cannot remember him saying or doing anything of unworthy nature.

Professor J. M. MUNRO KERR writes:

As one of Adamson's oldest friends, permit me to add a few lines to the intimate notice his oldest friend, Sir Robert Muir, has furnished. "Bob" Adamson was a great fellow in every respect—a great family practitioner, beloved by his patients; a wonderful friend; a dour opponent but doughty partner at golf; one of the best exponents of the nonsense speech at medical-club dinners. All he said and did showed quality. He followed to the letter the old and wise advice: "Whatsoever thy hand findeth to do, do it with thy might."

T. MILNES BRIDE, M.D.

Dr. T. Milnes Bride, honorary consultant ophthalmologist to the United Manchester Hospitals, died at his home at Alderley Edge, Cheshire, on October 11. He was 74 years of age.

Thomas Milnes Bride was born at Wilmslow, Cheshire, on December 10, 1881, the elder son of Dr. John Bride, and was educated at Cheltenham College and at Owens College, Manchester. He graduated M.B., Ch.B. from the Victoria University of Manchester in 1905, proceeding to the M.D. four years later. After graduation he held numerous house appointments at Manchester hospitals. In 1912 he became honorary surgeon to the Manchester Royal Eye Hospital, a position which he occupied for thirty-five years until he retired in 1947, when he was appointed honorary consultant ophthalmologist to the United Manchester Hospitals. He was also consulting ophthalmic surgeon to the Royal Manchester Children's Hospital and St. Mary's Hospital, Manchester, and visiting ophthalmic surgeon to the Military Hospital, Davyholme, and to the Crumpsall Hospital. He was also clinical lecturer in ophthalmology in Manchester University, and examiner in ophthalmology to Oxford University. He served as a captain in the R.A.M.C. in Mesopotamia and Italy in the first world war. During his long connexion with the Manchester Royal Eye Hospital he built up a reputation as a highly conscientious member of the staff and was much loved by his colleagues and by the nurses.

Bride was a member of the Ophthalmological Society of the United Kingdom, and a life member and president in 1924 of the North of England Ophthalmological

Society. One or two of his papers were published in the *Transactions of the Ophthalmological Society of the United Kingdom*. At the Annual Meeting of the British Medical Association held at Manchester in 1929 he acted as one of the honorary secretaries of the Section of Ophthalmology. A keen golfer, he was for many years secretary, with H. T. Ashby, of the Manchester Medical Golfers Association. He married in 1915 Sylvia Louise Ruthven, daughter of J. Farran Leech, of Eccles, Lancashire, and she survives him. Their only child, a daughter, died in infancy. They were a devoted couple, and the hospitality for which they were so well known always included vintage port, of which he was a connoisseur. At his home on Alderley Edge facing a wide view of the Cheshire plain his wife and he created a very beautiful garden, and in later years his leisure hours were often spent trimming roses, inspecting the vegetable garden, or spying the distant view of the Wrekin and the Welsh hills. Tom Bride leaves behind him the memory of a gentleman who was both courteous and helpful.—H. V. W.

Dr. H. G. BRAHAM died at his home at Huddersfield on September 18 at the age of 50 after a long and painful illness. His death occurred only two days before that of his elder brother, Dr. David Braham, of Bournemouth. Born at Leeds on December 18, 1905, Harvey Gordon Braham was educated at Leeds Central High School and at the School of Medicine of Leeds University, taking the Scottish triple qualification in 1933. He then held resident hospital appointments at Sheffield and Bournemouth, and later was in practice for several years at Rawtenstall, Lancashire. Much to the regret of his patients and a wide circle of friends in Rawtenstall, he moved to Huddersfield in 1946 and took over a practice in the Lindley district. With his kindness to his patients, his medical knowledge, and his charm and sincerity, he soon became as popular and as loved at Lindley as he had been in his previous practice. He was a member of the Huddersfield Hospital Management Committee and a founder member of the Huddersfield branch of the Marriage Guidance Council, and in other ways he entered actively into the life of the community in which he lived and worked. In 1952 he had an abdominal operation which, because of complications, kept him away from work for about six months. This marked the beginning of the deterioration in his health. He continued in his practice, however, working with the same diligence and consideration for his patients, but at a slower pace: even so, it could be said that he sacrificed his life for his work. The sympathies of his large circle of friends, his colleagues, and his patients, in fact all those with whom he came in contact, go out to his widow and three children in their sad loss.—H. W. D.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on July 28 the following degrees were conferred:
B.M.—S. Ardeman, J. A. Lofting, A. R. R. Cain, P. G. Newall Watson, Mrs. Ann G. Taylor, *J. P. H. Anderson, *F. John.
*In absence.

UNIVERSITY OF DURHAM

In Congregation on September 22 the Diploma in Psychological Medicine was awarded to A. C. Gibson and H. S. McWalter.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS

At a meeting of the Faculty held on September 3, with the President, Professor Stanley Graham, in the chair, the following were admitted Fellows of Faculty:

G. Church, I. W. W. Fingland, D. Harirajan, K. N. Kanwar, J. B. McGuinness, P. V. N. Raju, N. L. Sharma.

Medico-Legal

ARTERIOSCLEROSIS AND THE McNAUGHTON RULES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On June 27, 1956, an elderly man named Kemp, who was of excellent character and had always been thought to be devoted to his wife, found himself on trial before Mr. Justice Devlin and a jury at Bristol Assizes on a charge of causing her grievous bodily harm by striking her during the night with a hammer.

It was common ground between the medical evidence called for the prosecution and the defence that at the time of the act Kemp was suffering from arteriosclerosis which caused a congestion of blood in the brain accompanied by a temporary loss of consciousness, as a result of which he acted irresponsibly and irrationally. It was agreed that he was not conscious of picking up the hammer or that he was striking his wife with it.

He was therefore, in the words of the McNaughton Rules, "at the time of committing the act . . . labouring under such a defect of reason . . . as not to know the nature and quality of the act he was doing." The issue in the case was whether this defect of reason was "from a disease of the mind." If it was not, Kemp would have been entitled to be acquitted because he was not responsible for his act, since he could not have formed the guilty intent necessary to constitute the offence charged. If, however, there was a "disease of the mind" within the McNaughton Rules, s. 2 of the Trial of Lunatics Act, 1883, would apply, and the jury would be bound to find the special verdict of guilty but insane provided by that section. This amounts to a qualified acquittal resulting in the detention of the accused at Her Majesty's pleasure—that is, in a mental hospital.

Mr. Justice Devlin ruled that as a matter of law the arteriosclerosis from which Kemp was suffering and which caused his "defect of reason" was such a "disease of the mind." He pointed out that, however important it might be medically whether the defect of reasoning was due to a disease of the brain or to some other form of mental derangement, all that the law had to consider was the state of mind in which the accused was, not how he got there. The contention for the defence was that, though arteriosclerosis is capable of becoming a mental disease by causing degeneration of the brain, Kemp's had not gone so far but had only caused temporary interference by cutting off the blood supply in the same way as concussion might do: when it reached the point of interfering with the brain cells so that they degenerated, then it would be called a disease of the mind. However, the law was not concerned with the brain, but with the "mind" in its ordinary connotation of the mental faculties of reasoning, memory, and understanding. Defect of reason caused by a disease affecting the mind was what the McNaughton Rules required, and the condition of the brain was as irrelevant to that question as whether the disease was curable or incurable, temporary or permanent. The hardening of the arteries in Kemp's case was a disease which had been shown by the evidence to be capable of affecting his mind in such a way as to cause a defect, temporary or permanent, of its reasoning and understanding, and was thus within the Rules, and he would so direct the jury.

The full report of Mr. Justice Devlin's consideration of the problem is an excellent example of the lawyer's approach to the McNaughton Rules and the question of insanity as affecting criminal responsibility. If the lawyer's approach was more often expressed with the clarity and logic to be found in the report there would be less misunderstanding between the professions on what has been a thorny subject for both.

[1956] 3 All E.R. 249.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 29 (No. 39) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1956					1955

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases

Most infectious diseases increased in frequency in England and Wales during the week ending September 29. The largest rises were 314 for measles, from 1,082 to 1,396, 97 for acute pneumonia, from 195 to 292, 71 for scarlet fever, from 376 to 447, 67 for dysentery, from 390 to 457, and 65 for food-poisoning, from 235 to 300; the only large fall was 83 for whooping-cough, from 1,848 to 1,765.

The largest rise in the incidence of measles was 65 in Yorkshire West Riding, from 55 to 120. Only small fluctuations occurred in the local trends of scarlet fever. The largest falls in the number of notifications of whooping-cough were 46 in Yorkshire West Riding, from 166 to 120, 41 in London, from 141 to 100, 34 in Essex, from 152 to 118. 8 cases of diphtheria were notified, being 2 more than in the preceding week; 2 cases were notified in Leeds C.B. and in the metropolitan borough of Wandsworth.

131 cases of acute poliomyelitis were notified, and these cases were 21 more for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 25 (Manchester C.B. 12, Middleton M.B. 4, Stretford M.B. 4), Yorkshire West Riding 15 (Leeds C.B. 7, Sheffield C.B. 2), Cheshire 13 (Stockport C.B. 9), London 11 (Fulham 4, Paddington 2), and Surrey 8 (Chertsey U.D. 2, Godalming M.B. 2).

The largest centres of dysentery were Yorkshire West Riding 100 (Leeds C.B. 28, Halifax C.B. 13, Sheffield C.B. 13), Lancashire 75 (Liverpool C.B. 19), London 47 (Islington 9, Paddington 9), Surrey 29 (Esher U.D. 16), Warwickshire 27 (Coventry C.B. 18), Middlesex 21, Durham 21, and Worchestershire 21 (Oldbury M.B. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus ----, the figures for 1956 thus —. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending October 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 458, whooping-cough 1,487, diphtheria 2, measles 1,968, acute pneumonia 239, acute poliomyelitis 155, dysentery 421, paratyphoid fever 9, and typhoid fever 3.

Medical News

Dr. Morris Fishbein, of Chicago, internationally known as a medical editor, has been honoured as recipient of the 1956 Distinguished Service Award given by the American Medical Writers' Association. Dr. Fishbein is medical editor of *Excerpta Medica* and for very many years was editor of the *Journal of the American Medical Association*. He is equally well known as a writer, among his notable contributions being *Medical Writing*. The Distinguished Service Award is given annually to a member of the association "who has made distinguished contributions to medical literature or rendered unusual and distinguished service to the medical profession." The citation given in connexion with the award reads in part: "Eminent medical editor, voluminous writer, sparkling lecturer, university professor, as chairman or member of numerous official groups, you have given yourself to good works and patriotic causes. Recipient of multiple honours, you have been decorated by the governments of Cuba, Italy, the Netherlands, Spain, and your own United States of America. . . . From a position thus worthily won, you carried the anti-quackery fight to the public with a witty style that made of a threat a laughing-stock. With unerring

perception of a need unmet, you took to the road and the air, tirelessly, endlessly, speaking to and for practitioners of medicine, those ultimate guardians of the public health." The award, comprising a plaque and a gold medal, was presented to Dr. Fishbein on September 28 by the president of the association, Dr. RICHARD M. HEWITT, of the Mayo Clinic, who worked for many years with Dr. Fishbein as assistant editor of the *Journal of the American Medical Association*.

Lord Nuffield's Gift to Faculty of Dental Surgery.—At a lunch at the Royal College of Surgeons on October 12 Lord NUFFIELD gave a cheque for £100,000 to the dean of the faculty of dental surgery, Professor F. C. WILKINSON, to establish a chair of dental research in the new department of dental science at the College. Lord Nuffield's gift will provide the salary and expenses in perpetuity of a research professor who will also act as director of the department, which will, in close contact with the Institute of Basic Medical Sciences of the College, explore the fundamental problems of dental disease. It is hoped that the department may become a scientific centre not only for workers from this country but also for those from the Commonwealth. When Lord Nuffield decided to endow the research chair the appeal for funds for a new department had reached the halfway house. It had been given an excellent start by the Leverhulme Trust, which had assumed initial responsibility for the salaries of the scientific staff who will work under the Nuffield professor. Professor Wilkinson, thanking Lord Nuffield for his gift, said that future generations would wonder that one man could have done so much to foster the advancement of medicine in so many fields.

Harveian Oration.—Professor J. CRIGHTON BRAMWELL, formerly professor of cardiology and now emeritus professor at Manchester University, delivered this year's Harveian Oration at the Royal College of Physicians of London on October 18. His subject was "Practice, Teaching, and Research." There was no sharp dividing line between scientist and clinician, he said. The good teacher must have the spirit of an investigator—the powers of observation and deduction combined with the faculty of curiosity—although for teaching future practitioners clinical experience was more important than executive ability in research. Preclinical teachers should cultivate in their students the scientific attitude of mind and show them how to apply scientific methods to the solution of clinical problems. The rapid advance of medical knowledge had made specialization inevitable, continued Professor Bramwell; but the specialist whose field of vision was limited to his own specialty saw illness through tinted glasses. The specialist ought to be a general physician or surgeon who had added to his knowledge of general medicine a more profound study of one of the specialties. The fundamental unity of medicine could not be over-emphasized.

Leverhulme Research Awards, 1957.—Application is invited for fellowships and grants in aid of research. These awards are intended for senior workers of established position and are limited to British-born subjects normally resident in the United Kingdom; in exceptional circumstances the Trustees may waive the condition as to residence. No subject of inquiry is excluded from consideration, but preference is given to subjects in which existing provision for research is inadequate. The duration of the awards does not extend over more than two years or less than three months, and the amount depends on the nature of the research and the circumstances of the applicant. Application forms are obtainable from the secretary, Leverhulme Research Awards, St. Bridget's House, Bridewell Place, London, E.C.4. The closing date is December 31. Results will be announced in May and the awards will normally date from September 1, 1957.

Live Polio Vaccine Ready for Mass Trial.—According to reports from America, Dr. ALBERT A. SABIN, professor of research paediatrics at the University of Cincinnati College of Medicine, is now ready to test his live attenuated polio-

myelitis vaccine on a wide scale in humans. He has already arranged a trial in convict volunteers, and is stated to have enough vaccine to inoculate nearly two million people. The vaccine is given orally. Last year we published a paper by Dr. Sabin describing the results of a trial of an attenuated vaccine in 26 volunteers (*British Medical Journal*, 1955, 2, 160).

Glasgow Library.—The Wellcome Trust has agreed to grant £500 a year for five years for repairing the historical books in the library of the Royal Faculty of Physicians and Surgeons of Glasgow. The library was instituted in 1697, when the Faculty first obtained premises almost 100 years after its foundation by a grant from King James VI to Maister Peter Lowe. It now consists of some 150,000 volumes, more than 4,000 of them published before 1700. Many of these are of extreme rarity and some are unique. The preservation of this collection for the use of the medical profession not only in Glasgow but, by a system of inter-library loans, throughout the country has become a financial problem for the Faculty, and this gift will enable many of the older books to be repaired.

Convalescent Treatment under N.H.S.—The MINISTER OF HEALTH has appointed a working party with the following terms of reference: "To examine the extent to which the provision of convalescent homes in the National Health Service is meeting the demands placed upon it in the light of recent advances in medicine and modern conceptions of treatment and nursing care, to review the admissions machinery in the London area, and to make recommendations." The chairman is Dr. N. M. GOODMAN, a principal medical officer of the Ministry of Health, and the medical members are Sir HENRY TIDY, Dr. J. GRAHAM, and Dr. R. A. ANDREWS.

Royal Society Lecturers.—Dr. E. F. GALE, F.R.S., director of the Medical Research Council's chemical microbiology research unit at Cambridge, is to deliver the Leeuwenhoek lecture to the Royal Society on November 1. He will discuss the biochemical organization of the bacterial cell. The Ferrier lecture, on December 6, will be given by Sir WILFRID LE GROS CLARK, F.R.S., professor of anatomy at Oxford. He will lecture on the anatomical basis of olfactory discrimination. Both lectures are at 4.30 p.m.

Royal College of Surgeons.—At a council meeting on October 11 the president, Sir HARRY PLATT, presented the Walker prize to Dr. C. P. RHODES, of New York, whose Imperial Cancer Research Fund lecture is summarized elsewhere in this issue (p. 935). The Cecil Joll prize for 1956 was awarded to Professor P. R. ALLISON, of Oxford, for his contributions to thoracic surgery.

Leader for Antarctic Expedition.—The War Office has agreed to the appointment of Colonel R. A. SMART, late R.A.M.C., deputy director of Army Health, Western Command, as leader of the main party of the Royal Society International Geophysical Year Antarctic Expedition. The main party, which leaves London on November 15, is expected to reach its base at Halley Bay by the end of December. It will relieve the advance party, under another doctor, Surgeon Commander D. G. DALGLEISH, R.N., which went out last November.

Albert Schweitzer Medal Award.—Major C. W. HUME, director of the Universities Federation for Animal Welfare, which he founded in 1926 as the University of London Animal Welfare Society, has been awarded the Albert Schweitzer Medal of the American Animal Welfare Institute and a cheque for \$500 in recognition of his services to the welfare of laboratory animals.

Colindale.—Lieutenant-Colonel H. J. BENSTED retired from the directorship of the Central Public Health Laboratory at Colindale on October 3, and Dr. W. C. COCKBURN will perform the duties of acting director until a successor is appointed.

Dr. James Walker was inducted into the Chair of Midwifery and Gynaecology at St. Andrews University during the graduation ceremony there on October 10.

Dr. W. Mayer-Gross, of the department of experimental psychiatry, Birmingham, is going as a W.H.O. consultant to the All-India Institute of Mental Health, Bangalore, to advise on its further development. He will be away until the end of February.

COMING EVENTS

Worcester General Practitioners.—The College of General Practitioners has made arrangements with the staffs of the Worcester Royal Infirmary and Ronswood Hospital for a course of six medical meetings this autumn as follows: October 25, Worcester Royal Infirmary, "Antenatal Care," by Dr. M. IVOR COOKSON, general practitioner, and Mr. A. T. MARSHALL, obstetrician. October 31, Worcester Royal Infirmary, "The Diagnostic Processes," by Dr. D. L. CROMBIE, general practitioner. November 8, Worcester Royal Infirmary, "The Use of the X-ray Department by the General Practitioner," by Dr. A. A. VICKERS, radiologist. November 14, Worcester Royal Infirmary, "Anaesthesia in General Practice, with Special Reference to Dentistry," by Dr. W. D. STEEL, general practitioner. November 22, Worcester Royal Infirmary, "Ophthalmic Pitfalls in General Practice," by Mr. C. MARTIN DOYLE, ophthalmologist. November 29, Ronswood Hospital, open meeting. All meetings will be at 3.30 for 3.45 p.m., except the first meeting, which will start at 3.15 p.m.

Association of Anaesthetists of Great Britain and Ireland.—Annual meeting, November 1 and 2, at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2. Details from the secretary of the association at that address not later than October 26.

Aberdeen University Club, London.—Annual dinner on November 8 at 7 p.m. at the Hyde Park Hotel, Knightsbridge. Tickets (30s.) and further details from Dr. W. C. COCKBURN, Central Public Health Laboratory, Colindale Avenue, London, N.W.9.

Immunology.—The first meeting of the British Society for Immunology will be held at the Wellcome Foundation, 183, Euston Road, London, W.C.1, on Friday and Saturday, November 9-10. After introductory remarks by Sir HENRY DALE, O.M., F.R.S., at 10 a.m. on the Friday, scientific papers will be read, and in the afternoon there will be a symposium on complement. Particulars from Professor G. PAYLING WRIGHT, Department of Pathology, Guy's Hospital Medical School, London, S.E.1.

Semaine Endocrinologique.—At the Hôpital Laënnec, 42, Rue de Sévres, Paris, 7, November 26 to December 1. The subject will be prognosis in endocrinology. Details from the secretary of the hospital.

Sydney Watson Smith Lecture.—Professor JOHN McMICAHEL will lecture at the Royal College of Physicians of Edinburgh on November 27 at 5 p.m. His subject will be "Valvular Incompetence and Heart Failure."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, October 23

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. V. P. Whittaker, D.Phil.: Metabolism of Choline Esters.

CHADWICK TRUST.—At Royal Society of Tropical Medicine and Hygiene, 5.30 p.m., Dr. W. Emrys Davies, Ph.D.: The Message of Public Health—How It Should be Told.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Vitamins and Skin Metabolism.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson: Demonstration by Dr. L. W. Proger: Osteomyelitis.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Professor H. H. Evers: Significance of Rubella in Early Pregnancy.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. T. Rowland Hill: neurological demonstration.

Wednesday, October 24

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At 154, Great Charles Street, Birmingham, 8 p.m., joint meeting with Midland Branch of British Psychological Society and Midland Mental Deficiency Society. Dr. M. L. Kellmer Pringle, Ph.D.: Some Aspects of Emotional Re-education.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: Use of Vitamins in Dermatology.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. J. R. Belcher: Some Aspects of Mitral Valvotomy.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. A. R. Harrison: Tests of Renal Function.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in hygiene and public medicine by Professor A. Charlotte Ruys (Amsterdam): Influence of Various Environmental Conditions on the Epidemiology of Tuberculosis.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. G. J. Popjak: Fat Metabolism.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Cicely D. Williams: Needs and Opportunities for Maternal and Child Health in International Organizations.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP—NUTRITION PANEL.—At 14, Belgrave Square, S.W., 6.30 p.m., debate: That in the Opinion of this Panel, Sugar is an Unnecessary Article in the Diet. Proposed by Dr. A. E. Bender, Ph.D., F.R.I.C. Opposed by Mr. H. C. S. De Whalley, M.I.Chem.E.

WESTMINSTER HOSPITAL.—At Meyerstein Theatre, Westminster Medical School, 5.30 p.m., Professor H. K. Beecher (Massachusetts): Treatment of Severely Wounded Men.

Thursday, October 25

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. Mary Barber: Resistance of Staphylococci to Antibiotics.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., Dr. T. Anderson: Good Relations in Medicine.

HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Mr. I. S. Smillie: Loose Bodies in Joints.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., symposium to be opened by Dr. J. P. G. Rogerson and Mr. H. V. Corbett: General Practitioner Midwifery Services.

LONDON UNIVERSITY.—At St. Thomas's Hospital Medical School, 5 p.m., special university lecture in human anatomy and morphology, by Sir Geoffrey Jefferson, F.R.S.: Effects of Brain-stem Lesions.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Thomas Vicary Lecture by Dr. William Brockbank: The Man Who Was Vidius.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Aspects of Refraction Work—(3) The Reduced Eye, and Retinoscopy.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Queen's College, Dundee, 5 p.m., Professor G. McC. Wyburn: Present Limitations of the Interpretation of Structure with the Electron Microscope.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. M. A. Partridge: psychiatry demonstration.

SOCIETY OF CHEMICAL INDUSTRY: MICROBIOLOGY GROUP.—At 14, Belgrave Square, S.W., 6.15 p.m., medical films (Institut Pasteur, use-use control, action of antibiotics, etc.).

UNIVERSITY COLLEGE LONDON AND UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—At Anatomy Theatre, 5.30 p.m., Rickman Godlee Lecture by Sir Gavin de Beer, F.R.S.: Science and the Humanities.

Friday, October 26

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: Alopecia.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson and Mr. J. R. Belcher: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOLGY.—3.30 p.m., Mr. M. P. Ellis: Secretary Otitis and Eustachian Obstruction.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. D. Band: Personal Experience of Methods of Vesical Exclusion with a Reasonable Follow-up; 4 p.m., Sir Francis Walshe, F.R.S.: Traumatic Neurosis.

SIGERIST SOCIETY.—At Club Room, Imperial Hotel, Russell Square, W.C., 8 p.m., Drs. Angus and Barbara McPherson: Medical Visit to China. A short colour film of their journey will be shown.

Saturday, October 27

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—9.45 a.m., Professor W. I. C. Morris: Post-maturity.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Beswick.—On October 9, 1956, at the Women's Hospital, Nottingham, to Sylvia (formerly Welch), wife of Dr. Hubert Beswick, a son.

Coutanceau.—On October 1, 1956, at the Liverpool Maternity Hospital, to Paula, wife of Henri Coutanceau, M.B., B.S., D.A., a sister to Suzanne and Maurice—Denise Madeleine.

Grant.—On October 6, 1956, at the Simpson Memorial Maternity Pavilion, Royal Infirmary, Edinburgh, to Dr. and Mrs. Peter W. Grant, of 127, Mayfield Road, Edinburgh, a son.

Jones.—On October 6, 1956, at University College Hospital, London, W.C., to Monica (formerly Cogman), M.B., B.S., wife of Peter H. Jones, M.V.O., F.R.C.S., a son.

Patey.—On September 18, 1956, at Paignton Hospital, to Jean (formerly Mason), M.B., F.R.C.S.Ed., wife of Mr. John Patey, a brother for Robert Johnny, and Margaret—Patrick Joseph.

Reilly.—On October 8, 1956, in Plymouth, to Joy, wife of Michael Reilly, M.S., F.R.C.S., a son.

DEATHS

Gray.—On September 24, 1956, in hospital, the result of an accident, Douglas Gray, M.B., of 84, High Street, Henlow, Beds, formerly of Bolton, Lancs, aged 78.

Hinkman.—On September 23, 1956, at Edinburgh, John Forrest Hinkman, M.B., Ch.B., late I.M.S., of Carlisle, Lanark.

Porter.—On September 11, 1956, at the Grove Hospital, Tooting, London, S.W., Joseph Herbert Porter, M.C., M.B., B.Ch., of 114, Cavendish Road, London, S.W.

Shaw.—On September 26, 1956, at 7, Midhurst Avenue, Fortis Green, London, N., Ernest Henry Shaw, F.R.C.S., M.R.C.P., aged 89.

Willoughby.—On July 16, 1956, at her home, 13808, 98th Avenue, Edmonton, Alberta, Canada, Dorothy Willoughby, M.R.C.S., L.R.C.P.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Chronic Haemospermia

Q.—An epileptic on phenytoin sodium reports that his ejaculate is almost pure blood. Is this related to the phenytoin therapy and how seriously must this phenomenon be regarded? Is there any indication for further investigation?

A.—The aetiology of chronic haemospermia is still largely obscure. It seems very improbable that, in the patient described, it could be due to the phenytoin therapy; and it is doubtless no more than coincidence that, like one of five patients reported by McDonald,¹ he has epilepsy. The blood in these cases appears to originate in the seminal vesicles, and, provided there is no obvious abnormality of these, further investigation is unlikely to yield useful information.

The condition, though alarming to the patient, appears otherwise to be of no consequence. According to McDonald, treatment with oestrogen (e.g., ethinyl oestradiol, 0.05 mg., from three times a week to twice daily, according to the response, and continued for from three to seven weeks) is very likely to stop the haemospermia, though it may recur later.

Preparation of Benzocaine and Urethane Solution

Q.—A solution of 2% benzocaine and 40% urethane in distilled water¹ has been advocated recently for the treatment of simple rib fractures.² Is this a standard solution marketed by any firm, or a solution made up by individual hospital dispensaries? In the case of the latter, please give me details of the dispensing.

A.—The first use of the benzocaine-urethane injection in this country was by Nitali and Kohn,³ who used a proprietary preparation "prolongal benzocaine" made by Zori, of Tel Aviv. This does not seem to be on the market in Great Britain. An injection of the strength mentioned in the question is in use in St. Giles's Hospital, London, and Queen Mary's Hospital, Roehampton.¹ In both hospitals the injection is prepared in the hospital pharmacy and is a simple solution of 2% of benzocaine and 40% of urethane. In the former filtration is used for sterilization and in the latter autoclaving.

If solutions are exposed to temperatures much below 20° C. some of the urethane may crystallize out, but it redissolves on warming. There are conflicting reports on the solubility of urethane in water. The B.P. and the B.P.C. give the solubility as 1 in 1.5 at 20° C., the U.S. Dispensary and Merck Index give it as 1 in 0.5, and the Extra Pharmacopoeia (Martindale) gives it as 1 in 2. The last three volumes mentioned state no temperature. Even taking the lowest solubility figure the strength of the benzocaine-urethane injection is well within the limit.

Benzocaine is stated in the B.P. and the B.P.C. to be almost insoluble in water, whereas the U.S. Dispensary, Merck Index, and Extra Pharmacopoeia give a solubility of about 1 in 2,500. Thus the amount of benzocaine in the injection is well in excess of its solubility in water. The amount required, however, dissolves readily in the urethane solution. That it is the urethane which crystallizes out is shown by the fact that, if a plain 40% solution of benzocaine is cooled to below 20° C. beside a sample of the benzocaine-urethane injection, crystallization occurs in both simultaneously and the volume of precipitate is as great in the plain

solution as in that containing benzocaine. The addition of 10% of alcohol reduces the liability to crystallization, but is not really necessary.

The following procedure is recommended for the preparation of the injection. Dissolve the urethane in a little distilled water with the aid of gentle heat and dissolve the benzocaine in the urethane solution. Place in ampoules or a rubber-capped container, as required, and sterilize by autoclaving at 10 lb. per sq. in. (0.7 kg. per square cm.) for 30 minutes. Rubber-capped bottles should not need any added preservative, as urethane is bacteriostatic. This solution should remain bright and clear at the temperature of most wards and theatres. At temperatures appreciably below 20° C. a crystalline deposit may appear. This can be dissolved by gently warming and shaking: often the heat of the hand in shaking the bottle is sufficient to cause the precipitate to dissolve. The solution is then quite suitable for use.

Treatment of Pethidine Addiction

Q.—What treatment is advised for pethidine addiction?

A.—Careful nursing care and continuous medical supervision are essential in the treatment of pethidine addiction. Additional vitamins and a full diet should be given if the patient's physical condition is poor. When pethidine addicts are no longer allowed access to the drug a withdrawal syndrome develops. This is usually similar to, but less severe than, that arising from the removal of morphine, possibly because pethidine gives rise to much less euphoria. If pethidine administration is stopped abruptly symptoms rise to a peak in about eight to twelve hours and have usually disappeared in five days. It is usually better to withdraw the pethidine in stages over a period of three to four days. Sedatives such as chloral hydrate or paraldehyde may be required to produce sleep. A full psychological investigation should be carried out after withdrawal symptoms have disappeared, and subsequent supervision for several years is desirable.

Air-conditioning for Asthma

Q.—What are the indications for air-conditioning the bedroom of an asthmatic? How is this best achieved in cases where it would be of benefit? In such cases is there an optimum humidity for the air, and, if so, how can this be maintained?

A.—There is general agreement that excessive humidity and extremes of temperature are poorly tolerated by asthmatics and that they are most comfortable in a climate where the humidity is low and the temperature warm and even. However, attempts to relieve asthma by air-conditioning the bedroom have been disappointing. Several publications of such experiments appeared in the literature between 1924 and 1938,^{1,2} but little has appeared since. H. L. Rogers³ summarizes the position as follows: "Before asthmatic patients go to the expense of buying air-conditioning units, they should visit some friend or place where they can experiment with them. Most times they will decide they are not worth while."

Asthmatics sensitive to house dust should have a bedroom made as free from house dust as possible by correct furnishing and proper cleaning methods; feather pillows and eiderdown, horsehair mattress, and other sources of animal dander should be excluded. Episodes of infective asthma can be reduced by maintaining a warm, even temperature in the bedroom during the winter months by central heating or gas or electric fires, and this is especially helpful to young children and the elderly.

Treatment of Disseminated Sclerosis

Q.—Have there been any recent advances in the treatment of long-standing disseminated sclerosis? Is nicotinic acid of value?

A.—There have been no important advances in the treatment of long-standing disseminated sclerosis, and until something is known of the aetiology of the disease it is very unlikely that any important therapeutic advance will be made. Provided the patient has not become bedridden, it is usually possible for the physiotherapist to help these patients by appropriate exercises or the provision of sticks or crutches. It is sometimes, but by no means always, possible to diminish spasticity by taking mephenesin by mouth; it is perhaps best taken in the form of tablets each containing 0.5 g. mephenesin carbamate; the dose of this preparation is slowly increased, and there seems to be almost no upper limit.

There is nothing to suggest that nicotinic acid has any place in the treatment of disseminated sclerosis.

Indications for Operation in Pelvic Tuberculosis

Q.—What are the indications for operative treatment in pelvic tuberculosis in women?

A.—The primary treatment of nearly all forms of genital tuberculosis in the female is now by means of streptomycin (1 g. daily) combined with P.A.S. (12 to 20 g. daily) or isoniazid (300 mg. daily). These are used in various combinations, sometimes alternating one with another, for a total of at least two months and preferably for three months. The best technique has still to be formulated and the long-term results determined. Meanwhile the short-term results, as regards eradication of active disease rather than restoration of fertility, are so promising that the place for surgical treatment of genital tuberculosis is strictly limited. It cannot yet be defined exactly, especially as chemotherapy is continually being developed. In general, it may be stated that operative treatment, if carried out, must be radical and only undertaken by an expert after considering all the circumstances of an individual case. It might be indicated by extension of the disease process, by the continuation of symptoms such as epimenorrhagia and pelvic pain, by fistula formation, and by the persistence of large appendage masses with caseation (small, symptomless, non-tender appendage swellings are not important) despite adequate and repeated courses of antibiotics and antibacterial drugs. Sometimes social and economic factors might influence the decision, and so might evidence that the tubes are so closed that it is certain that fertility cannot be restored even if active infection is eradicated by medical measures.

When there appears a good indication for surgery in any particular case there is still reason to hesitate if the clinical features suggest the presence of plastic peritonitis, which increases the risk of fistula formation as a result of operation. Moreover, all surgery should be "covered" by chemotherapy given for two weeks before, and for six weeks after, operation.

Gas-and-Air in Domiciliary Midwifery

Q.—What place has gas-and-air analgesia in domiciliary midwifery nowadays? Are there any definite contraindications to its use?

A.—Gas-and-air still has very nearly the same place in domiciliary midwifery as it has had for years. Trichloroethylene in one of the approved inhalers provides slightly more potent analgesia during the last few hours of labour. The liability to cumulation with trichloroethylene, and the danger of respiratory depression if its administration is combined too closely with large doses of pethidine, impose, however, certain limitations on its use. Gas-and-air may be used over longer periods of time, but needs a certain amount of experience for the best results to be obtained. Definite contraindications to gas-and-air analgesia exist

when in the opinion of the doctor the somewhat vigorous respiratory effort needed to inhale the gas from the apparatus, and the low oxygen content of the mixture (10% oxygen), would tire or harm the mother. The conditions in which this may be the case include cardiac and pulmonary disease (especially bronchiectasis and tuberculosis), anaemia, and severe toxæmia with hypertension.

Micro-methods for E.S.R.

Q.—What simple micro-methods are available for estimating the erythrocyte sedimentation rate? How reliable are the results compared with those from the usual methods?

A.—The usual methods for estimating the E.S.R.—for example, Westergren and Wintrobe—require 2 ml. citrated or oxalated venous blood. If there is difficulty in obtaining venous blood, micro-methods have been advocated which require about 0.2 ml. of blood from a skin prick. Speed in obtaining the blood specimen and mixing it with the anticoagulant is essential, since any degree of clotting will give misleading results. The technique for one such micro-method is as follows: 0.05 ml. trisodium citrate (3.8% solution) is drawn into an ordinary capillary pipette. Skin-prick blood, which must flow freely, is now taken up to the 0.2 ml. mark of the pipette. The specimen is quickly expelled into a small tube, which is rotated to aid mixing. The citrated blood is now sucked up into a special capillary pipette to a height of 100 mm. The internal bore of this pipette is 1.5 mm. The pipette is set vertically in a stand similar to the one used for Westergren pipettes. If the specimen can be obtained rapidly and mixed thoroughly with the anticoagulant the results are similar to and as reliable as obtained by the Westergren method. But the technical skill needed for this micro-method is considerable.

NOTES AND COMMENTS

Sore Tongue from Pipe-smoking.—Dr. H. D. FORBES FRASER (Crowthorne, Berks) writes: May I enlarge on the reply to the question about sore tongue from pipe-smoking ("Any Questions?" September 29, p. 778)? The patient referred to is clearly a learner pipe-smoker. He should inspect the proximal end of the mouth-piece of his pipe, and select one with a large, wide slot, and never use the cheaper circular opening. The wide slot distributes the hot smoke, the circular opening directs a hot jet on one spot on the tongue. The learner smoker should take courage to try a fairly strong, dark-coloured tobacco, which will give a cooler smoke. A fine-cut light-coloured tobacco will smoke hot. The pipe should be only half-filled until it begins to get nicely carboned. The learner pipe-smoker must learn. He should sit down and concentrate on the action of clear, quite regular draws, avoiding hurried puffing. He will at first be unable to converse while smoking, but will become a good listener. After about three weeks he will begin to enjoy his pipe.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Attilology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: Medisecra, Westcent, London.

AETIOLOGY AND MANAGEMENT OF LESIONS OF THE FEET IN DIABETES

BY

WILFRID OAKLEY, M.D., F.R.C.P.
Physician, Diabetic Department, King's College Hospital

R. C. F. CATTERALL, M.Chir., F.R.C.S.
Orthopaedic Surgeon, King's College Hospital

AND

M. MENCER MARTIN, M.D., M.R.C.P.
Leverhulme Research Fellow, Middlesex Hospital; late Registrar,
Diabetic Department, King's College Hospital

It is generally held that there is an association between diabetes and arterial disease. Joslin *et al.* (1940) state that "arteriosclerosis is excessive and has become the major cause of death among diabetics generally," and this view has many supporters. Opinion, however, differs on the nature of the arterial lesion, which is regarded by some—for example, Warren and Le Compte (1952), Barach and Lowy (1952), and Katz and Stamler (1953)—as atherosclerosis, and by others—for example, Lundbaek (1954)—as a specific form of angiopathy associated with long-standing diabetes.

Histologically it would appear to be impossible to differentiate between non-diabetic and diabetic arterial disease, and, although Lundbaek and Posborg Petersen (1953) have found statistically significant differences in the calcium, cephalin, and lecithin content of the coronary arteries in non-diabetic and diabetic subjects, these differences are admitted by them to be small. Lundbaek bases his belief on the existence of specific diabetic angiopathy largely on statistical grounds, sex incidence, and the presence of such associated lesions as retinopathy and the renal lesions described by Kimmelstiel and Wilson (1936).

Object of the Survey

The present investigation is particularly concerned with peripheral vascular disease of the lower extremities, and was carried out with the prime object of increasing our knowledge and understanding of the aetiology and treatment of lesions of the feet in diabetes; the results obtained, however, may have some bearing on the wider issue of the nature of the arterial lesion in diabetes.

In a recent survey of patients attending the diabetic clinic at King's College Hospital during the period 1950 to 1953, one of us (M. M. M.) found symptoms and signs of occlusive peripheral vascular disease affecting the lower extremities in 146 out of a total of 3,788.

These 146 cases have been analysed in order to determine the relationship between this condition and age, sex, and duration of diabetes.

Table I shows that symptoms and signs of peripheral arterial disease of the lower extremities were entirely

absent below the age of 40, and that there were only three cases between the ages of 40 and 49; thereafter the incidence rose sharply, being greatest above the age of 60. The same trend was observed in both sexes, although the incidence was greater in men.

TABLE I.—Incidence of Peripheral Occlusive Arterial Disease in Diabetes with Respect to Age and Sex

Age Group	Males per 100 Diabetics	Females per 100 Diabetics	Ratio Male/Female
20-29	—	—	—
30-39	—	1	2/1
40-49	2	2	2/1
50-59	4	4	2.75/1
60-69	11	5	4.6/1
70+	23	—	—

These results expressed as a percentage incidence of the diabetic population attending the clinic show that peripheral arterial disease was twice as common in patients of 70 and over as it was in the 60 to 69 age group.

Table II shows the relative sex incidence of occlusive vascular disease; it will be seen that male diabetics were much more commonly affected than females, especially in the older age groups.

TABLE II.—Age and Sex Distribution of Peripheral Occlusive Arterial Disease in a Population of Diabetics Attending King's College Hospital

Age Group	Male Distribution		Female Distribution		Total		Incidence in Diabetic Population
	Arterial Disease	Diabetic Population Used	Arterial Disease	Diabetic Population Used	Arterial Disease	Diabetic Population	
20-29	—	186	—	221	—	407	—
30-39	—	222	—	203	—	425	—
40-49	4	227	2	226	6	453	1.3%
50-59	11	280	9	531	20	811	2.5%
60-69	31	292	28	762	59	1,054	5.6%
70+	36	159	25	479	61	638	10.5%
Total	82	1,366	64	2,422	146	3,788	3.9%
Percentage	56	36	44	64	—	—	—

Peripheral Arterial Disease

It is significant that the incidence of symptoms and signs of peripheral arterial disease (Table III) appears to bear no relationship to the duration of the diabetes, the number of patients being approximately the same in all groups.

TABLE III.—Incidence of Peripheral Occlusive Arterial Disease in Diabetics with Respect to Duration of Diabetes

Duration of Diabetes in Years	No. of Patients
Less than 1	20
1-4	26
5-9	29
10-14	25
15-19	26
20 and over	20
Total	146

In a recent follow-up of some 250 diabetics in whom the disease began before the age of 15 and in whom it had been present for not less than 10 years, and in many for 20 or more, one of us (W. O.) was unable to find a single lesion attributable to occlusive vascular disease; this, of course, does not exclude the presence of such disease. In the great majority of these young diabetics the disease was severe and its control variable. In short, old age seems to be the common factor in these cases, and the duration, severity, and control of the diabetes of secondary importance. It would not, however, be true to say that lesions of the feet occur only in diabetics of 60 or over. Sepsis, perforating ulcers, and even gangrene are by no means uncommon below this age, but it has been assumed too readily that such conditions are due to peripheral arterial disease alone or combined with a lowered resistance to staphylococcal infection. Careful examination shows that the great majority of these comparatively young patients have a quite adequate blood supply as judged by peripheral arterial pulsation, oscillometry, and skin temperature tests, the common defect being diabetic neuropathy.

The importance of neuropathy in this connexion became apparent as a result of a detailed investigation of the incidence and manifestations of neuropathy in the diabetic department of King's College Hospital (Martin, 1952), in which there was observed to be a high incidence of septic and apparently ischaemic lesions in patients with severe neuropathy. Neuropathy, unlike retinopathy and most other diabetic complications, was found to be related less to duration than to control of the diabetes: this led to a reassessment of our older patients in whom lesions of the feet were often associated with diabetes of comparatively short duration. To our surprise we found that in most cases the increased incidence of lesions of the feet in diabetics could be explained by the superimposition of neuropathy on the degree of arterial disease common to non-diabetics of the same age and sex; the appreciation of this is essential, in our opinion, to a proper understanding of the aetiology and treatment of the diabetic foot.

Nature of Diabetic Neuropathy

In order to appreciate the part played by neuropathy in the production of lesions of the feet in diabetes, it is essential to understand something of the nature and manifestations of diabetic neuropathy.

Diabetic neuropathy is a degenerative condition of peripheral nerves occurring as a complication peculiar to the diabetic state. It affects mainly the nerves to the lower extremities at their periphery and is much more common than the published reports suggest.

Peripheral nerve involvement, although occurring in diabetics of all ages, is more commonly seen in the elderly, in whom the insidious onset of diabetes in middle and later life often results in long delay in diagnosis and treatment.

Neuropathic lesions of the feet are among the common complications for which such elderly diabetics may first seek medical advice.

Severe diabetic neuropathy, with extensive sensory loss and muscular weakness, may not be a frequent finding in smaller diabetic clinics, but less severe involvement of the nervous system characterized by pain, paraesthesiae in the feet and hands, calf tenderness, and vasomotor disturbances are commonly encountered. Although neuritic symptoms in the absence of physical signs have been regarded as distinct from diabetic neuropathy with its more permanent findings of peripheral nerve damage (Rundles, 1945), there is little doubt that they have a common aetiology (Martin, 1952).

The earliest phase in the development of diabetic neuropathy, characterized by diffuse and ill-localized pain, vasomotor disturbances, thermal paraesthesiae, changes in the tendon reflexes, and often alteration in pain sensibility in the feet without much impairment of perception of touch or pressure, is due to widespread degeneration of non-myelinated nerve fibres (Martin, 1952). The impairment of autonomic vasomotor responses and, to some extent, pain conduction due to interruption of the lower sensory neurone predisposes to excessive trauma and lowers tissue resistance (Lewis, 1927). Thus, even when the blood supply to such an area is intact, its tissues may be regarded as relatively ischaemic so far as the local defence and repair are concerned; this is the minimum degree of ischaemia which can be recognized clinically (Learmonth, 1953).

There is now a good deal of evidence that non-myelinated nerve-fibre degeneration occurs in a high proportion of diabetic patients, who, on clinical examination, show no evidence of "clinical" diabetic neuropathy (Martin, 1953). The presence in diabetics of such nerve-fibre disturbance explains the frequent finding of persistently cold feet and their proneness to traumatic lesions.

Cutaneous neuropathic changes commonly start as blisters about the tips of the toes or at the site of a corn or callosity in places constantly exposed to irritation by an ill-fitting shoe. Frequently the deceptive lack of normal sensation, and particularly pain sensation, leads the patient to ignore the lesion and delay treatment until secondary infection with deep penetration of the tissues or severe inflammation is present. The blood supply in many of these cases is quite adequate, and suitable local treatment, combined with good control of the diabetes, usually results in normal healing.

Classification of Lesions of the Feet.—For purposes of description it is convenient to divide lesions of the feet in diabetics into the following types (Oakley, 1954): (1) septic, (2) neuropathic, (3) ischaemic, and (4) combinations of 1, 2, and 3.

1. Septic Lesions

Uncomplicated sepsis produces essentially the same lesion in the diabetic as in the non-diabetic foot, and, apart from control of the diabetes, the treatment is the same, the chief measures being rest, drainage, and antibiotics.

2. Neuropathic Lesions

Loss or impairment of superficial sensation, and especially the appreciation of heat and pain, are important factors in the production of callosities, ulcers, and local gangrene. Loss of deep sensation may cause Charcot joints, while weakness of the intrinsic muscle may produce characteristic deformities which not only favour the formation of chronic ulcers but also add to the difficulties of surgical treatment.

A considerable number of diabetics complaining of their feet prove, on inspection, to have varying degrees of a quite typical deformity. The toes are held dorsiflexed at the metatarso-phalangeal joints with flexion at the inter-phalangeal joints, but these claw toes are never accompanied by the tight plantar fascia and short tendo achillis of fully developed pes cavus (Fig. 1). This deformity is often met with in the presence of an apparently normal circulation, but

is constantly associated with signs of neuropathy. An excessive keratinization of the horny layer of the skin is also usually present, although these last changes are minimized by regular attention. The cocked-up position of the toes is that into which they would be drawn by simultaneous contraction of the long flexors and extensors with the normal balancing force of the intrinsic muscles removed. The association of this deformity with sensory disturbances lends colour to the belief that this deformity is indeed a manifestation of a peripheral motor neuropathy. Proof of this

FIG. 1.—Typical deformity of toes associated with diabetic neuropathy.

FIG. 2.—Pressure gangrene of big toes associated with diabetic neuropathy.

FIG. 3.—The same patient as in Fig. 2 after conservative treatment.

contention is difficult, since the established deformity is often so stiff that electromyography is useless, and biopsy, for obvious reasons, is not lightly undertaken.

Such a foot produces symptoms sometimes attributable to ruthless shoe-pressure on a numb foot. Areas of superficial necrosis can appear with dramatic suddenness, but, provided further pressure is avoided, usually heal uneventfully (Figs. 2-3); in the case of the decubitus ulcer on the heel the patient should be confined to bed and the limb suspended until healing is well advanced.

In the presence of stiff and deformed toes the absence of the normal heel-and-toe movements in walking places

an abnormal thrust on the metatarsal heads, and the underlying neuropathic skin passes inexorably through the stage of ugly callosities to the formation of indolent ulcers (Fig. 4).

Treatment

These changes are only hastened by the use of appliances which, unable to affect the shape of the foot, become mere space-occupying lesions in the shoe. It cannot be emphasized too strongly that the use of any appliance inside the shoe in the presence of stiff toes will precipitate the very disasters it is intended to prevent. Appeasement can be obtained only by shoes made to measure, although a rocker bar on the sole may help in mimicking a normal heel-and-toe movement.

Once deep perforating ulceration has occurred, surgical intervention is essential. The object of the operation is to

remove the underlying bony pressure point and obtain skin cover without tension. Suture of the wound is permissible only when there is ample skin cover, no sepsis, and an adequate blood supply as judged by the haemorrhage at operation. Fortunately placed incisions, however, with or without primary Thiersch grafting, will allow rapid healing provided that the bone section has been radical enough. The problems presented by the neuropathic foot rarely carry an immediate risk to life, and consideration must be given to the long-term effects of the bone section proposed, since removal of more than one of the three middle toes will always result in further deformity, with the formation of new sites of pressure. If more than one toe has to be removed amputation of all five toes at once leaves a more shapely foot with a far better prospect of useful life. The "moccasin" prosthesis described by Downie (1956) seems to solve the problem of the aftercare of these feet.

FIG. 4.—Perforating ulcers of sole of foot in diabetic neuropathy.

3. Ischaemic Lesions

The generalized ischaemic lesion unassociated with neuropathy is not so common as is generally supposed, and must be differentiated from the local ischaemic disaster in an essentially neuropathic foot. The recognition of ischaemia is based on the history, clinical examination, and special tests. Pain of a burning character, worse at night and aggravated by heat, is suggestive of ischaemia but by itself does not exclude neuropathy; associated intermittent claudication greatly favours a diagnosis of ischaemia. The foot is typically cold and may be pale or pink, the latter colour being the more often associated with pain. The skin is often smooth, hairless, and shiny, and there may be trophic changes in the nails. Arterial pulsation may be absent at any level below the femorals, but inability to palpate posterior tibial and dorsalis pedis arteries does not necessarily mean that the blood supply to the foot is seriously inadequate. The intelligent use of the oscillometer is often helpful in this connexion, and, although it gives no information about the blood supply below the ankle, it is of considerable value in assessing the level of arterial patency above this level. Skin temperature tests are difficult to interpret, but, as one of us (M. M. M.) has shown, when used in conjunction with intravenous vasodilators such as

tolazoline hydrochloride they may be of considerable value in differentiating between arterial occlusion and vasomotor disturbances associated with neuropathy.

X-ray films of the lower limbs for arterial calcification are of little value in estimating arterial sufficiency, but arteriography provides more accurate and precise information than any other single test; it is, however, not readily available in the majority of cases, and is a somewhat specialized technique. The diagnosis of ischaemia can usually be established without the use of this test.

The two main manifestations of ischaemia in the diabetic foot are pain and gangrene; pain may be associated with gangrene or occur independently as the painful ischaemic foot.

Painful Ischaemic Foot.—This clinical condition is almost confined to the old, and usually affects both feet, although not necessarily to the same degree. The affected foot is typically cold, pink, and intensely painful, especially in bed at night. Gangrene of one or more toes may supervene, but is often absent or long delayed.

Treatment

Treatment is most unsatisfactory; vasodilator drugs are ineffective, the only conservative measures of any value being local cooling, analgesics, and hypnotics. Sympathectomy seems to relieve the pain in some cases, but amputation is the only reliable method of treatment, and is often carried out at the request of the patient.

Gangrene

True ischaemic gangrene usually starts in the distal phalanges of one or more toes and is often painless. Purple discoloration leads to the formation of a terminal black patch which tends to extend proximally, and, so long as there is no infection, causes little discomfort to the patient; severe pain is suggestive of a superadded infection. The lesion may remain localized or may, if untreated, spread so as to involve the skin of the dorsum of the foot; when this occurs local surgical treatment must give place to more radical amputation. The single dry gangrenous toe presents a serious problem, and the decision must be made whether to leave the gangrenous area to separate or to remove the toe.

In our experience the former policy carries with it certain definite disadvantages and dangers. In the first place, the length of time required for separation is always a matter of weeks and often months; secondly, there is the risk of extension of the lesion on to the dorsum of the foot; and, last but not least, infection may supervene. Furthermore, if the patient is confined to bed there is the very real possibility that the combination of pressure and ischaemia may result in ulceration of the heels, while the practice of allowing the patient to be up and about exposes the affected area to the danger of trauma and sepsis. For these reasons it is usually wise, in our opinion, to remove the single gangrenous toe by disarticulation, the wound being left open and allowed to granulate; primary suture is undertaken only if the bleeding at operation indicates the presence of a reasonably good blood supply and if the skin edges can be approximated without tension. In this connexion special mention must be made of ischaemic lesions situated over the heads of the fifth metatarsal; these are commonly due to pressure from tight-fitting shoes.

Such lesions present a special problem, as amputation of the fifth toe together with the head of the metatarsal bone often leaves a raw area for which it is impossible to provide any adequate skin cover, the patient being left with a chronic ulcer for which the only effective treatment is amputation of the leg. It is in such lesions that it is vitally important to distinguish between ischaemic and neuropathic ulceration, for in the latter the blood supply is often good enough to allow of the raw area being covered by a skin graft. In the case of the big toe, skin cover presents less difficulty, as it is usually possible to preserve a flap of skin from the

surface of the toe, which can be used to cover the site of amputation. When more than one toe is involved it is generally better to amputate all five toes by separate racket incisions, the resulting foot being functionally sound and rarely a source of further trouble. When the area of gangrene extends proximally beyond the toes on to the dorsum of the foot, local amputations are likely to prove unsuccessful, and amputation of the leg is the only reliable method of treatment. Various types of transmetatarsal and transtarsal amputations have been advocated as a means of avoiding amputation of the leg.

Such operations, in our experience, have seldom proved successful, the reason being that, in order to obtain a functional stump, closure of the wound is essential; such closure can very rarely be made without tension or the risk of tension from post-operative haematoma or sepsis. For some years it has been our practice at King's College Hospital to carry out such amputations below the knee. This operation has almost completely replaced the older practice of amputation above the knee in the treatment of diabetic gangrene, and represents one of the most important advances in the surgical treatment of this condition.

Amputation in the Diabetic

Before describing the technique for below-knee amputation, laid down by Silbert (1944), certain general rules of procedure for amputations in the diabetic subject are worthy of consideration.

(a) Expert general anaesthesia is essential, local analgesia being clearly impossible; we have had no experience of freezing in this connexion, but consider it contraindicated by the devitalized state of the ischaemic tissues. Many patients are bad operative risks and so demand the highest anaesthetic skill.

(b) No sort of tourniquet should ever be used on these limbs at any level or in any circumstances.

(c) Pressure points must be protected before, during, and after the period of anaesthesia. The skin of these avascular limbs is very fragile, and the disaster has befallen us of having a patient submit to amputation only to find, on recovering consciousness, that his hitherto good foot had a black heel. All bony points must be supported on a soft foam-rubber pillow throughout the whole period of narcosis; the ordinary "sorbo" mattress on the operating table is not soft enough.

(d) Tension must be avoided during and after operation. This is the only key to success, and conditions the entire design and performance of the operation. We are convinced that it is tension, often due to over-ambitious attempts at skin suture, which precipitates the so-called post-operative spread of gangrene; such tension must at all costs be avoided.

Below-knee Amputation

In the past eighteen months 50 below-knee amputations have been carried out by Silbert's technique in the diabetic department at King's College Hospital without a single re-amputation or a single death attributable to operation.

The operation is done through a circular incision 7 in. (18 cm.) below the knee. The skin is reflected up very gently for 2 in. (5 cm.) and the muscles are divided by a guillotine incision at this level. Blood vessels are ligated and the dissection continued in the subperiosteal layer until a 4-in. (10-cm.) tibial stump is obtained; the fibula is divided at a slightly higher level. The anterior border of the tibial stump is bevelled, and the soft tissues are allowed to fall down over the cut ends of the bones. The stump is bound up in gauze impregnated with petroleum jelly, the skin edges being turned in over the raw area, and the limb supported on a plaster trough extending well up the thigh. On the tenth day the patient is given an anaesthetic, and the stump is inspected; if there is any doubt about sepsis, healing is allowed to take place by granulation, but if, as usually happens, all is well, a delayed primary suture is carried out. Healing may then be expected in about three weeks.

4. Combinations of 1, 2, and 3

The coincidence of sepsis, neuropathy, and ischaemia presents an urgent and desperate problem which merits special consideration.

The sepsis usually arises in the forefoot where shoe-rubbing is most marked, and, since treatment by rest will involve putting the patient to bed with the foot supported on slings to prevent skin necrosis of the heel, gravity encourages the natural tendency of the infective process to spread into the hindfoot. In the surgical treatment of such an abscess really radical incisions arranged to divert the gravitational flow on to the skin of the sole are essential, and enough bone must be removed to allow the edges of the wound to fall together without tension. In our experience the filling-in of large dead spaces by granulation rarely occurs on account of the ischaemia, and the only hope of preserving the foot lies in obtaining early healing of the skin with an absolute minimum of raw area. We have also found that, if the primary drainage, although apparently satisfactory, proves within a few days to have been inadequate, a useful result seldom follows a second attempt at

FIG. 5.—Spring suspension of lower limbs.

local drainage. Under these circumstances we are convinced that, if there is not good evidence of healing within ten days, a below-knee amputation should be advised to save the patient an indefinite period of pointless suffering. The treatment of suppurative tenosynovitis or web-space infection is so disappointing that signs of sepsis in an ischaemic toe should be regarded as a most urgent indication for local disarticulation; optimistic expectancy will often cost the patient his foot.

Whether the condition be due to neuropathy, ischaemia, or to a combination of these two factors, there is always the danger that, with the patient in the supine position, pressure on the heels may cause blistering, ulceration, or gangrene. For many years this complication has constituted a serious problem in the treatment of lesions of the feet in diabetes, and not a few limbs have had to be amputated on this account. For the past two years it has been our practice to suspend the lower limbs of all such cases (Oakley, 1954), and as a result we have not since had a single serious heel lesion in any patient. Each limb is swung a few inches above the mattress by means of two long springs, such as are used by the physiotherapists, the tension of the springs being 30 to 50 lb. (13.6 to 22.8 kg.), according to position and weight of the limb (Fig. 5). The slings are specially made of canvas lined with orthopaedic felt; a strap attached to the distal sling is passed round the sole of the foot to prevent the development of an equinus deformity. We regard this as a major advance in the management of diabetes with neuropathic and ischaemic lesions of the feet, and believe that this type of suspension should be used as a routine in the treatment of all such cases.

Discussion

From a long and wide experience of the treatment of lesions of the feet in diabetes we are convinced that the most important factors are the age of the patient, neuropathy, and ischaemia; sepsis is usually a complicating factor, and, in the absence of neuropathy or ischaemia, never gives rise to gangrene. Gangrene itself is of two types: one due to a localized arterial thrombosis resulting from trauma in a foot desensitized by neuropathy, and the other to generalized occlusive arterial disease; this second type may or may not be associated with neuropathy, and sepsis may complicate both types.

When the foot lesion is the result of neuropathy, and there is an adequate blood supply to the foot as a whole, local surgical measures with or without skin grafting give excellent results; when, however, there is generalized occlusive vascular disease, local surgery is attended by the serious risk of chronic ulceration, and more radical surgery, such as below-knee amputation, is likely to be required to cure the condition. The close relationship between age and the incidence of foot lesions in the diabetic, and the absence of any such relationship between duration and severity of diabetes, would appear to cast doubt on the generally accepted view that diabetes is itself a common cause of occlusive peripheral arterial disease. The high incidence of neuropathy seems to us to explain, in part at any rate, why lesions of the feet are more common in diabetics than in non-diabetics of comparable age; the susceptibility of the poorly controlled diabetic to staphylococcal sepsis may also be of some importance in this connexion.

Summary

The incidence of lesions of the feet in the diabetic population attending King's College Hospital Diabetic Clinic has been related to sex, age, and duration of diabetes.

Attention is drawn to the importance of neuropathy, alone and in association with ischaemia, as a factor in the production of localized ulceration and gangrene.

The treatment of lesions due to neuropathy and ischaemia is described, and the value of such operations as removal of all five toes and below-knee amputation are emphasized.

A method of protection of the heels in patients confined to bed is described and illustrated.

Reasons are given for doubting the validity of accepting the high incidence of so-called vascular lesions of the feet in diabetes as evidence that this disease by itself commonly causes peripheral occlusive vascular disease.

PITFALLS IN MEDICINE*

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.

Senior Physician to Guy's Hospital

How often are we wrong? One searches in vain for precise information pointing to the error-proneness of physicians, surgeons, and general practitioners. Some indication of consultant fallibility is offered by Scandinavian analysis based on a thousand consecutive necropsies. This reveals 67 completely faulty diagnoses and a higher number of incomplete assessments of the morbid processes during life. Carcinoma of the stomach and bacterial endocarditis in old people rank high in the list.

Mistakes largely due to vagaries of disease rather than to faulty approach by the physician can be traced as a rule to unusual patterns of symptoms—less often to puzzling physical signs.

Misleading Symptoms: Coronary Artery Disease

Rather surprisingly, perhaps, we find coronary artery disease may present in such strange ways, or be mimicked so closely by other conditions, that it provides a formidable pitfall even for those who devote themselves to diseases of the heart. A few case histories may be of interest.

A middle-aged man ran over a common in pursuit of his dog. He was pulled up short by intensely unpleasant pain across the middle of the chest. He walked home slowly, the pain abating in the meantime, but not disappearing until he had rested in bed for two days. Seen by a cardiologist on the second day, he was told he had angina pectoris and probably coronary thrombosis, in spite of a normal electrocardiogram. At the end of a week a further pain seized him in the same position, this time radiating into the left arm. It now fluctuated in intensity, but did not completely disappear even at rest. X-ray examination revealed carcinoma at the root of the left lung.

A man of 52 sought guidance on whether he had angina pectoris. His pain was felt across the chest at the level of the third and fourth ribs. It was constricting in character, never coming on during exercise, of which he took plenty, but occurring only when sitting in his chair. A complete overhaul and an electrocardiogram revealed no abnormality. He died three months later of coronary thrombosis.

Another man of 53 about to re-marry complained of pain on exertion of type and distribution typical of angina pectoris. There were no physical signs of disease and his electrocardiogram at rest and after exercise was normal. He was alarmed by being told that he had angina and must greatly restrict his activities. He married nevertheless and became a father, and had no attacks after the first day of his honeymoon, which was now seven years ago. Presumably fear of inadequacy produced these symptoms, but how is this to be distinguished from such a case as the following?

A man of 58 years was seized with agonizing constricting pain across the chest. He became pale and sweaty and the pulse was feeble and rapid. His blood pressure was 90/60. His doctor diagnosed coronary thrombosis and injected morphine. A cardiologist a few hours later agreed, but noted normal E.C.G. Apart from a little left pectoral soreness next day the man felt well. There was no pyrexia, leucocytosis, or raised sedimentation rate during the following week. The B.P. returned to his normal of 136/72 and

*The second of two Croonian Lectures delivered at the Royal College of Physicians of London on May 1 and 3, 1956. The first lecture was published last week (p. 895).

the electrocardiograms taken on the third and the eighth day were normal. His domestic background was that he had been at loggerheads with his wife for the last 10 years, and the doctor suspected that this might have in fact precipitated an attack simulating organic disease. He was a little short of breath after this seizure, and five weeks later the whole attack was repeated, as also were the normal findings. The obvious alternatives of gall-stone colic and hiatus hernia were excluded. He then went for a sea voyage and felt well, noticing, however, a little substernal tightening if he played deck tennis. Six months after the first attack he was seen in London, where he added to the above history that pain would occur in the usual anginal site if he walked quickly up an incline such as Regent Street. Electrocardiographic tracings failed to show deviation from the normal even after exercise. The general clinical examination revealed no disease. X-rays of the heart were likewise normal. He was told, nevertheless, that he suffered from angina pectoris and was advised to go slowly. He died suddenly in the street three weeks later, thus providing invaluable necropsy evidence. He had an extensive anterolateral infarct of the heart, a slight degree of coronary atheroma, but no sign of earlier infarction and no diffuse fibrosis of the myocardium.

Are his first two prolonged seizures to be attributed to coronary spasm? If not, how can we explain the remarkable course of events? How well this illustrates the enduring value of diagnosis based on symptoms in the face of contradictory instrumental revelations.

A different outcome is shown by a woman of 54 years who on exposure to cold winds, hurrying to catch a bus, or walking sharply after a meal, noticed what she described as a tight pain under the mid-sternum. She would then stand still, belch and recover, but if she walked quickly the pain would recur. A full clinical examination was unrevealing. The electrocardiogram was normal. She stressed that the pain never occurred except under the conditions I have mentioned. Angina pectoris was then diagnosed, but with a cautious afterthought that it was unusual in the female. This led to a cholecystogram which revealed gall-stones. Her appetite was unimpaired; she enjoyed rich food and never suffered from flatulent dyspepsia. Surgery has cured her.

Although the association of gall-bladder disease and angina has been recognized for half a century, it is seldom that such whole-hearted mimicking is encountered. Had the patient been a man it is doubtful whether the cause would have been searched for.

A retired bank manager of 62 suffered from recurrent pain in his front teeth. His doctor and dentist rendered him edentulous. He then had the pain in the jaws. The presence of pyorrhoea and lack of care in anamnesis directed attention to the wrong part of the body. In fact, the pain occurred only when he rolled the lawn, and was clearly anginal. The only occasion when it was felt in the chest was in the final fatal attack.

Here I will leave coronary disease, with a reminder in passing that spells of faintness or dizziness in old people are as often as not due to bundle-branch block and not, as is commonly supposed, to cerebral arteriosclerosis.

The Appendix

Passing to the digestive system in search of strange symptoms, we find, possibly with surprise, that appendicitis heads the list. The classical symptoms and signs of the disease are so well known that, when present, diagnosis is immediate; but what is not fully appreciated is that this organ may give rise to the most diverse and misleading symptoms with but few physical signs—for instance, pyrexia of unknown origin, ushered in with a little diarrhoea may be traced to a retrocaecally placed inflamed appendix. To this I would add two other examples.

One of these is a septicaemic variety in which the appendix lies in the pelvis, the offending organ being thus difficult

to affect by palpation through the abdominal wall. The onset of slight and transient abdominal discomfort, followed by swinging temperature, sweating, leucocytosis, shivering and rapid pulse, may well be all for several days. Rectal examination does not necessarily help at first. It is only by dogged perseverance and re-examination of the patient that the answer may be revealed, remembering always that the first symptom of a disease is, as a rule, the most helpful in elucidating the cause. Usually by the fifth day there is obvious tenderness on rectal examination. At operation one may find the appendix lying in the pelvis with a little serous effusion around it and thin vascular adhesions which have not adequately shut it off from the peritoneal cavity.

The other peculiar position of the appendix which causes trouble is when that organ runs upwards along the side of the ascending colon and, if unusually long, is actually attached to the liver or gall-bladder or to the transverse colon. In this position the inflammation causes severe high epigastric pain with tenderness over the gall-bladder, thus leading to the diagnosis of acute cholecystitis. Here a clue to the true nature of the trouble may be given by studying the course of the pain as it subsides. It usually moves downwards towards the right iliac fossa, whereas gall-bladder pain never moves in this direction.

Appendicular colic in the adult is diagnosed more often than not as colon spasm. The sudden intense pain felt across the mid-abdomen, lasting for perhaps half an hour and leaving no trace in its wake, is not readily explained. Only if the patient is seen in an attack is tenderness at McBurney's point likely to be found. The bouts occur at irregular intervals, often of long duration, and the complete freedom from discomfort between seizures lulls the practitioner into a sense of false security. Eventually the condition reveals itself by a frank attack of appendicitis, but not necessarily in less than several years.

A physician well known for his care and sound judgment told me that of 60 persons whom he had regarded confidently as sufferers from colon spasm no fewer than nine proved in fact to be suffering from appendicular colic and achieved cure through surgery.

Pancreas

Next to the appendix, the pancreas provides the majority of intra-abdominal pitfalls for the unwary, or indeed for the wary. The diagnosis of carcinoma of the head of the pancreas is usually a simple matter, because it is so commonly associated with increasing jaundice in the absence of pain. Occasionally, however, the common bile duct is not occluded by carcinoma, and a vague deep-seated discomfort may be the sole symptom to draw our attention to the abdomen. An x-ray film of the alimentary tract may be revealing to eyes which are trained to look, in that the loop formed by the duodenum is appreciably widened by the growth.

More difficult and more common problems associated with the pancreas, however, are presented when the carcinoma develops in the body. Here we have backache as a sole symptom, and it may be the only one for many weeks or even months before the true nature of the disease is clear. It has a peculiarly distressing boring nature and is felt in the upper lumbar region, although occasionally it is experienced between the shoulder-blades. It is not obviously affected by movement and does not as a rule radiate in any direction. It is just a persistent unpleasant backache felt day and night. Tenderness of the vertebrae is not present, neither is there abdominal tenderness. X-ray films of the spine and alimentary tract are normal. Examination of the stools is usually fruitless, and it is quite likely that the serum amylase will be found to be of normal value. No wonder, then, that so many of these patients are regarded as neurotic, and only later, when they start to lose weight or develop metastases in the liver, or when the growth spreads along to the head and causes jaundice, is

the organic cause of their symptoms apparent. Sometimes the growth spreads in the other direction, through the tail, and we may be faced with the puzzling condition of a deep-seated abdominal pain and an enlarged spleen. Enlargement of the spleen is due to direct involvement of that organ with growth or to invasion of the splenic vein. Direct spread from pancreatic carcinoma may be upwards towards the diaphragm and produce pain in the lower chest or even in the shoulder and downwards behind the peritoneum, so that it may in fact cause, as a presenting symptom, sciatica. It is fortunate that these symptoms and signs are associated with a disease for which little can be done in any case.

A woman of 60 was troubled with bouts of copious vomiting unaccompanied by pain. There was no recognizable pattern to her emesis, for it might occur twice in one day and then disappear for three or four days. An x-ray examination after a barium meal gave no clue to the nature of the trouble. There was no blood in the stools. Opinions on her condition were sharply divided. In the bouts she presented a picture of pyloric obstruction, and she had in fact lost weight. At this stage she was admitted to hospital under a physician who was much drawn to the study of psychosomatic disorders. On more than one occasion she was demonstrated as a classical case of hysterical vomiting. Later, under another influence she was subjected to laparotomy, and an unusual cause for such seizures was found. It was carcinoma which had so enlarged the head of the pancreas that its pressure produced obstruction, varying no doubt with her posture, of the second part of the duodenum.

Neuroses of the Digestive System

From time to time we meet patients who suffer from flatulent dyspepsia, a feeling of distension after food, and on occasion attacks of quite severe pain in the epigastrium which come on suddenly and which may last for two or three hours and then pass off, leaving a certain soreness in the upper abdomen. Sometimes, the next day, they are a little jaundiced. They are usually women, commonly in the late thirties. Examination between attacks will reveal some tenderness in the usual position of the gall-bladder, and in an attack it may be extreme.

It is not surprising that a diagnosis of cholecystitis and probably gall-stones is made, yet a normal cholecystogram may render this improbable. These patients form a section of a large and interesting group of individuals who do appear to suffer from spasm, here and there, of the various viscera. I have already mentioned that this diagnosis is a dangerous one, and we should be constantly on our guard against attributing to simple spasm what may be due to some serious disease. If there should be a history of headache, and if it be typically migrainous in character, then it is not far-fetched to attribute the condition to abdominal migraine. Presumably the fact that jaundice occasionally follows indicates that there is a true spasm of the sphincter causing a temporary hold up in bile flow.

Far more common than these cases of apparent cholecystitis are the bouts of colon spasm. It is wise to be chary of such a diagnosis unless the attack is felt on the left side of the abdomen, and unless, in a bout, the colon has been felt to be a hard, tender cord. It is unusual for colon spasm to involve the ascending colon, and only a little more usual for it to affect the transverse colon. We must never forget that the gut may go into spasm as the result of underlying disease. There is a form of spasm which can provide a great diagnostic difficulty. This is a ring contraction of the colon.

A middle-aged woman, known to be of anxious temperament but hard-working and capable, was seized with obstinate constipation, colicky abdominal pain, and inability even to pass flatus. Purges had been found unhelpful, and an enema had been returned uncoloured. Examination showed distension of the abdomen, a typically large intestinal distension, and an empty rectum. A

diagnosis of acute obstruction was made, the cause probably being diverticulitis or carcinoma. A barium enema showed a ring constriction about the level of the anterior superior spine on the left side which was confidently diagnosed as a string carcinoma. Nevertheless, the suddenness of onset without previous history is so uncommon in carcinoma that the surgeon in charge refused to be panicked into operation and ordered the administration of a bile enema. This resulted in copious emptying of the bowel, and a later x-ray examination showed a completely normal gut.

The reverse of the picture was provided by a man of 60 who had been having attacks of left-sided abdominal pain, colicky in nature, associated with intermittent constipation. He did not pass blood or mucus. The history was very suggestive, therefore, of partial obstruction of the large gut. Carcinoma was diagnosed on the symptoms, although the physical signs were unrevealing. A barium meal was given and followed down into the large intestine. At the junction of the descending and iliac portion there was some narrowing and hold-up of the meal, but a little had trickled through distally. No obvious irregularity pointing to growth could be observed. The radiologist's view was that this was suspicious but that he could not commit himself without a barium enema. This was carried out and the colon seen to fill well. The man was told that he had colon spasm. A month later he was seized with acute pain which was due to perforation of the large gut above a carcinoma of the colon.

This example illustrates the value of a clinical appraisal as opposed to specialized investigation, and also sets at naught the argument used by some radiologists that it is pointless to follow the barium meal beyond the ileo-caecal region, in that reliable information about the colon can be obtained only from a barium enema. This is utterly false, because they do not take account of the effect of a large amount of barium on the gut. When it is run into the colon it acts powerfully as a distensor, and an irregularity such as was shown in this case when the barium reached the bowel by the normal route is completely obliterated by hydrostatic pressure. The man's life could have been saved if that point had been appreciated.

Gall-bladder

The gall-bladder, like the appendix, has by no means a constant position in the abdomen, although it is less capable of wandering than is the latter. When it is in its customary position, inflammation or stone will as a rule produce the typical symptoms and signs. At other times, however, it lies a long way lateral to its usual point and may give rise to pain, not across the epigastrium, but well to the right side. Although visceral pain is usually felt fairly symmetrically across the middle line, at times the inflammatory process causes it to coincide with the actual position of the organ by involvement of the parietal peritoneum. Thus a gall-bladder placed laterally, the fundus lying approximately in the continuation of the anterior axillary line, is especially prone to cause acute pain in the right side of the chest aggravated by breathing and suggestive of pleurisy. As there is associated inhibition of the diaphragm, it is only a matter of an hour or two before impairment of resonance over the right lower lobe can be detected, as the result of the air's being rapidly absorbed from the partially immobilized lung. The physician may therefore be faced with a patient breathing rapidly and shallowly, clearly in pain, with diminished movement of the right side of the chest and impairment of resonance, and tenderness over the tip of the eleventh rib. It is not unknown for him to make a diagnosis of pneumonia with diaphragmatic pleurisy, when in fact the basic lesion lies in the abdomen. For the first 24 hours it may be extremely difficult to make a diagnosis on clinical grounds, and an x-ray film of the lungs will also be of no help in distinguishing this manifestation of cholecystitis from pneumonia. Acute pneumonia does not necessarily show in an x-ray picture in the first 24 hours. From then on the diagnosis becomes easier because there is an

absence of the normal adventitious sounds one would expect in a right basal pneumonia, the respiration rate tends to fall rather than to rise after the initial acceleration, there is no flushing of the face, and indeed jaundice may appear.

Gall-bladder disease may simulate so closely that of coronary thrombosis as to present an obstacle to diagnosis. This is especially so if the organ be medially directed. The pain may be constricting in nature and felt across the lower third of the chest and not in the abdomen at all. The patient will probably be of the same build and age that commonly is affected by one or the other disease. He may well be pale, sweaty, and vomiting in either. The blood pressure and pulse may not be affected by coronary thrombosis for several hours. When it comes to examination of the abdomen there will be tenderness over the area of the gall-bladder, but in acute coronary thrombosis there may be sudden congestion of the liver with expansion and stretching of the capsule. The distinction between liver and gall-bladder tenderness is not easy to recognize in an individual groaning in pain. On paper the differential diagnosis is easy; in practice it has felled more than one expert physician and surgeon. It should be remembered that there is a practical side to the differential diagnosis, because nowadays the treatment of acute cholecystitis is highly effective by the use of suitable antibiotics, whereas the administration of morphine is unwise when we bear in mind that its normal action is to cause a great rise of intrabiliary pressure.

Diaphragmatic Hernia

Heartburn, for many years an inexplicable form of indigestion, we now know to be more often than not due to reflux of acid contents into the oesophagus as the result of hiatus hernia. The fact that this has been overlooked for so long is as much of a reproach to physicians and radiologists as the inability to grasp the mechanical nature of sciatica was a discredit to us and the orthopaedic surgeons. Nowadays this presents no particular pitfall except by confusion with the phrenic ampulla. The para-oesophageal hernia is still providing a number of diagnostic mistakes in respect of anaemia. This form of hernia is often associated with a high-grade hypochromic or, rarely, a normochromic anaemia, which will on occasion respond to full doses of iron but sometimes is most intractable until surgical correction of the abnormality has been performed.

Peptic Ulcer

I shall not dwell on peptic ulceration, for the features of this condition, whether in the oesophagus, stomach, or duodenum, are well known, although perhaps it is not so widely appreciated, except by those who have practised our art for many years, that the distinction between gastric and duodenal ulcer on clinical grounds is not nearly as easy and straightforward as is suggested by the textbooks. I would like to refer to an extraordinary reflex from duodenal ulceration which I have met only five times in a series of 800 cases, and that is pain felt entirely in the lower abdomen but relieved by food and present when the patient is hungry. These patients have been trustworthy witnesses. There was in fact no suspicion of epigastric pain. Pain in two was felt in the hypogastrium, in three in the left iliac fossa. The explanation, I think, is revealed by the finding in these three, by x rays, of a ring spasm of the descending colon which was extraordinarily persistent. The barium had been taken by mouth, and when this spasm was seen the stomach was empty; when the patient was given a glass of milk to drink the abdominal pain vanished and signs of spasm also disappeared. When there was a relapse in two cases the spasm recurred. We are familiar with a reverse form of reflex in which acute lesions of the large gut cause pylorospasm and vomiting, but that which I have just described can be claimed to be a rarity.

Only twice in thirty years have I seen obstructive jaundice caused by a chronic duodenal ulcer. In one example the diagnosis was suggested by an associated profuse melaena

which had been attributed to the haemorrhagic tendency induced by such icterus. In point of fact obstructive jaundice never gives rise to appreciable melaena.

In both cases the common bile duct was found to be greatly distended, a state which was shared by the gall-bladder. The ulcer was close to the junction of the first and second parts of the duodenum, though in the former. The obstruction was not due to invasion of the bile papilla but due to inflammatory thickening and oedema of the gut wall. It is surprising that this is not commoner.

Diarrhoea

The symptom which is the most difficult to associate with a firm diagnosis at a single consultation is diarrhoea. Of the serious causes carcinoma comes to mind, and it is particularly the growth which is difficult to discover which is most likely to cause it without pain and without the passage of blood and mucus obvious to the naked eye. Carcinoma of the caecum seems singularly evasive to radiological investigation. From time to time a lump may be felt in the right iliac fossa, but on other occasions this sign has disappeared and the physician is apt to assume that he has just felt a loaded caecum, and an opportunity for a life-saving operation is lost.

No unexplained case of diarrhoea should be allowed to pass from observation without the most careful examination, and if all appears normal except for persistence of occult blood we should not shrink from laparotomy. If the diarrhoea be associated with anaemia the diagnosis of carcinoma in this position is made highly probable. In fact, the presenting symptoms here may be shortness of breath with pallor, only trivial reference being made to loose stools. Taking, however, the cases of diarrhoea as the only presenting symptom—that is to say, where no pain is felt—although occasionally we find the cause lies in uraemia or Addison's disease, the majority prove to be simply those of intestinal hurry. My impression is that this is increasing and possibly is associated with the apparent increase in states of anxiety which we see.

The story, then, is usually that for many years the stools have tended to be rather on the loose side and to occur especially on rising in the morning and perhaps once or twice after breakfast; there is peace for the rest of the day. As years pass the diarrhoea becomes a little more frequent, there is no associated anaemia occurring after all meals. There is no associated weight loss, but there is a feeling of exhaustion. Radiological examination by barium meal will show a remarkably rapid transit of barium from mouth to anus. The stomach is usually hyperactive, emptying itself in a quarter to half an hour, the caecum is reached in anything from half an hour to three hours, and the barium arrives at the splenic flexure a short time afterwards. As a rule these patients are not suffering from any profound disturbance of the psyche, but are those of intense personality, ambitious, hardworking, never relaxing in mind, and seldom taking exercise for the body. They carry their problems home with them and their work occupies them at week-ends. When they go on holiday they take the unwise of all—namely, in car-driving from one part of the Continent to another. In the minority we trace the matter to gnawing anxiety, which seems to reflect itself on the alimentary tract. Apart from dealing, if one can, with such underlying anxiety, the physical approach to this, which is nearly always successful, is the administration of one of the many drugs that will delay the rate of passage through the alimentary tract. Of the traditional remedies a combination of hyoscyamus and codeine will often prove effective, and in the more stubborn cases the powerful parasympatholytic agent tricyclamol will succeed.

Prognosis and Misleading Physical Signs

Failure in respect of prognosis dogs us throughout our professional life. This must always be so, for there are too many imponderables influencing the course and outcome of a disease to allow of accurate forecasting. Although a

fair degree of certainty can be expressed in relation to carcinoma of the stomach, motor neurone disease, pneumonia, and many other afflictions, cardiovascular diseases vary so greatly from patient to patient in their lethal power that it is wise to be a little vague and usually to lean towards optimism. Statistical evidence is singularly unhelpful in assessing the individual problem. My impression is that the physicians of the earlier generations who relied solely on experience and their five senses were far more accurate in their prognoses than most of us who practise to-day.

A remarkable example of prognostic failure was occasioned by a business man highly successful in his financial dealings, aged 59, limited in activity by virtue of visual defect, happily married, and living in comfort. He developed headaches, drowsiness, thirst, occasional loose stools, nausea, and loss of weight. His doctor, who examined him, found that the urine was of fixed low specific gravity (1004); it was loaded with albumin and contained some granular casts. The blood urea was 76 mg. per 100 ml., rising in a month to 110 mg. The blood pressure had risen from his normal of 150/80 to 190/106. The urea clearance test revealed 18% of normal function. He concluded that his patient had chronic nephritis, a view which was endorsed by the consultant to whom he brought the case. In the course of the next three months the symptoms became worse. Albumin was found in considerable quantity in nearly all specimens of urine. A bad prognosis was given. It was thought that the patient would die within the next three months. He was instructed in the traditional lines of dieting for chronic nephritis, and he followed these with care. After a week or two he asked his doctor if the consumption of Worcestershire sauce was in any way harmful. It seemed that he had been taking from half to one bottle of it daily for many years. He said he did so because he liked it. Whatever the reason for his consumption of this enormous quantity, the fact remains that he did take it as a beverage. It was promptly stopped. Within a month the albumin and casts disappeared, the blood pressure and the blood urea had returned to normal, the patient rapidly put on weight. Two years afterwards, he is symptomless, and the only sign of latent renal disease is occasional albuminuria. So far as I know, this is unique. It is, I think, an error in prognosis which might be forgiven.

Lumps in the upper left quadrant of the abdomen cause more trouble in diagnosis than masses elsewhere in the body, not only to the inexperienced but to physicians and surgeons of many years' standing. A slowly enlarging mass appearing from under the left costal margin, dull to percussion and seeming to have a well-defined edge, often proves to be a retroperitoneal sarcoma. The absence of a notch is a small point—that is to say, the finding of a notch stamps it as a spleen, or usually does, although I will give you an example in a moment where even this fails. Even in considerable splenomegaly it is not always possible to feel it. Furthermore, a very large spleen can be felt bimanually, the other hand being in the loin, and confusion with an enlarged kidney is readily made. It is a matter of interest to observe how few candidates for the Membership recognize polycystic kidneys, usually calling the left one spleen and the right one an enlarged liver.

A woman who had suffered from pernicious anaemia for many years started to go downhill, to become anaemic in spite of the usual treatment, and to lose appetite. She was known to have had a gastric ulcer many years previously. On examination, apart from signs of anaemia, she was found to present a lump which emerged from the left hypochondrium and which moved with respiration. It was firm to the touch and not completely dull, but had not the resonance of gut or stomach. It could not be felt in the loin and there was a notch on the inner border. It was postulated that this was a spleen enlarged from pernicious anaemia, which had escaped control owing to a faulty preparation of liver. I should add that this case dates to the days when only liver injections were available and were of varying quality. In spite of changing to more recent and highly potent preparations, she continued to go downhill

and the lump increased in size to an extent never met with in a spleen of pernicious anaemia. To cut a long story short, she had a carcinoma of the stomach. The point of special interest here is that at necropsy it was found that she had, as it were, a notch in the stomach, and it had been produced by cicatricial contraction arising as a result of a chronic gastric ulcer which had healed years previously and thus simulated the general structure of the spleen. This is a difficulty which is not likely to be met often.

A young man fell from his motor-cycle and cut his leg. His doctor administered antitetanic serum. Ten days later the patient noticed stiffness in the movement of his jaw, and pains and muscular aching in the back and limbs. The onset of all symptoms was simultaneous: this highly significant fact was overlooked at a hospital where he was given antitetanic serum intravenously on the strength of a misdiagnosis of tetanus. He died promptly of anaphylactic shock.

The confusion between serum sickness and tetanus is by no means uncommon, though fortunately not as a rule leading to such a lethal result.

The physical signs presented by changes inherent in old age will from time to time mislead the unwary. Petechial haemorrhages, anaemia, tremor, albuminuria with casts, bouts of giddiness, to mention but a few of the common manifestations of advancing years, are apt to lead the less experienced into searching for some far more serious cause than the march of time. We must remember also the great frequency with which degenerative changes occur in the spine in individuals over 50, and in fact with every ten years of age after that period of life the incidence of spondylosis mounts very rapidly. Although modern work has revealed the remarkable manifestations which may be directly due to cervical spondylosis, many of them in the neurological field, I observe here the same overswing of diagnostic enthusiasm that we met in connexion with the lumbar disk lesion. In the last year I have seen attributed to cervical spondylosis such diverse conditions as intraspinal tumour, senile tuberculosis of the spine, motor neurone disease, carcinoma of the stomach with metastases in the spine, and poliomyelitis.

Conclusion

I have purposely refrained from discussing failure to recognize rare diseases—in the first place because, for obvious reasons, this is uncommon, and, secondly, because it provides no help in facing the problem of rarities encountered in the future.

Lurking, however, in the diagnostic undergrowth are traps set by the appearance of well-known physical signs, which are usually, but not always, associated with readily recognized diseases. The examples which come to mind are atrial fibrillation as the first sign of bronchial carcinoma, and the clinical picture of Cushing's syndrome from the same cause.

Idiopathic thrombophlebitis migrans is very rare, but the accepted physical signs may be perfectly reproduced by metastases in the venous walls. This so often proves to be the case that every apparent example of the disease should be searched for primary growth, which in instances I have witnessed occurred in bronchus, pancreas, and rectum. Thrombophlebitis migrans may also herald in its recurrences over several years the ultimate development of thromboangiitis obliterans, just as the reverse process may be seen. In fact, a clear-cut distinction between these arterial and venous inflammatory states is no longer tenable.

Self-criticism is far more important than criticism of others, for, although we may learn by their mistakes, to criticize them directly or obliquely in the presence of colleagues or patients is surely the one unforgivable sin.

Criticism, writes Matthew Arnold, is a disinterested endeavour to learn and propagate the best that is known and thought in the world.

It is in that sense that I have endeavoured to pay tribute to William Croone.

DEVELOPMENT AND EVALUATION OF A POROUS SURGICAL DRESSING

BY

Manchester

This paper discusses the properties required of the ideal surgical dressing and describes the development, laboratory investigations, and clinical trials of a new dressing which largely meets the requirements.

Minor skin injuries result in a major national problem both in industry and in the home. It has been estimated that in this country nearly half a million skin injuries occur each day which require at least a first-aid dressing (Squire, 1951), but it is not possible to determine the working time lost and the inconvenience caused by lacerations, abrasions, incisions, puncture wounds, and small burns, particularly those minor injuries which occur and are treated in the home. The healing time of a wound is dependent on many factors, not the least of which is the type of dressing employed.

The functions of a dressing are to allow a coagulum to form and so prevent loss of tissue fluid, to protect the wound from further injury while it is healing, and to prevent infection.

When the epidermis is penetrated, damage of the dermal blood supply occurs, with loss of blood to a greater or less extent. Loss of tissue fluid by itself can result through damage of the deeper layers of the epidermis. Hartwell (1955) confirmed the view of Arey (1936) that the healing of human wounds depends primarily on the migration of the cellular elements of the epidermis across the damaged area, division of cells of the basal area of the epidermis being only of secondary importance. This migration of cells is dependent on a healthy dermal layer, free of infection and debris. Sepsis may ensue, following the introduction of organisms at the time of injury, by the passage of infected material through the dressing, during dressing procedures, and from the skin surrounding the wound. Dehydration of the protoplasm of the epidermal cells is essential for proper keratinization. It is important that wound dressings allow the evaporation of water vapour from the wound area. Beneath a dressing a considerable quantity of water can accumulate which arises (a) from the sweat glands of the skin surrounding the wound; (b) from normal insensible water vapour loss due to its transudation through the epidermis and from the dehydration of epidermal cells; and (c) from loss of tissue fluid from the wound itself.

Burch and Winsor (1944) showed that 1.63 g. of water is lost per square metre of the body surface every 10 minutes at a relative humidity of 50% and with an

*Now working at the Institute of Psychiatry, Maudsley Hospital, London.

ambient temperature of 24° C. This would represent approximately 235 g. per square metre per 24 hours. They also found that the loss of tissue fluid from the floor of a blister raised by cantharides is nearly 10 times greater. Thus, from their figures, a dressing would need to have a porosity of 2,350 g. per square metre per 24 hours. This high porosity is, of course, needed only for that small area of the dressing which corresponds to the area of the wound. Bloom (1945) used waterproof vapour-permeable "cellophane" in the treatment of war wounds and stated that secondary infection was prevented. Bull, Squire, and Topley (1948) showed that if normal skin was covered with a dressing of a water-proof but vapour-permeable "nylon"† film, and the seal between the dressing and the skin was maintained for three days or more, *Staphylococcus aureus* could not be recovered from the area under the porous part of the dressing and that maceration of normal skin was prevented.

Schilling, Roberts, and Goodman (1950) reported that wounds covered with the nylon† film dressing healed more quickly than comparable wounds covered with an occlusive dressing. They left the nylon† dressings *in situ* till healing occurred, but changed the occlusive dressing after the first three days and then daily. Heifetz, Lawrence, and Richards (1952) noted that considerable epithelial debris accumulated under dressings after the third day, and they suggested that keeping dressings on for longer periods might have an adverse effect on wound healing. We have found that the healing rate of a wound appears to be delayed if the dressings are not changed after the first 24 hours following injury.

Properties of Ideal Dressings

The ideal dressing, which may be a composite structure—that is, a covering film plus a pad—should possess the following properties (Scales, 1954). (1) It should have a high porosity to water vapour, preferably at least 1,400 g. per square metre per 24 hours, measured at 37° C. with a relative humidity of 75% (P.A.T.R.A. (1948) tentative standard method). (2) It should not adhere either to blood clot or to granulating surfaces, nor should it allow the penetration of capillary loops. It must, however, absorb free blood or exudate and give "protection" to the wound. (3) It should be a barrier to the passage of micro-organisms. (4) It should be capable of following the contours around a joint during movement—for example, flexing of a finger. (5) It should be unaffected by domestic or industrial fluids—for example, detergents and oils. (6) It should not produce a tissue reaction when applied to normal skin or granulating surface, nor a state of allergy or hypersensitivity. (7) It should be non-inflammable. (8) It should be capable of being sealed to the skin. (9) It should be capable of being sterilized. (10) It should be available at a low cost.

The properties which the dressing should possess depend on the extent of the loss of the epidermal cell layer and of the damage to the dermis, and the events that occur following injury and during healing of a wound. With present materials it is impossible to produce the ideal dressing and it seems likely that future dressings will be a compromise. The dressing described in this paper has certain properties not possessed by any existing dressing. Plastic film dressings have certain advantages over traditional fabric dressings, but they also possess certain undesirable features—for example, the occlusive waterproof dressing causes maceration of the skin surrounding the wound and an increase in the bacterial flora of normal skin. Both nylon and cellophane are insufficiently permeable and flexible.

†Imperial Chemical Industries Limited C109/P nylon.

Microporous Polyvinyl Chloride Film

For some time a rigid microporous polyvinyl chloride sheet containing intercommunicating cavities has been manufactured as a separator for lead-acid batteries and as a filtration medium. Its porosity can be readily varied from 40 to 6,000 g. of water vapour per square metre per 24 hours at 37° C. and 75% relative humidity, by varying the particle size, the quantity of the filler, and the method of manufacture. The sheet is manufactured by incorporating a pore-forming ingredient such as starch or salt into the plastic mass prior to extrusion of the sheet. This pore-forming agent or "filler" is then removed, leaving a structure the porosity of which depends on the number and size of the intercommunicating pores between the cavities.

A microporous film which has been made flexible by the incorporation of a plasticizer and having a porosity of the order required for dressing purposes is unlikely to be a perfect bacterial filter under all conditions. The filler would have to be of a constant particle size and shape and be evenly dispersed throughout the plastic mass. If the pores are less than 1.5 μ , due to a molecular film of plasticizer on the surface of the pores, adhesion of the walls may occur with loss of porosity. Flexing and stretching of the film will also alter the dimensions of the pores. Owing to the large surface area exposed by a microporous structure, the usual phthalate type plasticizers were found unsuitable as they migrate into the adhesive mass and are removed by detergents and solvents. The dressing-film described is plasticized with a polymeric plasticizer—polypropylene sebacate.

Determination of Permeability to Water Vapour

The water-vapour permeability of the film was determined by the gravimetric dish method. Dishes containing anhydrous granular calcium chloride (mesh 10–14) were covered by a known area of the film and weighed. They were placed in a humidity cabinet at 37° C. and 75% relative humidity, with a wind speed in excess of five miles an hour. The rate of transmission of water vapour was found from the rate of increase in weight of the desiccant.

At 37° C. and 75% relative humidity the vapour pressure is 46 millibars. Since the atmosphere between the film and the desiccant is nearly dry, the water-vapour-pressure gradient across the film approximates to that given below for January.

The average atmospheric water-vapour pressure in January at 4.4° C. and 80% relative humidity is 6.7 millibars. In July, at 16.7° C. and 60% relative humidity, it is 11.4 millibars. Thus the water-vapour-pressure gradient across the dressing would be 44.6 millibars in January, and 39.9 millibars in July.

It has been found that there is a linear relationship between the permeability of the porous film and the relative humidity at a constant temperature.

The values for the porosities of the films used in the experiments are expressed as the number of grammes of water vapour which pass through a square metre of the film at 37° C. with a relative humidity of 75%, or a water-vapour-pressure gradient of 46.6 millibars.

Types of Dressings Used in Clinical Trials and Laboratory Investigations

Eighty different batches of material have been investigated in the development of this film. Only certain aspects of three of these are reported in any detail here. No. I was used in the investigation on normal skin flora and for the laboratory tests, and Nos. II and III were used in the clinical trial on wound healing. The porosities of these films are given in Table I.

An assessment of the value of dressings using these films was made by comparing them with a standard waterproof

TABLE I

Dressing	Porosities of Dressing	Film Ref. No.
I	1,400-1,800*	M.P.F. SNB/739/1
II	2,300-2,900	M.P.F. Film SN
III	1,000-1,500	M.P.F. Film SNA
IV	38-43	O.F. standard waterproof occlusive (control)

* A dressing with a porosity of 1,400-1,800 is now being marketed by Smith and Nephew Limited under the name of "elastoplast airstrip."

dressing of the type approved by the Chief Inspector of Factories. This occlusive dressing, No. IV, was completely spread with adhesive and had a base film of polyvinyl chloride plasticized with dibutyl phthalate; it was found to have a very low porosity.

Fig. 1 shows a porous dressing. The adhesive is spread in the form of a lattice which occludes approximately 50% of the porous film. It has been found technically very difficult to produce a dressing with the portion of the film beneath the pad free from adhesive. Thus the actual porosities of the film before they are lattice spread are approximately double the values quoted. All dressings carried a bleached knitted cotton interlock pad. For the investigation on normal skin flora half the number of dressings used were impregnated with 0.1% domiphen bromide B.P.C. Domiphen bromide has not been shown to produce any tissue reaction, allergy, or hypersensitivity reaction when applied to skin or minor wounds, and is itself a mild antiseptic in the concentration used. A trace of auramine was included to colour the pads yellow, so that those impregnated could be easily differentiated from the unimpregnated. This substance, in the dilution used, has been shown to have no bacteriostatic or bactericidal action. In the clinical trial the pads of all dressings were impregnated.

Effectiveness of the Dressing as a Bacterial Barrier

Sterility of Dressings

With the exception of those used in the clinical trial all dressings were sterilized by electron irradiation with a dosage of two mega rads, using a Van de Graaf electrostatic generator. The dressings are taken on a conveyor belt under the scanned electron beam. The output of the machine is sufficient to allow the required dosage to be given in about one second. This treatment seems to have no effect on the physical or chemical properties of the constituents of the

FIG. 1.—A, Pattern spread microporous dressing. (M.P.F. of text.) B, Standard occlusive waterproof dressing. (O.F. of text.)

dressing. Samples of each type were incubated in nutrient broth for four days at 37° C. No growth was obtained from any of the 35 samples tested. The dressings were sterilized by this method because half of them contained no domiphen bromide.

In the clinical trial non-irradiated dressings with impregnated pads were used. Twenty representative dressing pads were tested and found to be sterile.

Filter Test. Method I

The porosity of the microporous film dressing used was between 1,400 and 1,800 (film No. I) and that of the standard waterproof occlusive film between 38 and 43 (film No. IV). Both types carried impregnated pads. The apparatus was sterilized and set up as shown in Fig. 2 A with 2 ml. of sterile broth in the chamber. The outer surface of the dressing was contaminated by: (1) A swab dipped in 1:100 dilution of an 18-hour culture of the Oxford staphylococcus (8 tests, 4 with No. I and 4 with No. IV). (2) A swab dipped in 1:100 dilution of an 18-hour culture of *Ps. pyocyanea* (4 tests, 2 with No. I and 2 with No. IV). (3) A swab dipped in 1:100 dilution of an 18-hour culture of *E. coli* (2 tests, 1 with No. I and 1 with No. IV). (4) A wound swab infected with *Staph. pyogenes* and *Ps. pyocyanea* (2 tests with No. I). (5) A wound swab infected with *E. coli* (2 tests with No. I). (6) A swab of the scum from a washing-up basin (2 tests with No. I). (7) A swab of floor dirt (2 tests with No. I). (8) Coughing directly on to the exposed surface of the dressing (2 tests with No. I).

The tubes were incubated at an angle of 45 degrees in a moist atmosphere at 37° C. for 18 hours. The inner surface of the dressing-pad was then swabbed and plated, and the dressing-pad removed and dropped into sterile broth and incubated for 48 hours.

Results.—It was found that most of the broth diffused through the microporous film, though the dressing remained firmly adherent to the flange, but not at all through the waterproof dressing. No recovery of test organisms was obtained from any pad or pad swabbing. This test was designed to produce in a crude fashion the contamination to which hand dressings might be exposed. The number of tests of this nature was small (24 in all), but showed that under these conditions the microporous dressing acted as a bacterial barrier.

FIG. 2.—A, Glass filter, used in method I, with dressing on flange. B, Stainless steel apparatus, used in method II. Dressing clamped between two flanges, held together by toggle clamp.

Filter Test. Method II

In this test the conditions were far more stringent. The dressing was clamped between the flanges of two sterile stainless steel chambers, fitted with taps through which samples from either side of the membrane could be taken. Then 10 ml. of sterile broth was placed in the chamber on the pad side of the dressing and 10 ml. of an 18-hour culture of the Oxford staphylococcus in the chamber covering the outer surface of the dressing. The assembled apparatus (shown in Fig. 2 B) was incubated in a horizontal position at 37° C. Samples were taken at hourly intervals from the chamber containing the sterile broth. These were plated and examined after 24 and 48 hours' incubation at 37° C. Tests were made with No. I dressing carrying impregnated and non-impregnated pads.

— No growth. + Recovery of test organism.

Results.—From Table II it can be seen that the No. I dressing in this experiment acted as a barrier to the passage of the Oxford staphylococcus for a period of seven to eight hours. (The domiphen bromide appears to have played no part in these experiments.) The broth acted as a wetting agent on both surfaces of the film. In neither of the tests was movement of the film possible. When a layer of cotton interlock impregnated with 0.1% domiphen bromide is substituted for the microporous film, organisms are recovered from the "sterile" side of the filter from one hour onwards. No samples were taken from the chamber before one hour.

Effect of Impregnation of Pad, etc.

Fig. 3 A shows the diffusion of the domiphen bromide in the agar and the inhibition of growth of the Oxford staphylococcus. Fig. 3 B shows the reduced zone of inhibition when the test is repeated using a blood-agar plate. Variations in the zones of inhibition have been found with different types of agar base. For all work on normal skin flora and laboratory investigations swabs were plated on Oxo agar. In the case of the clinical trial the swabs were plated on blood agar.

Normal Skin : Bacteriological Studies

In order to compare the effect of a microporous film dressing (M.P.F.) with an occlusive film type of dressing (O.F.) on the bacteria of the skin, the following procedure was carried out. The normal skin flora of both forearms of 39 male and female patients, who were either ambulatory or confined to bed, was determined by daily swabbing for four or five consecutive days. The swabs were moistened with sterile saline and well rubbed over the flexor surfaces of both forearms and wrists. The swabs were plated on Oxo agar and incubated in 7%–10% CO₂ at 37° C. Final readings were made after 48 hours. The results are shown in Tables III and IV. Fig. 4 shows classification of growth.

Four types of dressings were used: (1) No. I, with non-impregnated pad (M.P.F.), (2) No. I, with impregnated pad (M.P.F.), (3) No. IV, with non-impregnated pad (O.F.), and (4) No. IV, with impregnated pad (O.F.). The day before using the dressings the forearms were shaved. Twelve dressings, three of each type, were applied, care being taken that no one group was on the same forearm, otherwise a random distribution was made. One of each type of dressing was removed at 24, 48, and 72 hours. Swabs were taken from the area of the skin under the dressing-pad; these were plated, incubated, and examined as before.

From Fig. 5 it can be seen that the bacterial growth obtained from the skin is reduced when covered by a microporous film carrying the impregnated pad, compared with that obtained from under the occlusive film with a similar pad.

Fig. 6 shows results obtained when neither of the pads were impregnated, but the porosities of the two films differ. There is a marked increase in growth obtained from skin covered by the occlusive dressing. Table V expresses as

FIG. 4.—Classification of type of growth.

a percentage the number of swabs from which no growth was obtained. It can be seen that there is a marked rise in the number of "no growth" swabs obtained from the skin under the microporous film.

Coagulase-positive staphylococci were recovered 21 times (6.1%) from the 346 swabs obtained from normal skin. They were never recovered from the skin under the microporous dressing with a non-impregnated pad. The low

incidence on normal skin may be due in part to the fact that this hospital is situated on the top of a hill and the wards are light and well ventilated, and the patients spent much of their time in the open air during this investigation.

Clinical Trial

During the course of the work on microporous dressings several clinical trials have been undertaken to assess various factors. The small trial reported here was carried out at the Body Repair Depot of the London Passenger Transport Board Executive at Aldenham, Hertfordshire, in June-July, 1955.

The object of the trial was to compare the healing of minor injuries treated with microporous film dressings with a similar group treated with standard waterproof occlusive dressings. In particular it was desired to obtain information regarding (1) the healing-times of wounds, (2) the state of the skin under both types of dressings, (3) the opinion of the users, and (4) the changes in the bacterial flora under the dressings.

Method

The patients were employed by the London Transport Executive and by contractors working on the site. Those who had sustained an injury one hour or less previously were treated in the factory surgery. If a dressing had been applied by one of the first-aid workers in the factory, these patients were not included in the trial.

For bacteriological purposes a sterile swab moistened with saline was taken before cleaning the skin with methylated ether. Excess blood and dirt were removed; no cleaning agents such as cetavlon were used.

So far as possible alternative patients were treated with M.P.F. dressings. The remainder were treated with O.F. dressings. Where applicable a tube gauze protective dressing was applied, or a cotton bandage. Certain injuries—for example, those on the forehead and buttock—could not be covered.

The patients were asked to report at the end of the shift for a clean protective covering if their job was a particularly dirty one. They were asked to leave the protective covering on until seen the next morning. At week-ends each patient was given sufficient bandages and asked to keep the dressing covered. Dressings were removed at 24-hour intervals during the working week. The wound was swabbed with a sterile swab moistened with saline and a new dressing applied.

Most of the employees worked a five-day week, and hence the wound examined on Friday morning was not seen again until the following Monday morning—a period of three days. A few of the employees were examined on Saturday and Sunday. All patients were asked to report back to the surgery at once if their protective dressing came off. The wound was judged to be healed when, in the opinion of the sister, the wound could be left without a dressing.

After approximately 30 patients had been treated with M.P.F. No. II dressings, the lower porosity No. III dressings were used on all new patients. A standard "tick" form was used to record all data. This was done to reduce personal opinion to a minimum.

Selection of Cases and Method of Assessment

A total of 113 wounds were treated—59 had M.P.F. Nos. II/III dressings and 54 had O.F. dressings. Of these, 12 with M.P.F. and 17 with O.F. dressings were rejected from the series because the patients discontinued to report (mainly because of absence or holidays) or because they re-dressed the wound themselves. Two cases, originally dressed with O.F., were excluded as, owing to excessive granulation or maceration, the dressings were changed to M.P.F.

The number of wounds finally used for the assessment of healing times was 47 with M.P.F. II/III and 37 with O.F. dressings. A number of these healed over the week-end or

after an absence of a day (Table VI) and have thus been excluded from the healing-time figures, as they could have healed at any time during these three days.

As dressings on the fingers have a more harsh treatment than on other sites, the finger wounds are considered separately.

Finger Wounds

Healing-time (excluding those healing over a week-end).—M.P.F.: 18 wounds, average healing-time 4.1 days, standard deviation 2.1. O.F.: 15 wounds, average healing-time 6.3 days, standard deviation 3.0. This difference is just significant ($t=2.3$, $P=0.03$). This indicates that M.P.F. is better than O.F. for finger wounds. The two series were examined with respect to other factors which might affect healing-times; there was no appreciable difference in any aspect (Table VII). All but two fingers with either type of dressing

were covered with a cotton bandage to protect the dressing. This had a greater adverse effect on M.P.F., as when the bandage became saturated there could be no drying of the skin and wound underneath the dressing, thus reducing one of the main advantages of the microporous film. The average healing-time of finger wounds with this protective bandage was 4.4 days for M.P.F. and 6.3 for O.F. Those wounds on the fingers which healed over the week-end had an average healing-time of 5.0 days under M.P.F. (2 cases) and 8.0 days under O.F. (7 cases).

Condition of Wound and Skin.—The condition of the wound and skin was recorded after cleaning the wound and before the initial dressing, and again at each renewal of the dressing. From Table VIII it can be seen that the skin surrounding wounds dressed with M.P.F. was never soggy. At

each change of M.P.F. dressing it was noticed that some wounds were reopened because of adhesion. This did not occur under the O.F. dressing, because the wound remained moist. There were no cases of skin reaction under either the pad or adhesive of either type of dressing covering fingers. There was one case of clinical sepsis, a finger covered by an O.F. dressing.

Patient's Opinion.—During the course of treatment the patients were asked their opinion of dressings that had been applied. The replies favoured the M.P.F. dressing (Table IX), but since it is a new type of dressing this novelty may have affected the answers.

"Other Sites" Wounds

Healing-time (excluding those healing over a week-end).—M.P.F.: 18 wounds, average healing-time 6.3 days, standard deviation 3.0. O.F.: 12 wounds, average healing-time 5.1 days, standard deviation 2.5. This difference is not statistically significant. It is interesting to note that the four leg wounds in these groups had the longest healing-time of all wounds, three were in the M.P.F. series with healing-times of 9, 10, and 13 days, and one in the O.F. series taking 9 days to heal. This partly accounted for the higher M.P.F. average for "other sites." Another factor which influenced the healing-time was that 11 of the 18 cases treated with M.P.F. were lacerations, compared with 4 of the 12 treated with O.F. dressings. It has been found that adherence of dressings to wounds is most pronounced in the case of lacerations and abrasions.

Condition of Wound and Skin.—In this assessment all wounds, including those healing over the week-end, are given (Table X). There was no case of clinical sepsis among the

"other sites." The relatively wet state of the skin under O.F. during healing was noted, but there was actually a greater proportion of dry skins under O.F. for "other sites" than for fingers. There were four cases of skin reaction under O.F. dressings and none under M.P.F.

Patient's Opinion.—The patients' opinion of the dressings are shown in Table XI. The opinions are less divergent for the two types of dressings for "other sites" than for the finger group.

TABLE XI

Healing-time

With finger wounds, those covered with an M.P.F. dressing had a significantly shorter average healing-time than those with an O.F. dressing. With wounds on "other sites" the reverse was the case, but the difference here was not statistically significant.

In this and other trials the present type of dressing-pad tends to adhere to the wound when it is covered by a microporous film in situations where free evaporation is possible. In finger dressings the pads never completely dried out. There was no statistical difference found in the healing-times of the wounds under the two types of microporous film used in the treatment of the 47 patients.

Bacteriological Methods and Results

Methods and Materials.—(1) Cotton-wool swabs moistened in sterile saline were used to take wound swabs (a) initially before any cleaning or dressing, and (b) immediately after the old dressing was removed at the daily inspections. (2) 2% blood-agar plates: the swabs were plated and incubated aerobically and anaerobically at 37° C. Final readings were made after 48 hours. (3) Coagulase production by staphylococci was tested by slide/tube method.

Results

Of the 80 cases which were swabbed initially, 39 (49%) produced no growth. Twenty of these 80 cases were rejected for various reasons. The remaining 60 were divided into three groups—those receiving M.P.F. dressings II and III, and those receiving the control O.F. dressings. The results are given in Table XII.

TABLE XII

Type of Dressing	Initial Swab		24-hour Swab		48-hour Swab	
	Growth	No Growth	Growth	No Growth	Growth	No Growth
II (15 cases)	8	7 (47%)	8	7 (47%)	5	10 (67%)
III (14 ")	10	4 (28%)	12	2 (14%)	11	3 (21%)
IV (31 ")	14	17 (55%)	26	5 (16%)	27	4 (13%)

It can be seen from Tables V and XII that when normal skin and wounds are covered with a microporous film carrying a pad impregnated with 0.1% domiphen bromide, the "no growth" recovery rate is increased. It also appears from the results that the higher the porosity of the film the lower the recovery rate of organisms from the wounds.

No *Staph. pyogenes* was isolated from any wound swabbed initially or during the first 48 hours of healing, or from the M.P.F. group at any time. It was recovered subsequently from five cases, all treated with O.F. dressing; in one finger wound this organism was recovered on the third day and appeared consistently in all subsequent swabs until healing had taken place on the tenth day. No beta-haemolytic streptococci or anaerobes were recovered from any site at any time.

Summary

A new microporous film wound dressing is described. The results of various experiments in the laboratory, on normal skin, and on minor injuries are given for films of varying porosities.

A microporous film with a porosity of 1,400–1,800 g. per square metre per 24 hours, carrying a cotton interlock pad impregnated with 0.1% domiphen bromide and having an overall pattern spread adhesive, results in a dressing which largely fulfils the criteria stated earlier and is an improvement on other first-aid dressings, with respect to both wound healing and ability to reduce bacterial flora.

The problem of adhesion of the pad to the wound has yet to be overcome. This adhesion depends on a variety of factors which are being investigated.

While this report deals with the clinical and bacteriological aspects of a first-aid skin dressing, other applications of the film as a pre-operative skin covering, as a pressure bandage in the treatment of varicose ulcers, and as a dressing for burns merit investigation.

The development of this dressing has been made possible only by the co-operation and efforts of many people and patients. Our thanks are due to all these, and in particular to Professor R. E. Lane, of the Nuffield Department of Occupational Health, University of Manchester; to the medical officers and sisters of the following organizations: Vauxhall Motors Limited, Luton; Ford Motor Company, Dagenham; London Passenger Transport Board Executive; Messrs. Pritchett and Gold and E.P.S. Company Limited, Dagenham; to Mr. L. W. Plewes, Luton and Dunstable Hospital; to Messrs. Pritchett and Gold and E.P.S. Company Limited, in particular Mr. F. Sharp, and to Messrs. Smith and Nephew Research Limited, especially Mr. J. Dow, who have produced large quantities of equipment, material, and dressings, including all dressings used in this trial, and without whose assistance none of the work could have been undertaken; to Mr. S. Holt, of the Plastics Division of Imperial Chemical Industries Limited, who suggested that a microporous plastic battery separator, known as "porvic," might have medical application; to Dr. A. Charlesby, of Tube Investments Research Laboratories, Hinxton Hall, Cambridge, who undertook the sterilization of the dressings; and to Dr. C. H. Lack, pathologist to the Royal National Orthopaedic Hospital, in whose department the bacteriological investigations were made, with technical assistance from Mr. B. J. Newman. Finally, but not least, we wish to acknowledge the invaluable technical help of Mr. G. D. Winter, of the Department of Biomechanics and Surgical Materials.

This work has been supported by a grant from the Medical Research Council.

The Minister of Agriculture, Fisheries, and Food, the Minister of Health, and the Secretary of State for Scotland have approved for publication a report presented to the Food Standards Committee by its preservatives subcommittee recommending that the use of emulsifying and stabilizing agents in food should be subject to statutory regulations. The subcommittee considers that control should be secured by specifying the substances which may be used—that is, by adopting a "permitted list." Apart from certain substances which are natural constituents or already common ingredients of food and need not be regulated, the subcommittee recommends that official approval should for the present be restricted to the following substances: super-glycerinated fats, synthetic lecithin, propyleneglycol alginate, propyleneglycol stearate, methyl cellulose, methyl ethyl cellulose, sodium carboxymethyl cellulose, stearyl tartrate, diacetyl tartaric acid esters of super-glycerinated fats, monostearin sodium sulphacetate, and sorbitan esters of fatty acids. The report recommends that the addition of emulsifying and stabilizing agents to milk should not be allowed, and that of the permitted substances only super-glycerinated fats and stearyl tartrate should be allowed in bread. It is not considered necessary or practicable to specify limits to the amount of a permitted emulsifying or stabilizing agent which may be present in food, although the amount used should always be the smallest quantity consistent with the best commercial practice. Before deciding what action should be taken on the subcommittee's recommendations the Ministers concerned will consider any representations from interested parties. The report may be obtained from H.M. Stationery Office, price 9d. net.

**FLUOTHANE*: A NON-EXPLOSIVE
VOLATILE ANAESTHETIC AGENT**

BY

R. BRYCE-SMITH, D.M., F.F.A.R.C.S.*First Assistant*

AND

H. D. O'BRIEN, M.B., F.F.A.R.A.C.S.*Nuffield Dominion Clinical Assistant**Nuffield Department of Anaesthetics, University of Oxford*

"Fluothane" is a new volatile anaesthetic agent developed and manufactured by Imperial Chemical Industries (Raventos, 1956; Raventos and Suckling, 1956). It is the most promising member of a series of agents with non-flammable and non-explosive properties which are being investigated independently by the Medical Research Council. It is a clear, colourless, heavy liquid with a specific gravity of 1860 (cf. chloroform 1500), a boiling-point of 51° C., and a sweetish odour not unlike that of chloroform. Chemically, it is a halogenated ethane with the structural formula

**Clinical Trials**

Fluothane has been administered as the sole or the principal anaesthetic agent to a number of volunteers and to 310 patients (varying in age from 7 months to 91 years) for a variety of surgical procedures (lasting from 3 to 150 minutes). There were no deaths under anaesthesia in the series, although many of the patients came to operation in a poor physical state. The pre-operative conditions included diabetes, obstructive jaundice, cardiac failure, thyrotoxicosis, and asthma, but none were affected adversely by the anaesthetic.

One patient died during the post-operative period, but this was probably not attributable to the anaesthetic.

An 84-year-old man received open drop fluothane for the amputation of a gangrenous toe. The administration was uneventful and lasted for 15 minutes. The patient recovered consciousness before leaving the operating theatre and was quite well for the next four days. He then became increasingly irrational, developed bronchopneumonia, and died on the seventh post-operative day.

The object of this investigation was to confirm the promising results obtained in animal trials; to ascertain in humans the effect of known concentrations of fluothane vapour; and to exploit the administration of the drug by simple methods.

Methods of Administration

Since it was known that the administration of fluothane in conjunction with nitrous oxide and oxygen from a standard Boyle apparatus was being investigated elsewhere (Johnstone, 1956), we have limited our attention to the administration of the drug by the "open drop" method and by its use in an E.M.O. inhaler (Epstein and Macintosh, 1956) modified and calibrated to deliver known concentrations of fluothane vapour in air. In this way it has been possible to observe the action of fluothane without the complication of other anaesthetic agents, and to obtain an im-

*The trade name given by Imperial Chemical Industries to 2-bromo-2-chloro-1,1,1-trifluoro-ethane. The drug is not yet freely available.

pression of the effects produced by known concentrations of the agent.

Open Drop Induction.—Fluothane has been administered by the open drop method to 63 patients and to a further 29 after the preliminary injection of a "sleep" dose of thiopentone (rarely more than 0.2 g.). In most instances, induction was smooth and pleasant, producing unconsciousness in about one minute. Swallowing during induction was not uncommon, but this did not interfere with the administration and was not followed by vomiting. Coughing was rare and was always relieved by raising the mask. Struggling and breath-holding were unusual. Surgical intervention could often be tolerated after three to four minutes, although a further eight to ten minutes was necessary if the surgical stimulus was to be severe. We found that the rate of drop should be somewhat faster than when chloroform is administered, but otherwise the same general principles should be followed—that is, the head turned to one side and no Gamgee tissue placed between the face and mask. In 58 cases open drop anaesthesia was maintained throughout the operation. In 31 other cases open drop induction was followed by maintenance with the inhaler.

Fluothane Calibrated E.M.O. Inhaler.—Twenty-three cases were induced with the inhaler without the preliminary injection of thiopentone. Induction was slightly slower than with the open drop method, and an excitement stage was seen rather more often; but in either case a small preliminary dose of thiopentone makes induction smoother and pleasanter for the patient. An advantage in using the inhaler and its associated bellows (Macintosh, 1953) is the ease with which respiration can be assisted or controlled. When respiration is depressed from any cause the bellows is a great help in ensuring efficient respiratory exchange.

Anaesthetic Concentrations of Fluothane

The concentrations of fluothane required to produce certain effects were tested on volunteers, and these findings were confirmed in clinical practice.

The inhalation by volunteers of 0.5% fluothane in air (v/v) for periods up to five minutes did not produce unconsciousness. In most instances the subjects noticed flushing of the face and a general sensation of warmth after 10–12 breaths, and shortly afterwards sounds became accentuated. There was no "muffling" or the effect of distance so common during the inhalation of weak mixtures of nitrous oxide or trichlorethylene. There was a slight reduction in sensation to pin-prick after one minute, but this was not considered to be of clinical value. Even after continuous inhalation for five minutes it is doubtful whether any worth-while analgesia was produced.

In volunteers the inhalation of 1% fluothane in air invariably produced loss of consciousness. The onset of a light level of unconsciousness usually occurred in the second minute, and the depth did not alter appreciably during a further four minutes' inhalation. Volunteers were unaware of painful stimulation during this period, although it often increased the rate or depth of respiration. Consciousness was regained almost as soon as the mask was removed and mental alertness returned rapidly. A not unpleasant sensation of lassitude persisted for a further two to three minutes, after which the subject could sit and stand unaided. Most, however, complained of diplopia during this period, even though other muscle activity seemed to have returned to normal. Dryness of the mouth was often noticed for a further 15–20 minutes, but there were no other unpleasant sequelae.

Concentrations of up to 1.5% fluothane in air were well tolerated by all volunteers and evoked no unpleasant sensations of suffocation or irritation of the respiratory tract.

In most patients 2% fluothane in air provided a satisfactory level of surgical anaesthesia, although it was necessary to administer 3% for short periods to robust subjects and those in whom an extreme degree of relaxation was necessary.

Airway

Although the majority of our patients received some form of premedication, 20 cases did not have atropine. Even in these, the absence of pharyngeal secretions was noticeable.

There was rapid relaxation of the masseter muscles and a depression of the pharyngeal reflexes: an oral airway was therefore tolerated early. A laryngoscope blade could be introduced after four to five minutes, although the passage of an endotracheal tube usually required a further three to four minutes of anaesthesia. Even when intubation was attempted at a light level of anaesthesia, laryngeal spasm was short-lived and was more commonly an adduction of the cords rather than true spasm. It was therefore possible to cocaineize the cords at an early stage, thus facilitating the introduction of a tube within five to six minutes of the beginning of an administration without response. Out of a total of 132 patients who were intubated, less than half received succinylcholine chloride for this purpose, and even then its use was usually dictated by the demands for speed during long surgical lists.

Premedication

Several combinations of drugs for premedication were used in this series:

No premedication	8
Atropine only	27
Morphine and atropine	28
"Omnopon" and scopolamine	135
Pethidine and atropine	66
Others (barbiturates, barbiturates and atropine, etc.)	46
	310

If respiration is not to be assisted or controlled, we are impressed by the advantages of using "light" premedication, which avoids undue respiratory depression. Thus, in patients who received atropine only, or pethidine (50 mg.) and atropine, induction was smooth and rapid; moreover, recovery was not delayed. We advise that drugs with a marked central respiratory depressant effect should not be given within one and a half hours of the induction of anaesthesia.

Effect on Cardiovascular System

We have come to expect a slowing of the pulse under this anaesthetic, and rates of 60-70 were common soon after induction. The pulse rate appears to fall as the depth of anaesthesia increases, and on occasion we have observed rates as low as 40 a minute. To some extent, atropine counteracts this effect, and on these grounds we believe that premedication with atropine is advisable although not essential.

Patients with cardiac irregularities were anaesthetized without alteration in their rhythm. Dropped beats persisting for periods of about two minutes were observed in two patients during anaesthesia. They occurred after unwise attempts at intubation under very light anaesthesia which provoked vigorous bouts of coughing and breath-holding. The irregularities might well have been provoked by a similar insult under light anaesthesia with any other agent.

A fall in blood pressure was common, and systolic pressures in the region of 90 mm. Hg were usual within five minutes of starting an administration, and occurred both with and without the preliminary administration of thiopentone. Just as the pulse rate tended to slow with deeper anaesthesia, so also did the blood pressure tend to fall, but we found experimentally that as a rule this could be reversed by the administration of atropine or methylamphetamine. The consequent dry, bloodless operating field is similar to that obtained with hypotension deliberately induced by other methods. With the exception of a brief period of mental confusion in one elderly patient, no ill-effects were seen from either the slow pulse or the low blood pressure.

Respiratory System

Concentrations of 1% fluothane and higher caused well-marked changes in the character of respiration. During light anaesthesia in volunteers breathing 1% fluothane in air the rate generally increased or stayed within a range of 18-24 a minute. On a few occasions the rate fell to 4-6 a minute. In patients undergoing surgical stimulation these slow rates were never seen: 30 a minute was common, and we considered this normal, but higher rates were observed on occasion.

In both volunteers and patients the depth of respiration decreased whenever the rate increased or remained normal. This was apparent clinically, although it was not until the volume of inspired gases was measured with a spirometer that the full extent of the respiratory depression was appreciated. Neither the rate nor the depth of respiration could be related to the depth of anaesthesia, and thus these signs of anaesthesia, so well recognized with many other anaesthetic agents, became meaningless. As is to be expected, surgical stimulation during light anaesthesia increased the rate and depth of respiration, but even in these circumstances the minute-volumes recorded were much below the expected values. Thus a recording as low as 1.2 litres a minute was made in one volunteer after breathing 1% fluothane in air for only three minutes, while several of our patients gave readings of 3-4 litres a minute during the course of an operation.

With such a degree of respiratory depression, cyanosis was seen frequently unless respiration was assisted or oxygen added to the inspired mixture, and in the second alternative carbon dioxide retention might be occurring insidiously. Such degrees of respiratory depression also limit the depth of anaesthesia obtainable during spontaneous respiration using either the open drop technique or a draw-over inhaler. Thus it may become necessary to assist or control respiration to circumvent these hazards. By increasing the respiratory exchange at the end of an administration it is possible to excrete fluothane at an increased rate and thus hasten recovery.

Under fluothane/air anaesthesia, respiration was usually smooth, quiet, and regular. No irritation is caused to the respiratory tract, and it was therefore possible to control respiration with the greatest of ease.

Occasionally, however (in 12 cases), the induction was interrupted by periods of apnoea, sometimes lasting for one to two minutes. These never occurred after induction with thiopentone nor after the second minute of inhalation. The apnoea differed from active breath-holding in that inflation could still be performed with perfect ease. Spontaneous respiration usually restarted after applying a painful stimulus to the patient. No explanation can be offered for this phenomenon, although it occurred with remarkable frequency in previous experiments on dogs (A. B. Bull, 1955, personal communication).

Muscular Relaxation

On occasion it was difficult to achieve an adequate degree of muscular relaxation while respiration was spontaneous. On the other hand, respiration could be controlled easily, and it then became possible to provide adequate conditions for surgery quickly in most cases. This suggests that fluothane behaves in a similar manner to cyclopropane in that a quiet, depressed respiration limits the intake of the agent and thus the depth of anaesthesia.

An additional factor occurs when the E.M.O. or other inhaler with similar characteristics is being used. Such inhalers operate efficiently within certain ranges of inspiratory flow rates (usually about 7-12 litres a minute). If the flow rate falls below this range, so also does the concentration of vapour leaving the inhaler, and these circumstances were experienced in our series when low inspiratory minute-volumes were demonstrated.

During intra-abdominal operations in which muscular relaxation was adequate, peristalsis was seen on several occasions.

Use of Muscle Relaxants

Succinylcholine chloride was administered (20-100 mg.) to 68 patients under fluothane anaesthesia. The effects were identical to those seen when this muscle relaxant is used with other anaesthetic agents.

Twenty patients received gallamine triethiodide, and, in view of reports suggesting that profound blood-pressure and pulse-rate changes might be expected with the use of relaxants, it was given with caution. Injections of 40 mg. caused the usual slight rise in pulse rate, and little or no change in the blood pressure. Larger doses (up to 120 mg.) sometimes caused a slight fall in blood pressure, although this was no more pronounced than that to be expected with fluothane by itself.

On the other hand, when neostigmine was used at the end of the operation to counteract the effect of any residual gallamine triethiodide bradycardia was particularly noticeable. Preliminary doses of atropine should therefore be able. Greater than the usual 1/100 gr. (0.65 mg.). When doses of 1/75-1/50 gr. (0.97-1.3 mg.) were used severe bradycardia was avoided, but we would stress the advisability of giving neostigmine cautiously, and in divided doses (0.5 mg. at a time, with a total dose not exceeding 2.5 mg.).

D-Tubocurarine was administered in doses of 7.5-15 mg. to 20 patients. More than half showed little or no change in their blood pressures despite the use of controlled respiration. However, in some, particularly the elderly, there was a fall in blood pressure of 30 mm. Hg or more. When spontaneous respiration remained, this fall was not serious, but it was frequently aggravated by the establishment of a controlled respiration. Thus in a 77-year-old man with a pre-operative blood pressure of 220/105, a systolic pressure of 45 mm. Hg was recorded 15 minutes after the injection of 10 mg. of D-tubocurarine with subsequent control of respiration. However, the patient looked well and the blood pressure started to rise as spontaneous respiration returned. With one exception, the general appearance of all these patients was satisfactory:

A 45-year-old woman undergoing vaginal hysterectomy received thiopentone, 0.25 g., followed by 2% fluothane/air from the inhaler. After intubation, 15 mg. of D-tubocurarine was injected and respiration controlled with 1% fluothane. Ten minutes later her systolic pressure had fallen from 145 mm. Hg to 55. Her pulse rate was 64 and she appeared pale and slightly cyanosed. Atropine, 1/50 gr. (1.3 mg.) raised her pulse rate to 120 without affecting the blood pressure. Neostigmine in divided doses raised her systolic pressure to 75 mm. Hg before spontaneous respiration restarted and her colour improved. The patient made a satisfactory recovery.

Thus, in view of the profound changes which may occur on occasion, further investigation is required on the use of muscle relaxants and in particular D-tubocurarine during fluothane anaesthesia.

One patient who was receiving mephenesin in the course of the treatment of tetanus was anaesthetized with fluothane/air without any unusual response.

Recovery

Consciousness may be expected to return within ten minutes of stopping the administration. However, depressed respiration due either to the fluothane itself or to unnecessarily heavy premedication increased the time interval by as much as three-quarters of an hour in 15% of our cases.

Nausea and vomiting were strikingly rare, and most patients stated that they felt very fit. The rapid return of mental alertness has already been mentioned. Apart from a few frontal headaches—which may well have been co-

incidental—only two attributable post-anaesthetic sequelae were observed in this series:

Shivering.—Fourteen patients had generalized attacks of shivering as consciousness was returning. These were sometimes quite violent and lasted three to four minutes.

Restlessness.—Six children were confused and restless for up to an hour after return to bed. This might be due to a rapid recovery from the anaesthetic, with no residual analgesia while the effect of a barbiturate premedication still persisted. Restlessness did not occur when an analgesic was administered soon after the return of consciousness.

Effect on Sympathetic Nervous System

As a rule, a flush starts in the face and neck within the first minute of the administration and the skin feels warm to the touch. Later there is a noticeable injection of the conjunctivae and the superficial veins become prominent. Sweating is absent or minimal, and when present there was usually an accompanying respiratory depression, so that the cause might well have been carbon dioxide retention.

Miscellaneous Observations

From the evidence of volunteers, fluothane appears to have little value as an analgesic agent. Loss of consciousness occurs before there is any appreciable diminution in sensitivity.

Fluothane has been spilt in the eyes inadvertently. No harm resulted, although the response by a lightly anaesthetized subject was vigorous.

Solutions of adrenaline in which the total dose did not exceed 0.5 ml. (1/1,000 concentration) were injected subcutaneously into 14 patients to provide haemostasis (thyroidectomy, mastoidectomy, and antrostomy). The only noticeable response was a small rise of pulse rate in two cases.

On 19 occasions fluothane was employed as an induction agent before administering ether. The change-over was always effected rapidly and smoothly, and was followed by a rise of pulse rate and blood pressure to normal.

Under ideal conditions, fluothane is a stable compound, but in the presence of air, moisture, and light it can decompose slowly into the various acids of the halide group. In consequence, the drug should be stored in a cool place in amber-tinted bottles. These decomposition products can affect some metals, including tin and aluminium, both of which may be found in everyday modern anaesthetic apparatus. In addition, fluothane may be taken up by rubber, causing it to soften and to swell. The rubber reverts slowly to its previous state when exposed to air. This effect has been noted on the standard rubber corks found in drop-bottles, and in the corrugated hose of anaesthetic apparatus, which then tends to slip from metal connexions. We have seen no adverse effects on patients attributable to decomposition products, but on theoretical grounds one should bear in mind the toxic effects of these acids.

Conclusions

Fluothane is a volatile anaesthetic agent which, like ether, can be administered by the simplest possible methods. It has the advantage of being both non-flammable and non-explosive.

Since it does not stimulate pharyngeal secretions, premedication with atropine is not essential: on the other hand, atropine is advisable to counteract the marked bradycardia encountered in deep and protracted anaesthesia.

Induction is smooth, rapid, and not unpleasant even by the open drop technique. Recovery is similarly rapid and unassociated with unpleasant complications.

The range of anaesthetic concentrations lies between 1 and 3% fluothane in air, and within these limits adequate conditions can be provided for most types of

surgery. Unfortunately, few upper abdominal cases were encountered, and in these the muscular relaxation was not always perfect. The fault here may well have been due to our inexperience in the use of this new drug.

Fluothane causes a slowing of the pulse rate and a fall in blood pressure in most instances, but these do not appear to be harmful. In fact, the hypotension has often been appreciated by the surgeon, who has remarked on the dry operating field. Excessive falls in blood pressure or pulse rate can quickly be treated by the injection of atropine or methyl amphetamine, or the administration of ether.

The greatest disadvantage exhibited by fluothane is the depression of respiration which occurs not infrequently and may be sufficient to cause cyanosis and CO₂ retention. These undesirable features may be overcome by assisting or controlling respiration, which will also enable greater depths of anaesthesia to be obtained and thereby increase the scope of this agent.

In our opinion, this disadvantage is great enough to warrant limiting the use of the agent to all but skilled anaesthetists until more is known about its properties. It is possible that the disturbances of respiration which we encountered can be avoided by refinements in technique. If this is so, we believe that fluothane may become a valuable anaesthetic agent with a wide variety of uses. By virtue of its non-flammability and the simple method by which it can be administered, it could then attract the general practitioner for use in minor operations, provided he is equipped to treat the respiratory depression which may be encountered. Because of its flexibility it may be preferable to trichlorethylene except in respect of its analgesic properties. Indeed, with the high cardiac safety factor which has been suggested (Johnstone, 1956) fluothane compares advantageously with chloroform.

The pleasant and rapid induction is of particular value in children. A smooth change-over to ether can be effected if required, but when used as the sole anaesthetic agent it provides uniformly good muscular relaxation.

We wish to express our gratitude to Imperial Chemical Industries for the supplies of fluothane; to Dr. H. G. Epstein for his willing help and assistance in matters relating to the inhalers; and to Sir Robert Macintosh for his encouragement and advice.

The General Council of the Press, at its meeting on October 17, considered a complaint from the Town Clerk of Ayr against the *Sunday Mail* of Glasgow in respect of an article about a visit to the Ayr Welfare Home and Hospital. The ground of the complaint was that the article would create a false impression of the institution. The editor had refused to publish any withdrawal of the allegations and criticism because he was satisfied that the article was fair comment on a matter of public importance. The Council expressed the view that the *Sunday Mail* had approached the matter in a responsible manner and held that the article was fair comment on a matter of public interest.

THE PHYSIOLOGICAL CASTRATION SYNDROME IN BREAST CANCER

BY

GEOFFREY J. HADFIELD, M.S., F.R.C.S.

J. A. G. HOLT, M.B., Ch.B., F.R.C.S., D.M.R.T.

Formerly of Department of Radiotherapy, Bristol Royal Hospital

The treatment of metastatic breast cancer is still rather empirical. It can be put finally on a scientific basis only when specific tests for the various factors which influence the growth of breast cancer can be easily performed. At present, however, clinical observation of these cases under treatment can yield valuable information on the course of the disease.

This paper describes clinical observations on a series of cases of metastatic breast cancer treated by a variety of methods. An overall picture of the course of the disease is available, as they are for the most part completed cases.

Introduction

Scowen (1955), in his Langdon-Brown lecture at the Royal College of Physicians in 1955, showed from his experience that the occurrence, either naturally or artificially, of the menopausal state was one of the main factors in regression of tumour growth. This state is manifested by a fall in oestrogen production and change of function of the anterior lobe of the pituitary with a great rise in gonadotrophin activity. It was suggested that the regression probably resulted from a combination of these circumstances rather than a simple oestrogen withdrawal, and that the conception of simple oestrogen dependence could not be fully substantiated.

At some time, from a matter of months to five years, after the menopause the oestrogen level rose and the gonadotrophin fell, giving a pattern similar to the pre-menopausal state. At this stage progress of the growth of metastatic breast cancer occurred, as it did before the menopause. The induction of a further menopausal state by adrenalectomy at this time caused a further regression of the growth.

This sequence of changes is summarized by the accompanying diagram (Scowen, 1955) which shows the classical effect

of a castration or the menopause, followed later by a reversal to the pre-menopausal state but without menstrual bleeding. Although true for the majority of cases, there were a few patients who did not follow this pattern.

All the patients in our series developed a carcinoma in the pre-menopausal period. It has been shown by Clemmesen (1948), Clemmesen and Busk (1949), and Anderson *et al.* (1950) that there are two peaks of incidence in breast cancer. They occur roughly in the five-year periods before and after the menopause. It would seem that the fall in incidence of breast cancer at the menopause occurs with the consequent drop in oestrogenic activity at this time. Of course this can influence only those carcinomata which are primarily hormone-dependent, and so generally affects only about 45% of the patients.

Diagram showing the commonest menopausal pattern induced by castration or occurring naturally. A further follow-up of this shows a reversal to the pre-menopausal state.

In an effort to enhance the results of local treatment by the natural but temporarily beneficial effects of the menopause, radical mastectomy combined with the removal of the ovaries has been tried (Taylor, 1932; Smith and Smith, 1953) in pre-menopausal women. Comparison of these cases with those treated only by radical mastectomy showed that oophorectomy lowers the incidence of metastases developing in the 3-5 years' post-operative period.

Huggins (1954) has shown from an analysis of his patients treated by adrenalectomy that the chance of regression is proportional to the mastectomy-adrenalectomy interval. Where this interval was five years the chance was 60%.

These observations fit in very well with the histories of patients with breast cancer and explain the variability of the progress of the disease.

Present Investigation

Table I summarizes the histories of 19 hormone-dependent tumours treated by removal of ovaries or adrenals, or both.

TABLE I.—Oestrogen-dependent Tumours

C=Surgical castration. M=Menopause. A/W=Alive and well.

In order to make the interpretation of the tables clear, Case 1 from Table I will be taken as an example. It shows that the primary growth was treated two years and four months before the menopause. Secondaries appeared seven months before the menopause, which in this case was produced artificially by castration and caused a regression of the secondaries for a further three months; a further regression occurred for five months after adrenalectomy. The patient is now dead.

The time of appearance of the various steps in the history of the cancer process in the patient is related in years to the menopause. This is done rather than giving the patient's age in years, as there is so much variation of the time at which the menopause occurs.

The time of the menopause was obtained from the patient's history. In those which were considerably post-menopausal a single date was given when the periods ceased, and this time was used as the date of the menopause. In the younger ones, however, the usual menopausal history of an episode protracted over some months was given. In of these cases the end of that time was taken as the date of the menopause.

The case histories seem to show the following common features: (1) Regression of metastases with the menopause or castration. (2) Reactivation of metastases, from a matter of months up to five years later, which can be controlled by adrenalectomy. In addition, stilboestrol administration sometimes aggravated metastatic growth. If it does so this suggests that a response is likely to be obtained from the removal of ovaries or adrenals.

TABLE III.—Cases With Regression on Stilboestrol Therapy

Case No.	Interval after Menopause		Results
	Primary Treated Years	Secondaries Appeared Years	
31	9	13	Complete regression for 5 yrs. Now A/W.
32	5	14	Regression for 2 yrs. then reactivation.
33	19	20	Regression of skin secondaries for 2 yrs. then reactivation.
34	8	9	Regression for 2 yrs. followed by reactivation.
35	10	18	Regression for 2 yrs. Now A/W.
36	12	13½	" " 1 2/12. Now A/W.
37	14	26	" " 1½ yrs. Now A/W.

Table II summarizes the histories of eleven hormone-independent tumours. Here again the following common features were present: (1) No effect on metastases with the menopause or castration. (2) No effect obtained by hormone addition or deprivation. (3) Rapid and relentless progression of metastases.

Table III shows some cases in which regression has been produced by stilboestrol. The majority of these were in the ten-year post-menopausal region. The regression was striking, and often lasted for a number of years, but this response appears to be the exception rather than the rule. One may wonder whether these cases are of primary pituitary-dependent nature, the stilboestrol serving to lower the secretion of mammatrophic hormone by the pituitary.

Summary and Conclusion

This paper records clinical observations on a series of cases of metastatic breast cancer treated by various methods.

It is suggested that the behaviour of metastatic breast cancer during a natural or artificial menopause indicates the probability or otherwise of hormone dependence.

Our thanks are due to the surgeons and members of the staff of the Department of Radiotherapy of the Bristol Royal Hospital for permission to use their cases for this study, and to Professors Sir James Paterson Ross and R. Milnes Walker for their help and advice in preparing this paper.

CIRCULATION IN THE HANDS IN HYPERTENSION

BY

R. S. DUFF, M.D., F.R.F.P.S., M.R.C.P.

Senior Registrar to the Cardiological Department,
St. Bartholomew's Hospital, London

Despite its great importance the peripheral circulation in chronic arterial hypertension has not yet been adequately investigated in man. Available studies show no general agreement; thus the circulation in the extremities in essential hypertension has variously been described as low (Mendlowitz, 1942; Stewart, Evans, and Haskell, 1946), normal (Pickering, 1936; Stead and Kunkel, 1940), and raised (Abramson and Fierst, 1942). This disparity is at least partly attributable to a failure clearly to distinguish the stage of the disease, although it is over forty years since Volhard and Fahr (1914) drew attention to the red complexion of patients with benign hypertension by contrast with the pallor of those in the malignant phase.

There is no satisfactory method of accurately measuring the calibre and condition of those blood vessels in the face and neck that determine the complexion, but a good indication of the cutaneous circulation may be obtained by studying the blood flow in the hands, feet, and digits.

The present paper describes some quantitative observations on the volume of blood flowing through the hands of patients with various grades of hypertension, by comparison with a group of healthy subjects.

Methods

Because of the ease with which various local and systemic influences may cause vasoconstriction in the hands, the experimental conditions were controlled so far as was possible (Neumann, Cohn, and Burch, 1942). Each subject had eaten more than two and a half hours prior to the investigation and rested on a couch in a room maintained at $23 \pm 1^\circ \text{C}$. during and for one hour before the period of observation. Metal plethysmographs (Barcroft and Edholm, 1943; Duff, 1952) were fitted to both hands, which were elevated to a comfortable position just above the level of the heart. The plethysmographs were filled with water kept at $34 \pm 1^\circ \text{C}$., and inflatable rubber cuffs were applied around the wrists. At regular half-minute intervals the cuffs were inflated at a pressure of $55 \pm 10 \text{ mm. Hg}$ to occlude temporarily the venous outflow from the hands. The resulting increases in hand volume due to arterial inflow were transmitted from the plethysmographs to volume displacement recorders inscribing on a kymograph. At the end of the test the instruments were calibrated and the displacement volume of each hand was measured. The blood flow was then calculated and expressed as ml. per minute per 100 ml. hand volume. Each value reported in this paper is the average of six observations.

Under these conditions 36 healthy subjects and 25 untreated hypertensive patients (with blood pressures consistently above 200/100 mm. Hg) were studied. The normal subjects had no clinical evidence of cardiovascular disease and included medical students, Civil Servants, and colleagues. They comprised 31 men and 5 women, aged between 20 and 50. The hypertensive group included patients of all grades of severity between those without symptoms or clinical abnormality (other than the elevated blood pressure) and those with papilloedema and marked enlargement of the heart. Patients with gross congestive failure or recognizable

hormonal disturbances such as thyrotoxicosis, Cushing's disease, or phaeochromocytoma were excluded from the series.

When the heart size, electrocardiogram, and urine were normal and the retinal vessels appeared healthy or to have only minimal changes the hypertension was graded *benign* irrespective of the height of the blood pressure, provided it had remained stationary for at least six months. With fluoroscopic or electrocardiographic enlargement of the left ventricle, or symptomatic or electrocardiographic evidence of coronary insufficiency, or albuminuria, or gross irregularity of the retinal vessels, especially with perivascular exudate or haemorrhage, the condition was graded *progressive*. In the presence of gross cardiovascular damage, including ophthalmoscopically measurable swelling of the optic disks, the disease was considered *malignant*.

Results

Blood Flow in the Hands of Healthy Subjects.—The resting blood flow was measured in both hands of 36 healthy subjects. In the great majority the circulation was approximately equal on both sides, although in a few there were distinct differences, the flow usually being higher in the right

R.H., L.H. = hand blood flow in ml./100 ml./minute in right and left hands.

FIG. 1.—Blood flow in right hands of 36 healthy individuals.

hand (Table I). The mean flow in the hands varied widely between different individuals, ranging, in the right hand (Fig. 1), from 2.7 to 22.2 ml./100 ml./minute. The average for the whole group was 10.5 ml./100 ml./minute.

Blood Flow in the Hands of Hypertensive Patients.—The hand blood flow differed widely in the 25 hypertensive individuals, but the range of 2.1 to 22.5 ml. (Fig. 2) in the right hand was similar to that of the healthy subjects, despite the disparity in age of the two groups. In the majority the difference between the two sides was small, but in nine it amounted to more than 3 ml. (Table II). When the patients were graded according to the severity of structural damage it was seen (Table II) that those in the (B) phase tended to have higher blood flows than those in the progressive (P) or malignant (M) category. An even closer relationship was found between hand blood flow and diastolic blood pressure: the average flow in the right hands of 11 patients with diastolic pressures under 130 mm. Hg was 14.2 ml.; that of 11 with diastolic pressures between 130 and 160 mm. Hg was 9.2 ml.; while in the three with diastolic pressures over 170 mm. Hg it averaged 3.3 ml.

FIG. 2.—Blood flow in right hands of 25 hypertensive patients grouped according to diastolic blood pressure.

Discussion

The first interesting finding of the present study was that the volume of blood flowing through the hands of members of a fairly large group of healthy adults extended over a very wide range (Table I). The lowest individual blood flow (right hand) was 2.7 ml. and the highest 22.2 ml./100 ml./minute, a range of over 800%. Even on the assumption that the level of arterial pressure was directly related to hand blood flow in these healthy subjects, inequalities in their blood pressures could not account for differences in blood flow greater than 50%. Clearly, therefore, the differences in blood flow between various individuals were much too great to be attributed to any inequality of blood pressure at the time of examination. None of these subjects suffered from high blood pressure, although doubtless a small proportion might be expected, on actuarial grounds, to develop hypertension before they die. The possibility that a tendency to hypertension, not yet manifest, might have influenced the blood flow in these individuals cannot therefore be entirely excluded.

It was next found that in patients with hypertension of all degrees of severity the hand blood flow varied from case to case, with an overall range (2.1-22.5 ml./100 ml./minute) similar to that of the healthy subjects. When, however, the hypertensive group was subdivided into three categories according to the level of diastolic blood pressure it was seen that on average the higher the pressure the lower the hand blood flow (Table II). Those with high blood

TABLE III.—Right Hand Blood Flow of Groups of Subjects

	Healthy Subjects	Hypertensive Patients		
		Diastolic Blood Pressure (mm. Hg)		
		100-120	130-160	170-190
No. of subjects	36	11	11	3
Mean blood flow (ml./100 ml./min.)	10.5	14.2	9.2	3.3
Standard error	0.87	1.3	2.9	3.3
Coefficient of variation	49.8%	49.5%		

flows and relatively low pressures may well correspond to the "red" hypertensives, while, at the other extreme, those with low blood flows and very high diastolic pressures could exemplify the "pale" hypertensives of Volhard and Fahr (1914).

The level of blood pressure was fairly closely related to the incidence of cardiovascular damage, none in the "benign" phase having a diastolic pressure over 140 mm. Hg and only a few individuals in the "progressive" phase (with vascular lesions or left ventricular hypertrophy) having diastolic pressures lower than 140 mm. Hg (Table II).

Information on the pressure/flow relationship in the peripheral circulation in man is still too inadequate for precise evaluation of these findings, but some inferences may be drawn.

The patients with diastolic pressures under 130 mm. Hg were seen to have hand blood flows averaging more than that of the healthy subjects (Table III). There can be little or no reduction in the calibre of the blood vessels in the hands of these patients. In the group of patients with diastolic pressures of 130 to 160 mm. Hg the blood flow in the hand was of the same order as that of the majority of normal subjects. It may be deduced that the blood vessels in the hands of such patients are on the whole of smaller calibre than normal. The great reduction of blood flow in those with still higher diastolic pressures suggests that the mean vascular calibre tends to be disproportionately reduced as the disease advances.

The blood flow in the hands under ordinary conditions is largely dependent upon the level of sympathetic vasomotor activity. In a healthy person at rest in a comfortable environment (such as that in which the present study was under-

taken) fluctuations in vasomotor tone cause striking variations in the volume of blood flowing through the hands. These are not accompanied by any corresponding change in arterial pressure. After surgical sympathectomy the blood flow in the hands may increase fivefold, without any significant alteration in blood pressure (Barcroft and Walker, 1949; Duff, 1951). In some healthy subjects the prevailing level of sympathetic vasoconstrictor tone is unusually high, so that the volume of blood flowing through their hands tends to be low (Table I). But these individuals do not have higher blood pressures than others with less sympathetic tone.

These considerations support the conclusion of Pickering (1936) that increased vasomotor tone is not an important factor in the production of chronic hypertension. It is more likely that the increased peripheral resistance in hypertension is related to a functional abnormality of the vessels themselves rather than overactivity of the vasomotor nerves. Some direct evidence of this has recently been obtained. In patients with hypertension a tendency to increased adrenaline sensitivity was demonstrated in blood vessels of the hands (Duff, 1957). There is also some indirect evidence of abnormal vascular sensitivity to pressor hormones in the nailfold (Greisman, 1952) and bulbar conjunctiva (Lee and Holze, 1951) in hypertension.

The abnormality of vascular function in essential hypertension may, of course, be a result rather than a cause of the elevated blood pressure. Studies of vascular sensitivity in patients with early hypertension—that is, with hyperaemic hands and relatively slight increases in pressure—may be expected eventually to decide whether this phenomenon predisposes to hypertension or develops after hypertension has been established.

Summary

The resting levels of blood flow in the hands of 36 healthy and 25 hypertensive subjects were measured by venous occlusion plethysmography under standard conditions.

In the healthy subjects the blood flow varied widely between different individuals, but averaged 10.5 ml. per 100 ml. hand volume per minute for the entire group.

In the hypertensive patients the level of hand blood flow tended to be inversely related to the height of the diastolic arterial pressure; in those with mild hypertension the flow was on average higher than in the healthy subjects, while in those with severe hypertension the hand flow was much below normal.

The results are interpreted as evidence that in hypertension a functional abnormality of the vessels themselves is probably more important than excessive activity of the vasomotor nerves.

I am grateful to Dr. Geoffrey Bourne and Dr. Graham Hayward for advice and encouragement, to Professor Sir James Paterson Ross for making available some of the apparatus, and to Professor Henry Barcroft for laboratory facilities. I am indebted to colleagues, patients, students, and friends who acted as subjects and helped in other ways, and to Mr. D. F. Kerridge for statistical advice.

UNILATERAL SWEATING OF THE SUBMENTAL REGION AFTER EATING (CHORDA TYMPANI SYNDROME)

BY

A. GREVILLE YOUNG, F.R.C.S.Ed.

Senior Consultant Surgeon, Lister Hospital, Hitchin, Herts

Various reports of sweating and flushing of the face after eating have been published, but these have almost entirely concerned cases of the auriculo-temporal, or Frey's, syndrome. It would appear, however, that only one case of unilateral sweating confined to the submental region after taking food has been recorded, and that was by Uprus, Gaylor, and Carmichael (1934). Their patient was a young woman of 22 who at the age of 5 had had enlarged cervical glands removed from the right side of her neck, and some two years later began to suffer from profuse sweating under the chin on the same side as a constant response to the stimulus of eating.

An almost identical case is now presented and discussed.

Case Report

The patient, a young healthy girl aged 12½ years, was referred to me by Dr. Warner Smith on October 13, 1954, on account of profuse sweating of the right submental region after eating.

She had been admitted to the Lister Hospital on January 5, 1944, when she was nearly 2 years old, for the removal of tonsils and adenoids. Readmitted on February 23, 1944, on account of enlarged tuberculous glands of the right side of the neck, she underwent an operation for the removal of the glands on March 10, the right submandibular salivary gland being removed at the same time. The wound broke down, but during the next ten weeks it slowly healed.

She kept well until 1952, when she was readmitted on account of enlargement of the liver. There was no jaundice, but cervical glands were palpable on both sides. Various investigations were carried out, but as the findings were within normal limits the patient was detained in hospital for only eight days.

Towards the end of 1952—that is, when she was 10 years old—it was noticed that at mealtimes the chin on the right side became red, and beads of perspiration formed on it, which a little later would drop unless dabbed by a handkerchief. This phenomenon occurred at every meal, and, though some types of food seemed to bring it on more quickly than others, it occurred with any kind of food. There was no pain.

On examination the girl seemed perfectly healthy and of normal size for her age of 12½ years. There were two scars on the right side of the neck; one 3 in. (7.5 cm.) long, extending from below the mastoid process to within 1 in. (2.5 cm.) of the midline, and the other, very short, 1 in. (2.5 cm.) inferior (Fig. 1). There was no loss of cutaneous sensation over the affected area.

FIG. 1.—Diagram showing extent of abnormal sweating (shaded area) and site of scars.

She was given two biscuits and an apple to eat, and within one or two minutes of her finishing these the skin over the right submental area, ending exactly at the midline, began to get red followed by profuse sweating. If nothing further was eaten, the erythema gradually faded and sweating ceased. Figs. 2 and 3, taken before and after eating, show the scars, site, and extent of the reaction.

Investigations

The patient was admitted for further observation and tests in November and December, 1954, and again in October, 1955. These tests consisted of: (1) reaction to various substances chewed and/or swallowed; (2) reaction after taking tincture of belladonna; (3) reaction after sympathetic block; and (4) reaction after lingual nerve block.

Reaction to Food or Other Substances.—After eating a normal meal flushing of the affected area was observed 10 to 15 minutes, and sweat exuded from under the chin on the right side about three minutes later. An apple would bring on the reaction in three to five minutes on most occasions. Sucking a lemon produced erythema in three minutes, followed rapidly by sweating. This continued for further five minutes, and then ten minutes after beginning to suck the lemon the erythema began to fade and sweating ceased. A similar reaction occurred on sucking cotton-wool soaked in 0.5% acetic acid. Drinking a small quantity of tea without food produced no erythematous reaction. Reaction to sucking a lemon half an hour after taking 30 min. of tincture of belladonna showed little or no difference—erythema and sweating appeared in three

FIG. 2.—Photograph taken before eating.

FIG. 3.—Photograph taken after eating, showing site and extent of reaction.

minutes. After 60 min. (3.6 ml.) of the tincture, however, a lemon produced erythema but not sweating. Local applications of antiperspirant lotions or ointments did not prevent the reaction.

Sympathetic Block.—A stellate ganglion block was carried out on the right side, using 0.5% lignocaine hydrochloride, and Horner's syndrome was produced. However, it had no effect in stopping the flushing and sweating after ingestion of foods as above.

Lingual Nerve Block.—Right lingual nerve block was carried out, and this did succeed in stopping the reaction. Even sucking a lemon produced no erythema or sweating.

Present Condition

When last seen (January 16, 1956) the patient stated that the disability was just the same, but it did not seem to be worrying her unduly. Eating an apple brought on the reaction as before.

The Literature

Unilateral sweating of part of the face or neck may occur following trauma or suppuration involving the parotid gland or after cervical sympathectomy; it may even be connected with disturbance of the central nervous system—for example, in cephalitis (Vámos, 1938) and epilepsy. An interesting example of the latter condition was described by Maggiolo *et al.* (1954). Their patient was an epileptic who suffered from sweating of the left cheek one to one and a half minutes after eating. There was no previous history of an operation on the neck or face, nor any sign of cranial injury. Treatment for the epilepsy by sedation with phenobarbitone, etc., did not affect the reflex unilateral sweating.

Wilson (1936), in an interesting article on facial sweating, describes and discusses four cases, two of which manifested unilateral sweating after eating. One was a case of syringomyelia, and sweating involved the left side of the face; the other followed right superior cervical ganglionectomy, when sweating occurred on the right side of the face during eating. (In this latter case section of the sensory root of the right trigeminal nerve, and also removal of an extracranial portion of the right glossopharyngeal nerve, had been carried out several years previously.) In both these cases sweating occurred after any stimulus to salivation.

However, over the past hundred years, beginning with Baillarger (1853), most of the numerous reports in the literature on unilateral sweating of the face on eating have been concerned with lesions of the parotid gland; and, because the area of hyperhidrosis corresponds more or less to the cutaneous distribution of the auriculo-temporal nerve, these have come to be known as manifestations of the auriculo-temporal syndrome. There is no need to describe this syndrome in detail, as it is now well known.

Langenskiöld (1946) describes two cases of the auriculo-temporal syndrome, one of which, interestingly enough, also presented features similar to the case reported by Uprus *et al.* (1934), and the one recorded here. The patient was a farmer aged 33 who came under his care in 1924 on account of gustatory local hyperhidrosis, having been operated on when 16 years of age for bilateral tuberculous cervical lymphadenitis. About two years later he began to get trouble after eating; this caused perspiration over the right cheek, which remained intensive over a small area underneath the chin on the right side. This affected area under the chin was treated with success by excision of the portion of the skin from which the sweat appeared. When examined 21 years later the patient stated that he had been much improved by the operation, but that the skin in front of the ear and along the right mandible still perspired to a certain degree, as did the left cheek occasionally, after eating something acid.

Langenskiöld, before discussing the mechanism and pathogenesis of the auriculo-temporal syndrome, says that the term is not fully correct, as the hyperhidrosis in some

cases comprises also regions of the skin innervated by the cervical plexus. Summing up the various theories on causation, he is inclined to support the suggestion of List and Peet (1938) that it is a humoral reflex closely connected with the functions of the salivary glands. By "humoral" he explains "that there is an increased irritability in the autonomic synapses in a limited skin area near the big salivary glands after an injury in the parotid region, or on the sympathetic. When the patient is eating, acetylcholine is constituted in the salivary glands in connexion with their function, and this substance diffuses in the surrounding tissue enough to cause sweat secretion and hyperaemia in the supersensitive area."

Various other theories on the cause of the auriculo-temporal syndrome may be summed up here. Wilson (1936), with reference to his cases mentioned above, concludes that the sweat glands of the human face have a double nerve supply—the sympathetic secretory fibres and an accessory set of fibres. He states that both these sets of fibres are cholinergic and believes the cause of the sweating to be due to a reflex. He also suggests that an abnormally reactive condition of the sweat glands may follow degeneration of sympathetic secretory nerves. Fulton (1949), however, points out, as have other physiologists, that there is no anatomical evidence of a double innervation of sweat glands.

Ford and Woodhall (1938) suggest that when the auriculo-temporal nerve is injured various groups of nerve fibres contained in it may be severed and in the process of regeneration may become misdirected along pathways other than those they originally pursued, so that they form connexions with the sweat glands and blood vessels of the skin. Thus nervous impulses passing over the parotid fibres, as when eating, may cause paroxysmal sweating and vasodilatation in the distribution of the auriculo-temporal nerve.

Payne (1940), in an article entitled "Pneumococcal Parotitis and Antecedent Auriculo-temporal Syndrome," regards the syndrome as a reflex from taste stimuli from the posterior third of the tongue.

Goatcher (1954), after describing a case of typical auriculo-temporal syndrome following excision of a portion of parotid gland for parotitis, sums up the various views held concerning its causation and then finally states: "It becomes apparent that the mechanism of the auriculo-temporal syndrome is not fully explained."

Bell, Davidson, and Scarborough (1953) state: "Although the fibres to the sweat glands are in fact post-ganglionic sympathetic fibres, they act in most animals, including man, by releasing acetylcholine"; or, as Fulton (1949) puts it, "sudomotor sympathetic fibres, in contrast to vasomotor and pilomotor fibres, are cholinergic."

Incidentally, it should be noted that gustatory reflex sweating may occur physiologically as when eating spicy foods, but it is ordinarily confined to the face, the upper lip, and tip of the nose (List and Peet, 1938).

Discussion

Unilateral submental sweating on eating as observed by Uprus *et al.* and by Langenskiöld and in the present case would seem to be analogous to the auriculo-temporal syndrome but due to damage to the submandibular salivary gland as distinct from the parotid gland. (In Langenskiöld's case there was probably damage to both the parotid and the submandibular salivary glands on the right side, as the scar on that side extended from just below the lobe of the ear and sweating was not confined to the submental region.)

Uprus *et al.* carried out numerous tests on their patient, one of which was the effect of atropine. They found that after the administration of the drug (2 mg. subcutaneously) flushing but not sweating occurred on eating an apple. (It has been shown that a corresponding test in the present case produced similar results.) They point out that the effect of atropine pharmacologically on the salivary glands is to render stimulation of the chorda tympani ineffective in causing secretion without impairing its vasodilator activity,

for the chorda tympani is known to have true vasodilator fibres as well as secretory fibres. They also state that in all cases with such abnormal flushing and sweating injury has occurred to or in the vicinity of nerves which are known to contain true vasodilator and secretory fibres, and unknown to occur within the neighbourhood of a nerve which does not contain vasodilator fibres. Whilst they have no evidence to connect the fibres of the chorda tympani with the vessels and sweat glands of the abnormal area they consider that the period of latency between the original trauma and the onset of symptoms is consistent with an unusual regenerative phenomenon having occurred. They conclude that it is an abnormal reflex and that it has been identified with that of the salivary reflex, and that the abnormal effect is related to activity in the chorda tympani.

In the case presented above it is of particular interest to observe that the right submaxillary gland was removed and that the wound did not heal by first intention. It is possible that some portion of the gland remains, and in any case the surrounding area must have suffered trauma at the time of the original operation.

From perusal of the literature and after consultation with others it seems there is as yet no completely satisfactory explanation of the phenomenon, but the theories regarding the cause of the auriculo-temporal syndrome could be applied to these cases of unilateral submental sweating, except that a different nerve is involved—namely, the chorda tympani and not the auriculo-temporal.

In the three cases of submental sweating which have been described there was a long interval between the original operation and the onset of symptoms. This supports the theory that some abnormal regeneration of fibres had occurred. Further, in the case of Uprus *et al.* and in the one presented here, blocking the lingual nerve (chorda tympani) caused temporary total abolition of the abnormal response, whereas blocking the cervical sympathetic did not. This would support the theory that the syndrome is a salivary reflex related to activity in the chorda tympani. This nerve contains a few preganglionic parasympathetic (secretomotor) fibres which enter the submandibular ganglion which sends post-ganglionic fibres to the submandibular and sublingual glands (Gray, 1949).

Therefore it is suggested that the phenomenon of unilateral submental sweating on eating, following a previous operation on the neck involving one or other submandibular salivary glands, be known as the "chorda tympani syndrome" as distinct from the auriculo-temporal syndrome, which is related to lesions of the parotid gland.

Treatment

Treatment of such a condition is difficult. Destruction of the lingual nerve would lead to undesirable side-effects. Belladonna also has side-effects and cannot be taken indefinitely but might be used on special occasions. X-ray application to the skin has been suggested, but the radiotherapists consulted thought this might harm the skin, altering its texture without affecting the symptoms.

Another suggestion was to reflect the skin affected and divide all nerves supplying this skin. Excision of the affected skin area was carried out in Langenskiöld's patient with apparently good effect. This has not been tried in the present instance, and in any case might lead to undesirable scarring in a young girl. The condition therefore persists, but the child is not seriously worried about it at present. Time may prove to be a healer, but this does not seem to have been so in the other cases mentioned.

Summary

A case of flushing and sweating of the right submental region after eating is described. The various responses to the intake of certain foods before and after atropine administration, stellate ganglion block, or lingual nerve block were observed.

The history of one identical case, and another somewhat similar case recorded previously by other authors, are summarized, and theories of causation are discussed particularly in relation to the analogous auriculo-temporal syndrome.

The aetiology is somewhat uncertain, but the phenomenon would seem to be due to a reflex definitely related to the chorda tympani and abnormal regeneration of nerve fibres. It is suggested that the symptom-complex be termed "the chorda tympani syndrome."

I am indebted to Dr. E. A. Carmichael for his advice and for the photographs, which were taken at the National Hospital, Queen Square; to the librarian of the Royal Society of Medicine; to Mr. D. S. Hawke, my registrar; and to the sisters, house-surgeons, and colleagues at the Lister Hospital, who have helped with various tests, or have given suggestions regarding aetiology and treatment of the syndrome described in this paper.

SIMPLE CLINICAL TEST FOR THE DIAGNOSIS OF EARLY PREGNANCY

BY

G. DOUGLAS MATTHEW, F.R.C.Sed., F.R.C.O.G.
Senior Lecturer, Department of Obstetrics and Gynaecology,
University of Edinburgh

In 1953 Matthew and Hobson published their observations on the effects of intramuscular injections of progesterone and oestrogen ("disecron") as a means of diagnosing pregnancy. Although this test was associated with a high degree of accuracy and was more reliable than the Hogben test in the early weeks of pregnancy, it involved the disadvantages of two consecutive daily injections. To overcome this element of discomfort and inconvenience to the patient a further series of cases has been accumulated to show the effects of the administration of oral progesterone and oestrogen in circumstances similar to the earlier trial.

Present Series

As a dosage reasonably comparable with the injected preparation, a total amount of 100 mg. of ethisterone and 0.5 mg. of ethinyloestradiol has been given over two consecutive days. This entailed the administration of five tablets ("orasecron") each containing 10 mg. of ethisterone and 0.05 mg. of ethinyloestradiol on each of the two days. The tablets were taken singly at three-hourly intervals and in this way caused no real upset, although a few patients complained of mild nausea. In all, 94 patients have so far been subjected to this test. The interval from the last menstrual period did not exceed 16 weeks (112 days) in any instance; in fact, cases have not been included in which the diagnosis of pregnancy would be reasonably certain as a result of pelvic examination.

Patients have been derived mainly from the sterility clinic, and the average age of the total series was 27.6 years.

The cases have been divided into two groups according to whether uterine bleeding was associated with the administration of the test dosage of combined progesterone and oestrogen or not.

Time Menstrual Period Overdue

Days Menstrual Period Overdue	No. of Cases	
	Group 1	Group 2
1 to 7	9	10
8 " 14	28	13
15 " 21	18	4
22 " 28	3	1
29 " 84	4	4
Total	62	32

Group 1 consists of 62 patients (average age 27.7 years) in whom follow-up examination established the ultimate diagnosis of pregnancy (see Table). In this group there were no instances of uterine bleeding associated with the administration of progesterone and oestrogen in the dosage prescribed. It should be noted from the Table that in 37 patients (60%) the calculated interval between the first day of the missed period and the administration of the tablets was within 14 days, the period of pregnancy during which the Hogben biological test is not regarded as being reliable (Matthew and Hobson, 1953).

Group 2 consists of 32 patients (average age 27.5 years) in whom follow-up examination excluded the presence of pregnancy (see Table). Although cases of short-term secondary amenorrhoea in the absence of pregnancy are less often encountered, and thus the total number included in this group is smaller than in group 1, it would seem that the two series are comparable, especially in the timing of the test (see Table). In every patient in this group uterine bleeding occurred within a reasonable time from the taking of the progesterone/oestrogen tablets. The time interval before bleeding occurred varied up to a maximum of 14 days. Six patients began bleeding on the second day of the test, four on day 1 after completion of the course of tablets, one on day 2, six on day 3, three on day 4, one on day 5, two on day 6, and two on day 7. Thus in 78% of the cases bleeding occurred within a week of the test. Of the remainder, one patient had bleeding on day 8, one each on days 9, 10, 11, and 14, and two on day 12.

Summary

A further step has been taken in investigating withdrawal bleeding following the administration of progesterone and oestrogen in women of child-bearing age complaining of short-term amenorrhoea. Parenteral administration used in the previous trial has now been succeeded by oral administration and the results observed in a series of 94 cases. When amenorrhoea was due to pregnancy no withdrawal bleeding occurred and no untoward effects upon the pregnancy were noted. In cases of non-pregnancy amenorrhoea withdrawal bleeding occurred within a varying period of time up to a maximum of 14 days. Thus the oral administration of combined progesterone and oestrogen in the dosage prescribed would appear to constitute a reliable clinical method of diagnosing early pregnancy.

Generous supplies of orasecron were kindly made available by British Schering Ltd. for use in this trial.

GRANULOMA INGUINALE (VENEREUM)

BY

G. H. KNIGHT, M.D.

*Director, Venereal Disease Department, General Hospital,
Birmingham*

AND

W. FOWLER, M.D.

*Consulting Venereologist, Royal Hospital, Wolverhampton,
and General Hospital, Birmingham*

Granuloma inguinale is endemic in the West Indies and other subtropical areas and in the southern part of the United States, but was rarely seen in this country until the West Indians began to immigrate in substantial numbers. In the second half of 1951, the first period for which records are available, no cases of granuloma inguinale were reported in England or Wales. Six cases were reported in 1952, two in 1953, nine in 1954, and twelve in the first six months of 1955. Since the beginning of July, 1955, eight male cases have been seen in Birmingham and Wolverhampton. Because of this rising incidence it is thought worth while to recall briefly the main features and treatment of the disease.

Granuloma inguinale is generally regarded as a venereal infection with an incubation period of two days to eight weeks, but other modes of transmission have been suggested (Fergusson and Roberts, 1953). The disease is commoner in women than in men and in coloured than in white races. The infectious agent, *Donovania granulomatis*, is a Gram-negative pleomorphic rod which grows readily on media containing egg yolk (Goldberg *et al.*, 1953). In Giemsa- or Leishman-stained films of scrapings or sections from the lesion the organisms tend to occur in pairs and are found lying free in the tissues and, characteristically, encapsulated in vacuoles in the cytoplasm of large monocytes.

The disease predominantly affects the inguinal, genital, crural, perineal, and perianal regions. The primary lesion is a vesicle or papule which is surrounded by an area of induration and erythema. The overlying epithelium soon disintegrates and the lesion develops either as a tumour consisting of vegetative granulations or as a slightly raised ulcer with a rolled edge and clean, smooth granulosomatous floor. Pain and tenderness are not features of the lesion unless it becomes secondarily infected. In the latter event, too, the edge of the ulcer may become undermined and the floor covered with a

grey foul-smelling slough. The lesion progresses slowly by peripheral extension and also by the formation of satellite lesions due to auto-inoculation. The lymph nodes are not affected, but an indurated subcutaneous swelling may follow a lesion on the genitalia, the pseudobubo of Greenblatt's school. Complete recovery does not occur without treatment, but there may be partial healing with the formation of thick scar tissue. Later marked deformities may arise as a result of this scar tissue contracting.

Present Series

Seven of our patients were from the West Indies and one was from East Pakistan. The Pakistani had been treated for a similar condition one year previously in his own country and he denied any extramarital coitus. Five of the other patients had not indulged in sexual intercourse since leaving the West Indies. Three of these developed the lesion during the voyage to Britain, as did the Pakistani; the other two had been in this country for three and four weeks respectively before the lesion was noticed. The possible incubation in these five cases was 15, 21, 25, 63, and 84 days. The two remaining patients had been in England for over two years. One of these men gave a history of coitus with a Jamaican consort five weeks and with a white consort four weeks before the lesion developed. The other had indulged in very frequent coitus with coloured and white women up to the time the lesion appeared.

One of these patients presented a typical granulomatous ulcer in the inguinal region (Fig. 1). Another had a perianal ulcer with hypertrophic granulations growing in towards the centre from the edge, which was undermined (Fig. 2). The lesion was situated on the penis in the other six cases. In one case there was a small raspberry-like tumour over the fraenum (Fig. 3). In another the granulations were also proliferative, and were situated in the coronal sulcus on either side of the fraenum. The lesion was ulcerative in the remaining cases and involved the fraenum in two cases, the coronal sulcus in one case, and the free edge of the prepuce in one case. In one of these cases the ulcer was grossly secondarily infected. In the others it consisted of a slightly raised plaque with an eroded clean surface and a narrow surrounding area of induration. In two cases two lesions were present, while in another there was a slightly tender subcutaneous swelling in the inguinal region.

In every case the diagnosis was established by demonstrating Donovan bodies in the cytoplasm of larger monocytes. Greenblatt *et al.* (1951) recommend that a piece of clean granulation tissue should be obtained by biopsy punch and the under surface smeared on a slide. In these cases we obtained satisfactory results with material obtained by drawing a needle deeply through the tissues near the edge of the lesion.

FIGS. 1, 2, and 3.—Different clinical aspects of granuloma inguinale.

Medical Memoranda

A Rare Type of Muscular Dystrophy

In the following case the clinical picture corresponded with that occurring in the distal type of myopathy first described by Gowers (1902), the diagnosis being substantiated by laboratory and electrical investigations.

CASE REPORT

A soldier aged 24 was admitted to hospital complaining of weakness of both lower limbs and difficulty in walking. These symptoms had begun at the age of 6 and had continued to date. The weakness had fluctuated a little from time to time, but had not progressed in severity to any marked degree. Earlier it had been said that pes planus was the most probable cause for his unusual gait. There were no other symptoms relating to muscular or nervous dysfunction. In his family history a relevant fact was that his niece, aged 3, had experienced difficulty in walking, and it was stated that she was suffering from hereditary muscular dystrophy. The rest of his family were quite well.

Examination of his nervous system showed that he had marked wasting of both calves and also of the lower third of both thighs, thereby giving the appearance resembling an "inverted champagne bottle" frequently seen in patients suffering from peroneal muscular atrophy. The power of his calf muscles was considerably diminished, more on the left than on the right. On contraction of his quadriceps femoris a well-marked "bunching" of the muscles was seen, a sign which is ascribed to the wasting of the distal end of the muscles. The deep reflexes in his lower limbs were unexpectedly brisk and the limbs were slightly spastic. Both plantar responses, however, were flexor and his abdominal and cremasteric reflexes were normal. His gait was "waddling" in character, resembling the gait seen in bilateral congenital dislocation of the hip-joints, and the paces were shorter than normal. When asked to stand on his feet from the lying (supine) position no Gowers's figures were present. Clinically there was no abnormality in his facial musculature, the sternomastoids, shoulder-girdle musculature, or the muscles of his upper limbs. All his cranial nerves appeared intact. Sensory changes were not discovered in any region of the body, and muscle co-ordination was quite normal. All other systems were normal on examination.

Investigations.—(1) Cerebrospinal fluid : no increase in pressure ; quite clear ; protein, sugar, and chloride contents were within normal limits : the cells seen were less than 1% lymphocytes ; the Lange colloidal gold curve was negative. (2) Urinary studies of creatine showed a 24-hour excretion of 60 mg. (normal value usually nil) ; urinary creatinine excretion showed a 24-hour value of 1.7 g. (normal 0.4-1.8 g. in 24 hours). (3) Electrical muscle responses :—Rheobase-chronaxie studies showed abnormalities of the following muscles compatible with a diagnosis of myopathy : tibialis posterior and flexor hallucis longus, and to a less extent in the extensor brevis digitorum, extensor hallucis longus, soleus (left only), and peronei longus and brevis ; all changes noted were bilateral with the exception of the soleus. (4) Biopsy of muscle tissue taken from the left gastrocnemius showed the changes of muscular dystrophy by the presence of swollen muscle fibres, increased sarcolemmar nuclei, and marked interstitial fat. (5) X-ray examination of the long bones of the upper and lower limbs showed no rarefaction.

COMMENT

In Gowers's distal myopathy, wasting begins in the legs and is usually followed later by involvement of the hands and forearms. It is still doubtful, however, whether Gowers's original case was in fact one of true distal myopathy; his patient was a youth of 18 who not only had weak anterior

Treatment

American authorities have shown that streptomycin, chlortetracycline, chloramphenicol, and oxytetracycline are more effective in the treatment of this infection than the antimony preparations. Greenblatt *et al.* (1952) treated a large number of cases with these antibiotics and found that the average total amount of each necessary for cure was streptomycin, 23.96 g.; chlortetracycline, 35.5 g.; chloramphenicol, 36.1 g.; and oxytetracycline, 31.6 g.; and that approximately 9%, 15%, 24%, and 6% of the cases treated with these four substances respectively required re-treatment. They also found that 5% of the cases treated with streptomycin were resistant to this antibiotic, and one case (2.2%) was resistant to chloramphenicol. Later Greenblatt and Barfield (1952) concluded that oxytetracycline was probably the treatment of choice and that the optimal dosage was 2 g. daily for 10 to 20 days. In a small series of cases Wright *et al.* (1951) obtained good results with oxytetracycline 1 g. daily for 28 to 35 days. Niedelman *et al.* (1951) considered that 40 g. was the minimum amount of oxytetracycline necessary for complete recovery, although one of their patients was cured with 2 g. daily for nine days.

The dosage of oxytetracycline used in our series was 2 g. daily and of streptomycin 1 g. daily. With a migrant population like the Jamaicans effective follow-up is difficult. One case treated by streptomycin defaulted before healing was complete. Two cases given streptomycin for nine and fourteen days respectively defaulted two weeks after the lesion had healed. One case treated with streptomycin for three weeks has remained healed for four months. One case treated with oxytetracycline defaulted before healing was complete. One case given a three-weeks course of oxytetracycline defaulted a week after healing had occurred. Two cases given a four-weeks course of oxytetracycline have remained healed during an observation period of two months.

It is obvious that we cannot offer any comment of value on the treatment of granuloma inguinale, but we wonder if 1 g. of oxytetracycline daily for 30 days or longer would not prove more effective than a larger amount in a shorter period.

Earlier it was mentioned that the manner in which granuloma inguinale is transmitted is uncertain. If, however, it is a venereal disease the low incidence in the white population of endemic areas leads one to believe that it should not become a serious social problem here, although it may provide occasional diagnostic difficulties unless the possibility of its occurrence in white people is borne in mind.

The Research Defence Society has published a pamphlet, *Anti-poliomyelitis Vaccination* (price 3d.), which poses and answers outstanding questions on this subject. The society exists to publicize the advances in medical knowledge due to animal experiments, and the fact that this involves no cruelty "in spite of the allegations to the contrary made by those who would like to bring this sort of medical research to an end." The questions and answers deal with the making of the vaccine, the chance of a child getting poliomyelitis, the proportion of paralytic to non-paralytic cases, and the conditions under which the monkeys needed for the vaccine travel and live. Inquiries to the Secretary, Research Defence Society, 11, Chandos Street, Cavendish Square, London. W.1.

tibial muscles but also had atrophied sternomastoids, paresis of frontalis and orbicularis muscles, and a wasted tongue. It is quite probable, therefore, that that case may have been an unusual type of dystrophia myotonica. The predominance of involvement of the leg muscles in the present case indicates that it is an example of distal myopathy. In view of the electrical abnormalities found in the peronei muscles, and the "inverted champagne bottle" appearance of the lower limbs, the diagnosis of Charcot-Marie-Tooth syndrome was excluded by the absence of any sensory changes and by the normal upper limbs.

An interesting point in the above case was the presence of slight spasticity and hyperreflexia in the lower limbs. In most cases of muscular dystrophy the tendon jerks are reduced or lost *pari passu* with the muscle-wasting. A number of cases have, however, been recorded in which muscular dystrophy was associated with spasticity in Friedreich's ataxia (Bramwell, 1893; Hodge, 1897; Rook and Dana, 1890). There was in this case, however, no evidence of cerebellar ataxia or of any of the commonly found features of Friedreich's disease. Creatinuria is a common finding in muscular dystrophy, and is found even on a creatine-free diet (Boothby, 1932). It is often associated with a diminished urinary excretion of creatinine. These findings have been attributed to the loss of muscle tissue occurring in the disease. This patient's urine showed an increased creatine excretion, but the amount of creatinine present in the urine was within normal limits. Bony changes of rarefaction and increased fragility have been described in muscular dystrophy by Spiller (1905a, 1905b) and Merle and Raulot-Lapointe (1909), but these were not evident in this case.

My grateful thanks are due to Major-General R. Priest for his valuable criticism and advice on this case report.

Desmoid Tumour Resembling a Pseudo-Pancreatic Cyst in a Male

A man aged 40 was first examined on March 27, 1954, when he was complaining of swelling of the upper abdomen with discomfort and nausea for a month. Two months previously he had been hit in the epigastrium by a small child, but there was no history of major trauma or any surgical scars. The upper abdomen contained a palpable mass which extended down to the umbilicus. This mass was hard and smooth. His general condition was very good. Barium-meal examination showed pressure on the stomach from below and a greatly widened duodenal loop (Fig. 1). Various pathological tests were normal.

On April 2, under general anaesthesia (Dr. T. Lamrock), a biopsy was performed, and the tumour, which was infiltrating the posterior rectus sheath and rectus muscle for at least 15 cm. of its length, was found to be firm, pink, very vascular, and filling the upper half of the abdomen. Macroscopically the tumour resembled an invasive, rapidly growing sarcoma. The microscopical appearances of the sections were similar to those of a desmoid tumour. The tumour had not extended through the anterior rectus sheath, but the overlying subcutaneous tissues contained numerous very dilated veins. There was no increased peritoneal fluid, and, as was to be expected, there was no indication of metastases.

On June 4, under general anaesthesia (Dr. J. Bowen) and through an inverted T incision, the old wound, the tumour, the upper half of each rectus muscle with its sheath, the adjacent peritoneum, and adherent omentum were all removed en

bloc. The gap in the abdominal wall (23 cm. long, 5 cm. wide at the upper end, and 13 cm. wide at the lower end) was covered with tantalum gauze. The skin was then closed and the wound drained. Convalescence was uneventful.

The excised tumour (Fig. 2) was encapsulated on its deeper aspect and measured 30 by 24 by 10 cm., with a portion of the rectus sheath and muscles 23 cm. long attached. The tumour had a fairly tough greyish-pink cut surface with coarser fibrous bands in places, and weighed 11 lb. 14 oz. (5.3 kg.). Microscopical examination showed rather vascular loose fibro-cellular tissue. The nuclei were small and uniform and mitoses were difficult to find. The appearances were consistent with a diagnosis of desmoid tumour.

Since then there has been no indication of an incisional hernia or of any recurrence of the tumour.

FIG. 1.—Barium-meal examination showing that the stomach was displaced upwards and that the duodenal loop was considerably widened.

FIG. 2.—Anterior aspect of the tumour showing the adherent strip of skin and rectus muscle. The scale is in inches.

COMMENT

Desmoid tumours are not common and may present difficulties in diagnosis, especially when occurring in males or in situations other than the anterior abdominal wall. In this case the tumour projected posteriorly into the abdominal cavity and prior to operation appeared to be a pseudo-pancreatic cyst. When exposed at operation the macroscopic appearances of the tumour resembled those of a rapidly growing malignant neoplasm.

Wide removal of a desmoid tumour is imperative if recurrence is to be prevented (Strode, 1954), but after such removal the magnitude of the gap in the abdominal musculature and peritoneum may be so great as to preclude any attempt at simple closure. In this case the underlying gap was bridged with a piece of tantalum gauze which overlapped the aponeurosis by at least 3 cm. all round. This gauze was fixed in position with numerous cotton sutures. Although the tantalum was left in direct contact with the stomach, bowel, and omentum, no evidence of any adverse reaction to this has been noticed. The skin of the abdominal wall had not been involved by the tumour, and thus there was no problem with its closure.

Other materials available for closing such a gap in the abdominal musculature include fascia lata, skin, polyvinyl sponge (Schofield *et al.*, 1954), and steel mesh (Burnell, 1951); but no material could have been any more effective to date than the tantalum gauze has been here. The abdominal wall is firm and the patient is free of symptoms despite resumption of his usual activities as a general practitioner.

Although Touroff (1954) has suggested phrenicectomy to reduce tension in such a wound until it becomes firm, this manoeuvre was not employed, as it is considered that lateral tension on the wound may be reduced sufficiently by bands of adhesive plaster encircling the body. Such encircling bands have previously been used in many cases of repair of extensive incisional herniae without deleterious effects, and were also used in this case.

Aneurysm of the Pulmonary Artery Resulting from a Chronic Pulmonary Embolus

The following case is an example of chronic cor pulmonale developing as a result of pulmonary embolism, and we feel that it is of interest because of its rarity and because of the time that elapsed between the original embolism and death.

CASE HISTORY

The patient, a spinster, was born in 1902. She was admitted to hospital on February 28, 1945, suffering from a paranoid psychosis. A frontal leucotomy was performed in January, 1947, operation and convalescence being uneventful. Her mental state did not improve very much, but she was active and industrious.

In March, 1950, she was seen to be limping and was found to have a thrombosis of the left femoral vein. This was treated with paravertebral injection of procaine hydrochloride and support with an elastic stocking, and the symptoms and signs subsided. In January, 1953, thrombosis of the left femoral vein was diagnosed, and on one occasion she complained of tightness of the chest and unproductive cough. The oedema of the leg subsided and she again became ambulant, continuing to wear an elastic support. In December she was noticed to be dyspnoeic on exertion and slightly cyanosed, and in February, 1954,

oedema of both ankles developed. In April she had one attack of vomiting and became gradually more dyspnoeic. X-ray examination of the chest in July showed an aneurysmal dilatation of the left pulmonary artery. She now presented clinically as a case of chronic cor pulmonale, and a second x-ray examination in November showed further cardiac enlargement. In January, 1955, she collapsed and died.

Post-mortem Findings.—The body was that of a well-nourished middle-aged woman. The face and extremities were intensely cyanosed and both legs were oedematous to the thighs. The trachea and larynx were congested, and the lungs, though showing fibrotic changes throughout, did not contain any areas of infarction. Very marked hypertrophy and dilatation of the right ventricle and a small patent foramen ovale were found. There was a large embolus at the bifurcation of the pulmonary artery extending into both main branches and almost completely occluding the left. The clot was organized and organizing, largely endothelialized on the inner surface. It had clearly been *in situ* for some time, long enough for hypertrophy of the right ventricle to occur. Apart from a little atheroma there was no underlying disease of the vessel. The liver and spleen showed chronic congestion and the spleen showed scars of old infarcts. The left femoral and popliteal veins were thickened and fibrosed, with obstructed lumen, the result of past thrombosis and partial recanalization.

COMMENT

The almost complete occlusion of the first part of the left pulmonary artery by clot and the resultant dilatation behind the stricture gave rise to a striking radiological appearance suggestive of aneurysm. Aneurysms of the pulmonary artery are uncommon lesions, though simple dilatation may occur in mitral stenosis (Watkins and Harper, 1954). Brenner classifies the causes as traumatic, mycotic, congenital, and syphilitic. Others consider atheroma to be a significant aetiological finding.

Clifford *et al.* (1950) described a case of aneurysm of the pulmonary artery due to multiple emboli, and Boucher *et al.* (1951) reported a case due to embolism and diagnosed radiologically.

Our thanks are due to Dr. E. P. H. Charlton for permission to publish this case report.

Several new Italian journals dealing with medicine and its allied sciences have been announced recently. *Minerva Fisioterapica*, a quarterly journal devoted to physical therapy and nuclear medicine, is an addition to the series published by Edizioni Minerva Medica, 83, Corso Bramante, Turin. Annual subscription is 3,000 lire. *Il Bassini*, a quarterly journal from the Pio Istituto Bassini, 1, Via Recordi, Milan, contains clinical and biological papers, preferably of surgical interest. Annual subscription is 1,000 lire. *Anatomia e Chirurgia*, another quarterly journal, contains papers on surgery with special reference to its anatomical relations. It is published from 1a, Via Palestro, Rome, 305 (annual subscription 4,000 lire). *Archives Italiennes de Biologie*, founded in 1882 by Angelo Mosso and suspended in 1935, is to recommence publication in 1957 under the editorship of Professor G. Moruzzi, Pisa. Its past volumes contain many important contributions from Mosso, Bizzozzero, Golgi, Grassi, Luciani, and other eminent figures in Italian medical science. It will publish original work on physiology, in either French or English. Annual subscription \$10 (Sala delle Stagione, 1, Lungarno Paccinotti, Pisa).

Reviews

NORADRENALINE

Noradrenaline: Chemistry, Physiology, Pharmacology, and Clinical Aspects. By U. S. von Euler, M.D., F.A.C.P. (Pp. 382+xxi; illustrated. 87s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications, 1956.

Professor von Euler demonstrated in 1946 that noradrenaline was present in the body and that there were large amounts in the nerves of the sympathetic chain. This very important discovery has led to work in different parts of the world which has been published in no fewer than 750 papers and of which an account is given in this book. The chemistry of noradrenaline and the chemical methods of estimating and of discriminating between noradrenaline and adrenaline are described in great detail, and the figures for the occurrence of these two amines in tissues throughout the body should be valuable to many. The author is a man of clear opinions, and it is a pity that these are not expressed more frankly; the book would have gained in interest if they had been. For example, he points out that figures obtained for the amines in blood by the method of Weil-Malherbe and Bone show very small variations, although biological estimates of the amounts in the blood of the adrenal vein show very great ones. This implies doubt about what Weil-Malherbe and Bone actually measure, but the author does not point out the implication. Since the number of workers anxious to have a chemical method for estimating noradrenaline and adrenaline in blood is large, it would seem wiser to have emphasized the doubt.

An interesting, though rather short, account of the physiological action of noradrenaline is given, with evidence for the existence of separate hypothalamic secretory centres for noradrenaline and adrenaline—a subject to which the author has made an important contribution. There is a valuable discussion of the excretion of noradrenaline in the urine. The author's discovery that large amounts of noradrenaline are contained in the urine of patients with adrenal medullary tumours has been of great help in diagnosing the presence of these tumours. Finally the therapeutic use of noradrenaline, including its value for raising the blood pressure, is described. On the point that prolonged infusion of noradrenaline is followed by a fall in blood pressure in animals, the author quotes Churchill-Davidson that this does not happen in man. There are many, however, both in this country and in the United States, who have observed such a fall, and have found it necessary to continue the infusion for days on end. It seems important to discontinue the infusion very gradually if the fall is to be avoided.

The author is to be congratulated on this useful book.
J. H. BURN.

PHYSIOLOGICAL APPROACH TO CARDIOLOGY

Cardiac Diagnosis: A Physiologic Approach. By Robert F. Rushmer, M.D. (Pp. 447+vi; illustrated. 80s. 6d.) Philadelphia and London: W. B. Saunders Company, 1955.

The present physiological approach to cardiology suffers from an inadequate number of competent teachers. The student learns physiology before he can appreciate its practical significance, and by the time he has achieved specialist status he is apt to have forgotten these basic principles. The modern cardiologist may become an amateur physiologist in his field, but he is rarely a professional. Unfortunately, however, the professional physiologist usually knows remarkably little about cardiology, and his floundering in that practical world are apt to be as naive and clumsy as those of his amateur colleague.

Dr. Robert Rushmer, who is an associate professor of physiology and biophysics, courageously takes up the challenge to teach cardiologists the basic physiology of their subject, but, although he collates much that is valuable and helpful, has merely emphasized the observations made above

when he enters cardiological fields with which he is obviously unfamiliar. The section on heart sounds and murmurs illustrates this very well, for it would be difficult for a cardiologist to write so unhelpfully and with so little insight on so important a clinical subject. Unfamiliarity with many of the cardiologist's real physiological problems is equally evident in the chapters or sections on rheumatic carditis, aortic stenosis, and congenital heart disease. The author is more at home in the first half of the book, which deals with normal anatomy and physiology, heart failure, and certain physiological techniques, and much of this is admirable. Electrocardiography might have been better omitted in a book of this kind, for the subject is more than adequately covered by a large number of excellent monographs. Although the book is called *Cardiac Diagnosis*, only Part V (136 pages) is allotted to the diagnosis of cardiac disease, and in this section there are chapters on myocardial ischaemia, myocarditis, valvular disease, congenital heart disease, and possible heart disease; but none on hypertension, pericardial effusion, constrictive pericarditis, syphilitic aortitis, cor pulmonale, or the hyperkinetic circulatory states. No explanation is given for this curious selection.

No doubt much labour has been expended in the preparation of this book, and it may seem ungenerous to be too critical about it; but the fact remains that a physiologist has set out to teach the cardiologists the scientific basis of their subject, and has revealed that it is well-nigh impossible to do this unless he understands the subject itself.

PAUL WOOD.

SPLENIN EXTRACT IN RHEUMATIC FEVER

Splenin A in Rheumatic Fever. The Testing of Splenin A as an Anti-inflammatory Agent. By Alvin F. Coburn, M.D., Lucile V. Moore, M.D., Judith Wood, M.D., and Mary Roberts, R.N. (Pp. 87+xii; illustrated. 27s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications, 1955.

This monograph, as its subtitle indicates, describes the clinical evaluation of the action of a splenic extract originally prepared by Ungar on the inflammatory manifestations of rheumatic fever. According to Ungar the spleen elaborates two substances, splenins A and B, which are antagonistic to one another, the former having a cortisone-like action on inflammation. Coburn has previously claimed that in animals splenin A would suppress anaphylactic arthritis after splenectomy when cortisone would not, suggesting that the latter exerts at least part of its action on inflammation via the spleen.

In the work under review no attempt has been made to adopt the method of the controlled clinical trial comparable to that employed by the Medical Research Council for the evaluation of cortisone and A.C.T.H. in rheumatic fever. It is stated that this method was not applicable under the particular circumstances, and that it was therefore necessary to rely on clinical judgment. No very sweeping claims are made, but the extract seems to be non-toxic, and in adequate dosage it appeared to exert some anti-inflammatory action in a majority of cases of acute rheumatic fever. Whether the effect is equivalent to that obtainable with A.C.T.H., cortisone, or salicylates is not clear, but it is claimed to be of the same order. The supplies of splenin A were strictly limited and it is not available commercially. Further work on a much larger scale would be required to determine whether this substance has any therapeutic advantage over remedies at present available, and in particular whether it is suitable for long-term treatment of cases of rheumatoid arthritis.

F. E. T. SCOTT.

The *Britannica Book of the Year, 1956* (Encyclopaedia Britannica Ltd., 84s.), includes a short account of important developments in medicine during 1955. Mention is made of poliomyelitis prophylaxis, retrolental fibroplasia, drowning, mitral valvotomy, etc. Advances in surgery and the other principal specialties give the layman an authoritative picture of the progress made during the year.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 27 1956

INHERITANCE OF RAISED BLOOD PRESSURE

Since more people than formerly are reaching old age, the incidence of hypertension is probably increasing. This points to a difficulty in assessing the role of inheritance in determining the blood pressure of any individual, for the parents and relatives of a middle-aged patient may not themselves be available for examination, and past records and death certificates are notoriously unreliable in establishing the level of blood pressure during life. W. Weitz,¹ writing in 1926, considered that essential hypertension was inherited as a dominant characteristic, but that dominance could not always be demonstrated. This view was supported by W. Allan,² who thought that hypertensive cardiovascular disease might be a dominant trait. R. Platt,³ noting the difficulties of clinically elucidating a hereditary factor in the aetiology of hypertension, emphasized that the familial factor was obvious, that early familial studies of patients with hypertension had shown a hereditary factor in about 80%, and that the family history was useful in separating essential from other varieties of hypertension. In a well-documented hypertensive family recently reported⁴ all members of three generations were considered to be hypertensive. Others writers⁵⁻⁸ have considered that there was a familial factor; hypertension has been found to occur three times as frequently among the siblings of hypertensive individuals as among those of persons with normal blood pressure. Platt³ thought that his data were compatible with the hypothesis that essential

hypertension is conveyed as a Mendelian dominant with a rate of expression of more than 90%, though they did not prove this. Furthermore, he stated that the inherited factor might merely represent a tendency to arterial or arteriolar change, in the renal, coronary, or cerebral vessels, as opposed to its being specific for hypertension.

P. Sjøbye,⁷ in an exhaustive survey of heredity in essential hypertension and "nephrosclerosis," studied both clinically and genetically 200 propositi who were suffering from "nephrosclerosis" (the propositus is the member of a family from whom a genetic investigation begins). "Nephrosclerosis" appears to approximate to what would be termed malignant hypertension in Britain. He concluded that essential hypertension and nephrosclerosis constituted a clinical entity which was probably always due to a dominant hereditary gene, and that the age at which essential hypertension developed, within the groups of siblings, which he studied, depended on hereditary factors. Recent studies by G. W. Pickering and his group⁸⁻¹² have re-emphasized the uninterrupted gradation of normotension into hypertension. They claimed that their investigation, which was based on data collected by themselves and by Sjøbye,⁷ showed that arterial pressure is inherited as a characteristic whose variation throughout the range is continuous.

Various factors may affect the blood pressure of an individual. A study of the general population by Pickering and his colleagues⁸ showed that considerable variation existed in the rate of rise of blood pressure with age. They firmly state that any sharp dividing line denoting raised blood pressure is arbitrary. No natural dividing line was found in any decade; rather, there appeared to be a gradual merging of normal into high blood pressure. Thus an adjustment must be made in this type of study of arterial blood pressure both for age and for sex.⁹ In recording blood pressure indirectly, by a cuff, the reading may be affected by the thickness of the arm. Pickering and his colleagues¹¹ found that with increasing age women's arms tended to become fatter and men's to become thinner. However, in their study a correction for this did not significantly alter the findings on the growth rate of arterial pressure with age. In assessing the role of inheritance in the aetiology of essential hypertension Pickering recorded^{10, 12, 13} the blood pressure in the first-degree relatives of 109 patients with essential hypertension and 102 subjects with normal blood pressure; the age distribution of each group was similar, and higher pressures were found to occur in the relatives of subjects with essential hypertension. When the blood-pressure readings of the hypertensive propositi were

adjusted for age, hypertension appeared to occur as a graded characteristic. Pickering considered that the family histories provided evidence not of the inheritance of high blood pressure but of vascular disease. His observations led him to agree that heredity plays some part in the inheritance of hypertension, but not that inheritance is by means of a Mendelian dominant. For blood pressures in the higher ranges Pickering and his colleagues considered that some resemblance between the arterial pressures of first-degree relatives was proved. They added that the genetic element in the determination of arterial blood pressure had probably many aspects, including that of environment, which had not yet been fully investigated, and that the contribution of inheritance was probably slight. W. E. Miall and P. D. Oldham¹⁴ considered that the tendency of relatives to resemble each other in developing hypertension merely reflected a general tendency in these groups to have similar blood pressures. The importance of the environmental factor has been stressed by S. Uchigasaki,¹⁵ who also noted the prevalence of a hereditary predisposition. N. Szent-Györgyi¹⁶ claimed that different racial groups born in the U.S.A. have an incidence of hypertension which is higher than for each group if born in their own country of origin.

Several points of clinical importance emerge from this mass of painstaking work. None appears to surpass the value of Platt's observations on the value of the family history in separating essential from other forms of hypertension. There is a reluctance to regard essential hypertension as a distinct disease, but this is not to say that a high blood pressure is harmless. The view that essential hypertension is not a disease entity is helpful only if it is held in proper perspective, which must be that the finding of raised blood pressure is only one clinical sign; it may be of slight significance, or it may point to other evidence of hypertensive disease. The need for further field studies on the aetiology of hypertension, with particular regard to the effect of environment, is apparent.

UNITS OF RADIATION DOSAGE

Hitherto the unit of radiation dosage for both x and gamma radiations has been the roentgen or r . This unit is dependent upon the ionizing effect of radiations on air, and is in fact based on the measurement of the number of ions produced by the radiation per unit volume of air. Since the chief effect of the passage of radiation is the formation of ions, whether in air or in solid tissues, and since the biological effect of radiations is dependent upon ionization, there is a relationship between the ionization produced by a given dose

of a given radiation as measured in air and the biological effect produced by that dose in a given tissue. The unit based on this relationship, the r , has proved serviceable and sufficiently accurate for clinical purposes, and dependable within certain limits. However, recent developments in radiotherapy, and in particular the advent of megavoltage therapy, have surpassed these limits, with the result that the r is no longer an accurate reflection of the biological dose over the range of radiations now in use.

What matters in relation to biological effect is the dose of radiation actually absorbed—that is, the amount of energy imparted to the tissues by the ionizing particles. While over a considerable range the absorbed dose runs parallel with the air-ionization dose, it is this relationship which varies for different types of radiation. In order to meet this difficulty a new unit has been introduced which is known as the "rad." This unit is defined as "the amount of energy imparted to matter by ionizing particles per unit mass of irradiated material at the place of interest." It is an absolute unit, one rad being equivalent to 100 ergs per gramme. "The rad is the simplest possible unit of dose. If a dose of 1 rad is given to a cell, a portion of tissue, or an organ, then irrespective of its chemical composition and position in the body, irrespective of its proximity to lead, bone, or any other high atomic number materials, and irrespective of the kind of radiation used, each gram of the irradiated tissue will have received an increase in energy of 100 ergs."¹ The rad has now been internationally agreed upon as the unit for dosimetry of all radiation, though the relationship between it and the roentgen has yet to be established accurately.

Although in certain centres in Britain the rad has already been adopted as the unit of dosage, the uncertainty about its relationship to the r , as well as the replacement of the familiar and well-tried ionization methods of measuring radiation by other and more exacting methods—calorimetric and chemical—suggest that the time has not yet come for its universal adoption. Indeed, Dr. Ralston Paterson, in the opening paper to a symposium recently published, sounded this note of warning: "It is dangerous for clinicians to make any changes until both the confusion about röntgens and the indecision as to the rad have been thrashed out, for we will only get clinically into all sorts of muddles."² Since that was written, progress has been made in solving these difficulties, and doubtless they will soon be completely overcome. When this has been achieved we shall be a great step nearer a universally applicable unit of measurement of dosage of ionizing radiations. Nevertheless, the r

¹ Gray, L. H., *Brit. J. Radiol.*, 1956, 29, 355.
² Paterson, R., *ibid.*, 1956, 29, 353.

will not disappear from the scene, for at the recent International Congress of Radiology in Mexico City it was redefined so as to serve as the unit of radiation exposure—that is, as the measurement of the output of the radiation source.

FLUOTHANE AND FLUOROMAR

The possible risk of an explosion whenever ether or cyclopropane is administered, particularly in conjunction with oxygen in high concentration, has stimulated research to find an anaesthetic which would be non-explosive yet combine with this property the potency and ease of administration of cyclopropane and the pharmacological safety of ether. The first reports on the clinical use of some new fluorinated compounds came from the United States, where "fluoromar" (trifluoro-ethyl-vinyl ether) has been given with successful results.^{1,2} However, it is unlikely to gain widespread popularity because it is almost as inflammable as ether. From Great Britain J. Ravenöf has described³ the pharmacological properties in animals of a halogenated hydrocarbon—"fluothane" (2-bromo-2-chloro-1,1,1-trifluoroethane)—which fulfils many of the desired criteria. Among these are the fact that it is non-explosive in the presence of 50% oxygen, it does not decompose in the presence of warm soda-lime, and it does not irritate the mucous membrane of the respiratory tract; onset of anaesthesia is rapid, while recovery is quick and without nausea or vomiting. All these findings augur well for the advent of this new agent, but much more work still remains to be done before it can be considered suitable for general clinical use.

A report by M. Johnstone on the cardiac effects of fluothane in 500 cases⁴ gives a salutary warning that hypotension and bradycardia must be expected if concentrations reach as high as 2-4%, and similarly it may prove dangerous if combined with D-tubocurarine. In this issue of the *Journal* Drs. R. Bryce-Smith and H. D. O'Brien report at p. 969 a further series of 310 patients anaesthetized with fluothane. Their conclusions suggest that this agent may prove to be a useful general anaesthetic, but they draw attention to the severe respiratory depression that may follow its use, particularly in the presence of heavy premedication.

These two series alone are insufficient to enable any judgment to be passed on the general safety of this drug, but they offer an encouraging stimulus to further investigation. At present hypotension, bradycardia, and respiratory depression are the chief undesirable features that have been mentioned, though these do not seem to be prominent during light planes of anaesthesia. The constant search for safer anaesthetic agents continues. Meanwhile these preliminary reports suggest that fluothane may well rival trichloroethylene as a supplement

to anaesthesia with thiopentone, nitrous oxide, and oxygen, or it may replace ether in obstetrical anaesthesia. However, the dangers already mentioned serve only to emphasize that the most important single factor in the safety of anaesthesia is the skill and competence of the administrator rather than any particular property of the agent used.⁵

DIAGNOSIS OF EARLY PREGNANCY

Before the introduction of the Aschheim-Zondek test¹ in 1928 the diagnosis of early pregnancy rested on the sum total of symptoms and signs, general and local. Other biological tests followed, the mouse being replaced successively by the rabbit,² the female toad,^{3,4} the rat,^{5,6} and the male toad.⁷ All these tests, performed with urine or serum, have a very high degree of accuracy, but technical and financial disadvantages attached to the use of laboratory animals led to the search for a simple biochemical method. But none of the methods tried proved reliable, and it seemed rational as well as economical to use the patient herself as the test animal. Examinations of vaginal smears⁸ and of cervical mucus^{9,10} have both been described as practical tests, but they need specialist interpretation. As the first symptom which brought the patient to seek medical advice was usually amenorrhoea, methods were sought which would produce uterine bleeding only if the patient were not pregnant and which would not harm the pregnancy if present. The injection of neostigmine for this purpose was at one time popular, and recently the use of physostigmine and atropine has been advocated.¹¹ In 1942 B. Zondek¹² reported a quick method of treating secondary amenorrhoea by inducing a withdrawal bleeding with progesterone or oestrogen or both. Several workers saw in this a basis for a pregnancy test when the amenorrhoea was of short duration, and in 1953 G. Douglas Matthew and B. M. Hobson¹³ claimed that two consecutive daily injections of progesterone and oestrogen could be used as an accurate diagnostic test of pregnancy, and was more reliable in the earliest weeks of gestation than the Hogben test (the injection of urine into the female African toad, *Xenopus laevis*). In this issue of the *Journal* Dr. Matthew reports on the results obtained since oral administration of the hormones was substituted for injections. Ninety-four women with amenorrhoea of less than 112 days' duration were given 50 mg. of ethisterone and 0.25 mg. of ethinylloestradiol by mouth on each of two consecutive days. In 62 there was no subsequent uterine bleeding and all these proved pregnant; but in the 32 in whom follow-up excluded pregnancy there was uterine bleeding within 14 days—in the majority within a week.

This clinical test for early pregnancy has much to commend it, including simplicity and relative economy. It will therefore no doubt be welcomed, especially by the general practitioner. Some qualifications must, however, be made. Dr. Matthew writes that when the amenorrhoea was due to pregnancy no withdrawal bleeding occurred and no untoward effects on the pregnancy were noted. This could only be stated with complete confidence if in all the women who did have a withdrawal bleeding the flow was examined microscopically and an endometrial biopsy carried out. It might therefore be worth while repeating a clinical trial including these precautions, in addition to carrying out simultaneous Hogben tests on all the women. It would also be interesting to apply the test to patients in whom sterility is associated with infrequent periods, in order to find out whether withdrawal bleeding merely interrupts the current cycle or whether it brings it to a premature end. A more obvious drawback to the type of test described by Dr. Matthew is that it cannot be used in the case in which the aid of a pregnancy-diagnosis test is perhaps most often sought—that is, when there has already been some vaginal bleeding and the clinical picture is not typical of pregnancy. Finally, there is usually no urgency for a certain diagnosis of early pregnancy, and if the family doctor cannot make a confident diagnosis re-examination of the patient in three or four weeks' time is nearly always conclusive. Pregnancy, like murder, will out.

OZONE POISONING

Recently the potentiality of ozone as an occupational hazard to the health of human beings has been recognized, though it has long been known that it decreases the rate of pulmonary ventilation, lowers output of carbon dioxide, and in large amounts damages the respiratory system of experimental animals. Three cases of illness in welders using a new technique in welding exemplify the clinical features and the difficulty in diagnosis of this relatively infrequent industrial disease.¹ These three welders had been using, for the previous three to fourteen days, a new consumable electrode for welding, which gave rise to a concentration of ozone in the working environment of 9.2 parts per million. (The present threshold limit, according to most recent acceptable standards, is 0.1 part per million.) All three presented with similar symptoms of severe headache, dyspnoea, cough, and substernal oppression. Clinical examination revealed some adventitious sounds in the lungs and loss of weight in two of the men; chest radiographs gave no help in the differential diagnosis from pulmonary oedema, acute myocardial infarction, or congestive heart failure. The most common causes of pulmonary oedema—phosgene and nitrous fumes—were excluded by air analyses at the working point. Acute myocardial infarction, strongly suspected in one case, was inadmissible in the light of a normal electrocardiogram and a subsequently negative cardiac history. The increased bronchovesicular markings and an area

of consolidation in the x-ray films of one case were consistent with bronchopneumonia, and also compatible with the pulmonary inflammatory disease known to be a possible effect of exposure to ozone.

A feature which has not hitherto been emphasized in cases of ozone poisoning was the delay in disappearance of residual symptoms. When all clinical and roentgenological abnormalities had disappeared one man was still complaining, nine months after exposure, of moderate fatigue, cough, dyspnoea on exertion, and loss of weight. This man's initial symptoms had been exceptionally severe, and he had a transient renal injury manifested by proteinuria, scattered white and red cells in the urine, and finely granular casts. Treatment of such cases is essentially symptomatic—rest in bed, analgesics for the severe headache and chest pain, administration of oxygen, cough mixtures, and, if necessary, antibiotics. Prevention is a matter of isolating the manufacturing process and providing local exhaust ventilation.

WOUND DRESSINGS

Many thousands of wound dressings are applied every day. How many of them achieve their purpose? Studies of the course of healing show how actively the skin reconstitutes its structure. Within a few hours migrating epithelial cells begin to cover an abraded surface. In deeper wounds invasion by fibroblasts and capillary loops is a little slower, but in suitable conditions is still quite fast. An ideal dressing would provide conditions helpful to these processes. Its full specification is still not known, but some requirements are evident. The wound must be protected from further physical damage; chemical interference must be avoided; infection must be prevented. Dressings in use to-day commonly fail in one or more of these simple functions.

The routine dry dressing of gauze, cotton-wool, and bandage has the great virtue of simplicity, and is good while it remains dry. Dry cotton-wool protects the wound and keeps out bacteria, but let the housewife put her hands in water, or the factory worker do an oily job, and the dressing fails completely. At the other extreme is the adhesive impermeable film. This also is good at first; it is neat, easily applied, and it protects the wound from noxious materials, but it often becomes an impermeable reservoir of moisture whether from the skin, from the wound, or through accidental leakage from outside. This excessive moisture leads to a sodden wound, which is liable to infection. The fact that certain plastics such as "cellophane" and "nylon" can be prepared so as to be permeable to water vapour has been the basis of attempts to achieve a dressing which provides an effective barrier to bacteria but allows drying of exudate.^{1,2} The nylon dressing was shown to be practical and effective in many industrial wounds.³ A fresh attack on this prob-

lem is described by Dr. J. T. Scales and his colleagues at p. 962 of the *Journal* this week. The new dressing includes a microporous polyvinyl chloride plastic which is more flexible and more permeable than the nylon film, over which it is claimed to have practical advantages.

The clinical impression that wounds heal better when kept dry is supported by evidence that drying destroys commonly occurring bacteria.⁴ This effect is less marked if serum is present, but may still have some relevance to the surprisingly satisfactory results of leaving certain wounds open to the air. If drying is obtained with scab formation, then abrasions and burns sometimes heal without clinical sepsis, though contamination with organisms can often be shown. Should these organisms obtain a foothold under the scab, the full picture of sepsis may be seen.⁵

Experiments with these plastics permeable to vapour have shown further the self-sterilizing power of the skin. When the normal skin is sealed under a nylon dressing, it rids itself of *Staphylococcus aureus* previously present and other organisms are reduced in numbers. At least part of this effect is attributable to the unsaturated fatty acids of the skin, though their action is impaired by serum albumin such as might escape from a wound.^{6,7} The results which Scales and his colleagues report confirm that this self-sterilizing action of the skin is present with their new vapour-permeable dressing, whereas organisms persist under impermeable dressings. It is not enough for dressings to meet ideal requirements in the laboratory. They must stay in place wherever the wound may be on the body and resist the wear-and-tear of working life. A useful advance has been the development of flexible adhesive dressings which mould to the contours of the skin and permit movement of the part without breaking their seals. The new dressing incorporates these advantages, though there may still be room for improvement. It would, for instance, be preferable for a non-adherent surface to be presented to the raw areas. Tearing of the delicate migrating epithelial layer when a dressing is removed may well defeat some of the advantages gained by an otherwise good design. Nevertheless, dressings on the lines of those described promise to be an advance on anything previously available.

HEPARIN IN MYOCARDIAL INFARCTION

Discussions about anticoagulant therapy in myocardial infarction, and in particular whether "good risk" patients do not require it, have too seldom taken account of the fact that anticoagulant therapy has two distinct phases in which two entirely different anticoagulant drugs are used. The indications for treatment with heparin need not be the same as those for treatment with coumarins. It is important to consider the object of therapy with each of these agents, with a view to deciding what is the most reasonable action a doctor should take when confronted with a case of acute myocardial infarction within a few hours of its occurrence.

It now seems clear that "good risk" cases, as defined by H. I. Russek and colleagues¹ (those showing no

serious complications within the first twenty-four hours) do not benefit from coumarin therapy; or at any rate no benefit is reflected in the mortality rate, which is very low in these patients however they are treated. These patients are less liable to thrombo-embolic complications, whether from intracardiac thrombosis or thrombosis of the deep veins of the leg, than the group classified as "poor risk," in whom coumarin treatment reduces the death rate dramatically. It seems most likely that coumarin drugs produce their benefit by preventing these secondary thrombotic complications rather than by any direct action on the infarct itself or the coronary arteries. There is not yet any conclusive evidence that they will prevent a further infarction.² Coumarin drugs are therefore not for treating the acute infarction and its immediate hazards. They are given in an attempt to reduce, during the three or four weeks following the acute emergency, the mortality in the group of patients who are most likely to develop the later thrombo-embolic complications.

The action of heparin, and the object of treatment with it, are quite different. Its interference with the clotting mechanism is immediate and more dramatic than the action of the coumarins. In addition to an anti-thrombin action, it may have vasodilator activity and also actions on the blood lipids that are possibly of clinical importance. Its immediate effects in myocardial infarction are not well documented, and the nature of the problem makes unequivocal evidence difficult to obtain. Whether its beneficial effects are due to its anticoagulant or to its other properties, or what precise effect it has on the occluded vessel and the infarcted muscle, is uncertain. Nevertheless, suggestive evidence in favour of heparin does exist, and more than one observer has noted rapid improvement in the patient's condition, including relief or diminution of pain, after an injection given early in the attack.

At present, when anticoagulant therapy is decided upon, it is customary to begin with heparin by intravenous injection of 10,000–15,000 units, repeating this every six hours for 48 hours, or alternatively 20,000 units intramuscularly at eight-hour intervals for 48 hours.³ By this time orally administered coumarin preparations should be exercising their effects on the thromboplastin-prothrombin system in the blood. The chief usefulness of heparin, therefore, is in the emergency treatment of the infarction, not only as a means of covering the interval before coumarins act, but possibly as a beneficial measure for other reasons.

These considerations are relevant to the controversy on whether the selection of patients for anticoagulant therapy according to their assessment as good or bad risks is justifiable. The chief objection to this method of selection, urged especially by I. S. Wright,⁴ is that twenty-four hours must elapse before it can be applied, during which time the situation may change rapidly and confident prognosis is impossible. During these hours

serious complications may occur, such as extension of the infarction, which might have been prevented by heparin. This objection does not affect the validity of Russek's classification at twenty-four hours, or the influence it may have on the selection of patients for subsequent coumarin treatment, but it does emphasize the desirability of treating every patient seen early after the onset of symptoms with intramuscular or intravenous heparin. The practitioner in charge of the case will then have to decide whether he is going to give a full course of coumarin anticoagulants for a period of several weeks, or a shortened course as suggested by Gilchrist and Tulloch,⁵ or whether he is justified in denying the patient the undoubted protection against thrombo-embolic complications which coumarin anticoagulants offer.

NOBEL PRIZE

Three pioneers in the development of cardiac catheterization have been chosen to receive the Nobel Prize in Physiology and Medicine this year. One of these, Dr. Werner Forssmann, of Bad Kreuznach, West Germany, is the first man known to have inserted a catheter into the living human heart through a blood vessel in a limb. The other two are Professors André F. Cournand and Dickinson W. Richards, of New York, prominent among those various workers who in the last 15 years have added greatly to our knowledge of cardiac function by means of this technique.

At the age of 25 Dr. Forssmann, who is now 52, described¹ how with the help of a colleague he inserted a cannula into his own right antecubital vein, and passed through it a well-lubricated ureteric catheter for 35 cm. At this point the colleague, considering the experiment to be dangerous, ended it. A week later Forssmann by himself undertook a second experiment, this time inserting a catheter for 65 cm. into the left antecubital vein. He walked from the operating-room where he carried out this manoeuvre to the x-ray apparatus, and a radiograph was taken. It is reproduced with his article and clearly shows the catheter lying in the right auricle. In conclusion Forssmann referred to the "many prospects of new possibilities for research into metabolism and heart function" that his experiments had opened up. A month later Forssmann reported² that Professor E. Unger had drawn his attention to a trio of earlier publications³⁻⁵ in which F. Bleichröder, Unger himself, and W. Löb described the introduction of catheters by the first two authors into the arteries of human subjects in 1912 for the administration of "collargol." They were encouraged to make this direct attack on septicaemia then "because of the progress in chemotherapy."³ But while their object was different from Forssmann's the occasion is of interest because a catheter may have entered the living human heart then for the first time; for Unger revealed that in a preliminary experiment carried out on Bleichröder, but not published, they were led to infer from the length of catheter that passed up an arm vein, and a piercing pain he felt, that it had reached his heart.

Professor Richards, aged 60, and Professor Cournand, 61, of Columbia University and the Bellevue Hospital, New York, were encouraged by Forssmann's experiments to try cardiac catheterization in their studies of cardio-respiratory physiology. Their work, begun on chimpanzees in the later 1930s, and soon continued in the human subject, confirmed the safety of the procedure and showed the wealth of new information to be gained by it. Their studies of gaseous exchange and blood pressure in the heart and pulmonary arteries from about 1940 onwards have greatly extended the benefit, especially by surgery, that it is now possible to offer patients with heart disease. Indeed, Professor J. McMichael, of London, another pioneer in this field, has described⁶ catheterization of the heart as "the most significant advance in cardiological method in the present generation." As a diagnostic procedure it is now performed as a routine in all the larger cardiac clinics.

SCIENTIFIC EXHIBITION, 1957

In the short period of five years the scientific exhibition has become one of the main attractions at the Annual Meetings of the B.M.A. For this the Association has to thank the exhibitors, whether from hospitals, medical schools, research departments, or general practice, who have gone to such trouble in preparing and demonstrating their exhibits. Often a visitor gains a more vivid impression of current research or of clinical and epidemiological investigations from studying a cleverly arranged display at the exhibition than from listening to a paper read at a meeting. For this reason there is much to be said for linking some of the scientific exhibits with the sectional discussions. Most exhibitors would agree that the visitors are not the only ones to benefit from the exhibition: a good display tends to evoke discussions in which medical men and women from many parts of the world may take part. These exchanges of ideas are stimulating to all concerned.

Next year the Annual Meeting of the B.M.A. is to be held at Newcastle-upon-Tyne from July 15 to 19, and arrangements are already being made for the allocation of stands at the scientific exhibition—not to be confused with the exhibition of pharmaceutical products and medical appliances. Space is limited, and the final date for the receipt of applications is December 31. Forms are obtainable from the Secretary of the Association.

The Lister Medal for 1957, which is awarded in recognition of distinguished contributions to surgical science, has been granted to Sir Stewart Duke-Elder for the services he has rendered to the advancement of knowledge through his researches and writings in ophthalmic medicine and surgery. Sir Stewart Duke-Elder will deliver the Lister Memorial Lecture in London on April 5, 1958, under the auspices of the Royal College of Surgeons of England.

THE PHYSICALLY HANDICAPPED CHILD

FUNCTIONAL ASSESSMENT OF THE DISABILITY AS AN AID TO PLANNING

BY

E. P. QUIBELL, M.R.C.S., L.R.C.P., D.C.H.

Medical Administrator, Chailey Heritage (Craft School and Hospital), Chailey, Sussex

Founded in 1903 by Dame Grace Kimmins and Miss Alice Rennie, Chailey Heritage (Craft School and Hospital) has passed through several phases in its evolution from a derelict Industrial School building, which housed the original seven crippled boys from London. These boys came under the aegis of the "Guild of the Brave Poor Things," to be trained in crafts to enable them to earn a livelihood. Vocational training of the crippled was in its infancy then, and the demand grew quickly: expansions came as money was raised by public appeals. A similar project to include training for girls soon followed: next, under the pressing influence of Sir Robert Jones, the need for treating the disabilities was accepted; as a result the hospital side was developed and Surgeon Commander G. Murray Levick (of Polar fame) was appointed Medical Director.

Thus a craft school and an orthopaedic hospital grew up alongside each other in lovely rural Sussex surroundings.

Finally, the spate of post-war social legislation overtook the Heritage, bringing it under the Ministry of Health in July, 1948. The school section was designated an independent special hospital school, and a separate committee of management was appointed. All children admitted, whether ambulant or bed cases, are, however, patients under the National Health Service, and therefore the final responsibility rests with the hospital authority.

Children are accepted from widely over the British Isles and the Channel Islands, and this poses considerable social problems. With increased provision in local areas for physically handicapped children planned under the 1944 Education Act, the trend has been for the more severely crippled to be referred: this stimulated new thought about the approach and led to the functional method outlined here.

Nature of the Problem

This paper refers mainly to the severe and complicated handicaps, because, with the badly disabled child, very realistic thinking is called for in order to evaluate the important defects and to plan how to tackle them. Functions of daily life and self-protection are the hard core—feeding, dressing, washing and bathing, toilet management, ambulation. Equally vital is the time factor: if the time taken in the accomplishment is excessive, it remains a serious problem in living.

In the final issue the amount of assistance needed decides the type of placement for the child: for example, the developmentally paraplegic child, with a meningomyelocele, presents difficulties of management with which few homes can cope. The laundry involved, adequate educational provision, the increasing weight of the patient, the treatment and prevention of trophic lesions, manual bladder expression, the need for bowel training and possibly regular enemata—all these demand a range of knowledge and services beyond

the reach of the average home, even with the most devoted parents; and it is sometimes a revelation what the parents have achieved and the ingenuity they have displayed in caring for their child.

Certain other conditions present major problems. Bilateral upper-limb poliomyelitis can cause a gross degree of handicap in daily life; and severe arthrogryposis, extensive Still's disease, the bad athetoid form of cerebral palsy, the bilateral developmental defects of the arms, are further types.

Need for a Method

To tackle adequately the problem outlined demands a systematic approach to function: this form of evaluation highlights the important deficiencies, and upon it a coherent plan of treatment may be evolved.

Faced increasingly often with just such cases, I had felt that the anatomical analysis alone was inadequate, except in deciding the detail of operative treatment. There is even a risk that corrective surgery which at first sight appears to be anatomically sound may in fact reduce residual function still further. This was illustrated recently by a surgical colleague who had done a triceps-to-biceps transplant in a housewife to produce elbow flexion. Soon afterwards she returned highly indignant because she had lost the ability to cut a loaf of bread—evidently an important function in her life.

So much depends on what function is most valuable to the patient. This can be judged only by the test of the activities of daily life: can the hand, in fact, be used better in pronation or supination? The advantages of effective opposition of the thumb in ordinary life is rarely called into question, and tendon transplants to hold a foot in a functionally better position afford unquestioned gains.

It is mainly in the upper limb that what constitutes the most useful function is more problematical. The hand and arm have to perform so many and such varied tasks; adequate length of the arm and the ability to get it behind the trunk are necessary for cleansing after defaecation; and elevation of the limb is required for combing the hair, shaving, applying cosmetics, brushing the teeth, and endless daily jobs.

The practical test seems the only valid way for deciding the issue when advising the patient. This principle has been widely adopted in the field of industrial rehabilitation but perhaps applied too little to the problem of the disabled child; yet it leads to clearer thinking and improved planning, especially if the long-term aim of equipping the child for living and for a job is the purpose from the start.

This approach, too, can resolve such specific problems whether hand and arm function is too poor to warrant the expenditure of time and of training effort (Case 1); if so, attention can be directed to the feet. In the latter event careful thought must be given to the type of footwear, clothing, and methods of supporting clothing—elastic-sided shoes, elastic belts, zip-fasteners with big rings, coat type of shirts, and any dressing aids which are a practical help.

I believe, too, that adequate analysis of function can improve the planning of any operative surgical programme by better timing, and sometimes by even obviating doubtful and unrewarding surgery (Case 2).

In considering the badly handicapped child, one must remember that he lives (or ought to live) in a continuously expanding world, where experience and education need to keep pace with advancing years. All too often such children have lost vital years, but if operations can be timed (Case 3), so as to avoid important examination hurdles, for instance, a greater measure of progress may be preserved, provided it is without prejudice to the surgical criteria. Bone growth decides the optimal age for certain definitive surgery: even so, if the forward programme is well thought out the other needs can be woven into the pattern. Another material factor is that the aims are more precisely defined and continuity is given to the programme from all aspects.

Method

This has two stages: (a) the actual functional analysis and documentation of the findings in considerable detail, followed by (b) a full case conference of all the staff directly concerned, to evolve a planned programme for each child.

Functional Analysis and Documentation

It was decided to adopt a modification of the "proforma" used by the Bellevue Medical Center, in New York.¹ This breaks down daily life functions, under certain broad headings, into considerable detail: their presence or absence is indicated by "blocking in" squares. Each function is put to a practical test. A section can be added, where applicable, to make the proforma comprehensive enough to include speech defects in cerebral palsy.

This initial documentation is done by a special staff; feeding, toilet, washing, bathing, and dressing are analysed and recorded by the nursing staff; elevation and ambulation by the physical treatment staff; certain hand functions, and sometimes dressing techniques, by the occupational therapist; speech disabilities by the speech therapist. In addition, whenever possible, an intelligence test is carried out by the clinical psychologist: this is valuable as a guide to the degree of co-operation to be expected.

By this means we obtain a full and factual picture of the problem to be faced.

The Assessment Proforma.—This is lengthy; the main headings are given below, each of them being subdivided to give full details.

I. *Non-walking Activities.*—(a) Bed activities; (b) hygiene; (c) eating activities; (d) dressing and undressing activities; (e) hand activities; (f) wheel-chair activities; (g) elevation activities.

II. *Walking Activities.*—(h) Progressing activities; (i) gait; (j) climbing activities; (k) travelling activities.

III. Summary.

IV. *Recommendations.*—(1) Physical Treatment: (a) physiotherapy; (b) remedial gymnastics; (c) occupational therapy. (2) Operative Treatment. (3) Speech Therapy. (4) Aids. (5) Other. (6) Educational. (7) Social Adjustment.

Case Conference

When the proforma has been completed by the staff concerned it is returned to me a day or two before the conference; this enables me to study the extent and the salient points of the disability, and helps in leading the discussion.

At the conference, the report is considered by all the staff directly concerned—medical, nursing, physiotherapy, remedial gymnast, occupational therapist. The almoner attends, as direct social problems are so often involved. The psychiatrist, clinical psychologist, and speech therapist are invited to participate whenever their special help is needed. The teaching staff also participates, and their presence proves very valuable. The details of the proforma are discussed section by section, and the possibilities weighed up; opinions are freely invited and decisions made on both the way and the person to tackle the particular function in question.

At this stage the child attends so that his or her own opinion can be sounded and any particular problem studied—for example, whether writing is better done by mouth than by hand.

The above procedure gives the staff a clear picture of the extent of the disability and provides as wide a context as possible for considering the child's future programme; further, it helps to eliminate overlapping and waste of time. It may bring to light psychological factors adversely affecting the child's morale and co-operation (Case 4). Expert advice can then be sought from the psychiatrist.

My secretary sits in at the conference to keep notes of the proposals put forward and conclusions reached. These are typed and distributed to the staff involved in the

rehabilitation programme, which defines clearly what is delegated to each participant.

A system of periodical progress reviews is being planned: with larger experience this will yield much valuable knowledge of the results and the time taken to achieve them. Already certain features stand out as vital. Under the hygiene section, the question of toilet management requires very careful analysis; in employment it may be a deciding factor, and undoubtedly it drastically increases the person's self-respect. Even a quite young child resents being dependent on others for such help. The time factor in dressing and putting on appliances can be a serious hindrance; careful thought and practice given to the method of doing these can be rewarding. For example, it may be better for a child to put on his footwear and callipers before a spinal support, otherwise he may find it impossible. These are elementary points, but frequently they are overlooked and much time is wasted. A practical try-out can soon settle the doubt.

As our team's experience grows, the advice can become more precise and be given earlier. Simple modifications of clothing which really economize time and effort can be settled at the start: there is here real value in having a mixed team.

Value of the Method

Even in the limited period of its operation the value of the approach has seemed clear, and the staff have found it instructive, stimulating, and, on occasion, starkly revealing of how severe these handicaps can be in daily life. It has evoked really hard thinking with regard to ways and means of overcoming these handicaps. Sometimes the difficulties prove baffling. Equally, the conference allows a much greater pooling of ideas and suggestions: this has been especially so in matters of clothing adjustments, aids, and functional training. It avoids the predicament of discovering a serious social limitation at the last moment, when employment is looming up and no time is left to tackle it.

Where a psychological attitude impedes co-operation the psychiatrist can advise and the whole team then work in concert to overcome it. This can sometimes be the key to success; a severe attack of poliomyelitis coming in early teenage can have a devastating impact, and it needs very good team-work, in an atmosphere of guarded optimism and confidence, to tide over the worst phase. This we have seen more than once.

The team involved may appear large and the method extravagant of time. So far this has not been borne out—if anything, rather the reverse: by having the complete picture presented to all simultaneously it has reduced cross-reference of difficulties. The seriously disabled child calls on many services—medical, nursing, physical treatment, educational, social, psychological; therefore the closer the integration of the team-work the better the results.

As experience grows we find each case can be considered more expeditiously and quicker solutions reached. The question of medical responsibility may be raised against the method. I do not think this responsibility is affected: the surgeon decides what surgery should be done, and when; and the plan is worked out by agreement. Medically, I think we have moved into the era of team-work, and frank discussion can extend one's knowledge usefully: thus in the long run one may become a wiser and more considerate counsellor.

Finally, the courage and optimism of such disabled children give a spur—if such is wanted—to our ingenuity, and act as a reminder of our own good fortune in having whole limbs. "Over and over again this courage has enabled them to do the seemingly impossible."

Illustrative Cases

Case 1.—Girl aged 6 years 11 months; average intelligence, I.Q. 100+. Disability: poliomyelitis, upper limbs; left arm flail; right arm, limited hand function only. Socially very

handicapped: can perform a number of play activities—for example, dressing dolls—with her feet. Cannot adjust clothing for toilet; can feed herself a little, using a spoon or fingers; needs almost all dressing done; is afraid of stairs (had a fall at home and fractured her left humerus) as she cannot protect herself. The problem posed was whether hand function would be adequate to gain much independence, or whether she should be trained to use her feet. The case conference showed that training could achieve much regarding toilet; modifications to clothing could help with dressing; training, and the building of confidence, could overcome the fear of stairs. Operative treatment would improve thumb opposition, and hence hand function. It was agreed that the hand was sufficiently good for every effort to be made to improve its use and not to turn entirely to feet training.

Case 2.—Girl aged 15 years 9 months; I.Q. 87. Disability: arthrogryphosis multiplex congenita, all limbs; minimal power in both arms and both legs. Between May, 1942, and May, 1954, this girl had 13 orthopaedic operations—six on the arms and seven on the legs—also 10 manipulations under general anaesthesia, with plaster-of-Paris splints; at various hospitals. At the end of this formidable programme she remains grossly handicapped: virtually everything has to be done for her—feeding (mainly), dressing, toilet, washing, and bathing (completely). She can roll from side to side in bed; she can write with her mouth, and drink by holding a cup in her teeth or using a straw; she can walk with callipers and surgical boots (when they are put on for her) on the level and up a slight incline going sideways. She cannot protect herself if she falls. It seems possible that some of the surgery may have had an adverse effect; certainly much of it failed in its purpose. The case conference clearly exposed the serious degree of social handicap, and showed that residential placement was the only solution in view of family difficulties. It was decided that work, using her mouth, should be found to give her an interest and a sense of usefulness. Had the functional method of assessment been applied at an earlier stage the amount of operative and manipulative treatment might well have been reduced. As she cannot manipulate knee locks on the callipers, sitting is very awkward: she has to either stand or lie. She requires a special chair with foot-rests; this is being evolved.

Case 3.—Boy aged 11 years 4 months; I.Q. 165. Disability: poliomyelitis, upper limbs; right arm flail; left arm, very limited function. A highly intelligent boy who has taught himself many trick methods: limited over toilet, cutting up food, and parts of dressing and washing. Left-hand function could be improved by surgery. Should go for academic career; educational needs are therefore very pertinent. The case conference revealed that simple modifications of clothing would assist with toilet management; special toothbrush and long sponge needed; tests for feeding aids were required. Operation should be undertaken early to allow time for working for G.C.E.; date settled. These were the main immediate agreed points; each was allocated to the appropriate person—for example, occupational therapist to evaluate feeding aids, assistant matron to arrange clothing alterations with sewing-room staff.

Case 4.—Boy aged 14 years 4 months; I.Q. 111. Disability: poliomyelitis, upper limbs; right arm flail; left arm very poor. Late onset of poliomyelitis at age of 12. Always keen to take up farm work. Average intelligence, deeply resentful of his disability. Is heavily handicapped, requiring help with toilet, feeding, dressing, washing, bathing; has to use his mouth in writing. Social conditions difficult: mother deserted family; father lives in lodgings, but is concerned for boy's welfare, financial position difficult. The case conference emphasized the serious degree of handicap: the psychological attitude required expert advice by the psychiatrist. Surgery could improve the function of the left hand, and should be started at once, as time is short; even then he should be trained to get the maximum use of his feet. The home conditions need careful investigation and

stabilization, so that simple home aids can be used. Employment will require hard thought. Modified footwear is desirable.

Conclusions

Proper evaluation of this approach to functional disability needs prolonged and careful study by a team who can watch and review the children over the full period of training and treatment.

The method can anticipate forward problems, thus allowing time for better advance planning.

It provides a forum at which experience and advice can be pooled and the overall needs of the child considered.

The approach is factual and systematic; it presents a complete picture and provides a method of checking progress.

Social difficulties are more clearly foreseen; hence the almoner can start early investigations and discussion with the family and authorities.

When the scheme has been longer in operation it should yield a useful pool of experience with wider applications.

The method is designed to deal with the more complicated and severe handicaps in children.

It improves team-work, yet need not conflict with medical responsibility.

I would like to thank the many members of the Heritage staff who are co-operating so helpfully in the scheme.

CHALLENGE OF MONGOLISM

A meeting on "Current Research in Mongolism" was held on October 3, with Dr. L. T. HILLIARD in the chair, at the Fountain Hospital. Professor L. S. PENROSE, F.R.S., of the Galton Laboratory, began by describing mongolism as a challenge. It was a specific disorder and a common one, yet little was known about its causation. Many theories had been put forward, but they had little value without new data. Attempts must be made to find new data even though the results would often be negative. For example, the anti-genetic relationships between mother and child had been studied, but any deviation from expectation was in the direction of resemblance, not dissimilarity.

Studies on twins were difficult to interpret. One or two examples of concordant pairs of dizygous twins were now known, but no proved example of a discordant monozygous pair. Family studies showed only a low incidence of mongolism in the sibs of mongols; there was perhaps a two- or three-fold increase in the risk to sibs. The effect of maternal age was well known, but there was little evidence that maternal ill-health predisposed to mongolism. A maternal cytoplasmic factor was a possibility. He had therefore been interested in a pair of monozygous twin mothers in Dr. Carter's survey, who had each had a mongol child within a few years of each other. But he had also heard of an instance where it was the fathers who were monozygous twins.

Heredity and Environment

Dr. C. O. CARTER described some results of a survey of over 550 mongols on which he had been engaged with Mrs. K. EVANS at the Hospital for Sick Children, Great Ormond

Street. They had paid particular attention to possible aetiological and social factors. The findings on aetiology illustrated many of Professor Penrose's points. Among the twin pairs in the series, the 4 unlike-sex and 5 like-sex but probably dizygous pairs were discordant. Of the 4 like-sex pairs of unknown type because one twin was dead, one pair had been concordant. The finding that dizygous pairs were usually discordant suggested a genetic element in causation, since a purely environmental cause would be likely to affect both twins. The incidence in the sibs was low, but perhaps higher than one would expect by chance when allowance was made for the mother's age. Of a little over a thousand sibs 4 were also mongols, the random expectation being 2.6. Øster, in his second publication, reported that 7 sibs were mongols, the expected figure being 3.5. In contrast there were single families reported with several sibs affected, in one instance no fewer than 5; perhaps in a small proportion of families there was a higher risk of mongolism.

In looking for environmental factors it was important to remember the probable time in embryonic development at which the retardation in mongolism occurred. It had been suggested that this was from the 6th to the 9th week. In this series the malformations occurring unduly often all represented an interference with development concentrated within the 6th week. However, the histories of the mothers' pregnancies showed no consistent pattern of abnormal happenings at this time. Even if the fallibility of mothers' memories was allowed for, it was difficult to believe that any memorable event was the major cause of mongolism; the environmental factor was more likely to be something subclinical.

It was interesting that 3 of the 119 mongols in the series had died of leukaemia, an association which had been reported also from America this year. This might have some bearing on the findings of the next speaker.

Dr. URSULA MITTWOCH described some unusual features of the polymorphonuclear leucocytes in mongolism. These cells tended to have fewer lobes in the nucleus in mongols than in normals. In addition she had found that female mongol children had fewer "drumsticks" in the nucleus than in control children. There was an association between the number of lobes and of drumsticks in both mongols and controls, but if the number of lobes was held constant the mongols still had relatively fewer drumsticks than the controls. It was improbable that infection was the cause of the low lobe count, since the total white cell count in these mongols was not increased.

Educable Mongols

In the discussion following, Mrs. K. EVANS described some of the social findings in the survey from the Hospital for Sick Children. Most mongols were best brought up in their own families and trained in occupation centres. A period at home was usually desirable even if the children later had to go to an institution. Some of the unhappiest parents were those who had been over-persuaded to send their children to an institution in infancy. A few mongols managed well in schools for the educationally subnormal, and it was wrong to assume, without test, that a mongol child was ineducable. It was important in helping parents to make a good adjustment that someone should spend some time explaining, preferably on more than one occasion, the implications of mongolism. They should also offer the moral support of their hospital or institution in the early years of adjustment. Dr. J. STERN, of the Fountain Hospital, described biochemical changes he had found in mongolism, especially that the gamma-globulin was raised and that this was not explained by infection. Dr. L. CROME showed the brain of a mongol, explaining that the frontal lobe was particularly undeveloped, together with the middle lobe of the cerebellum, which was linked to the frontal lobe.

WESTMINSTER MEDICAL SCHOOL

The inaugural meeting of the session of the Westminster Medical School was held on October 22, when the prizes were distributed and a brief address was given by the Rt. Hon. VISCOUNT CHANDOS. The chair was taken by Mr. H. M. CLOWES, and a report on the year's work of the School was given by the Dean, Mr. H. E. HARDING. Among others present were Lord Nathan, chairman of the Board of Governors of Westminster Hospital, Lord Kershaw, a member of the Board, the Directors-General of the Army and Royal Air Force Medical Services, and the very Rev. A. C. Don, Dean of Westminster.

Before presenting the prizes and certificates, Lord CHANDOS spoke on rewards in the professions. Although professional people were not primarily concerned with monetary rewards, he said, such rewards did have a stimulating value. Few people turned down completely the possibility of reward, though he thought that doctors, who worked longer hours than most others, had on the whole smaller rewards. But those who devoted themselves to the cure and prevention of disease had the reward which came from investment in health, which properly understood was one of the richest investments possible. "I am not one of those who decry the principles of the National Health Service," said Lord Chandos. "I remember that when the Government of the day brought in the National Health Service on its present lines the Conservative Party, of which I am a member, supported them, and I still think that if we can eliminate the area of waste and reduce frustration such an investment by the State is socially desirable and economically productive."

Of the doctor himself he said that a man with a second-class brain, but having sympathy and imagination, could generally be more successful than a brilliant man who lacked such qualities. The more remote, impersonal, standardized, and inflexible the organization, the more necessary were the human qualities which the doctor brought to his task. The vote of thanks to Lord Chandos was proposed by Dr. G. H. MACNAB and seconded by Dr. R. I. S. BAYLISS.

Future Development

Mr. H. E. HARDING, the Dean, said that during the year the School had been visited by the University Grants Committee, and they were able to discuss what faced the School in the next quinquennium and the projects which it was hoped the Committee would support. Ten years ago the School Council thought plans should be made for a pre-clinical school; a premedical school as well was out of the question, as there was not enough land. Five years ago, however, when making their policy for the quinquennium, the Academic Board stressed the urgent claims for extension of the clinical school. The Board and the School Council had recently reviewed very carefully the space available, and were agreed that it would be entirely needed for expansion of the clinical school, and that plans for premedical and preclinical departments should be dropped. Westminster Hospital now had access in its teaching group and affiliated hospitals to nearly 1,000 beds, and the present clinical school was strained to capacity.

The proceedings terminated with a vote of thanks to the Chairman, proposed by Dr. F. DUDLEY HART.

Speaking at the annual meeting of the Metropolitan District Nursing Association on October 17, Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, said that 24 million visits were paid by home nurses to over 1,100,000 patients in 1955. Owing to the introduction of new antibiotics there had been a great increase in the demand for injections. The nursing of old people to-day played a greater part than formerly, and the advantages of keeping sick children at home wherever possible had led to the development of special schemes in which hospital and district staff co-operated to provide care in the home.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Anaesthetic Deaths

SIR.—The leading article on anaesthetic deaths (*Journal*, October 13, p. 868) gives an unduly alarming picture owing to the omission of two vital facts: first, that the death rate for 1953 is the lowest recorded for nearly 30 years; and, secondly, that the number of anaesthetics given each year is continually increasing.

There has been a steady fall in the number of deaths reported to the coroner as occurring during operation or within 24 hours, and the figure of 562 for the year 1953 is the lowest recorded since 1925. This fall has coincided with the introduction of the muscle-relaxant drugs and the use of antibiotics to control post-operative complications. And it must be remembered that in 1925 operations were far less severe than they are now, and also that far fewer anaesthetics were given for diagnostic procedures.

The second point is the great increase in the number of anaesthetics given. Statistics from London teaching hospitals show that over the last ten years the number of anaesthetics given has more than doubled, and it is fair to assume that this increase is general throughout the country. Yet the mortality continues to fall.

Unfortunately the number of anaesthetics given in England and Wales each year is not known. The survey carried out by the Ministry of Health in 1954 gave a total of 2,775,000 for the hospitals of England alone. The figures for nursing-homes, general practitioners, and dentists are unknown, but it is fair to assume that they would bring the total up to at least 4,000,000. And for the sake of comparison with the coroners' reports, a further 250,000 would have to be added for Wales on a population basis, which would produce a figure of one death per 7,500 anaesthetics. But this figure in the absence of accurate details can only be a speculative one.

The report of the committee set up by the Association of Anaesthetists¹ to study anaesthetic deaths should be made compulsory reading for all anaesthetists and surgeons. And the most important statement in that report is, to quote the words of the committee, "If the anaesthetic or surgical misadventure had not occurred complete recovery would have been highly probable in 46.8% (of the anaesthetic deaths). When, by means of better training and more complete equipment, this figure can be reduced to zero, then anaesthetists will be able to feel with satisfaction that the death rate has been reduced to its unavoidable minimum. But much remains to be done before this ideal is attained.—I am, etc.,

MASSEY DAWKINS.

London, W.1.

REFERENCE

¹ Edwards, G., Morton, H. J. V., Pask, E. A., and Wylie, W. D. *Anaesthesia*, 1956, 11, 194.

SIR.—In your leading article on anaesthetic deaths (*Journal*, October 13, p. 868) you state: "Too often the acute observer can see unconscious patients left unattended or in the care of a junior probationer." I have had a death under such circumstances and I submit that this deplorable risk to the patient will continue to be accepted until it is understood that the over-long operating list is good for neither the patient nor the science of surgery.

There is a most dangerous tendency for our nationalized hospitals to become surgical sausage machines, with the result that an undue strain is placed on surgeons, anaesthetists, and nurses. A great many surgical misadventures are

certainly due to this cause, and overwork is the commonest single factor operating against the recruitment of hospital staff. In the public interest, now that we are a nationalized industry, let us work the same hours as other national services.—I am, etc.,

New Barnet.

JOHN E. ELAM.

True Hermaphrodites and the Prostate

SIR.—"A Case of True Hermaphroditism," by Dr. J. D. Arnaud and his colleagues (*Journal*, October 6, p. 792), is an interesting and well-illustrated article.

In this particular case the authors found that the right gonad was an ovary. The left gonad consisted of two portions, one an ovary and the other a testis. There was a complete uterus, cervix, and vagina, and the phallus more like a penis than a clitoris. There was no trace of a prostate, which is of particular interest to me, because I have always contended that it is the entire prostate which is the homologue in the male of the uterus and cervix in the female. From this it follows that the prostate is functionless. It follows, too, that the presence of a complete uterus, cervix, and vaginal cavity in any true hermaphrodite completely rules out the presence of a prostate. It is conceivable, of course, that a hermaphrodite with an incompletely formed uterus might also have an incompletely formed prostate.

The subject of genital homologues makes a fascinating study. Apart from the gonads all the active genital organs and structures in one sex are represented in a rudimentary and functionless state in the opposite sex—penis and clitoris, mammary glands and nipples, etc. These so-called homologues, rudimentary as they may be, are actually reproduced as perfect miniatures. The only outstanding exceptions are the homologues of the uterus and prostate, two organs which are structurally so alike that it is indeed strange that this circumstance has not been more freely commented upon.

Many years ago the late Sir Arthur Keith seemed to be faced with a dilemma when he had to find some explanation for the absence in the male of an adequate homologue of the uterus and cervix. He explained it away by stating that the Müllerian ducts, from which the uterus, cervix, and part of the vagina arise, proceed to atrophy in the third month of foetal life in the male. As the musculature and glands of the uterus and cervix in the female are not laid down until the fourth month of foetal life, this explanation would appear to be satisfactory enough, were it not for the fact that the vagina in the female is also not completed until the fourth month, and is quite adequately represented in the male as the sinus pudicus.

There is, however, a very much more powerful argument in favour of the prostate being regarded as the homologue of the uterus, and it is that the prostate has no known function. Let us face it—will a function ever be found for the prostate? There is little to be said for the prostatic glands. It is the inert and functionless condition of the prostatic musculature which should excite most wonder. If the prostate is a gland, then it is more richly supplied with unstriated muscle than any other gland in the body. The behaviour (or lack of it) of the unstriated muscle of the prostate is contrary to that in any other part of the body. Even thin strands of unstriated muscle give rise to the most excruciating pain at times, and a thick mass of it, as in the uterus, is capable of agonizing activity and of superlative *tours de force*. Only in the prostate does unstriated muscle, and no mean mass of it either, lie completely and for ever inert.

There is much more evidence in a similar strain concerning this subject,¹ but space does not permit of its pursuance here.—I am, etc.,

Beaconsfield.

Cardiovascular Collapse During Apomorphine Treatment

SIR.—In the course of investigation of anti-emetic drugs I have administered apomorphine to more than 100 normal subjects. I gave 1 mg. of apomorphine hydrochloride by subcutaneous injection, a much smaller dose than that used in "aversion therapy." Syncope occurred in six subjects. The usual course of events in these cases was that 5 to 10 minutes after the injection the subjects suddenly became very pale with cyanosis of the lips. Respiration deepened and there was profuse sweating. The subjects usually complained of dizziness and tinnitus, then cried out: "I feel I am falling away." An ordinary faint then followed, in the course of which the pulse rate usually fell to 40 or 50 per minute. The subjects regained consciousness within a minute or two, then slept soundly for an hour. One subject vomited during the faint and one on regaining consciousness. In three subjects the faint was preceded by tonic contraction of the extensor muscles of the back and neck lasting about 15 seconds, followed in turn by brief jactitating movements of the limbs and face, then by a fall to the ground. Many of these experiments were conducted with the subject seated immobile with restriction of head movement. In experiments when head and body movement were allowed, syncope also occurred, but less frequently. Syncope never occurred when apomorphine was administered to recumbent subjects.—I am, etc.,

BERNARD ISAACS.

Treatment of Iron-deficiency Anaemia

SIR.—Having read the article by Drs. E. Cope and R. O. Gillhespy and Mr. R. W. Richardson on the treatment of iron-deficiency anaemia, comparison of methods (*Journal*, September 15, p. 638), I would like to make a few comments on their findings. It is probably not generally understood that in the iron-deficiency anaemia of pregnancy the response to treatment, as estimated by the haemoglobin rise, varies considerably, depending on the stage of pregnancy. Up to the 20th week the response is usually very good. Between the 20th and 36th weeks, when the blood volume increases by about 25%¹ and the foetal demands begin to be felt, the rise in haemoglobin is naturally considerably less. Only after the 36th week does a slight improvement occur, and this appears to be due to a reduction in blood volume just before term. This triple type of response is seen with all modes of therapy, but is more obvious when iron is given by the oral route. Hence, in comparing methods of treatment, it is essential to make sure that the duration of pregnancy is the same in each group, especially when, as in Drs. Cope and Gillhespy and Mr. Richardson's series, small numbers of patients are being included in some of the groups.

Another factor which alters the rate of haemoglobin regeneration in pregnancy is that of hospitalization. On a normal ward diet, without adjuvants, the rate of haemoglobin regeneration with oral iron therapy is almost doubled once the patient is put to bed. This is not so obvious with intramuscular iron therapy. Drs. Cope and Gillhespy and Mr. Richardson did not make it clear how many of their patients on oral iron were admitted to hospital, but it is significant that optimum results in this group can only be obtained by admitting all patients to hospital, and this, of course, is a practical impossibility.

Finally, the amounts of iron actually given in their series are worthy of consideration. Seventeen days of oral iron therapy, as prescribed, would make a total of 1,785 mg. of metallic iron available to the patient, of which, according to the authors, 35%, or 625 mg., would be absorbed. Since all groups received the same, presumably 625 mg. of intramuscular iron was administered to the other patients in the seventeen-day observation period. This amount of iron is well below the average required by our anaemic patients, and, neglecting foetal demands and blood volume changes, which of themselves may require 500 mg. of elemental iron,²

would only raise the haemoglobin of an anaemic patient by an average of 1.8 g. Thus it is possible that in Drs. Cope and Gillhespy and Mr. Richardson's series some of their more severely anaemic patients were actually undertreated and would have shown greater haemoglobin increments if more intramuscular iron had been made available to them in the seventeen-day observation period.—I am, etc.,

SIR.—The very interesting article, "Treatment of Iron-deficiency Anaemia," by Drs. E. Cope, R. O. Gillhespy, and Mr. R. W. Richardson (*Journal*, September 15, p. 638) does seem to demonstrate that ferrous succinate is as valuable a haematinic as parenteral iron preparations. Further thought, however, raises two serious doubts.

The first is whether such a conclusion is justified even by the criteria implicitly laid down by the authors. For instance, 11 of their "medical" cases failed to respond to ferrous succinate, though they did respond to intramuscular iron. It is not stated whether these patients were included among those 45 medical cases for which the authors give an average daily haemoglobin rise; their omission could well lead to a figure for this rise that would not reflect the true picture. Then, too, as there were among the antenatal patients 133 on ferrous succinate but only 21 on intramuscular iron, the results in two such disproportionate groups might well not be significant. Will the authors tell us if any statistical analysis was, in fact, attempted? The second and more important doubt is whether the authors' criteria were in fact valid criteria to use. Should one assess the value of a haematinic, as the authors do, on an average haemoglobin rise over a period of only seventeen days or on the average time taken to bring the haemoglobin level up to 100% and on the patients' subsequent progress?

It is in the latter respect that recent work seems to demonstrate the superiority of parenteral over oral iron preparations. Very briefly, a healthy adult man has a body store, a reserve, of iron of some 1-1.5 g., compared with 3-3.5 g. of iron in circulating haemoglobin. The first step in the development of, say, a chronic post-haemorrhagic anaemia is the using up of these stores for haemoglobin synthesis: the haemoglobin stays for a time at 100% and there are no symptoms. It is only when these stores have been depleted that the haemoglobin level starts to drop and the patient to complain.

Now a good oral iron preparation, such as ferrous succinate, will in a high proportion of patients restore a low haemoglobin to a normal level reasonably quickly and without much in the way of side-effects. However, as the haemoglobin level rises so does the intestinal mucosal block to iron absorption become more effective; and indeed, at a haemoglobin level of 100%, iron absorption from any oral iron preparation is very small—certainly too small to build up the lost iron stores in any reasonable time. One group of American workers¹ has demonstrated, for instance, that even six months' administration of oral iron has no effect on depleted iron stores.

Parenteral iron preparations have not got to pass the mucosal block: they are always absorbed in their entirety, so that, in a manner of speaking, once they have restored the haemoglobin level to normal in an anaemic patient they at once go on to build up the body's stores of iron. With these repleted, the patient has a fairly adequate "buffer" against an early recurrence of the anaemia. Indeed, it is probably the failure of oral iron preparations to do more than merely raise the haemoglobin level that is responsible for those many patients who return to their doctors time and time again with anaemic symptoms—each time to receive oral iron, to respond, and then to relapse again in a few weeks.

This new and fascinating subject of body iron stores is excellently summarized in an article by F. G. J. Hayhoe,² and I should like to recommend this article to your readers.

OCT. 27, 1956

CORRESPONDENCE

BRITISH
MEDICAL JOURNAL 997

Whatever the views of Drs. Cope, Gillhespy, and Richardson on the relative merits of the two types of preparation in raising haemoglobin levels, they will, I feel sure, agree that ferrous succinate, unlike intramuscular iron, will not restore the body's reserve of iron except over a very long period. And that surely in 1956 is the crucial point in any comparison.—I am, etc.,

SIR.—The article entitled "Treatment of Iron-deficiency Anaemia" by Drs. E. Cope and R. O. Gillhespy and Mr. R. W. Richardson (*Journal*, September 15, p. 638) requires some qualifications with respect to its claim to fill a gap in scientific investigation.

No physician should be content to claim success in treatment until the disease he is treating is cured, and yet the authors compare the therapeutic value of oral and parenteral iron preparations by confining the observations to a 17-day period: the patients were therefore still anaemic at the time when conclusions concerning the therapeutic value of these iron preparations were drawn. A fair comparison can only be made by following patients until they are cured of their anaemia—and ideally this includes evidence of an adequate iron store, particularly in women and growing children.

In a severe iron-deficiency anaemia the initial response to treatment with most iron preparations, including ferrous sulphate B.P., is remarkably good. The limiting factor in haemoglobin regeneration is usually not the efficiency of intestinal absorption of iron but the bone marrow functional capacity. As the haemoglobin rises, the mucosal barrier becomes increasingly important and the poor absorption of oral iron now becomes a limiting factor in haemoglobin synthesis, and may considerably prolong or prevent full recovery and the replenishment of the depleted iron stores. The haemoglobin level at which oral iron absorption is severely impaired varies with each individual. It is, however, interesting to note that in their medical series the authors found that over 20% failed to respond at all to oral iron. These patients responded to intramuscular iron, but it is unfortunately not stated whether these oral iron failures were included in the figures given for the haemoglobin rise of the orally treated group. If the failures were in fact excluded from the oral iron group, the average haemoglobin rise for all patients treated by oral iron would of course be even lower.

In the antenatal and post-natal series the large differences in the number in each treatment group makes it difficult to draw significant conclusions from the available data, but it is highly improbable that even "ferromyn" (ferrous succinate) could alone account for such a satisfactory rise in the post-natal cases.

It appears that there still remains a gap in the scientific investigation of all the factors involved in the cure of iron deficiency anaemias.—I am, etc.,

BERTHA KLEMPMAN.

Penicillin V and Diabetes

SIR.—One of my patients, a severe diabetic aged 73, with arteriosclerosis, myocardial degeneration, and dyspepsia, recently developed pneumonia of the right lower lobe. He responded well to injections of procaine penicillin (600,000 units daily), so that his temperature settled and the clinical signs disappeared in 48 hours.

I continued the injections for two further days, during which his temperature remained normal, and he seemed well. Feeling then that injections were no longer required, but wishing to prolong the effect of the penicillin, I prescribed capsules of penicillin V (125 mg.), one four times a day. Within a few hours of taking the first capsule he developed heavy glycosuria and thirst, although he was being

maintained on his usual insulin (soluble insulin 120 units a.m. and 80 units p.m.), and was having less than his usual carbohydrate intake (because he "did not fancy it"). The worsened diabetic state continued for 36 hours, during which time the capsules were given, and then he started to vomit. The capsules were therefore stopped, and he returned to his normal stable condition within 12 hours.

The series of events suggests that the oral penicillin was the cause of the loss of control of the diabetes. Others who have occasion to treat severe diabetes with penicillin V should be on the look-out for a similar upset.—I am, etc.,

Treatment of Recurrent Urolithiasis with Aspirin

SIR.—I was interested to read your annotation on the treatment of recurrent urolithiasis with aspirin (*Journal*, September 15, p. 650). This treatment has been used very little, if at all, in this country and, as you say, is still in the experimental stage. I hope, therefore, that it will not be used indiscriminately until it has been properly worked out. At present we do not know if there are likely to be any untoward effects other than excitation of peptic ulcer.

I am at present, with the co-operation of some colleagues, trying out the effect of salicylamide on a series of recurrent stone formers, and we hope to have something to report in the future. The assessment of the prophylactic value of this treatment must not be made too soon, as it depends on a clinical comparison between treated and untreated cases. Moreover, the cases must have already had at least one recurrence, if not more. It will therefore be some years before one can really decide the true value.—I am, etc.,

S. HENRY C. CLARKE.

Hove, Sussex.

Abuse of Antibiotics

SIR.—May I correct the misconception which Dr. A. C. Mayer (*Journal*, October 13, p. 883) has placed upon my remarks about the abuse of antibiotics in this country (*Journal*, September 29, p. 767)? My aim was to condemn not a section of our profession but an attitude of mind which seems to me harmful—a motive similar, no doubt, to Dr. Mayer's own. I did not state, and I do not believe, that this light-hearted use of powerful drugs is confined to one section of the profession, although the example I quoted was from general practice.

It would obviously be rash to conclude that all men, or indeed all doctors, are fools on the strength of a single instance, but equally it seems unwise to allow overwork and underpay to creep in as justification for random prescribing, and the substitution of medication for diagnosis.—I am, etc.,

JOAN M. CURTIS.

London, N.11.

Early Management of Poliomyelitis

SIR.—I wish to point out to Dr. G. E. Breen (*Journal*, October 6, p. 828) that in my letter (*Journal*, September 15, p. 657) I did not retreat from my original attitude in the article of June 30 (p. 1539). I reiterated that the indications for admission were positive ones, and it still happens that patients are severely paralysed when first seen by their practitioners. Dr. Breen seems to be intent on misinterpreting what was written, or making unwarranted assumptions because he does not agree with the policy of home nursing under any circumstances. This policy is not a new one nor is it personal to me, and W. Ritchie Russell¹ considers that with adequate safeguards it has a place in the management of the pre-paralytic patient.

With regard to the statistics of admissions to the Blegdams Hospital, Copenhagen, during 1952-3, while these figures show a preponderance of paralytic patients (55%), Thomson² reports that in Denmark "in the epidemic year 1952, of 5,711 cases, 3,696 (65%) had no paralysis." Dr. Breen, by altering the context of my letter, makes it appear that I suggested that only a small proportion of meningitic cases

ever progress to paralysis. What I wrote was: "In advocating the domiciliary management of suspected and early cases in the meningitic phase—and after all only a small proportion ever pass beyond this stage . . ." My reason for stating that the suggested policy has not been a factor in the quoted fatality rate, and which he obviously disbelieves, is that it is only two years since the present policy was adopted and all the deaths, except four, occurred before this time, when all cases were accepted on request regardless of the stage of illness.

No one will disagree with Dr. Breen's rather obvious statement that all cases of life-threatening poliomyelitis should be brought under skilled observation and within reach of help at the earliest possible moment. But this does not mean that all cases of poliomyelitis are life-threatening, and it does not require "special divinatorial powers" (which I can assure Dr. Breen that my colleagues and I neither possess nor claim) to decide that a patient should go to hospital long before such an emergency arises—always supposing that the cases are seen early enough, and that does not always depend upon the doctor.

As long as the policy advocated is applied intelligently, the only figures likely to suffer are those of the hospital admissions.—I am, etc.,

E. G. BREWIS.

Pseudohaemophilia

SIR,—May I protest against the use of the word pseudohaemophilia? Provided the clinical condition under consideration is adequately defined, as in your annotation (*Journal*, August 11, p. 353), no great harm follows. But this word has been used to describe so many conditions that in itself it now has no meaning and should be dropped completely. Biggs and Macfarlane¹ use the term to denote a coagulation defect in the presence of an inhibitor. Whitby and Britton² apply the term to an abnormality of the clotting system, different from that described by Macfarlane, and also apply it to the familial syndrome with a long bleeding time, often called von Willebrand's disease. Even this latter appellation has been applied to cases dissimilar to those described by the author. At least one definite entity can be separated from this latter group which probably contains several syndromes. I called this syndrome diffuse capillary telangiectasia.³ This term, if cumbersome, is at least largely definitive.—I am, etc.,

Portsmouth.

Shadow in the Lung

SIR,—The following interesting case history has just fallen into my hands.

A thin, active, nervous man, past middle age, submitted himself to "mass radiography," when unhappily a small shadow was seen in the lung field. Fuller investigation was pursued: repeat x-ray examinations confirmed the presence of the shadow, but its shape and size remained unaltered. Bronchoscopy on two occasions elicited nothing abnormal. Finally, some weeks after the first x-ray, thoracotomy was advised. A few days prior to the operation the patient's chest was examined clinically—it would appear that this was the first occasion. On the back of the chest an infected cyst was found: this was forthwith removed—the shadow was absent from a subsequent radiograph.

This patient was caused a great deal of preventable anxiety, for he was only too aware of the possible and

sinister implications of a shadow in the lung field in one past middle age. This cannot be glibly dismissed as a cancerphobia. Again, considerable expense was incurred by his stay in hospital, radiographs, other investigations, doctors' time, etc. As well as expense, there was some concern over the diagnosis. This case would seem to emphasize yet again that laboratory tests, x-ray investigations, etc., must and should only be considered against a background of careful history-taking and thorough clinical examination, which starts with "looking" at the patient.—I am, etc.,

London, E.11.

ERIC K. GARDNER.

Amnion Implantation in Peripheral Vascular Disease

SIR,—I should like to thank Mr. R. Rowden Foote for his excellent letter (*Journal*, September 1, p. 553) *re* amnion implantation. It is most interesting to see that other diseases, apart from the intermittent claudication of arteriosclerosis, are being treated in this way. I quite realize that amnion implantation will be tried for other forms of vascular disease, and it is gratifying to see an early pioneer in any field of surgery. I wish him all success in his further work.

May I also thank Dr. H. St. John Mansbridge (*Journal*, September 8, p. 606) for sending up the letter about a patient that I treated by amnion implantation for intermittent claudication? It was indeed pleasing to read of such good results. At the same time, may I thank Dr. B. S. C. Gaster for his interesting letter in the same issue *re* a patient suffering from intermittent claudication and treated by amnion implantation? The letter states that he could walk from the Athenaeum to Piccadilly. I am quite sure that for many readers it is unknown that walking from the Athenaeum to Piccadilly entails walking up a long and moderately steep gradient; in fact this is a most important clinical finding—namely, that the aforesaid patient could walk up an incline without any pain.—I am, etc.,

London, W.C.2.

E. TROENSEGAARD-HANSEN.

Tranquillizers

SIR,—I am writing because I am rather disturbed that some of my fellow practitioners may be taken in by a recent circular from the chairman of a certain firm of manufacturing chemists.

This circular lists the tranquillizer drugs (but not all of them) in order of cost, and by inference suggests that the product of this particular firm is the least costly to the N.H.S. and therefore is the most economical to prescribe. I wish to point out that in actual fact one of the most generally useful drugs in this group is not included in this circular and is appreciably cheaper—11½d. per 25—than any of the drugs so listed.—I am, etc.,

Bath.

C. D. PETERS.

Suicide

SIR,—I was interested to read the article by Dr. E. B. Strauss (*Journal*, October 6, p. 818), which I found informative and instructive. I should, however, like to comment on Dr. Strauss's treatment of ceremonial suicide, particularly amok. During my sojourn in Malaya I had the opportunity of studying a number of cases of so-called amok, which in Malay means an impulse to murder. A number of these cases were obviously not suffering from this syndrome and were diagnosed as cases of catatonic excitement and post-epileptoid states.

The European concept of this disease and that of latak, to which it may be related, has been described by the late Sir Hugh Clifford, former Governor of the Straits Settlements, in his book *Studies in Brown Humanity* (1893). He said that the Malay who has lost face suddenly went amok, knowing that, as suicide was against his religious beliefs, anyone was privileged to shoot or cut him down. I spoke to many Malays, who informed me that they would never consider this method of death involving cutting down friend

or foe, old men and women or children; they said that such a person was suffering from "*kapela pusing*" (confusional state).

The cases which I considered to be suffering from amok had an initial period of anxious preoccupation passing into a phase of homicidal excitement, subsequently falling into a deep sleep. On awakening they were in an unstable nervous condition for several months. A sea captain, knowing of my interest in this disease, asked me to examine one of his crew who had been amok. The sailor, who had been sitting apart for several days, suddenly became wildly excited. He was seized and put into irons before any damage was done; meanwhile the sailor was screaming and shouting that he was surrounded by devils. Later he became quiet and fell into a deep sleep; on awakening he had no recollection of his conduct.

Although latak occurs in men and women, I have observed amok only in men. It has been suggested that amok is restricted to districts where quartan malaria is an endemic disease. A number of my cases were addicted to hashish. My experience would suggest that amok is not a ceremonial suicide but a definite psychiatric syndrome.—I am, etc.,

Wakefield Yorks

D. FENTON-RUSSELL.

SIR,—Dr. E. B. Strauss writes (*Journal*, October 6, p. 818) that as a boy he remembers "being very impressed by the half-starved, often deformed, repulsive-looking beggars whom one used to see congregated outside churches in Latin countries" and "expressing surprise that they did not commit suicide." He thinks that the answer is given by Durkheim,¹ who found that the suicide rate among Catholics is a mere fraction of that among Protestants. Dr. Strauss explains this by the compactness and cohesiveness of Catholic culture.

Unfortunately, the explanation does not look as if it will prove so simple. A recent Swiss monograph² fails to show this wide discrepancy between the religions in suicidal attempts, and suggests that in Catholic countries suicide is concealed and a statistical illusion is created. In support of this it is shown that in Switzerland the number of deaths by violence is the same in all cantons. While the suicides are indeed fewer in the Catholic cantons, the number of deaths by "accidents" is much higher than in the non-Catholic cantons. Helweg-Larsen's³ review of concentration camps showed that apathy and diminished power of spontaneous reaction were early and constant changes related to malnutrition. "Suicidal attempts were quite exceptional" he notes. Possibly the explanation of the beggars' behaviour lay in their half-starved condition. This, I believe, was already reckoned to provide some assurance of better things to come. It has perhaps not been widely recognized to date as a more immediate blessing in disguise.—I am, etc.,

A. A. ROBIN.

Wickford, Essex.

Liquorice-all-sorts as Anastomotic Aid

SIR,—It seems to be the general opinion, and it certainly has proved advisable in my experience, that anastomosis between a distended proximal and a narrow distal ileum in neonatal obstruction from ileal stenosis or atresia should be end-to-end. This is often technically difficult, chiefly because of the difference in size between the two ends, though the problem may be somewhat simplified by dividing the small segment very obliquely as suggested by Nixon.¹ It seemed, therefore, that some form of intraluminal splint over which the anastomosis could be performed would be an advantage so that the lumen at the site of anastomosis is properly maintained. Such a splint should be easily shaped at the operating table; it should be readily absorbable, but not too quickly so; and it should be of a consistency which

will not damage the intestine. We have found the solid, spiral cylindrical all-liquorice variety of liquorice-all-sorts to have these properties and to be very suitable for use for this purpose. For the last few years we have always had a collection of these sweets available when this operation is contemplated. It might also be that the very mild aperient action of liquorice is not a disadvantage in the distal collapsed segment of ileum.—I am, etc.,

PETER MARTIN.

Hibernation in Shocked Patients

SIR,—Congratulations to Dr. Sheila Kenny (*Journal*, July 28, p. 211) on her success with "hibernation" in her severely shocked patients. It occurred to a number of us doing our physiology for the second time after the war for the primary fellowship that the logical way to treat shocked patients was to cool them. The era of piling on blankets and hot-water bottles was passing and the exposure of a limb with doubtful blood supply was well established. However, we were unable to get any of our clinical colleagues sufficiently interested at that time. Of course we were not then thinking of the fully developed hibernation technique as used by Dr. Kenny.

Still, it would be interesting to hear how casualty surgeons are now treating their shocked patients, and to have their reactions to the possibilities of cooling, or at least not warming, them if they are not already doing so.—I am, etc.,

Nairobi.

ANDREW HICKS.

Troublesome Staphylococci

SIR,—The increasing incidence of staphylococcal disease has been causing anxiety to clinicians for some time. The papers by Professor Walsh McDermott (*Journal*, October 13, p. 837), and by Professor Ronald Hare and Dr. C. G. A. Thomas (p. 840), and your leading article on the troublesome staphylococci (p. 867) are well timed. In addition to the methods of transport of infection mentioned in these articles, the staphylococcus is spread by vulvo-vaginal secretions, as is shown by the development of signs in one child after another in the same household. Since such staphylococci have become resistant to penicillin and other drugs, the family doctor finds these children difficult to treat. The condition tends to become chronic and is responsible for many cases of long-standing vaginal discharge causing redness, vulval soreness, and irritation, but not necessarily any general ill-health.

In order to obtain a satisfactory culture of the organism so that its susceptibility to other antibiotics can be tested, specimens must be taken from the apex of the vagina and preferably from the cervix through a child's speculum. Investigation of even a mild case along these lines is likely to prevent the spread of infection in schools through the use of toilets, etc., and to reduce the incidence of vaginal discharges, for which advice is often only sought after puberty.—I am, etc.,

London, W.1.

G. M. SANDES.

SIR,—" . . . to-day we are seeing with greater frequency the actual development of staphylococcal disease in patients after they have come into our hospitals than was formerly the case" (Dr. Walsh McDermott, *Journal*, October 13, p. 837). This statement, made in New York, is equally true for England. Why has this change occurred? Part of the answer is provided by Professor R. Hare and Dr. C. G. A. Thomas (p. 840). In the leading article (p. 867) it is written: "There is at least a strong suspicion that antibiotic-resistant staphylococci have a greater capacity for epidemic spread than sensitive strains and perhaps a different capacity for producing lesions." This "epidemic spread"—apart from "food poisoning" outbreaks—is limited almost entirely to hospitals. Again, why? Briefly, because infective particles are principally disseminated in hospitals, and the density of these aggregations of infective particles is greater in the air

of hospitals than elsewhere (as Professor Hare has shown). There is some evidence that "wearing a sterile gown over ordinary clothing does not prevent dissemination of infected particles," but the sterile gown does appreciably reduce the density of infected particles in the circumambient air of the person under test. (By density I mean the degree of crowding of infected particles in the air.) In actual practice this aggregation of infected particles in air can be dispersed and neutralized by dilute "hibitane" used in a "microsol" sprayer. Infected dust clinging to hangings round ward beds can be sterilized by this means. Clothing can be disinfected regularly by exposing it to moist warm formalin gas in the hospital autoclave or in a "sparkhall." Clothing so treated is not damaged in any way. Important and very capacious reservoirs of infected particles in the shape of dust are the mattresses of hospital patients' beds, and their pillows (as Professor Hare mentions); both these reservoirs can be neutralized by regular treatment with hot moist formalin gas in an apparatus. Blankets should be washed regularly in "lissapol" and then soaked in "fixanol C" and dried without further rinsing. Sterile gowns soaked in dilute benzalkonium solution and dried without rinsing might be better protection than untreated sterile gowns. Efficient masks prevent the dispersion of infective crusts, etc., from the nose as well as "droplets," which are important for microbes other than staphylococci. Floor dust can be immobilized by a variety of methods.

Evidence for the measures here recommended can be found in the paper by Miss Helen Rodway and me.¹ I do not agree with Dr. McDermott when he writes: "Moreover, as staphylococci are so ubiquitous, an approach based on attempts to eliminate them from the environment would not seem hopeful." In my opinion, to eliminate staphylococci from the micro-environment represented by a hospital is not only feasible but would be rewarding in high degree.—I am, etc.,

Epping, Essex.

Speech Therapy

SIR,—May I, on behalf of speech therapists, say how much we welcome Dr. R. Macdonald Ladell's expression in his letter (*Journal*, October 13, p. 884) of the view that "stammering cannot be treated as if it were merely a matter of correct enunciation" but rather that it is the "domestic atmosphere" which requires a change. This we strive to bring about through our interviews with the parents at the clinic or in the home. I do not here refer to such problems as stammering clutterers or others such as those with cleft-palate speech who also stammer, but only to "pure" stammerers.

Since speech is a psycho-physical process of incredible complexity it is not surprising that when environmental circumstances are highly unfavourable a breakdown of this chief means of expression of thought and feeling should occur. As would be expected, this speech breakdown occurs, in the vast majority of cases, in the early years of the child's development. Unfortunately a great many stammerers do not reach us until years after the onset of the disorder—often not until they are adults. So we have also to strive to facilitate adjustment on the part of the stammerer to the social situation. Then, too, visits to the school are necessary so that we may guide the teacher—faced with a stammerer in the class—as to how to assist in the rehabilitation, and how to avoid exacerbating the difficulty of that particular stammerer at that particular moment.

As a considerable proportion of early stammerers do not recover spontaneously, we question whether the still fairly prevalent advice to the parents on the part of general practitioners that "he will grow out of it" is always of the best. So often, when at last the patient is referred, or when at last the parents have been able to accept the advice to avail themselves of the specialist's help, we find that the condition has deteriorated rapidly and severely.

Dr. Macdonald Ladell has noticed that the dammed-up aggression, which often to a great extent contributes to the inhibition of speech, is usually against the father. Would, therefore, the male therapist, by rule, be the more suitable one to deal with the stammerer?—I am, etc.,

Chepstow, Mon.

RUTH BENNETT.

Medical Witnesses

SIR,—We beg to draw attention to a topic which doctors often discuss with concern but which is not aired, presumably because it is a somewhat delicate matter. There is discernible a marked tendency for some medical witnesses to give evidence in categorical and emphatic terms which would be hard to justify on any set of facts in the present state of medical knowledge. This leads to inexplicably wide differences of opinion between medical experts who have the same evidence at their disposal. It is very confusing to the public, who draw their own conclusions. A High Court judge has said, "Doctors always disagree in court but always agree in consultation." Laymen may be excused if they wrongly conclude that medical experts are not very proficient or that they are influenced by the doctrine, "Who pays the piper calls the tune." This loses prestige for the whole profession. It leads to undignified divisions of opinion and unfortunate slurs on colleagues and medical institutions. Sometimes the cause of justice is badly served.

The large majority of doctors testify with a high sense of duty, but are often reluctant to appear at all. A minority, often very frequent testifiers, risk bringing discredit to the profession. "Science begets knowledge; opinion ignorance" (Hippocrates). It is indeed difficult to speak "the truth, the whole truth, and nothing but the truth." To approach this ideal, witnesses must have enough humility to recognize their own fallibility and the limitations of the corpus of medical science. These limitations can hardly be fully appreciated by the other learned professions who take part in the administration of justice, and this increases the load of responsibility borne by the expert medical witness.—We are, etc.,

Doctors in Hungary

SIR,—Having been in Hungary this summer I read with great interest the letter from Mr. Ron Ledger, M.P. (*Journal*, October 13, p. 886). I am sure that doctors in England would be grateful if he could amplify some of his statements. For instance, how much in forints per month is the salary given to each doctor? Does he have to incur expenditure on surgery accommodation, etc., in State and/or private practice? I am surprised to hear that the State Health Service only covers 5 millions of the inhabitants. We were informed that it was universal. Who and what are the 4.5 millions uncovered?

I agree that no one appears to starve in Hungary, but the dreariness, drabness, and low standard of living displayed everywhere makes one speculate as to where there can be a lucrative source of private practice.—I am, etc.,

London, S.W.12.

W. P. M. DAVIDSON.

Biography of James Braid

SIR,—I am collecting information about the life and work of James Braid, the Manchester surgeon who originated the term "hypnosis," with a view to writing a biography of him. He was born in 1795 and died in 1860. I should be grateful for any help which any of your readers may be able to give me, either by putting me in touch with descendants of Braid or by drawing my attention to letters by and about him or similar data. Any material forwarded to me at this address will be returned with care after it is examined.—I am, etc.,

Obituary

A. H. GALE, D.M., D.P.H.

Dr. A. H. Gale, director of medical postgraduate studies and lecturer in epidemiology at the University of Bristol, died on October 12, aged 55. Before moving to Bristol in 1950 Dr. Gale carried out numerous important epidemiological investigations while working as a medical officer at the Board of Education and at the Ministry of Health.

Arthur Harold Gale was born on August 31, 1901, the son of Dr. A. K. Gale, of York. From Dover College he went on to Trinity College, Oxford, continuing his medical education at University College Hospital. Qualifying in 1926, he graduated B.M., B.Ch. in 1927 and proceeded to the D.M. in 1933. After holding the posts of house-surgeon and house-physician at University College Hospital he took the D.P.H. in 1930 and became an assistant medical officer of health and assistant school medical officer in Surrey. One of the first papers he published, in 1933, was on the testing of children's hearing by the gramophone audiometer.

In 1933 he was appointed to the staff of the Board of Education as a medical officer, working under Sir George Newman and Dr. R. H. Crowley. One of his first duties was to investigate the effect of the economic depression on the nutrition of children. His clinical judgment was always sound, and he got on well with children, schoolmasters, medical officers, and educational committees. He was at his best dealing with the problems of the treatment and education of handicapped children, work which he carried out with skill and a very human tact and sympathy. An ideal colleague, he was modest, serene, kind, always ready to help, and as well liked by his opposite numbers of the administrative side as by his fellow medical officers. In the war he assisted the Ministry of Health in many ways, including the nightly inspections of air-raid shelters.

His work in the epidemiology of the infectious diseases of children brought him a larger audience. In 1944 he was Milroy Lecturer at the Royal College of Physicians, and his studies on the changes in the mortality and incidence of the principal infections of childhood were published in the *Proceedings of the Royal Society of Medicine*, the *Archives of Disease in Childhood*, and the *Monthly Bulletin of the Ministry of Health and Public Health Laboratory Service*. To the last-named he was also a frequent contributor on other subjects. In 1947 and again in 1949, with Dr. W. H. Bradley, he arranged two nation-wide hospital inquiries on poliomyelitis, and together they wrote the reports upon the facts they had ascertained, reports which are of outstanding importance in the history of poliomyelitis in this country. In 1949, with B. Benjamin, he wrote on the age-distribution changes shown in poliomyelitis in England and Wales. Other subjects which he ably illuminated included

children's deaths from violence and the causes of severe deafness in children. In a refresher course article published in this *Journal* he summed up the pros and cons of tonsillectomy.

In 1950 Dr. Gale accepted the newly designated office of director of postgraduate medical studies in the University of Bristol, together with the lectureship in epidemiology. He was also honorary consultant in epidemiology to the United Bristol Hospitals. He is survived by his wife and two children.—J. A. G.

We are indebted to Professor R. MILNES WALKER for the following appreciation:

The early death of Arthur Gale will leave a gap in the medical organization in the south-western region. Since 1950 he had held the Bristol University appointment of director of postgraduate studies, with which he combined a lectureship in epidemiology. This double appointment brought him into contact with the medical services from Gloucester to Land's End, but since the introduction of the pre-registration house appointments part of his time has been occupied in seeing that graduates of Bristol University found suitable resident posts. As a member of the joint Registrar Appointments Committee he was responsible for the interchange of registrars between the teaching hospital and the hospitals under the regional board. The thorough yet gentle way in which he set about his tasks and his solution of problems, often in the face of conflicting interests, led to a confidence in his guidance which was shared by all who worked with him; he would take endless trouble in seeing that all points of view were considered and that every claim received just treatment. In this way he formed an important link between the university, the board of governors, and the regional board, and he enhanced the happy relations which exist between them. During the last year he had had poor health, but he was always happiest when at work and was just getting into his stride again when the last illness burst suddenly upon him.

He was a man who sought nothing for himself and was always ready to help others; his colleagues in Bristol will miss him, as the work which he was doing so ably will have to continue; he has been responsible for making it an essential part of the medical services of the country.

D. K. L. LINDSAY, O.B.E., M.D., D.P.H., D.T.M.

Colonel D. K. L. Lindsay died at Bexhill on October 15, aged 52. Until recently he had been working for the World Health Organization in Ethiopia.

David Kenneth Llewelyn Lindsay was born of British parents on August 9, 1904, in Paraguay, where his father, the late Dr. J. W. Lindsay, was practising medicine. The Scottish accent of his father was mellowed by the Spanish that he learned as a child. Educated in Edinburgh, he graduated M.B., Ch.B. at the university there in 1929, proceeding to the M.D. in 1933. He took the Liverpool D.T.M. in 1930, and in the same year returned to Paraguay, where he was admitted M.D. at the University of Asunción. His stay there was short, but long enough for him to publish two valuable papers about medical practice on the Brazilian frontier and on American leishmaniasis. After returning to London he held postgraduate appointments before joining the Indian Medical Service in 1933. Much of his service was as a civil surgeon in Burma. Early in the Japanese advance into Burma in 1942 he set off from Lashio, after waiting longer than self-security dictated and no shorter than his duty allowed, to escape out of Burma. Within a few days he and the three medical sergeants with him were ambushed and their car lost. He dauntlessly led the party to Kunming, a walk of about 500 miles. He was next posted to New Delhi to plan and prepare the rehabilitation of medical services in Burma when that

country was freed. When he returned to Burma he showed the maturity of his character by his tremendous energy, sound judgment, and the highest standards of conduct, which were to remain with him the rest of his life. He was appointed O.B.E. in 1943, and was also mentioned in dispatches in 1946 for his gallant and distinguished services in Burma.

On leaving Burma soon after the country attained its independence, Lindsay completed his studies for the London D.P.H. in 1949, studies which had been interrupted by the war. His next appointment was to a hospital group at Prestwick, where he found his administrative experience in the I.M.S. of great value. When he felt he had done all that was required he resigned and soon after joined the field staff of the World Health Organization in 1952. He served with distinction in Libya for two years and was working in Ethiopia when the symptoms of his last illness first appeared in 1954.

J. H. B. writes: The death of Kenneth Lindsay, after an illness of nearly two years which, almost from its start, he knew must be fatal, brings to a premature close the career of one of the most outstanding officers of the late Indian Medical Service and a medical man of high attainments and great promise. In the I.M.S. he speedily made his mark and was selected for civil employ in Burma in December, 1935, after the minimum obligatory period of military duty of two years, during which, however, he had served as command consultant in dermatology.

In Burma Lindsay found ample scope, and his exceptional capabilities speedily became apparent. After holding various civil surgeoncies and a period of study leave spent mostly in Prague, in 1940 he was appointed civil surgeon, Northern Shan States, with his headquarters at Lashio. This district was notoriously unhealthy. Malaria was hyperendemic and the spleen rate, as Lindsay records it, 98%. Moreover, to the normal duties of a civil surgeon—responsibility for preventive measures in his district and the running of the district hospital and its satellite dispensaries on the curative side—was added responsibility for the preventive and curative care of the labour force of the western part of the Yunnan Highway, better known as the Burma Road. This involved preventive measures against all endemic and many imported diseases, for the latter of which the motley and cosmopolitan labour force and the inevitable crowds of clerks, overseers, traders, and adventurers which accompany such projects were responsible. Some idea of the magnitude of the task may be gathered from the fact that the main labour hospital organized by Lindsay received 40,000 acute cases in two years and was, in his words, "a clinician's paradise such as few have seen."

To quote him further: "Work here came to a sudden end in 1942 when the population fled before the Japanese armoured columns. Remaining behind to help refugees, I was attacked while assembling medical supplies, but, escaping with only a slight wound, reached a Chinese air-field [after a 500-mile walk] and joined the Army in India as a hospital commandant." This laconic report is typical of the man; what actually happened is equally so.

As the Japanese rapidly advanced northward up Burma permission was given to the district authorities to evacuate. Lindsay took no notice of this beyond the collection of medical supplies and their distribution to the various parties of refugees as they set off. Shortly afterwards he was ordered to evacuate ; but again took no notice as there were still many parties to supply. Then came a final categorical and personal order to evacuate which could no longer be ignored ; and Lindsay with three devoted followers, and all the supplies he could carry or get carried, started up the *via dolorosa* of the approaches to the Hawkong valley. At the end of every day's march, while others rested, Lindsay and his three assistants turned back over the way they had come to treat and help those who had fallen by the way. After five days of this progress of "two steps forward, one

step back," while returning along the route he ran into a Japanese patrol, was shot through the arm, but escaped into the jungle, where he met—or was discovered by—friendly tribesmen who took him in till his clean wound had healed. Then he and the survivors of his helpers, unarmed and without maps, trekked 500 miles through jungle and hills till they reached Kuming. Thence the Americans ferried him "over the hump" to India, and Lindsay proceeded to S.mia, where what remained of the Burma Government were accommodated, and laconically reported for duty. For this outstanding example of devotion to duty, courage, and initiative he received the not-over-generous award of the O.B.E.

After a period of work on the planning staff for the rehabilitation of Burma, he rejoined the Army for the re-occupation as A.D.M.S. Civil Affairs Staff (Burma) of the 14th Army or C.A.S.B. with the temporary rank of colonel and the responsibility for all aspects of civil health throughout the country—duties which he brilliantly discharged and for which he recruited *ad hoc* over 500 medical officers—British, Indian, Chinese, and Burmese. In this work he was employed except for a short period of leave till the grant of independence to Burma, after which internecine differences made further useful work impossible and he returned to Britain and proceeded to the D.P.H. (London).

After a period of service with the Scottish Western Regional Hospital Board he resigned and accepted appointment to the field staff of the Middle Eastern Bureau of the World Health Organization. His first assignment was to Libya, where, ably assisted by his wife, he rendered most distinguished pioneer service and gained the friendship and esteem of the Emir (now King) Sayed Idris. From Libya he was assigned to Ethiopia, where he repeated both his valuable health work and his capture of the esteem of the sovereign. It was in Ethiopia that the first symptoms of his fatal illness appeared and dictated an immediate return by air to England for operation. Characteristically, though well aware of the nature and course of his complaint, Lindsay insisted on returning to Geneva between periods of treatment to complete a survey and report which had been entrusted to him, and persevered in his work for W.H.O. until the point of no return was reached.

A man of wide culture—thinker, writer, and linguist—he was a loyal friend with a most delightful sense of humour and a dry wit, and I have never met a man with higher ideals or greater sense of vocation nor one more modest and unassuming. His career is the embodiment of those ideals below which he never permitted himself to fall. His love for and pride in the service he adorned were unflinching, and the pride and affection of its surviving members for a brother officer whose life was an embodiment of its traditions will last as long as they do.

He is survived by his mother, his second wife, and his son by his first marriage, to whom the warm and affectionate sympathy of all who knew him goes out.

C. J. H. writes: Lindsay was always critical of conduct lower than the high standard he had set himself. His love for his old service was wide and deep, and his respect and affection for those who had served in it with him never faltered. He was a good doctor and an above-average linguist. He died a relatively young man—certainly young in spirit—after a courageous struggle, in which he was loyally supported by his second wife, against an unrelenting foe. Although he was quite early fully aware of the close possibilities of his illness, he discussed them with his close friends in a detached manner and without complaint. So has passed a man always free of pettiness and of great integrity, high courage, and tireless endeavour.

J. R. GRIFFITH, M.B., F.R.C.S.

By the death of Mr. J. R. Griffith on October 14 the medical profession in Sussex has lost one of its most distinguished and popular members and the community a man who served it with skill for nearly forty years. He was 68 years of age.

Ост. 27. 1956

The grandson of a former headmaster of Brighton College, John Richard Griffith was born on November 18, 1887, the son of a well-known Brighton solicitor. He read classics at Christ's, his family college at Cambridge, and received his medical training at St. Bartholomew's Hospital, graduating B.Chir. in 1913. He took the M.B. in 1941. After graduation he became house-surgeon to Sir Anthony Bowlby at Bart's and then held a similar appointment at the Metropolitan Hospital. In 1916 he entered the R.A.M.C. and served as a surgical specialist with the 9th (Secunderabad) Division in India in 1917-18 and in Mesopotamia in 1918-19. He would always recount with pleasure the experiences he had while serving abroad. On his return to civilian life he obtained the F.R.C.S. in 1920, and became surgeon to Hove Hospital and assistant surgeon to the Royal Alexandra Hospital for Sick Children, Brighton. The children loved him and he was a master at gaining their confidence. His gentleness enabled him to be particularly successful with hare-lip and cleft-palate operations, and an oft-repeated injunction of his was, "Treat tissue as though you loved it." He also worked at the Southlands and Crawley Hospitals, but most of his life was devoted to the Royal Sussex County Hospital.

A colleague and friend writes: John Griffith was a true general surgeon, and his work was enterprising and original. He pioneered regional anaesthesia, using it for thyroidectomy, major abdominal surgery, and the setting of fractures. He introduced Waugh's technique of tonsil dissection to Sussex, and taught generations of his house-surgeons how to treat the septic hand according to sound anatomical principles. At all times he was glad to share his original ideas with others who later became specialists. His presidential address to the Brighton Medico-Chirurgical Society on the preparation of the patient before operation illustrated his surgical philosophy: it was delivered through the noise of an air raid, and the police sent in a message asking whether it was wise for all the doctors to be gathered in one room on such a dangerous night.

In the medical world of Sussex John Griffith will be greatly missed, but he will also be missed by a host of others. His delight in outdoor sports and his knowledge of nature were extensive. He was a keen fisherman, and during his retirement he developed an enthusiasm for his garden and delighted to entertain at his country home. In an organized shoot his prowess as a shot was always outstanding, but his greatest pleasure was rough shooting with his dog. Those who were privileged to have him as a companion on such an exploit will long remember his generous heart, his great knowledge of country ways and things, his splendid physique, his patience and endurance, his love of animals, and above all his love of his fellow men, peasant or peer alike. His last conscious hour was spent walking with his dogs in the woods he loved so well. In the midst of his happiness he was suddenly struck down by a cerebral haemorrhage and lay guarded by his faithful companions till their barking led searchers to their unconscious master. He was taken to hospital, but died next day without recovering consciousness.

John Griffith leaves behind him a family to carry on the medical tradition—one daughter, and two sons who followed their father at Christ's and later at Bart's. Through his wife, who is also a practising doctor, his sons are the fifth generation in a medical family. A memorial and thanksgiving service for his life and work was held at St. Andrew's Church, Hove, on October 18. In the crowded congregation were young and old from far and near throughout Sussex. All met to pay their last respects to an able doctor and a staunch and valued friend and loyal colleague.

Dr. DOROTHY WILLOUGHBY died at her home at Edmonton, Alberta, Canada, on July 16 at the age of 57. Dorothy Pease was born at Abington, Massachusetts, U.S.A., on April 8, 1899, and graduated B.A. in literature, with honours, at

OBITUARY

BRITISH MEDICAL JOURNAL. 1003

Tuft's College, Massachusetts, in 1919. In 1923 she entered the New York State Tuberculosis Service as a graduate nurse from Bellevue Hospital, New, York City. Later she came to live in England and studied medicine at Bristol University, qualifying M.R.C.S., L.R.C.P. in 1943. After qualification she held resident appointments at the Bristol General Hospital and at Bury, Lancashire, and Whitehaven, Cumberland, before entering general practice at Broadway, Worcestershire, in 1946. For a time she was also a member of the honorary staff of Evesham Hospital. She left Broadway in 1953 for Menai Bridge, Anglesey, but in the following year went back to North America with her husband, Dr. Lawrence Willoughby, setting up in general practice at Edmonton, Alberta. She died suddenly and unexpectedly, having seen patients up to within a few hours of her death. She is survived by her husband and one son.

The sudden death of Dr. S. S. YAVAGAL on September 9 at the early age of 30 was a great shock to his many friends in this country and in India. Shivalingappa Shivappa Yavagal was born on November 8, 1925, and graduated M.B., B.S. at Bombay University in 1951. After three years spent in house appointments in Bombay he came to England in 1953 for postgraduate study. The first two years he spent in Edinburgh and the north of England, and in the autumn of 1955 came to London to take up the appointment of house-physician to the tuberculosis wards at St. Margaret's Hospital, Epping. He had a special interest in diseases of the chest, and a good knowledge of this branch of medicine in particular. During the 12 months he was at St. Margaret's he showed himself to be not only a promising young physician but a person to whom nothing was too much trouble. He endeared himself to his colleagues, the nursing staff, and above all to his patients by his innate kindness, sympathetic understanding, and willingness to help all those with whom he came in contact. The opinion held of him by the staff of the hospital is perhaps best expressed by a remark made by a ward sister shortly after his arrival: "He is quite one of the nicest things which have ever blown into St. Margaret's." His early death, due to a coronary thrombosis, is a grievous loss to India, to which country he was planning shortly to return. Our deepest sympathy goes to his wife and other members of his family.—V. U. L.

Mr. D. A. LANGHORNE, surgeon to the Royal West Sussex Hospital, Chichester, died on September 20 after an illness of a few months. He was 51 years of age. Douglas Alfred Langhorne was born at Bennington, Hertfordshire, on March 4, 1905. He qualified M.R.C.S., L.R.C.P. from St. Bartholomew's Hospital in 1927, and then held appointments there as house-surgeon to Mr. Harold Wilson and Mr. (now Sir) Geoffrey Keynes, and as house-physician in the department of dermatology. He became interested in plastic surgery and was assistant to Sir Harold Gillies. However, after taking the F.R.C.S.Ed. in 1930, he returned to general surgery, which he pursued as surgical partner in general practice with Dr. A. H. Bostock, of Chichester. He was soon appointed assistant orthopaedic surgeon to the Royal West Sussex Hospital, and in due course surgeon to that hospital and to the Royal West Sussex County Mental Hospital. He was active in support of the British Medical Association and was honorary assistant secretary of the West Sussex Division for several years before the second world war. His high sense of duty led him to join the Territorial Army, and in the early stages of the war he served in Iceland. During the period of relative military inaction there he indulged his taste for natural history and wrote a delightful short book about the character and beauty of that island. Later he served for three and a half years on the Burma front. His gay courage and self-sacrifice among the casualties during the six months of siege in the Imphal pocket were an example to all about him. His appointment as M.B.E. in 1945 was well deserved. When the war was over, he returned to Chichester, but withdrew from general practice to devote himself exclusively to surgery. He was an able, kindly, and sympathetic surgeon, and at

his memorial service the little church at Bosham was filled to overflowing with patients, colleagues, and friends. Langhorne loved the sea and sailing. He knew every inlet of Chichester Harbour and spent hours studying the habits of sea birds and waders there. He painted a little and read archaeology. He devoted a great deal of his leisure to voluntary organizations in Chichester, where his interest was always to secure fair play for the individual and to preserve kindness in human affairs. He was a gay, handsome, friendly man, with a steady philosophy and an innate modesty. He was loved by all who knew him. He leaves a widow and three sons.—H. T.

Dr. DOUGLAS GRAY, of Henlow, Bedfordshire, died in hospital on September 24, after a car accident. He was in his 79th year. Douglas Gray was born in Aberdeenshire in 1878, and from Bedford Modern School went to Charing Cross Hospital Medical School. He graduated M.B., with honours in forensic medicine, in 1904, having qualified by taking the London Conjoint diploma two years earlier. After gaining experience at Charing Cross Hospital as house-surgeon, house-physician, and medical registrar, he started practice at Bolton, Lancashire, in partnership with Dr. Charles Macfie, continuing on his own after his partner's death in 1915. He became assistant surgeon at Bolton Infirmary in 1904 and was appointed honorary surgeon two years later, a position he held until 1939, after which he was appointed consultant surgeon. Altogether he served on the honorary staff of the infirmary for 43 years, and was chairman of the board of management for nine years. During the first world war he served in Salonika as a captain in the R.A.M.C. In politics he was a strong Liberal, and served on the town council for 14 years. A man of great integrity and unbounded energy, he was beloved by all who knew him. He leaves a widow and a son, Dr. G. Gray.—J. L.

Dr. W. M. WILSON died suddenly on September 28, at the age of 58, while on holiday at Blairgowrie, Scotland. William Muirhead Wilson was born at Edinburgh on February 21, 1898, and was educated at George Watson's College, where, in addition to playing Rugby for the first fifteen and cricket for the first eleven, he was dux of the school in 1915. On leaving school he enlisted in the Army as a combatant before his 18th birthday by giving a false age. He was badly wounded in 1916 and spent eighteen months in hospital. After the war he enrolled as a medical student at Edinburgh, graduated M.B., Ch.B. in 1923, and was captain of the university golf club. Following house appointments at Edinburgh Royal Infirmary and Durham County Hospital, Dr. Wilson settled in practice at Gateshead-on-Tyne in 1924, where he remained until the time of his death. In 1931 he proceeded to the M.D. with a thesis on pink disease. At Gateshead he held numerous appointments, including that of surgeon to the Children's Hospital from 1925 until his death—a voluntary appointment until 1948. He loved this work and gave to it his unsparing time, skill, and devotion. He was a staunch member of the British Medical Association, and during his long membership of the Gateshead Division held various offices, being chairman twice. During the second world war he did much useful work on various medical committees and was subsequently chairman of the Local Medical Committee from 1948 to 1954, and of the Medical and Pharmaceutical Committee from its inception until his death. For several years he represented Durham County on the committee of the North of England Medical Society. Dr. Wilson was made a magistrate in 1951 and by his wonderful knowledge of human nature and his own exemplary conduct was perfectly suited to carry out the duties of this office. He lived a very full and active life, as, in addition to his medical work, he had many outside interests and was very keen on all sports. He represented the North of England at bridge, and in spite of his severe war wounds played an excellent game of golf. His death is a great loss to his

wide circle of friends and to his adopted town of Gateshead, where he was greatly respected and loved by all classes. He was a very clear thinker with a deep sense of humour and with a great sense of duty. He inspired his patients and others with confidence, and throughout his full and useful life set a fine example for young doctors to follow. He is survived by his wife and twin daughters, both of whom are physiotherapists.—J. C. A.

Dr. J. R. McDONALD writes: The announcement of Bill Wilson's death has come as a severe blow to his many friends, especially in the Tyneside and Edinburgh areas. Their first instinct was one of profound sympathy for his wife, Jenny, and their two girls, Joan and Kathleen. After a strenuous thirty years in the centre of Gateshead, they had just comfortably settled in their new home on the outskirts. The profession has also suffered a severe loss in his passing. Fearless and independent, he never suffered fools gladly, but gave of his best to all. Nowhere will the loss be felt so much as among his old patients, who always looked to him for fatherly as well as medical advice. Slow in speech and heavy in manner, his appearance often belied the acuteness of his perception. Aloof from all petty bickerings, within the profession or otherwise, he was always a wise counsellor to colleagues and others. His record as dux of George Watson's College in 1915 was no fluke. His lameness, the result of a wound received in the first world war, prevented him from pursuing his favourite game on the Rugby field and limited his recreations to golf and bridge, at both of which he was an expert. As a magistrate and the mainspring of many local activities, he will be much missed in Gateshead. His friends will always remember him for his uprightness of character, his quiet urbanity, and his delightful sense of humour.

Dr. W. C. HARRIS died at his home at Kenton, Middlesex, on October 2 after a long and painful illness. He was 55 years of age. William Cecil Harris was born at Uddingston, near Glasgow, on April 12, 1901, and graduated M.B., Ch.B. at Glasgow University in 1926. He settled at Kenton in the following year to take up general practice, and in this he had the satisfaction of being well loved by his patients. He was also on the staff of Harrow Hospital. Appointed honorary secretary of the Harrow Division of the British Medical Association in May, 1934, he served in this capacity until he joined the R.A.M.C. soon after the outbreak of the second world war. He was wounded and captured at St. Valéry-en-Caux in 1940, and three years later was repatriated while still recovering from his wound. He resumed practice at Kenton a year or so later, retiring in 1953 owing to ill health. He is survived by a widow and a daughter.

The obituary of Dr. DORIS GORDON was published in the *Journal* of August 11 (p. 364). Dr. JOHN RICH, president of the Taranaki Division of the B.M.A., writes: Dr. Doris Gordon was one of the first women graduates in New Zealand and overcame great educational difficulties to enter Otago University. She then had a brilliant undergraduate career which was a promise of her great achievements in later years. For some time after the second world war she was director of Maternal and Infant Welfare in the Health Department of New Zealand. Her long struggle over the years did much to improve the standards for the treatment of maternity patients in New Zealand and they owe a debt of gratitude to her. She practised in Stratford for almost the whole of her medical life and was in partnership with her husband. She was loved and respected throughout the whole district. Recently Dr. Gordon added another success to her very full life when she published her entertaining biography *Backblocks Baby Doctor*. Dr. Doris Gordon was a woman with a most commanding personality and a vigorous proponent of what she considered right. The sympathy of the Division goes out to her husband, Dr. W. P. P. Gordon, and to her family.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 6 (No. 40) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1956					1955

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Spotting Epidemics

The quick detection of winter epidemics is the subject of a note in the latest *Monthly Bulletin of the Ministry of Health* (October, 1956, page 226). Medical officers of health are asked to select general practitioners in their district who are willing to act as spotters, though keeping in touch with all general practitioners, so as to have early information about the start of any epidemic. The note stresses that at crucial times the general practitioners are often overloaded with work, and consequently the minimum effort should be required of them to provide epidemiological information. The medical officers of health are also asked to invite the help of doctors in hospitals, industrial firms, schools, and other institutions. Other suggested sources of information include pharmacists, whose sales of "cough and cold cures" may go up at the beginning of an influenza epidemic; the local registrars of deaths, who can quickly make information available of deaths from influenza, bronchitis, and pneumonia; and the ambulance services, which can provide figures of cases removed to hospital.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The only large increase in the numbers of notifications of infectious diseases in England and Wales during the week ending October 6 was 572 for measles, from 1,396 to 1,968; the largest decreases were 278 for whooping-cough, from 1,765 to 1,487, and 36 for dysentery, from 457 to 421.

The largest rises in the incidence of measles were 130 in Lancashire, from 325 to 455, 58 in Cornwall, from 21 to 79, 52 in Montgomeryshire, from 6 to 58, and 50 in Monmouthshire, from 15 to 65. The outbreak in Montgomeryshire was localized, 55 of the notifications being recorded in Newtown and Llanllwchaearn U.D. 458 cases of scarlet fever, 11 more than in the preceding week, were notified; the largest rise was 27 in Yorkshire West Riding, from 40 to 67. The largest falls in the number of notifications of whooping-cough were 45 in Northumberland, from 76 to 31, 37 in Warwickshire, from 109 to 72, and 30 in Essex, from 118 to 88. 2 cases of diphtheria were notified, being 6 fewer than in the preceding week; both cases were notified in the metropolitan borough of Wandsworth.

155 cases of acute poliomyelitis were notified, and these were 4 more for paralytic and 20 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 33 (Manchester C.B. 19, Blackpool C.B. 3, Warrington C.B. 2), Cheshire 23 (Stockport C.B. 12, Altrincham M.B. 3, Bebington M.B. 2), London 18 (Kensington 9, Hackney 2, Wandsworth 2), Surrey 11 (Carshalton U.D. 3, Woking U.D. 3, Richmond M.B. 2), Durham 10 (Bishop Auckland U.D. 3, Darlington C.B. 2, Sunderland R.D. 2).

The chief centres of dysentery were Yorkshire West Riding 94 (Leeds C.B. 24, Sheffield C.B. 17, Colne Valley U.D. 14, Barnsley C.B. 10), Lancashire 79 (Liverpool C.B. 19, Bolton C.B. 9), London 66 (Islington 13, Southwark 12), Warwickshire 22 (Coventry C.B. 19), and Northumberland 20.

Scotland in Second Quarter

The birth rate in Scotland for the second quarter of 1956 was 19.5, being 0.8 above the rate for the corresponding quarter of 1955 and the highest rate for any quarter since the second quarter of 1948. The infant mortality was 26 per 1,000 registered live births; this was 3 below the rate for the corresponding quarter of 1955 and 5 below the average of the 5 preceding years. The death rate was 11.4 per 1,000 of the population, being 0.3 below the rate for the corresponding quarter of 1955 and 0.2 below the 5 years' average. The death rate from malignant neoplasms was

209 per 100,000, being 9 above the rate for the preceding second quarter and 15 above the average of the 5 preceding years. Only 31 deaths were attributed to the principal infectious diseases. These were 21 from influenza, 5 from meningococcal infections, 2 from whooping-cough, 2 from measles, and 1 from scarlet fever. Deaths from all forms of tuberculosis numbered 162; of these, 144 were due to tuberculosis of the respiratory system and 18 to other forms; the death rates were 11 and 2 per 100,000, respectively. Deaths from violence numbered 658, being 67 fewer than in the preceding second quarter. Road transport accidents accounted for 146 of these deaths and were 1 fewer than in the second quarter of 1955.

Week Ending October 13

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 532, whooping-cough 1,393, diphtheria 10, measles 2,146, acute pneumonia 261, acute poliomyelitis 150, dysentery 524, paratyphoid fever 4, and typhoid fever 8.

Medical News

Bisset Hawkins Medal.—Immediately after the Harveian Oration at the Royal College of Physicians on October 18, the Bisset Hawkins medal was presented to Dr. G. S. WILSON, director of the Public Health Laboratory Service, by the president of the College, Sir RUSSELL BRAIN. The medal is for the recognition of outstanding work in the field of public health. In the citation it is said of Dr. Wilson, "The indisputable fact that this country now possesses the finest national epidemiological laboratory service in the world is due largely to his wise guidance and constant stimulus." Dr. Wilson has directed the P.H.L.S. (originally the Emergency P.H.L.S.) since 1940.

Society of Medical Officers of Health.—The annual dinner of the society was held on October 18 with the President, Dr. J. D. KERSHAW, in the chair. In proposing the society's health, Miss PAT HORNSBY-SMITH, M.P., said that in the early days of the N.H.S. the stress had been on hospitals, but during the past two years greater emphasis had been laid on prevention and domiciliary services. The Guillebaud Committee had supported the idea of a domiciliary team of local-authority workers under the clinical leadership of the general practitioner. The success of this team depended on the success of the M.O.H. in securing co-operation. Miss Hornsby-Smith was sure the Ministry could count on the support of the society in the inquiry into toxæmia of pregnancy arising from the report of the Standing Advisory Committee on Maternity and Midwifery. She was delighted to know the society had formed a mental health group. The M.O.H. had reached a point in the development of preventive health work where further progress depended largely on the ability to work with and through his clinical colleagues. The field had shifted from sewage and pure water to problems inside the house. The M.O.H. was ideally placed to keep before the clinician those socio-medical factors which contributed to the prolongation as well as the inception of disability. In reply Dr. KERSHAW, referring to the current need for partnership between the M.O.H. and the clinician, said the gap had been bridged with general practitioners, who knew the social environment of their patients, but this was not the case with the hospital. He thought hospitals should have departments of clinical social medicine in which the M.O.H. would be on an equal footing with his clinical colleagues. The toast "The Guests" was proposed by Dr. C. FRASER BROCKINGTON and Dr. P. A. TYSER, and responded to by Lord WAVERLEY and Dr. ALEXANDER HALL.

Poliomyelitis Vaccines.—In an address to the New York Academy of Medicine on October 25 Dr. ALBERT B. SABIN put into perspective recent press reports that his attenuated

poliomyelitis vaccine is ready for mass trial. "We now have strains derived from single particles of virus that are sufficiently highly attenuated and stable under appropriate conditions of cultivation to justify their use for the next stepwise studies on immunization of human beings," he said. "Experience has taught me the importance of accentuating the negative," he continued, "and I therefore wish to stress that we are not ready for so-called mass trials of an oral vaccine but only for those tests on increasingly larger groups which must precede any consideration of tests on a large scale. I also want to accentuate the positive by saying that the Salk vaccine is the only polio vaccine available for public use at this time and that advantage should be taken of its protective effects to the maximum extent of its availability. I may add that some reservations that I had before disappeared with the demonstration that the antibodies and immunity produced by the Salk vaccine do not interfere with the alimentary infection produced by an oral attenuated vaccine or naturally acquired virus."

Future of the R.S.M.—The council of the Royal Society of Medicine is gravely concerned about the society's finances. If the society is to survive in its present form, says the council in its report for 1955-6, the annual income must be raised considerably. The council has a four-pointed policy to meet the situation: The creation of the Library (Scientific Research) Section (see *Journal*, September 15, p. 665) is hoped to tap new sources of subscription income; a request for an annual Government grant has been made to the Lord President of the Council; negotiations with London University are proceeding with a view to widening the readership of the library; and lastly, to stop the use of the society's facilities by those who are not entitled to them, entrance to the R.S.M. building is to be by ticket only. According to the last audited accounts (1954-5), the society's total income was £83,338 and the expenditure £81,316.

"Sigmamycin."—Pfizer Ltd. announced last week a new antibiotic preparation named "sigmamycin," consisting of a mixture of two parts (by weight) of tetracycline with one of oleandomycin ("matromycin"). The two antibiotics are claimed to act synergistically, so that lower doses can be given to achieve a desired clinical effect. The results of American trials of sigmamycin were presented at the fourth Washington Symposium on Antibiotics which opened on October 17. Clinical trials in Britain are now being arranged by the makers, but as yet the drug is not generally available here.

Glasgow Mass Radiography Campaign.—Dr. W. A. HORNE, M.O.H. of Glasgow, announced on October 17 that the City's mass radiography campaign to detect cases of pulmonary tuberculosis would take place between March 11 and April 12 next year. It was hoped to radiograph 25,000 people, he said, which, if achieved, would be a world record.

Royal College of Surgeons of Edinburgh.—At the annual meeting on October 17 Sir WALTER MERCER was re-elected president, and Professor R. C. ALEXANDER and Professor JOHN BRUCE vice-presidents.

Royal College of Physicians of Ireland.—Dr. F. J. O'DONNELL was re-elected president at the annual meeting on St. Luke's Day (October 18). This will be his second year of office. Dr. R. B. PRINGLE, physician to Dr. Steevens' Hospital, Dublin, and chief medical officer of A. Guinness, Son and Co., was elected vice-president.

Chair of Surgery at Khartum University.—Mr. JULIAN TAYLOR, vice-president of the Royal College of Surgeons of England and consulting surgeon to University College Hospital, London, has arrived in Khartum to fill the Chair of Surgery there. It is understood that his appointment is initially for a period of two years. Khartum University was constituted an independent university by an Act of the Sudan Government on July 24 this year, and in December the University is celebrating its new status.

Sydney Body Trust Medal and Lecture.—Mr. ALECK BOURNE, consulting gynaecologist to St. Mary's Hospital, was presented with a Sydney Body gold medal "for merit

in the field of obstetrics and gynaecology" when he delivered the third Sydney Body lecture at Southend-on-Sea Hospital on October 19. The presentation was made by Mr. S. F. BODY, M.P.S., who endowed the Trust named after him. The lecture is given annually, and has as its object the promotion of sympathetic understanding between members of the medical profession and the public.

Medical Film Appraisals.—The Scientific Film Association would welcome members of the medical profession at their appraisals of medical films. Appraisal meetings are being held on November 1, 15, and 29 and January 3 and 17 at the Shell Film Unit Theatre, Room 103, Shell-Mex House, Strand, London, W.C.2, at 5.45 p.m. Further details may be obtained from the hon. secretary of the medical committee, Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2. (Telephone: Temple Bar 4694.)

Birmingham University.—The following lecturers in the faculty of medicine have been appointed: Dr. D. M. MATTHEWS, in physiology; and Dr. D. S. ROWE and Dr. D. R. STANWORTH, in experimental pathology. Mr. S. S. SHULMAN, F.R.C.S.E., and Dr. L. KORNEL have been appointed temporary lecturers in anatomy and medicine respectively.

COMING EVENTS

Order of St. John.—Annual surgeons' conference will be held on November 3 and 4 at B.M.A. House.

Glasgow University Club, London.—Annual dinner on November 8 at 7.30 p.m. at the Trocadero Restaurant, Piccadilly. Graduates are invited to write to Dr. J. F. HEOGIE, North Middlesex Hospital, Edmonton, London, N.18, not later than October 31.

Bradshaw Lecture.—Dr. WILLIAM PHILLIPS will deliver the Bradshaw Lecture on November 8 at 5 p.m. at the Royal College of Physicians of London. His subject will be "The Disintegrative Action of the Nervous System."

Contraceptive Technique.—Lecture and demonstration by MARIE STOPES, D.Sc., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on November 1 at 5.30 p.m. No fee is charged, but tickets must be obtained in advance.

Lloyd-Roberts Lecture.—Sir MAURICE BOWRA will deliver the Lloyd-Roberts lecture on November 20 at 5 p.m. at the Royal College of Physicians of London. His subject will be "Greek Science; its Greatness and its Failure."

John Shields Fairbairn Memorial Lecture.—Dr. HANS F. BETTINGER, of the Royal Women's Hospital, Melbourne, will lecture on December 13 at 5 p.m. at the Royal College of Obstetricians and Gynaecologists. His subject will be "Unexpected Maternal Deaths Without Obvious Gross Organic Lesions." Tickets from the College.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 40, No. 8) is now available. The contents include:

SPONTANEOUS REGRESSION OF RETINOBLASTOMA. J. K. Steward, J. L. S. Smith, and E. L. Arnold.
COMBINED FORMS OF CONGENITAL COLOUR DEFECTS. A PEDIGREE WITH ATYPICAL TOTAL COLOUR BLINDNESS. R. A. Crook.
HISTOPATHOLOGICAL STUDIES OF EYES ENUCLEATED AFTER FAILURE OF INTRA-OCULAR ACRYLIC LENS OPERATIONS. Redmond Smith.
ANGIOD STREAKS AND PSEUDOXANTHOMA ELASTICUM. C. G. Keith.
CARBONIC ANHYDRASE IN THE VITREOUS BODY. J. Gloster.
ECTOPIA OF THE MACULA. Ian W. Payne and R. Pitts Crick.
CAROTID-OPHTHALMIC ANASTOMOSES. FREQUENCY OF EXTERNAL CAROTID AND OPHTHALMIC ARTERY ANASTOMOSES. Michael Shea.
PROTEIN DEFICIENCY IN KERATOMALACIA. Yap-Kie-Tiong.
CASE NOTES:
SCLERAL GUMMA. B. N. Bhaduri and S. K. Basu.
CONGENITAL FISTULA OF THE LACRIMAL GLAND. F. J. Damato.
EPIDEMIC KERATO-CONJUNCTIVITIS IN THE CLYDESDALE AREA. James Winning.

APPLIANCE:
AN ACCESSORY FOR THE OPERATING TABLE. H. Campbell Orr.
BOOK REVIEW.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Annals of the Rheumatic Diseases.—The new issue (Vol. 15, No. 3) is now available. The contents include:

RHEUMATOID ARTHRITIS AND THE POSITIVE L.E.-CELL PHENOMENON. J. H. Kiebits, J. Gossings, H. R. E. Schuit, and W. Hijmans.
NATURE OF ANAEMIA IN RHEUMATOID ARTHRITIS—III. J. Richmond, D. L. Gardner, L. M. H. Roy, and J. I. R. Duthie.
USE OF THE HYPOSPRAY JET INJECTOR FOR THE INTRA-ARTICULAR AND LOCAL ADMINISTRATION OF HYDROCORTISONE ACETATE. Morris Ziff, Vincent Contreras, and Frank R. Schmid.
THERAPEUTIC TRIALS IN ACUTE GOUTY ARTHRITIS. Melvin H. Levin, Stanley Marcus, David Strang, and Robert L. Swezey.
CLINICAL AND METABOLIC EFFECTS OF Δ^1 -DEHYDRO-9-ALPHA-FLUORO HYDROCORTISONE ACETATE. L. Villa, G. Sala, and C. B. Ballabio.
CHANGES IN THE INTRA-ARTICULAR TEMPERATURE OF THE KNEE WITH CUTANEOUS VASOCONSTRICTION AND VASODILATION OF THE TOES IN NORMAL SUBJECTS. Raymond Penneys and Nathan M. Smukler.
MODIFIED WAALKER-ROSE REACTION EMPLOYING SENSITIZED HUMAN CELLS. H. J. Gibson and N. R. Ling.
CHLOROQUINE AND RHEUMATOID ARTHRITIS. A. Freedman.
HYDROCORTISONE TERTIARY-BUTYLACETATE FOR INTRA-ARTICULAR THERAPY IN RHEUMATIC DISEASES. Jack Zuckner, Otakar Machek, and Arch M. Abert.
BOOK REVIEWS.
HEBERDEN SOCIETY.
AMERICAN RHEUMATISM ASSOCIATION.
LIGUE INTERNATIONALE CONTRE LE RHUMATISME.
CANADIAN RHEUMATISM ASSOCIATION.
ABSTRACTS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, October 27

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, 3 p.m., Miss Josephine Barnes: Working Mothers.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At Liverpool Royal Infirmary, 2.30 p.m., general meeting. Dr. E. E. Prebble: Treatment of Non-specific Urethritis; Dr. C. D. Alergant: Lymphogranuloma Inguinale.

Monday, October 29

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. S. Banks: Recent Advances in Infectious Fevers.

Tuesday, October 30

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. C. Amoroso: Endocrinology of Pregnancy.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Bacterial Flora of Healthy Skin.
LIVERPOOL UNIVERSITY.—At Liverpool Medical Institution, 5.15 p.m., Professor W. Schlapp: Galvani and Animal Electricity.
ROYAL STATISTICAL SOCIETY.—At Westminster Medical School, 5.30 p.m., Dr. C. R. Lowe: An Association Between Smoking and Respiratory Tuberculosis.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Professor Ian Aird: Post-operative Complications.
UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, 1.15 p.m., Dr. H. Kalmus: Behaviour and Heredity.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology (Part I).
WEST LONDON HOSPITAL MEDICAL SCHOOL.—5.15 p.m., 9th Alex Simpson Smith Memorial Lecture by Dr. T. Cecil Gray: Reflections on Circulatory Control.

Wednesday, October 31

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. B. Russell: Role of Pyogenic Cocci in Skin Disease.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. W. P. Cleland: Surgical Treatment of Bronchial Carcinoma.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. D. H. MacLeod: Problem of Endometriosis.
INSTITUTE OF UROLOGY.—4.30 to 5 p.m., Dr. A. H. Harkness: Non-gonococcal Urethritis.
LONDON UNIVERSITY.—At St. Thomas's Hospital Medical School, 5 p.m., special university lecture by Professor P. Dell (Paris): Aspects of the Physiology and Pharmacology of the Brain Stem Reticular Formation.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. F. W. G. Wolff: Biochemistry of Diabetes (II).
RENAL ASSOCIATION.—At 41, Portland Place, W., 4 p.m., Dr. V. Hall (U.S.A.) and Dr. J. Rhodin (Stockholm): Electron Microscopy of the Kidney.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Air Marshal Sir James Kilpatrick: Aspects of Health in the Royal Air Force (illustrated).
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Dr. L. B. Cole: Interpretation of Symptoms in Hypertension; 6.15 p.m., Dr. J. H. Hunt: Management of Hypertension in General Practice.

Thursday, November 1

●BRISTOL UNIVERSITY.—8.15 p.m., Carey Coombs Memorial Lecture by Mr. T. Holmes Sellors: Surgery of the Thoracic Aorta.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor W. J. Hamilton: Multiple Pregnancy.
FACULTY OF ANAESTHETISTS: ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Frederick Hewitt Lecture by Dr. R. F. Woolmer: Artistry and Science in Anaesthesia.
FACULTY OF HOMOEOPATHY.—5 p.m., Dr. N. J. Pratt: Reliable Indications for Arsenicum Album, Lachesis, Lycopodium, and Silica.
FARNBOROUGH HOSPITAL.—At Children's Department, 2.30 p.m., symposium on Poliomyelitis, dealing with epidemiology, virology, and clinical aspects. Speakers, A. D. Macrae, Dr. J. Marshall and Dr. Annie M. Peach. Visitors welcome.

ILFORD MEDICAL SOCIETY.—At Park Lane Hotel, 7 for 7.30 p.m., annual dinner and dance.
LIVERPOOL MEDICAL INSTITUTION.—At Adelphi Hotel, 7.30 p.m., annual dinner.
LONDON UNIVERSITY.—At Royal Society of Medicine, 5 p.m., Semon Lecture by Professor G. Portmann (Bordeaux): Physiology of Phonation.
MIDLAND THORACIC SOCIETY.—At Queen Elizabeth Hospital, Birmingham, 7.30 p.m., Dr. P. Forgacs: Management and Treatment of Tuberculous Pleural Effusion, both Primary and Secondary to Lung Disease.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Aspects of Refraction Work—(4) Prisms, and Their Use in Refraction Work.
ROYAL SOCIETY OF HEALTH.—At St. William's College, York, 10.15 a.m., Dr. Catherine B. Crane: Cancer Education; Mr. N. Hancock: Hygiene of Sports Arenas.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Queen's College, Dundee, 5 p.m., Dr. J. A. Fraser Roberts: Genetics of Essential Hypertension.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. J. Williams: neurology demonstration.

Friday, November 2

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. Muende: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. F. W. Hinson: pathological demonstration.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. D. Trevor: Management of the Displaced Hip-joint in Older Children; 4 p.m., Dr. J. F. Goodwin: Coarctation of the Aorta.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., Dr. J. A. W. McCluskie: Hyperparathyroidism—A Not So Rare Disease.

Saturday, November 3

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—11.30 a.m., special lecture by Professor G. Portmann (Bordeaux): Surgery of Cancer of the Base of the Tongue (with cinematograph film).

Sunday, November 4

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—10.15 a.m., clinical demonstration for general practitioners. Dr. H. A. Burt: The Rheumatic Diseases.

APPOINTMENTS

BORG, CHARLES, M.D., F.R.F.P.S.Glas., D.P.M., Part-time Consultant Psychiatrist, Parkside Hospital, Macclesfield, and Mid-Cheshire and South Cheshire Hospital Centres.
LAURIE, ALEXANDER, M.B., Ch.B., D.P.H., Medical Officer, Department of Health for Scotland.
MANCHESTER REGIONAL HOSPITAL BOARD.—T. G. Barlow, M.B., Ch.B., F.R.C.S., Consultant Orthopaedic and Traumatic Surgeon, Ashton, Hyde and Glossop Group of Hospitals; O. H. Simms, M.B., Ch.B., F.F.A.R.C.S., Consultant Anaesthetist, Lancaster and Kendal Group of Hospitals; I. W. Davidson, M.B., Ch.B., D.A., Whole-time Assistant Anaesthetist Salford Group of Hospitals; J. Cherkawsky, Med.Dip. Poznan, Whole-time Assistant Physician in Geriatrics, Burnley and District Group of Hospitals; A. R. Evans, M.B., B.Ch., Whole-time Assistant Pathologist, Wigan and Leigh Group of Hospitals; A. F. Robinson, M.B., Ch.B., F.R.C.S., Consultant Surgeon to Burnley and District Group of Hospitals; E. T. Downham, M.D., D.P.M., Consultant Psychiatrist to Burnley and District Group of Hospitals and to Whittingham Hospital, Preston; Madeleine B. Morris, M.D., M.R.C.P., D.C.H., Consultant Paediatrician, Barrow and Furness Group of Hospitals; E. A. Beetles, M.B., B.S., D.M.R.D., Whole-time Consultant Radiologist to Blackburn and District Group of Hospitals.
SMITH, S. B. S., L.M.S.S.A., D.T.M.&H., Assistant Medical Officer of Health and School Medical Officer, Swindon Borough Council.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

England.—On October 5, 1956, to May (formerly Kingston), wife of Eric G. England, M.B., D.P.H., D.C.H., D.P.A., Dip. Soc. St., of 1 May Park, Malahide Road, Dublin, a daughter—Janet Karen.
Evans.—On October 8, 1956, at 387, Queen's Road, London, S.E., to Alexa Evans (formerly Mitchell), M.R.C.S., L.R.C.P., wife of C. J. Evans, M.R.C.S., L.R.C.P., D.O.M.S., a daughter—Annabelle Louise.
Levis.—On September 23, 1956, at the Central Middlesex Hospital, London, N.W., to Renée, wife of R. D. Lewis, M.B., F.F.A.R.C.S., a son—Peter Desmond Arthur John.
Parry-Jones.—On September 25, 1956, to Mary (formerly Brooks), wife of Dr. J. Parry-Jones, a brother for Elizabeth.
Sartory.—On October 18, 1956, to Pamela (formerly Johnson), wife of F. B. Sartory, M.R.C.S., L.R.C.P., L.D.S., a brother for Geoffrey, Ghislaine, and Rosemary—Jonathan Mark.

MARRIAGES

Harland—Burke.—On October 6, 1956, at St. Mark's, Surbiton, David Henry Cave Harland, of Lewes, to Norah Burke, of Surbiton.

DEATHS

Catto.—On October 2, 1956, at Bouenmouth, Hants, Patrick Thomas Catto, M.B., Ch.B., of 7, Eaton Road, Coventry, Warwick, aged 65.
Craig.—On October 1, 1956, at Hill End Hospital, St. Albans, Herts, Robert Hunter Craig, M.B., Ch.B., of 28, Station Road, Orpington Kent, aged 57.
Evans.—On September 28, 1956, John Morton Evans, M.R.C.S., L.R.C.P., D.P.H., of 117, Ashley Road, Bristol, aged 85.
Fagan.—On October 2, 1956, at 5, Aurion Mansions, London, W., Charles Horace John Fagan, O.B.E., M.R.C.S., L.R.C.P.
MacRae.—On September 30, 1956, at Millbank Kessock, Duncan MacRae, M.B., Ch.B., of Gairloch, Ross-shire.
Piggott.—On October 2, 1956, Frederick Stanley Lawrence Piggott, M.R.C.S., L.R.C.P., of Teign Royd, Teignmouth.
Titcombe.—On October 3, 1956, Roland Hereward Titcombe, M.D., D.P.H., of Disley, near Stockport.
Trewby.—On October 2, 1956, at St. Bartholomew's Hospital, Joseph Frederick Trewby, M.R.C.S., L.R.C.P.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Frozen Shoulder

Q.—What is the underlying pathology of the condition known as frozen shoulder? What is its cause?

A.—Frozen shoulder—also known as periarthritis or capsulitis of the shoulder—is an obscure condition of unknown aetiology. Pathological changes as revealed by ordinary histological methods consist in some infiltration of the fibrous capsule of the shoulder-joint with lymphocytes and plasma cells; at a later stage, adhesions are found between the joint capsule and the humeral head. No biochemical or biophysical studies of the fibres or ground substance of the capsule have been reported and the cause of the sudden stiffening is still obscure. Frozen shoulder is not associated with any constitutional disturbance and the E.S.R. is not elevated. There is no association between this type of shoulder lesion and any form of polyarthritis.

Frozen shoulder is a self-limiting condition with a duration of six months to three years. It occurs in both sexes, mainly between the ages of 45 and 65 years, and many of the affected individuals are said to have a special anxious, worrying "periartritic" personality. In some cases the shoulder lesion follows coronary occlusion, cerebral vascular accidents, or herpes zoster. In such cases it has been suggested that the shoulder lesion is due to a "reflex dystrophy," and cases in which the hand also stiffens have been described under the title of "shoulder-hand syndrome." Alternatively, it has been suggested that pain in the shoulder region in patients with a periartritic personality leads to voluntary immobilization of the shoulder, which in middle-aged subjects leads to rapid stiffening and atrophy from disuse; this causes more pain, and so on. Neither of these mechanisms provides a satisfactory explanation of all the features of the frozen shoulder, and its essential pathology still remains to be discovered.

Phosphaturia

Q.—How should a case of phosphaturia be managed? Is prolonged treatment with sodium acid phosphate a safe and satisfactory method?

A.—One difficulty in answering this question is semantic, for the word phosphaturia is variously used to mean a symptom or to name a rather ill-defined disorder. But no matter how the term is used the essential feature is the passage of urine containing deposits of calcium and magnesium phosphates. These salts are not very soluble, particularly in alkaline solutions, and phosphaturia occurs only when the urine is alkaline.

Anything which leads to an alkaline urine, such as urinary infection with urea-splitting organisms, may cause phosphaturia, but although the reaction of the urine is of prime importance it is not the only factor. A high urinary calcium concentration resulting either from an increased calcium excretion, as may occur, for example, in hyperparathyroidism, or just because the patient does not drink very much, will favour the formation of calcium phosphate deposits: furthermore, it is believed that various unidentified urinary colloids may hold these salts in supersaturated solution. Possibly a breakdown in this mechanism may lead to phosphaturia.

As a symptom phosphaturia may occur in widely differing conditions, provided the urine is alkaline, but it may appear in patients who have no infection of the urine or obvious metabolic disorder, and such cases are said to be suffering from "phosphaturia." The condition is said to be common in neurotic individuals, and, although there is

no proof that psychological factors are causative, much anxiety can result from the disorder; reassurance is therefore essential.

The urine may be alkaline for quite simple reasons, such as the ingestion of absorbable alkalis in patent medicines or powders, and this, especially if combined with a lacto-vegetarian diet, can cause phosphaturia. The patient should be encouraged to drink plenty of fluids except milk. Drugs which acidify the urine will usually clear the deposits. Sodium acid phosphate can be used in doses of gr. 15 (1 g.) to as much as gr. 60 (4 g.) three times a day. It is said to have the advantage over other acidifying agents that it does not increase the urinary excretion of calcium.¹ However, it is often not so effective as ammonium chloride, which can be given in doses of gr. 15 (1 g.) three times a day. It is important when using these agents to determine whether they do alter the reaction of the urine; this can be done with indicator papers. If, in full doses, they fail to acidify this may mean that the renal mechanisms for excreting an acid urine are at fault. In these circumstances the continued use of the drugs will only increase the loss of fixed bases, sodium, potassium, and calcium, from the body. This is a danger of acidifying agents.

Hormone Therapy in Mongolism

Q.—Have hormones any place in the treatment of mongolism? Favourable results have been reported from the combined use of thyroid and pituitary hormones.

A.—There is at present no good evidence that hormone therapy has any place as a specific treatment for mongolism. Bourneville¹ used thyroid and Lewald² pituitary preparations, but neither obtained convincing results. Tredgold³ in 1929 recommended a mixture of thyroid, suprarenal, pituitary, thymus, and pineal, but later,⁴ in 1947, he said: "As a result of careful observation over a number of years on mongols who have and who have not been treated, I have come to the conclusion that gland extracts, whether administered orally or by injection, really have no effect upon the condition." Engler⁵ was favourably impressed by the effect of thyroid and recommended "substitution therapy" in general. Neither these nor many other similar views are based on carefully controlled trials, nor is there any clear evidence of any constant endocrine deficiency in mongolism, though there is a tendency to high values for blood cholesterol⁶ and to low steroid excretion. A recent study was made by Benda,⁷ who regards mongolism as hypopituitary dystrophy; he claimed increase in size and mental powers as a result of oral doses of pituitary hormones.

This is a subject for further investigation, but strict clinical and laboratory control is essential. An account of current research on mongolism will be found on p. 993 of this issue of the *Journal*. Meantime, as Jervis⁸ points out, there is no specific treatment for the condition.

Salmonella Bacteraemia

Q.—In salmonella infections is there always an initial blood-stream infection? If not, what determines this—the species of organism involved or the severity of the infection?

A.—Salmonella infections include the enteric diseases due to *S. typhi*, and *S. paratyphi* A, B, and C, as well as food-poisoning and other diseases due to any of the remaining

400 or more members of this genus. Although it has infrequently been demonstrated, it is probable that most cases of enteric fever have a light and transient initial bacteraemia before the proliferation of the organism in the spleen and liver finally lead to the more lasting and severe secondary bacteraemia and secondary intestinal infection, with the frank clinical manifestation of the disease. Following on this blood invasion there is usually a rise in the patient's serum agglutinins to the invading organism. It is possible that salmonella infections, other than those that develop into enteric fever, may have a light transient initial bacteraemia, but this is quickly dealt with by the normal body defences, and invasion proceeds no further, but knowledge on this point is not very precise. The sera from patients who have suffered from this type of infection show great differences. Some produce agglutinin titres, some show little or no reaction, which suggests that, even if invasion takes place, it is rare.

What determines the general invasiveness of an infecting organism may be an inherent and regular property of the species, as with typhoid and most of the paratyphoid bacilli, or it may be due to an unstable irregular property, a tendency-variation, by which invasion is likely to occur only under certain conditions of host-parasite relationship. *S. cholerae suis* and *S. enteritidis* var. *chaco* are organisms that are not infrequently found to be the cause of enteric fever, whereas other species usually cause gastro-enteritis. Experimental evidence has shown that different species, as well as different strains of a single species, may vary in their effect on human volunteers. The size of the infecting dose may play a part, but, while it is true that the great majority of salmonella strains never seem to show any tendency to invade, others in addition to those mentioned have been isolated, on rare occasions, from the blood stream.

Placentophagia

Q.—Why do most animals in their natural state, including the herbivores, eat their placenta? Is it because it contains valuable hormonal substances, or is it merely as part of the tidying up process to make the birthplace less conspicuous to enemies?

A.—Placentophagia is not confined to animals. It occurs also in man. The placenta is also widely used in various ritualistic, magical, or superstitious practices. In parts of Indonesia it is considered to be an animated body possessing a spirit or soul. In a few tribes the umbilical cord or placenta is eaten. Thus in Kamchatka it is reported that a post-parturient woman who hopes to become pregnant again will devour the umbilical cord. In parts of Brazil Indian women are said to eat the placenta, although the purpose of this practice is not disclosed. Placentophagia has also been reported in Java, where the placenta is cooked and eaten in the belief that the woman eating it will be the next to become pregnant. The use of dried and powdered umbilical cord as a medicament for a sickly infant is also recommended. However, although these practices are interesting, none of them would seem to shed any light on the widespread habit among animals; they all seem to be culturally rather than biologically determined.¹

Many animals, including primates, rodents, carnivores, and ungulates, eat the placenta. Since its consumption can occur only after parturition, the placenta may be eaten not so much for its caloric value as to balance some nutritional deficiency; or it may be eaten to supply some special substances—for example, vitamins or hormones—needed for lactation; or, as the questioner suggests, simply to cover up the traces of the birth from predators. It has been stated that only in circumstances where there is some nutritional deficit do rats, for example, eat the placenta, and the same may also be true of sheep and cattle. However, other animals, regardless of their nutritional state, eat the placenta and foetal membranes, and may even consume the amniotic fluids as well.² The placenta of many animals is known to be rich in oestrogens, progesterone, and pituitary-

like hormones. There is a theory that the ingested placental substance has an oxytocic principle which serves to bring about involution of the uterus and to reduce haemorrhage.³ However, Hartman⁴ reports the case of a monkey which gave birth to three babies and did not eat the placenta; yet, as determined by palpation, the uterus involuted normally just as in the other monkeys which had eaten the placenta. Claims for a galactogogic effect of placental extracts have also been reported.⁵

Congenital Hydrocephalus and Spina Bifida

Q.—A young couple have recently lost their first child as a result of severe congenital hydrocephalus and spina bifida. There is no family history of similar trouble. (1) To what extent do hereditary factors influence the appearance of this condition, and what is the prognosis with regard to future children in the family described? (2) The mother was inoculated with B.C.G. when two weeks pregnant. Could this, or other factors affecting the mother during her pregnancy, such as a virus infection or vitamin deficiency, have predisposed to these abnormalities?

A.—According to Record and McKeown¹ the risk of recurrence of these congenital abnormalities in any further offspring of this couple is about nine times as great as the average risk. They also find that the risk of such a malformed infant is greater at the first parity, and after the sixth, with a corresponding reduction in the intervening ones.

There is no good reason why B.C.G. inoculation during early pregnancy should be blamed. On the other hand, virus infections, especially mumps, have been incriminated, and the embryo is most vulnerable in the early months. Experimentally, x rays and various vitamin deficiencies have been shown to produce severe malformations in the C.N.S. of the offspring of treated pregnant animals. But so far there is no evidence that such vitamin deficiencies have any similar aetiological role in man. In any event the deficiency required to induce these malformations experimentally is of a high order, and hardly likely to occur in Britain in normal circumstances. On the other hand, maternal inability to utilize ingested vitamins is a possibility worth remembering.

The graph above is of an experiment to measure the effect of Transvasin on skin temperature on a subject. The red line plots the skin temperature before and at intervals after a single application of one inch of cream (0.924 grams) from a tube of Transvasin. The black line gives similar information with regard to the application of a plain vanishing cream used as a control. Skin temperatures were measured with an electro-thermo couple every five minutes for two hours. Photographs show the affected area before application; three minutes and thirty minutes later.

COMPOSITION OF TRANSVASIN

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible base ad	100%

Transvasin

IT is generally agreed that cases of soft-tissue rheumatism and of many types of arthritis benefit by hyperaemia of the affected tissues. Transvasin, which contains two quick-acting esters of nicotinic acid, induces such a deep and prolonged hyperaemia at the same time as it produces superficial erythema.

In addition to the esters of nicotinic acid, Transvasin contains the fat- and water-soluble esters of salicylic and p-aminobenzoic acids. Both these well-tried analgesic drugs are readily conveyed through the skin in therapeutic quantities and enable an effective concentration to be built up where they are needed.

Transvasin is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD.

11 Waterloo Place, London, S.W.1. Whitehall 8654/5/6.

TREATMENT OF HYPERTENSION*

BY

A. RAE GILCHRIST, M.D., F.R.C.P., F.R.C.P.Ed.
Physician-in-Charge, Royal Infirmary, Edinburgh

In the treatment of hypertensive vascular disease, a great variety of effective remedies are now available—so many, indeed, that considerable discrimination is required in the selection of the therapeutic procedures best adapted to a particular patient. Some are powerful remedies, not easy to administer or regulate, and call for the fullest co-operation between doctor and patient. Others, simple in themselves, demand skill in application to get the best results. Occasionally the justification for recommending a surgical procedure, remedial or palliative, will require careful consideration. With a multiplicity of aetiological factors, and with great variations in the pattern, course, and intensity of the disease, it is natural that treatment must vary widely from patient to patient and be adapted to the requirements of the particular individual. No single remedy is uniformly successful.

I. General Measures

Management

Of the general measures widely applicable, consideration must be given to the judicious and tactful management of the hypertensive patient. By their manner, attitude, and personality, some doctors are able to accomplish more than others for hypertensive patients. They owe their skill to the confidence they inspire. The first step in successful treatment is therefore the employment of conscious or unconscious psychotherapy. By this means the doctor establishes a relationship of mutual trust of particular advantage to the patient, who is thereby steadied in his outlook, reassured, and encouraged. The relief of emotional tension promotes a sense of tranquillity, which in itself can set a blood pressure at lower levels.

As a general rule, the fears of high blood pressure should be countered at the earliest opportunity, with the explanation that such a condition may persist for years without disagreeable happenings. It may even subside spontaneously, without serious embarrassment or permanent crippling. Doubts and fears can usually be set aside by explaining that the condition is comparatively benign, that suitable treatment is available when it is required, and that frequently no particular specific remedies are necessary. Such an attitude can do much for the patient, simplify his care and supervision, and permit the judicious use of appropriate remedies as and when these appear necessary.

Most people, and hypertensive patients in particular, feel better, make more headway, and have a lower pressure when under the protective and understanding care of a sympathetic and encouraging adviser. Relief from emotional stresses with the resolution of conscious or subconscious conflicts is of importance, particularly in

the earlier stages of the hypertensive process—that is, before irremediable damage has been done to vital organs. Conversely, it is bad practice to inform a patient bluntly that his blood pressure is worse and his drug treatment proving valueless. Such an attitude is never justified. It betrays a lack of appreciation by the doctor of the part he ought to play in the management of the hypertensive patient, whose confidence is readily undermined by injudicious comments and whose progress may thereby be affected adversely.

Neither doctor nor patient should be misled by blood-pressure readings. There is nothing to be gained by commenting on isolated readings, whether real or fictitious. The level of the mercury seldom correlates with well-being. Simple facts such as these can profitably be explained to the intelligent patient at the outset of treatment.

Advice on the better adjustment of the individual to real-life problems comes most appropriately from the patient's own practitioner. Expert psychiatric treatment aimed at the correction of personality and other defects is sometimes helpful and even occasionally curative in the earliest stages, but in the presence of established vascular disease, advancing at an increasing tempo, time should not be wasted on this particular aspect of treatment. For the great majority, simple measures, combining firm reassurance and steady encouragement, form the background of successful therapy.

Way of Life

The personal habits and way of life deserve consideration. It is often true that a routine which includes long hours of sleep, a short rest at midday, the quiet week-end, and a peaceful annual holiday, along with the cultivation of a placid and philosophical temperament, can counteract much of the nervous tension, irritation, and fatigue associated with long hours of exacting work, with all its present-day distractions and frustrations. Most hypertensive patients require advice on adapting their way of life to their blood pressure. Even in the severest grades of hypertension, blood pressure commonly falls temporarily to normal limits in deep sleep, whether physiological or induced by barbiturates or other sedatives. Hence the importance of adequate rest and sound sleep in relieving, even for a few hours at a time, the burden thrown on the vascular system. Amylobarbitone sodium, 3 gr. (195 mg.) at bedtime, repeated in an hour if necessary, is a valuable remedy in all stages of hypertensive disease.

Diet

Many hypertensive patients tend to overeat, and, if this be associated with corpulence, then a clear indication for dietetic treatment exists. The prescription of an exact diet of 1,500, 1,200, or 1,000 calories, with the cultivation of the habit of restricted indulgence, will do much to ease symptoms and increase a sense of well-being. Weight should be recorded at weekly intervals, and the figures are usually worthy of more attention on the part of the patient and

SAFE SYMPTOMATIC RELIEF FOR THE ANXIOUS PATIENT

OBLIVON-C is a new, long-acting derivative of Oblivon in tablet form, with the same wide margin of safety and freedom from side effects. In the treatment of anxiety states OBLIVON-C gives day-long freedom from tension and creates a climate of confidence in which simple reassurance can be accepted.

presentation: OBLIVON-C is presented as Ovets, each containing 100 mg. of methylpentynol carbamate. Containers of 100.

dose: 1-2 100 mg. Ovets three times a day and 2-4 Ovets at bedtime.

*A paper read in the Section of Cardiology at the Annual Meeting of the British Medical Association, Brighton, in July.

the doctor than casual blood-pressure readings. Begin by correcting obesity is a good rule widely applicable.

In the severer forms of hypertension, as exemplified by Grade 3 or Grade 4 retinæ, a reduction in sodium intake is known to be of definite value. For instance, in malignant hypertension (Grade 4) nearly half the patients will show a regression in papilloedema with restoration of vision when the sodium content of the diet is reduced to 200 mg. a day. Unfortunately, few patients will tolerate such restrictions for long, and indeed experience indicates that equally good results can be obtained in hypertensive heart failure, and in hypertension of Grade 3 or 4 severity, with a diet in which the sodium content is maintained at 500 mg. a day. This diet involves much less hardship. All food, including bread, should be cooked without salt and no salt be served with meals.

Patients vary in their tolerance to salt restriction. Many become habituated and make little complaint. Others react badly after a few days. Anorexia is a danger signal. It should at once suggest the salt-depletion syndrome characterized by weakness, nausea, vomiting, and collapse. For this reason it is seldom wise to continue the strictest diets (with a sodium content of 500 mg. or less) for more than two or three consecutive weeks. The dangers of uræmia are so real that the addition of small quantities of salt to the diet for a few days at a time are therefore justified every two or three weeks. Strict salt restriction is necessary only in the severest grades of hypertension. A reduction in sodium intake is not only of value in itself but it appears to potentiate the ganglion-blocking drugs.

LOW-SODIUM DIET

Approx. 0.5 g. Na; 1,400 calories; NaCl 1.6 g.

Breakfast: 1 egg—poached, boiled, or scrambled—or small helping of white fish. 1 slice of salt-free bread. Salt-free margarine or butter. Jelly marmalade if desired.

Mid-morning: Glass of fruit juice.

Dinner: Small helping of lean meat, fish, tripe, chicken, or rabbit. Avoid ketchups and sauces. Small helping of sieved vegetables. Small helping of mashed potato. Stewed fruit, fresh fruit jelly, fruit whip or snow with sugar *ad lib.*

Tea: 1 slice of salt-free bread. Very small helping of meat or chicken or fish, or an egg. Salt-free margarine. Jelly if desired.

Supper: 1 slice of salt-free bread. Jelly if desired. Salt-free margarine.

Bedtime: Glass of fruit juice.

Allowance for Day: $\frac{1}{2}$ pint (568 ml.) of milk. $\frac{1}{2}$ oz. (21 g.) of salt-free margarine or butter.

Provided the patient is not obese, as much sugar or glucose as desired may be added to the diet.

All food should be cooked without salt, and no salt served with meals.

Meat, Fish.—Avoid all tinned and preserved meat, including ham, bacon, sausages; kippers, finnan haddock; meat extracts as oxo and bovril, also marmite, because of their high salt content.

Fruit.—All fresh fruit is suitable, but dried fruit often contains too much salt.

To be successful the low-sodium diet requires detailed care, and note should be taken of the following considerations.

Special Instructions

(1) In the preparation of the food no salt to be added during cooking or served with the meal at table.

(2) All tinned foods which have salt already added, such as tinned meats and vegetables, tinned soups and tomato juice, are to be avoided.

(3) Smoked, brine-cured, and salty foods such as bacon, ham, sausages, smoked fish, kippers, and pickles are not permitted. This applies also to meat extracts and sauces such as bovril, oxo, marmite, ketchup, and relishes.

(4) Shellfish such as oysters and lobsters are not permitted.

(5) Only breads prepared with yeast and made without salt are allowed. Cheese is not permitted.

(6) Foods to which baking powder or baking soda has been added in their preparation are not permitted. This includes biscuits, wafers, scones, "cookies," and cakes.

(7) Only unsalted or "washed" butter is allowed.

(8) Dried fruits such as figs, dates, raisins, apricots, and prunes are to be avoided.

(9) It is particularly important that no sodium-containing medicines be taken while the diet is in use. This includes sodium bromide, sodium bicarbonate, soda-mints and most of the so-called "indigestion" tablets and powders. Similarly, "soda-water" must not be added to drinks. Salt gargles and toothpastes containing sodium are likewise forbidden.

Recipe for Salt-free Bread.—If salt-free bread cannot readily be obtained, it can be made according to the following recipe:

6 $\frac{1}{2}$ lb. (2.95 kg.) bread flour 10 oz. (284 g.) sugar
8 oz. (227 g.) shortening 4 oz. (113 g.) yeast
2 quarts (2.27 l.) of water

This makes six loaves. This bread takes a little longer to rise than ordinary bread.

Foods Permitted:

- (1) Meat, boiled fish, or poultry, prepared and served without added salt.
- (2) Eggs—not more than one daily.
- (3) Milk—limited to two glasses (one pint (568 ml.) as a maximum).

(4) Vegetables—any fresh or green vegetables prepared and served without salt.

(5) Fruits—all fresh and tinned or stewed fruits.

(6) Bread—only yeast bread prepared without salt.

(7) Cereals—the only dry prepared cereals permitted are puffed wheat, shredded wheat, and puffed rice.

(8) Potatoes and rice prepared without salt.

(9) Butter—only unsalted or "washed."

(10) Puddings and sweets—custards, junket and plain puddings made with the milk allowance and with no added salt. Pies with no salt added to the pastry and limited to a filling prepared with fresh or tinned fruit. Jellies, jams, marmalade, white or brown sugar, and honey.

(11) Drinks—tea, coffee, fruit juices, and carbonated drinks.

(12) Flavoursings—chocolate, cocoa, caramel, peppermint, lemon, orange, vanilla, cherries, cloves, cinnamon, nutmeg, ginger, and coffee.

(13) Seasonings—pepper, curry, mustard, mint, vinegar, sage and onion.

II. Aetiological Considerations

The next step is to clarify the diagnosis. A remedial cause must be sought, as an elevation of the diastolic pressure is a sign common to a number of different disorders. In the absence of a demonstrable cause, the hypertension is spoken of as essential or primary hypertension. Known aetiological entities associated with the production of hypertension may be arranged in four main groups: (a) *Renal diseases*: acute and chronic glomerular nephritis, chronic pyelonephritis, polycystic kidneys, hydronephrosis; (b) *Endocrine disorders*: Cushing's syndrome, pregnancy toxæmias, phaeochromocytoma; (c) *vascular disorders* (affecting renal blood flow): congestive heart failure, periarteritis nodosa, coarctation of the aorta; (d) *Neurological diseases*: certain brain tumours, bulbar poliomyelitis.

This classification is not intended to be exhaustive, nor does it account for more than 30% of all cases of hypertension. It is put forward to illustrate how the discovery of an aetiological factor may influence therapy. For instance, unilateral pyelonephritis may justify nephrectomy before hypertension has led to damage of the vascular supply of the opposite kidney. Similarly, effective treatment for the hypertension of Cushing's syndrome, if not due to a localized and removable tumour, consists of total or subtotal adrenalectomy. In younger people excision of a coarctation with reconstitution of the aorta can promptly cure this particular variety of hypertension. A less common example of a remediable cause is a phaeochromocytoma arising from the chromaffin cells of the adrenal medulla or extrarenal chromaffin tissue. The symptoms, which depend upon excessive production of adrenaline or noradrenaline, and the hypertension which occurs in either a paroxysmal or sustained form, can be completely relieved by the early operative removal of these tumours.

III. Selection of Patients for Treatment

A further principle in the medical care of these hypertensive people is to assess as accurately as possible the severity of the disability and adapt treatment accordingly. It is as important not to over-treat, when symptoms are absent or trivial, as it is to employ an intensive routine when serious dangers threaten. The patient's safety depends upon the integrity of his arteriolar walls. To gauge his vascular state as a whole and thereby arrange treatment appropriate to the individual, information of the greatest importance is obtained by direct inspection of the retinæ. Simple studies of renal concentrating power, heart size, and lability of the blood pressure are valuable aids in the assessment of the extent and severity of the arterial disease, but are subsidiary to ophthalmoscopic examination.

Retinal Grading

On the basis of the retinal appearances one of four grades of hypertensive vascular damage can be determined for each patient. The Table given below, constructed from the prognostic studies of Wagener and Keith (1939) on the course of essential hypertension, provides a basis for the adaptation of treatment to the severity of the vascular disease. This is a more satisfactory approach to therapy than the two alternatives customarily offered by dividing essential hypertension into its benign and malignant forms—both terms being misleading. Grades 1, 2, and 3 are often included in the term benign, Grade 4, being known as malignant hypertension.

TABLE

	Grade 1	Grade 2	Grade 3	Grade 4
Symptoms	None to slight	Slight Morning headache Vertigo	Moderate Frequent headaches Fatigue Dyspnoea Nocturia	Severe Intense headaches Weakness Loss of weight Dyspnoea Confusion
Blood pressure	150/100–200/120	180/100–270/130	180/110–280/140	240/130–300/180
Retinæ	Minimal arterial narrowing	Definite sclerosis	As in Grade 2 with either exudates, star figures, cotton-wool patches, or haemorrhages. Definite retinitis	Papilloedema, with or without Grade 3 changes. Advanced retinitis usual
Renal function	Normal	Satisfactory: faint trace of albumin occasionally present	Impaired: albumin with casts and R.B.C.	Impaired, as in Grade 3, but progressively deteriorating
3-year mortality rates	20%	35%	75%	95%

To show the four grades of hypertension, increasing in severity from 1 to 4. Grades 1, 2, and 3 are commonly included in the term benign essential hypertension, and Grade 4 is also known as malignant hypertension. Broadly speaking, Grades 1 and 2 may be classified as mild, Grade 3 as moderately severe, Grade 4 as very severe.

Broadly speaking, Grades 1 and 2 may be regarded as comparatively mild, Grade 3 as moderately severe, and Grade 4 as very severe or malignant.

The retinal appearances provide a measure of the intensity of the hypertensive process as a whole, but in addition consideration must be given to the efficiency of the heart and kidneys, either of which, after taking the brunt of the elevated pressure for many years, may begin gradually to show signs of failure, or even suddenly fail, without an advance in retinal appearances beyond Grade 2. Left ventricular failure, particularly in an acute form, is an urgent indication for relief of hypertension. Occasionally, uræmia, beginning insidiously, continues remorselessly to a fatal issue, without the development of retinitis. The efficiency of the heart and kidneys, as well as the retinal grade, are therefore the basic factors in determining suitable treatment. Account must also be taken of the age of the patient, more vigorous methods being justified in younger people than in the elderly, whose arteries are less resilient.

Degenerative changes in vital organs may be so advanced as to debar any hope of successful therapy. This applies particularly to the state of the kidneys. If renal function is impaired there is little or no hope of reversing the process. Hypotensive drugs aggravate uræmia. Furthermore, a prompt reduction of the blood pressure in elderly people may prove harmful, if not occasionally fatal.

These considerations lead to the conclusion that patients are best selected for treatment on the basis of their vascular state as it affects certain organs and on the intensity of the hypertensive process rather than on casual or even basal blood-pressure readings. The experienced motorist setting out on a long run is less concerned about the tyre pressures, which must vary with every bump on the road, than about the wear and tear of the tyre covers. So also to the hypertensive patient—the state of the walls of his arteries and their arterioles is more important than his blood pressure at any given instant in the course of a protracted disease. In general, treatment should be determined more by vascular state than by blood-pressure readings.

It will be generally conceded that the following groups of patients should be selected for energetic treatment: (a) all showing hypertensive retinopathy—that is, Grades 3 and 4; (b) those without retinopathy but who have or have had transient cerebrovascular episodes, attacks of left ventricular failure, or angina; (c) those disabled by severe hypertensive symptoms—for example, headaches associated with a persistently high diastolic pressure—120 mm. or more.

There remains a large group of hypertensive patients who may have no symptoms, or only minor ones, and who have no serious retinal, cerebral, or cardiac changes. These patients should be kept under observation at intervals of a few months and are better under-treated than over-treated; certainly the more powerful hypotensive drugs (ganglion-blocking agents and hydralazine) should not be used in view of their attendant discomforts and dangers. Mild hypotensive agents may be employed, but whether they prevent the development of serious vascular damage is not yet known. It is unlikely that they do any harm even when used continuously for many years.

In summary—treatment with the more powerful drugs should be reserved for patients presenting with symptoms or signs of retinal, cerebral, or cardiac impairment of hypertensive origin. Milder hypotensive agents and sedatives can be employed on a prophylactic basis when symptoms and signs are less severe.

IV. Drug Therapy

Rauwolfia serpentina

This drug has proved useful by itself in the treatment of the milder varieties of hypertension (for example, retinal grades 1 and 2) and in combination with other drugs when the response to it alone is incomplete or unsatisfactory. It has many advantages, as toxic symptoms are relatively uncommon and postural hypotension seldom occurs. It has a central action, producing a feeling of tranquillity without somnolence, which may result in a fall of 10 or 20 mm. in diastolic pressure. The object is to pacify without depressing.

Many preparations are available. The refined whole root (for example, "rauwiloid," 2–4 mg. thrice daily), the mixed alkaloids (for example, "raudixin" in 50-mg. tablets, 3 to 8 daily), or the single alkaloid (for example, reserpine, 0.25 mg. thrice daily) may apparently be employed with advantage for long periods and without ill effects. Full benefit is not obtained from this drug until it has been in use for two or three weeks. A fall of 10 to 20 mm. in diastolic pressure is then commonly observed.

Few disagreeable "side-effects" have been recorded from its use. If daytime sedation is excessive on the usual therapeutic routine, the entire daily quantity may be taken as a single dose at night. Mental depression is seldom observed when raudixin is in use, but the drug should be used with caution in the emotionally unstable and in those who have passed through phases of mental depression, lest exacerbations recur. A minor sense of stiffness of the nose and a tendency to diarrhoea are occasionally encountered. Vague pains in the back and thighs are sometimes noted, and in younger women lactation may occur. Administration of two 50-mg. tablets of raudixin three or four times a day, the first dose on rising in the morning and the last 12 hours later, makes a useful routine and may be supplemented by a phenobarbitone tablet, 30–60 mg. at bedtime, if necessary.

Veratrum

If after a fair trial rauwolfia fails to maintain the diastolic pressure below 100 or 110 mm., extracts of veratrum viride, or hellebore, may be added to the patient's treatment. "Veriloid" is a useful proprietary preparation of the active principles. It is available in 1- and 2-mg. tablets. Treatment may be started with 2 mg. four times a day, the dose being taken along with the quantity of raudixin already prescribed. With this drug a maximum hypotensive effect is usually obtained with a daily quantity 2 to 4 mg. less than that required to induce toxic symptoms. The margin between optimum benefit and early toxicity is narrow, and may amount to no more than 2 mg. in a 24-hour period. Accordingly, the dose of veriloid should be increased cautiously by adding a 2-mg. tablet to the daily dose every third or fourth day until the earliest symptoms of intolerance develop. Heartburn, increased salivation, nausea, and vomiting are the usual indications that the optimum daily dose has been exceeded. Veriloid intoxication subsides rapidly when the daily quantity is reduced by 2 to 4 mg. It is not

necessary to discontinue completely the use of this drug when toxic symptoms are induced.

Significant hypotensive effects can be induced in about half the patients taking this drug, more particularly if the maximum dose tolerated is taken steadily and in conjunction with raudixin. Most patients feel better, are less tired, and are free from headaches when full doses of veriloid are in use. Tolerance varies from patient to patient, and the daily quantity ranges from 18 to 24 mg. as a general rule. Minor toxic symptoms such as a peppermint-like flavour in the mouth or slight salivation are common. They tend to come and go, and conscientious patients ultimately learn to disregard them in the knowledge that thereby the drug is exerting a full effect. If no corresponding reduction is observed in the diastolic readings when full doses are in use, there is no justification for urging the patient to continue with this drug.

Ganglion-blocking Compounds

When signs of retinitis are present, or when the heart or kidneys are showing early signs of impairment, more energetic measures are required, firstly for the relief of symptoms, which tend to be more severe in this group, and secondly in an attempt to arrest or reverse the obliterative vascular disease. In recent years new ganglionic blocking-agents, consisting of the halogen salts of hexamethonium and pentamethonium, have proved increasingly useful. They act on both sympathetic and parasympathetic ganglia, and therefore produce a wide range of effects such as pupillary paralysis, gastric hyposecretion, and intestinal ileus as well as hypotension. At the present time, pentolinium tartrate ("ansolysen") is the methonium compound of choice. It closely resembles hexamethonium in its action, except that its effects last longer and it is about five times as strong. Its great advantage is that it can be given successfully by mouth in the majority of patients.

The ideal method of regulating pentolinium tartrate to the patient's particular requirements is by measurement of the blood pressure, taken lying and standing, at frequent intervals through the day. This can best be done in hospital by trained technicians or nurses. Where such facilities are not available a single timed reading of blood pressure each day in the erect posture between two and three hours after the morning dose of pentolinium tartrate may prove a useful guide, but fairly accurate control of dosage can be regulated by the production of hypotensive symptoms, the quantity of the drug being gradually increased by small increments, say 20 mg., until such symptoms occur. At, or a little above, the optimum dose the patient, on standing quietly at the time of maximum action of the drug, will notice slight dizziness, promptly relieved by sitting or lying down. If faintness occurs the dose should be reduced, while if no dizziness is noted the dose should be increased. The intelligent and co-operative patient can soon learn to regulate his pentolinium tartrate dosage. The dose requirements vary from patient to patient. The correct dose has to be determined by the individual's response.

The initial dose is 20 mg. twice daily, the first dose of the day being taken at 7 a.m. and the last at 10 or 10.30 p.m. The tablets should be taken crushed in a constant amount of water, preferably at least an hour before meals to ensure reasonable constancy of absorption. Doses at 12 noon and 5 p.m. suit most people. Blood-pressure readings can be recorded with advantage about 10 a.m., two hours after breakfast, and records kept of the response, with the patient lying and standing, from day to day until the dose is finally stabilized. The aim should be to obtain a systolic pressure of 120-140 in the erect posture when the drug action is maximum two to three hours after its oral administration.

If no symptoms are induced in the erect posture by 20 mg., then the following day 40 mg. is taken at 7 a.m. and 10 p.m. Assuming negative reactions, additional doses of 20 mg. each may be taken at noon and at 5 p.m. next day. The aim should be to obtain an adequate hypotensive effect throughout the 24 hours. Of the four doses, the evening one can with advantage be the largest in the hope of prolonging the effect overnight, the midday dose the smallest, and the

morning dose intermediate. When adjustments have been made and some tolerance has been developed, a day's routine after two or three weeks of cautiously increasing the dose might work out at 140 mg. at 7 a.m., 80 mg. at noon, 100 mg. at 5 p.m., 240 mg. at 10 p.m. The hypotensive effect of the evening dose can be augmented by having the patient sleep with the head of the bed raised on blocks 12 to 18 in. (30-45 cm.). If difficulties arise in adjusting the dose on the basis of hypotensive symptoms, it is usually necessary to have the patient in hospital in order to observe the blood-pressure response to a test dose over several hours.

There are two difficulties in pentolinium tartrate treatment worthy of particular consideration. Tolerance to the drug develops rapidly at first, and may in fact continue to develop to a slight extent for some months. The daily dose must therefore be raised day after day for two to three weeks, and later less frequently, if the desired postural effects are to be maintained, for without them the patient is not obtaining full benefit.

On effective methonium therapy most patients have some "side-effects." Constipation is a source of danger, as, following its relief, excessive absorption of methonium may occur with profound falls in pressure. Pentolinium tartrate is less likely to cause constipation than other hexamethonium compounds, but nevertheless the patient should be warned of its dangers and have a suitable remedy. A cascara pill or mixture may be necessary in generous doses. The bowel must be made to act at least once daily. Parasympathetic-stimulating drugs can also be used to combat constipation and also the dryness of the mouth. For this purpose oral neostigmine, 15 mg., carbachol, 0.25 mg., or pilocarpine, 1 mg. in water perhaps, thrice daily, may be used. If complaint is made of blurring of vision, physostigmine drops in a strength of 1/32% to 1/16% may help, but sometimes it may be necessary to provide an extra pair of glasses, refraction being adjusted to the change in the eye brought about by the action of the methonium compound.

Raudixin has proved very effective in counteracting the "side-effects" of the methonium compounds. When it is added to the methonium routine the response to pentolinium tartrate is enhanced, so that smaller doses prove equally effective. "Side-effects" of methonium are consequently diminished.

Mecamylamine

On account of its complete absorption and more protracted action, the powerful ganglion-blocking agent, mecamylamine, appears to be more predictable and constant in its hypotensive effects than the oral methonium compounds (Moyer *et al.*, 1956). Its "side-effects" are similar and tolerance is readily established, so that dosage must be adjusted to the individual's requirements. It is usually wise to begin with a small dose, say 2.5 mg. at 7 a.m. and 5 p.m. After two or three days these quantities may be doubled and, later, additional doses added at 12 noon and 10 p.m. As with pentolinium, the aim is to produce mild hypotensive symptoms in the erect posture two to three hours after taking the drug. A few weeks of careful study, during which the dose of the drug is titrated against the postural response, are usually required before a steady routine can be advised. The dose of all ganglion-blocking drugs can only be determined by trial and error. Preliminary experience with mecamylamine is so encouraging that it may yet prove to be the drug of choice in the severest grades of hypertension.

Malignant Hypertension

Patients in this category are gravely ill and commonly die within a few months in a confusional state, with or without evidence of left ventricular failure, and with varying degrees of renal inadequacy. Any success in treatment of this, the most serious form of hypertension, depends upon the early recognition of papilloedema, when symptoms may be comparatively slight, and on the employment of energetic measures to restore normal pressure levels. As a complication of malignant hypertension, left ventricular failure is more readily corrected than nitrogen retention. Uraemic

signs are of ill omen and usually betoken an unfavourable response to treatment.

If renal function is reasonably good, the blood non-protein nitrogen less than 50 mg. per 100 ml., and congestive failure absent or controlled, the prospects of lowering pressure and of arresting the progress of the vascular disease are reasonably good. Smirk (1953) considers that in these ill people the urgency of the situation demands that pentolinium should be used first as the "retard" preparation by subcutaneous injection in an initial dose of 3 mg. twice or thrice daily, increasing by 1 mg. per dose until suitable hypotensive levels are obtained. As much as 140 mg. daily may be required, but in our experience oral doses are equally effective, particularly when raudixin is also in use. The justification for the parenteral route is the necessity for rapid control of the blood pressure, as when hypertensive heart failure complicates the situation. Similarly, recurrent bouts of vomiting may preclude the effective use of the oral preparations. Parenteral administration is then the only alternative. With twice-daily subcutaneous injections at 12-hour intervals, a small supplementary oral dose may be given about midday, and, later, oral doses can sometimes be substituted for the two injections. As improvement is made, four oral doses of pentolinium tartrate may conveniently replace the subcutaneous injections.

Contraindications to Ganglion-blocking Compounds

A word of caution is necessary regarding the indiscriminate use of ganglion-blocking compounds. Unless the doctor is prepared personally to supervise their use, and succeeds in enlisting the intelligent co-operation of his patient, methonium or mecamylamine may do more harm than good. The patient must be taught to adjust and regulate his own treatment, and for this purpose he may be handed a leaflet giving him precise instructions. If he is uncooperative the attempt at home treatment should be abandoned.

Experience indicates that these compounds aggravate established uraemia. They should not be used in the presence of advanced cerebral arteriosclerosis, and only be commenced two to three months after either a cerebral or a coronary thrombosis. Prostatic symptoms call for considerable caution in the employment of these remedies.

Hydrallazine ("apresoline")

When renal function is moderately impaired, with a blood non-protein nitrogen in excess of 40-50 mg. per 100 ml., the response to treatment becomes less and less satisfactory. With a reduction in arterial pressure, renal function may in fact decline further. In these circumstances some success has been obtained by the oral use of hydrallazine in doses of 25 to 100 mg. It is a synthetic preparation which has the peculiar quality of considerably increasing renal blood flow while decreasing diastolic pressure. Cardiac rate and output are said to be increased. An improvement in renal function may warrant the cautious addition of pentolinium tartrate to the hydrallazine routine. When uraemia is in progress no drugs are of any avail.

Hydrallazine has distinct limitations, as "side-effects" and toxic reactions are frequent. Headache, flushings, and palpitations are common. Oedema of the skin observed about the hands and feet and drowsiness and dryness of the mouth also occur, but fortunately tend to disappear of their own accord after a few days when tolerance is gained. More serious signs of intoxication are the development of conditions resembling rheumatoid arthritis on the one hand and disseminated lupus on the other. Anaemia, hepatomegaly, and splenomegaly also occur. Intolerance for the drug usually subsides satisfactorily on its withdrawal.

V. Surgical Procedures

Lumbo-dorsal Sympathectomy

On the hypothesis that high blood pressure is the result of overactivity of the sympathetic system, bilateral excision of the paravertebral ganglia has been employed extensively during the past 20 years. Smithwick's procedure, which includes resection of the splanchnic nerves, together with excision of the sympathetic trunks from the level of the ninth

thoracic root to at least as low as the first lumbar, has yielded in expert hands striking benefit in the severest grades of hypertension. In younger people, provided renal function is reasonably good and congestive failure has not occurred, sympathectomy may produce a regression of the papilloedema, a fall in pressure, a restoration of a sense of well-being, and a prolongation of life which compares favourably with any other method of treatment at present available. It is, however, a major operation, commonly followed by a protracted convalescence and occasionally complicated by intractable root pains of a girdle type. Accidental wounding of the pleura can cause much respiratory embarrassment in the immediate post-operative period.

Sympathectomy has a limited use in the treatment of hypertension, as experience shows that a satisfactory result is most unlikely in the presence of impaired renal function, and, contrary to the use of the methonium compounds, patients who have suffered or are suffering from left ventricular failure never tolerate this surgical procedure. A poor response to methonium in combination with rauwolfia or hydrallazine, provided renal and cardiac functions are reasonably good, is a strong indication for sympathectomy, particularly in the severest grades of hypertension. For unintelligent and uncooperative patients, incapable of regulating their pentolinium or mecamylamine routine, sympathectomy is a justifiable alternative.

Bilateral Adrenalectomy

From the observation that the low blood pressure of Addison's disease could be corrected, and, indeed, overcorrected by the subcutaneous insertion of pellets of D.C.A. arose the suggestion that bilateral adrenalectomy might be justified in the severest forms of hypertension. Even with the help which cortisone and other substitution products provide, the post-operative findings indicate that subtotal or total adrenalectomy is a major undertaking, yielding uncertain results and imposing formidable risks among those surviving even a few months (Pickering, 1955). The immediate benefits resulting from the employment of the potent medical remedies now available, coupled with the substantial reduction in the mortality rate even in malignant hypertension, emphasize as nothing else can that there is no future for the employment of such a drastic upheaval as adrenalectomy in the treatment of hypertension other than in those instances where the suprarenal gland is primarily involved.

VI. Multiple Therapy

As already described, reassurance combined with light sedation in the form of small doses of barbiturates or rauwolfia are all that are required in the milder non-progressive cases of hypertension, with no more than Grade 1 or at most Grade 2 retinæ. The more powerful drugs—methonium and hydrallazine—are dangerous, but in combination have proved very effective when used cautiously in the severer forms of the disease.

Rauwolfia has the great advantage that it apparently potentiates other hypotensive agents, and when in use reduces the effective quantity of pentolinium, thus lessening the disagreeable "side-effects" of the latter preparation. In the opinion of Wilkins rauwolfia is the first hypotensive drug to try and the last to omit. Its stimulating action on the bowel may overcome to some extent the constipating action of the methonium compounds, its enhancement of vagal tone may restrain the cardiac acceleration of hydrallazine, and its central soothing action may augment the effects of veriloid by reducing that drug's tendency to gastric upset.

In the presence of hypertensive cerebral vascular disease, the combination of a low-sodium diet with rauwolfia, and later if necessary with veriloid in addition, is probably safer than intensive methonium therapy, at least in the first instance, whereas hypertensive heart failure calls for pentolinium or mecamylamine and a greater or less degree of salt restriction. Sodium retention is common when rauwolfia is in use, but seldom gives rise to difficulty if the diet is suitably adjusted and mercurial diuretics used from time to time.

For uncomplicated hypertension of Grade 3 or 4 severity, the combination of rauwolfia with a ganglion-blocking agent is the treatment of choice. This may be supplemented by salt restriction, and, if the response is incomplete or delayed, lumbo-dorsal sympathectomy may then be considered. It is said that a previous sympathectomy enhances the effects of hypotensive drugs.

VII. Conclusions

Hypertensive vascular disease presents in such a great variety of patterns, and runs such an unpredictable course, that the effects of treatment are difficult to assess.

Nevertheless, the remedies at present available, if selected judiciously, applied conscientiously, and adjusted carefully to the particular needs of the individual, offer more for hypertensive patients than ever before.

The maintenance of the blood pressure within the normal range permits a reversion of the vascular damage in the retinae, heart, and brain, provided renal function is not grossly impaired and massive tissue destruction has not occurred. Early treatment, even in the severe forms of hypertensive disease, should reduce the risk of serious complications and be the means of prolonging life.

In general, appropriate therapy, which is most often a combination of different remedies, should be determined more by the patient's vascular state than by blood-pressure readings. For the most part the retinal picture, taken with the state of the heart and kidneys, determines treatment.

Summary

A great variety of remedies are available for treatment of hypertensive vascular disease. General measures include: (a) simple psychotherapy; (b) advice regarding a physiological way of life; and (c) instructions regarding weight reduction and restricted Na intake.

The detection of a precise aetiological cause, and its prompt surgical removal, can lead to permanent cure.

In most cases treatment must be determined by the degree of vascular impairment rather than by blood-pressure readings.

All patients showing hypertensive retinopathy should have intensive therapy, also those without serious retinal changes but who have had transient cerebrovascular episodes, attacks of left ventricular failure, or angina. Most patients disabled by severe hypertensive symptoms will also require the more potent hypotensive remedies.

Patients who have no symptoms, or only minor ones, and who present no evidence of serious retinal, cerebral, or cardiac damage require advice about their mode of life, and only mild hypotensive agents such as rauwolfia.

Rauwolfia potentiates other hypotensive agents. Rauwolfia, with or without "veriloid," and a low-salt diet may keep hypertensive heart failure in check, but more commonly pentolinium and Na restriction will be required. Rauwolfia alone or with veriloid often helps the anginal patient with hypertensive coronary disease.

Low-sodium diet combined with veriloid is probably safer than intensive methonium therapy for cerebrovascular lesions. For uncomplicated Grade 3 or 4 hypertension rauwolfia with pentolinium is the treatment of choice.

Preliminary experience suggests that the effective dose of mecamlamine is more readily determined and more constant than that of the methonium compounds. It may therefore ultimately replace pentolinium, but the long-term results are not yet known.

In the presence of uraemia all hypotensive drugs are valueless, though in the milder grades of renal impairment hydrallazine ("apresoline") may prove helpful.

For patients incapable of regulating their pentolinium routine, or if the response to the drug is poor, lumbo-dorsal sympathectomy is indicated, provided renal and cardiac functions are reasonably good.

DURATION OF ANTICOAGULANT EFFECT IN RELATION TO URINARY EXCRETION OF DEXTRAN SULPHATE

BY

Research Unit, Birmingham Accident Hospital

It has already been reported that when the effect of single equipotent intravenous doses of heparin and dextran sulphate are compared the latter compound shows a slightly greater duration of effect. Comparison of repeated equipotent doses makes this disparity in duration of effect more pronounced (Ricketts *et al.*, 1953). This observation was confirmed by Donzelot *et al.* (1955), who reported that after three to five days' treatment with dextran sulphate the increase in duration of effect of successive doses was such that adequate control of the coagulation time and satisfactory clinical responses in cases of thrombo-embolic disease could be obtained by intravenous dosage at daily intervals or even on alternate days.

One factor which it was thought might be responsible for a cumulative effect of this kind, as compared with the absence of a similar effect with heparin, was a difference between the patterns of urinary excretion of the two drugs. Estimates of the urinary excretion of dextran sulphate in patients treated with dextran sulphate for periods varying from 10 to 23 days, and similar estimates in experimental animals given repeated injections for 10-day periods, were carried out and were related to measurements of the clotting-time of blood and the one-stage "prothrombin" time, in order to investigate this hypothesis. Certain further observations on the clinical effects of dextran sulphate were made incidentally in the course of this investigation.

Materials and Methods

Dextran sulphate ("dexulate," Batch No. 52DS041) was available as a 9% sterile solution, including 0.2% sodium bicarbonate and 0.7% sodium chloride. The dextran sulphate

contained 18.1% sulphur and the solution assayed at 1,200 units per ml. The unit of dextran sulphate is defined as the activity of 0.04 mg. of the standard preparation of dextran sulphate held by the Expert Committee on Biological Standardization of the World Health Organization. The *in vitro* effect of this unit is of approximately the same order of magnitude as the International Heparin Unit.

Estimation of Dextran Sulphate in Urine.—The method of MacIntosh (1941), which depends on the formation of an insoluble purple salt of the dye, toluidine blue, with sulphated polysaccharides, was modified as previously described (Ricketts *et al.*, 1954). Calibration against a dextran sulphate of known sulphur content enabled the results to be expressed as milli-equivalents of ester sulphate per litre of urine (1 mEq of ester sulphate is equivalent to 32 mg. of sulphur).

The blood coagulation time of patients was measured by the method of Lee and White (1913). With rabbits the method of Dale and Laidlaw (1911-12) was employed, using standardized capillary tubes containing steel shot of uniform size. All estimations were performed at 37° C. The "prothrombin" time was estimated by Quick's one-stage method (Quick, 1937) and the results were expressed as a percentage of normal by comparison with a normal serum dilution curve.

Method of Recovery of Dextran Sulphate from Urine.—4.26 g. of cetyltrimethylammonium bromide in 50 ml. of water was added to 2.14 l. of urine estimated to contain 2.13 g. of dextran sulphate. After standing to complete precipitation the insoluble dextran sulphate salt was separated by filtration and centrifugation, and dissolved in an alcohol-chloroform mixture (1:1 by volume). By adding approximately 2 M sodium chloride drop by drop to the clear solution in the organic solvent, sodium dextran sulphate was precipitated as a syrup. This salt was purified by treatment with charcoal, and repeated reprecipitation from alcohol-water solution finally yielded 275 mg. of dextran sulphate containing 18.95% sulphur. The anti-coagulant activity of the material recovered was compared with that of the material originally administered to the patient, using the method of Adams (1950) and an assay method previously described (Ricketts and Walton, 1953).

Design of Experiments

Clinical.—Observations were made on five patients who had been admitted to hospital for anticoagulant therapy but who were otherwise unselected. Two were cases of recent myocardial infarction and the other three were cases of venous thrombosis associated with pulmonary embolism. Therapy was initiated by twice- or thrice-daily intravenous injections of dextran sulphate after initial (baseline) values for the coagulation time and prothrombin time had been obtained. The coagulation time was measured before injection ("minimal" coagulation time) and, where necessary, one hour after injection ("maximal" coagulation time). Previous experience had shown that the coagulation-time response to this schedule of intermittent intravenous dosage took the form of a "picket-fence" curve. With thrice-daily injections the peaks (maximal clotting-time) and troughs (minimal clotting-time) of this curve became progressively elevated (Ricketts *et al.*, 1953). In the present investigation, once it was established in a given patient that a cumulative effect of this kind was occurring, the size of the dose and/or the number of injections was reduced in order to produce comparable responses on consecutive days. The general aim was to maintain a minimal coagulation time of at least twice the baseline value to ensure a continuous anticoagulant effect. Observations on the pro-

thrombin-time response were also made but were not used as a guide for the control of dosage. Twenty-four-hour specimens of urine were collected to allow estimation of the excretion of the drug.

Animal Experiments.—The duration of response to single intravenous injections of 750 units per kg. body weight was investigated in two rabbits. A week later the same animals were started on a course of thrice-daily intravenous injections of dextran sulphate, employing a dosage scheme similar to that initially used in the human subjects. The coagulation time was measured each morning before the first injection and again one hour later. Throughout the 10-day period of the experiment the animals were kept in metabolism cages and their urine was collected for each 24-hour period. The animals were maintained on a standard diet and allowed water *ad lib*.

Results

The clinical course of the thrombo-embolic disease in each of the five cases was satisfactory, and in no case was there any evidence of further embolism or thrombosis during therapy.

Coagulation-time Response.—The nature of the response to intermittent intravenous dosage was investigated by the use of different schedules of dosage. Progressive increase of the coagulation time on successive days in response to unaltered dosage, or a similar or increased coagulation time on successive days in response to a diminishing dosage, was taken as evidence of cumulation of dextran sulphate. The minimal coagulation time was regarded as the more sensitive index for this purpose and has been plotted together with the prothrombin percentage and total daily dose in Figs. 1-5. Judged by the nature of the minimal coagulation-time response, an effect ascribable to cumulation of the anticoagulant was observed in Cases 1, 3, 4, and 5. Case 2 presented special circumstances which are discussed separately.

Case 1.—A man aged 51 suffering from myocardial infarction was treated with dextran sulphate for 23 days. It can be seen from Fig. 1 that a daily dosage increasing from 8,400 units on the first day to 25,200 units on the third day raised the minimal coagulation time to the desired level. Evidence of cumulation was then obtained in that, in spite of reduction of dosage to 19,200 units on the fourth and fifth days, the minimal coagulation time continued to rise. Stabilization at the elective level of minimal coagulation

FIG. 1.—Case 1. Response of minimal blood coagulation time and of prothrombin percentage to variation of daily dosage of dextran sulphate.

time (15–20 minutes) was sought by variation of the dose between 13,200 and 3,600 units daily (given as two injections instead of three) during the 6th to the 12th day and by a

FIG. 2.—Case 3. Response of minimal blood coagulation time and of prothrombin percentage to variation of daily dosage of dextran sulphate.

FIG. 3.—Case 4. The minimal blood coagulation time response shows a marked cumulative effect.

three-day period (13th to 15th days) on a steady dosage of 8,400 units. Even this latter dosage resulted in a progressive increase of the minimal coagulation time, and final stabilization was secured on a daily dosage of 7,200 units. During the 23 days of therapy this patient received a total of 235,200 units (17.64 g.) of dextran sulphate.

Case 3.—A woman aged 54 showed clinical and radiological evidence of pulmonary embolism evidently originating from deep vein thrombosis of the right leg associated with a severe superficial phlebitis in the varices of the same leg. An initial dosage of 42,000 units over the first two days raised the minimal coagulation time to the desired level. Reduction of dosage to 13,200 units daily on the fourth to the seventh day produced little variation in the minimal coagulation time until the ninth day, when it showed a rise in level in spite of further reduction of the dose to 12,000 units daily (Fig. 2), suggesting a slower cumulative effect than that seen in the previous case. Dextran sulphate was discontinued on the 10th day, and two days later the patient was transferred to treatment with an oral anticoagulant. The subsequent course of this case is discussed in further detail below.

Case 4.—A man of 50 suffering from a recent myocardial infarction was also found to have chronic bronchitis with purulent sputum. On a daily dosage of 12,000–18,000 units a marked cumulative effect was observed (Fig. 3). The increase in slope of the minimal coagulation time was first noted on the third day and became most pronounced by the ninth day. In this instance, after reduction of the dose on the ninth day, with corresponding reduction in the minimal coagulation time, stabilization was achieved at 15,600 units daily.

Case 5.—A man aged 40 with left femoral vein thrombosis and clinical and radiological evidence of pulmonary embolization was treated with dextran sulphate for 14 days. An

FIG. 4.—Case 5. In this case unvarying daily dosage produced a slow cumulative effect on the minimal blood coagulation time. The reduction in the swelling of the leg affected by venous thrombosis and the fall in the serum cholesterol during therapy are also shown.

unvarying dosage of 18,000 units daily was given for the first three days. Reduction of dosage to 12,000 units on the fourth day (when previous experience had suggested the first evidence of cumulative effect might be anticipated) was not accompanied by a fall in the minimal coagulation time, and more definite evidence of cumulation was obtained when the daily dosage of 18,000 units was resumed (Fig. 4) for the remaining 10 days of this course of therapy.

Effects on Prothrombin Percentage

In all cases the prothrombin percentage was reduced rapidly after injection, and within one hour of the first injection might be as low as 40% of normal. In contrast with the coagulation time the prothrombin percentage did not revert to the baseline level before subsequent injections. The nearest approach was in Case 4, the prothrombin percentage after an initial fall to 45% rising again to 74% 15 hours after the first injection. In every case the prothrombin percentage for most of the therapeutic period lay between 30% and 50%. Fluctuations were less conspicuous than those of the coagulation time, but on the whole the changes in prothrombin percentage and coagulation time mirrored one another. Although, as stated earlier, the prothrombin percentage was not used in the present investigation as a guide to therapy, these observations confirm the contention of Hirschboeck *et al.* (1951) that the prothrombin time can serve as an index of the anticoagulant effect of heparinoids, and it is possible that where both an oral and this intravenous anticoagulant are to be used in sequence it may serve for the control of each drug and for the transition from one to the other. In this latter connexion it was observed that following cessation of therapy with dextran sulphate in Cases 1 and 3 (treated for 23 and 10 days respectively) the coagulation time and the prothrombin percentage did not fall to the baseline values until 48 hours after the last injection.

Urinary Excretion of Dextran Sulphate

Cases 1, 2, and 4 were studied. Some day-to-day variation occurred in the amount of dextran sulphate excreted in the urine in each case, but over the whole therapeutic period the percentage of the total dose accounted for in the urine was close to 40% in all three patients (Table I). No close relation could be seen between the total daily dose and the percentage daily excretion, nor was the latter related to mean daily urinary volume. After the cessation of injections, dextran sulphate continued to be excreted for two to three days, as shown in Table II.

Observations in Rabbits

Anticoagulant Effect.—The two animals placed on a dosage regime similar in frequency and spacing of injections to that used in patients showed no evidence of any cumulative effect of the drug. The peaks and troughs of the maximal and minimal coagulation times were comparable in amplitude for a given dose day after day throughout the

course. Even when the size of the dose was increased from the initial 3,600 units daily to 4,800 units daily from the sixth day onwards in rabbit No. 2 (Fig. 5) no evidence of progressive increase in response was found. It should be noted that this absence of cumulation was observed although the animals were given an average dose in excess of 2,000 units per kg. of body weight per day as compared with the cumulative effect observed in man with doses of the order of 200 units per kg. body weight per day.

FIG. 5.—Maximal and minimal coagulation-time responses to dextran sulphate in the rabbit. Note absence of cumulative effect.

Urinary Excretion.—Analysis of the urine showed that the rabbits excreted 66.2% and 58.1% of the total dose administered. Small amounts of dextran sulphate were detected in the urine two to three days after the cessation of injections (Table III), although no anticoagulant effect was observed seven hours after the last injection.

Examination of Material Excreted

It has been claimed that when heparin is injected the material recovered from the urine, "uroheparin" (Best and Jaques, 1948), differs in physico-chemical characteristics and in biological activity (Marbet and Winterstein, 1951) from the material administered. In a previous study carried out with dextran (³⁵S) sulphate (Ricketts *et al.*, 1954) it was found that during the first hour after intravenous injection of dextran sulphate in the rabbit the material appearing in the urine showed a slightly different R_f value by paper chromatography from that of the material administered. This was assumed tentatively to be explained by the excretion of a low molecular-weight fraction of the injected material.

The present investigation allowed recovery of a larger amount (275 mg., representing 12.9%) of the material appearing in the urine and further examination of its characteristics. On this occasion the material recovered from the urine of Case 1 showed no chromatographic difference from the original material. Its anticoagulant potency *in vitro* and *in vivo* appeared identical with that of the injected drug. This may possibly be accounted for by the fact that the product used in the present work was of more uniform and slightly lower average molecular weight than that used previously.

Other Clinical Effects of Dextran Sulphate

In the three cases with thrombosis of leg veins (Cases 2, 3, and 5), all presenting with painful oedematous limbs, dextran sulphate produced a lessening of pain and a

reduction of the swelling of the affected leg within 48 hours. In Case 5 the circumference of the initially swollen left leg, measured 4 in. (10 cm.) above and below the patella, gradually decreased to equal the corresponding measurements of the unaffected right leg during the 14 days of therapy (Fig. 4). During the first six days, accompanying the reduction of the oedema of the leg, the patient lost 8.5 kg. in weight, suggesting a reabsorption and excretion of about 8.5 litres of oedema fluid during this period.

It had previously been observed that dextran sulphate, like heparin, produces "clearing" of the turbidity of the plasma *in vivo* during alimentary lipaemia (Brown, 1952). The available evidence suggests that this phenomenon is due to the activation of a lipase acting principally on β -lipoprotein, the main carrier of lipids and cholesterol in human plasma. Alteration in the electrophoretic mobility of the lipoproteins following the injection of dextran sulphate has been shown to accompany the clearing phenomenon (Jeavons and Ricketts, 1956). In the present investigation the injection of repeated doses of dextran sulphate was observed to lower the level of plasma cholesterol even where the initial level was not greatly elevated, as in Case 5. The plasma cholesterol was lowered throughout the period of therapy but had reverted to its pre-treatment level 14 days after the last injection (see Fig. 4). Similar observations on the effect of dextran sulphate on plasma cholesterol have been made by Cohen and Tudhope (1956).

Complications and Side-effects of Dextran Sulphate Therapy

The response to dextran sulphate in Case 2 merits more detailed discussion.

Case 2

The patient, a woman aged 45, had previously undergone total hysterectomy and oophorectomy for bilateral ovarian carcinoma. At operation deposits were seen in the pouch of Douglas and pelvic tissues, so a post-operative course of deep x-ray therapy to the lower abdomen to full tolerance was planned one month later. Treatment was given by

FIG. 6.—Case 2. Effect of radiotherapy on platelet count prior to and during dextran sulphate therapy. Note increased sensitivity of minimal blood coagulation time to dextran sulphate therapy during second episode of thrombocytopenia.

wide-field irradiation to a field area 40 by 40 cm. at 230 kV; H.V.L., 2.5 mm. Cu; F.S.D., 100 cm. An incident dose of 3,220 r to each of two fields over a period of 38 days gave a total of 3,500 r.t.d. (roentgen tumour dose). Blood counts were carried out at three-day intervals during treatment, and as the course progressed the blood platelets showed a steady decrease from an initial level of 295,000 per c.mm. to 119,000 per c.mm. by the end of the fourth week (Fig. 6).

On the 28th day of treatment the patient complained of a sudden sharp pain in the chest, and on the following day of pain and swelling in the left leg and thigh, suggesting pulmonary infarction associated with femoral vein thrombosis. Radiotherapy was suspended and treatment with dextran sulphate instituted. Twice-daily doses of dextran sulphate in amounts increasing to 19,200 units daily by the eighth day failed to produce a sustained rise in the minimal coagulation time to the desired level, although an anticoagulant effect was secured for the major portion of each day during this period. The pain in the chest disappeared on the third day of treatment and the pain and swelling in the left leg abated on the fourth day. During the first eight days of dextran sulphate therapy the platelet count rose till it had reached 243,000 per c.mm. The dosage was maintained at 18,000 units. Radiotherapy was resumed from the ninth day. An increasing response of the minimal coagulation time now became apparent and this continued in spite of reduction of dosage to 12,000 units daily (Fig. 6) on the 13th day.

A haematoma appeared at the site of venepuncture on the 15th day and the platelet count was found to have fallen once more to 121,000 per c.mm. Dextran sulphate was discontinued on the 16th day. The coagulation time continued to be elevated for three days. There were no further haematomata and no evidence of bleeding elsewhere was found. Radiotherapy was suspended on the 18th day and the platelets subsequently rose again, but the normal level was not regained for three weeks.

The patient's clinical condition progressed satisfactorily and she was alive and well with no evidence of recurrence of tumour and no further history of thrombo-embolic episodes when seen 18 months later.

Comment

The second fall in the platelet count in this patient was more precipitous than the first (Fig. 6). Whether this was due to an increased sensitivity of the marrow to a second dose of radiation before full recovery had occurred from the effects of the first, or whether the simultaneous administration of dextran sulphate with the second dose of radiation contributed to the thrombocytopenia on the second occasion, are questions it is not possible to decide unequivocally. Thrombocytopenia occurring during intensive therapy with a depot-heparin preparation in 13 out of 30 patients has been reported by Plancherel (1952), and platelet agglutination and thrombocytopenia have been recorded in experimental animals given a variety of sulphate polysaccharides (see Astrup, 1953, for references).

However, Soulier (1955) and Astrup, Flyger, and Gormsen (1955) have confirmed the absence of any direct effect upon platelets of dextran sulphate of the kind used in the present study, as originally reported by Walton (1953). Periodic platelet counts in the other four cases in the present series disclosed no significant changes (Table IV). On balance, therefore, it appeared to us more likely that the thrombocytopenia observed in Case 2 was occasioned by the heavy dosage of radiotherapy.

It was perhaps significant that while the platelet count was rising in this case (during the first eight days) the patient appeared to be relatively resistant to the anticoagulant effect of dextran sulphate, but showed a marked increase in sensitivity to the drug when radiotherapy was resumed and the platelet count again fell to low values. This may be analogous to the increased sensitivity of response to heparin in the presence of thrombocytopenia

reported by Conley *et al.* (1948), and emphasizes the necessity for caution in the administration of these anticoagulants to patients with low platelet counts.

Case 3, as described above, was treated with dextran sulphate for 10 days, during which time the oedema of the right leg (due to thrombosis of the deep veins and superficial phlebitis of varices) subsided and no haemorrhagic manifestations occurred. It was decided to continue treatment with an oral anticoagulant (phenindione), and this was instituted three days after cessation of the course of dextran sulphate. On the following day a few red cells were seen in the urinary deposit, and on the next day a profuse haematuria with clot retention occurred. At this time the coagulation time was normal. Subsequent investigation revealed a right-sided hydronephrosis, a mild left hydronephrosis, and a grossly trabeculated bladder associated with uterine prolapse. In view of the interval between the cessation of dextran sulphate administration and the occurrence of the haematuria, and also because of the normal coagulation time when this complication occurred, it seemed unlikely that the haemorrhage could have been caused mainly, if at all, by the dextran sulphate. However, another feature of this patient's subsequent history was possibly related to dextran sulphate therapy. Six weeks after her discharge from hospital (eight to nine weeks after the course of dextran sulphate) she developed a transient partial alopecia from which she had recovered fully two months later. The present case is the first within our own experience to show this side-effect, but Donzelot *et al.* (1955) reported its occurrence in 6 out of the 60 cases they treated with dextran sulphate and it was encountered in 3 out of 11 cases treated by Cohen and Tudhope (1956).

Discussion

The present results confirm and extend previous reports concerning the cumulative effect in human subjects of repeated intravenous injections of dextran sulphate. This cumulative effect is in sharp contrast with the effect of heparin similarly administered in doses of equivalent *in vitro* potency. It is generally agreed that the anticoagulant effect of a single intravenous dose of 5,000 units of heparin lasts two to three hours (Estes and Allen, 1950; Duff, Linman, and Birch, 1951; Brown and Douglas, 1952), and that, to secure a satisfactory clinical and anticoagulant effect, repeated intravenous injections of 10,000 units or more must be given at four- or six-hourly intervals throughout a course of therapy—that is, 40,000 to 60,000 units daily.

In contrast, the present investigation has shown that when a total dosage of 30,000–48,000 units of dextran sulphate is given within the first three to four days, the first evidence of cumulation appears. Thereafter continuous control of the coagulation time and prothrombin time and a satisfac-

tory recovery from the effects of thrombo-embolic disease can be secured with a daily dosage of 8,000 to 16,000 units given in single or divided intravenous doses. Intramuscular injections were not used in our patients, but this route has been employed with apparent success by Donzelot *et al.* (1955). It should be noted that the intravenous dosage scheme now recommended is larger than that used by Donzelot *et al.*, who, using somewhat different criteria of the clinical efficacy of dextran sulphate, obtained results which they regarded as satisfactory by reducing intravenous dosage after a few days to as little as 2,500 units daily or on alternate days, suggesting an even more pronounced difference from heparin in duration of effect.

In considering what might determine this disparity in duration of effect between the two anticoagulants, it is convenient to scrutinize separately the relative proportions of an administered dose which are excreted and retained.

With regard to the proportions excreted, obviously disparity might arise if considerably more of one drug than the other were eliminated. It has been shown by many workers (for references see Jaques *et al.*, 1953) that 40–60% of the dose of heparin administered intravenously can be recovered from the urine in the human subject and in experimental animals. This percentage is very similar to that now found for dextran sulphate. Disparity in duration of effect might also result from selective elimination of qualitatively different fractions of the injected material; for instance, a fraction of small molecular weight and low biological activity in the case of one drug but not in the case of the other. Most commercial heparins are known to be greatly heterodisperse in regard to molecular size and activity (for references see Walton, 1955), and, as mentioned above, evidence has been presented that the fraction recovered from the urine, uroheparin, does differ in physical characteristics and activity from the material injected. In the present experiments, employing the dextran sulphate commercially available, no difference could be detected between the excreted fraction and the original material.

With regard to the portion retained in the body, while it may be assumed that the anticoagulant activity of these drugs is mediated only by the fraction actually present in the circulating blood and free to interact with the "clotting proteins" of the plasma, it is also necessary to consider the distribution of these drugs in the total body fluids. It has long been appreciated that small diffusible molecules injected into the blood rapidly gain access to the extravascular tissue-spaces. It is only in recent years that it has been shown that even relatively large, charged molecules may also pass into the extravascular compartment, and that the concentration in the blood in such instances depends on the establishment of an equilibrium between the concentrations in vascular and extravascular fluid. This concept, generally applied to bodily constituents by Schoenheimer (1942), has been supported, for instance, in the case of individual plasma proteins in experimental animals and man by the work of Whipple and Madden (1944), Miller *et al.* (1949), Sterling (1951), Myant (1952), Gitlin and Janeway (1953), and others.

In applying this concept to the distribution in the body of polysaccharide sulphates it has seemed reasonable to question whether material of such relatively large molecular size and high electro-negative charge could, in fact, permeate through capillary membranes. But it is known that both heparin and dextran sulphate, when added to plasma, form loose complexes with the plasma globulins as a result of which the charge on the polysaccharide sulphate molecule is partially neutralized. With regard to molecular size, a study of the composition of lymph in animals has shown that in certain regions the blood capillaries are freely permeable to the largest protein molecules and even to small particles (Field *et al.*, 1937). Recently direct evidence of the passage of heparin into the extravascular compartment has been provided by von Kaulla and Pratt (1955), who demonstrated that the concentration in lymph alters in parallel with that in the plasma after intravenous injection,

thus supporting the contention that an equilibrium between heparin levels in vascular and extravascular fluids is accomplished.

The pattern of cumulative effect resulting from repeated injections of dextran sulphate is such as to suggest that if a similar equilibrium between vascular and extravascular compartments occurs, the latter may serve as the main reservoir. This might explain why, early in therapy, when this reservoir is low, the coagulation time reverts rapidly to normal. On the other hand, after a few days' treatment, when the reservoir has been raised, the next injection is followed by a slower fall in plasma concentration and coagulation time. Finally, after the administration of the last dose of a prolonged course, the reinforcement of plasma concentration from the extravascular compartment might explain the slow decline to a normal coagulation time occupying a period of about 48 hours, as compared with an effect lasting only five to seven hours from the same dose at the beginning of treatment.

The rate of inactivation or destruction of the portion of the drug retained in the body must also influence its duration of effect. In the case of heparin it has been suggested that inactivation is effected by an enzyme "heparinase" (Jaques, 1940). However, this enzyme has been isolated only from rabbit liver. An attempt to obtain similar material from beef liver was unsuccessful (Jaques and Keeri-Szanto, 1952). The enzyme from rabbit liver was found to show lack of specificity in that, in addition to acting upon heparin derived from various species, certain synthetic polysaccharides were also degraded. Recently it has been found that a dextran sulphate similar to that used in the present experiments is also susceptible to attack by rabbit heparinase preparations (Jaques and Cho, personal communication).

If, as postulated, the cumulative effect of dextran sulphate in man is accompanied by accumulation in the extravascular compartment, it seems likely that the rate of inactivation or destruction of dextran sulphate must occur more slowly than that of heparin, which, similarly distributed, shows no cumulative effect. Preliminary experiments (Wiegel, Ricketts, and Walton, unpublished) with ^{14}C -labelled dextran sulphate suggest that, in rats, metabolic breakdown (as measured by the appearance of $^{14}\text{CO}_2$ in the expired air) does occur at a slow rate, but direct comparison with the rate of metabolic turnover of heparin in experimental animals or man has not yet been attempted.

Nevertheless, if the inactivation of these anticoagulants in the body is in fact accomplished enzymatically, as the present evidence indicates, it is tempting to suggest that differences between given species in the relative turnover rates of these drugs might be accounted for by differences in the substrate-specificity of their enzymes. Thus the observed disparity in duration of effect of heparin and dextran sulphate in man might be due to a more marked specificity of the human enzyme for the "natural" substrate, heparin, which is accordingly degraded more quickly and completely than the synthetic analogue dextran sulphate. On the other hand, the similar duration of effect of the two drugs in the rabbit might be due to the ability of rabbit heparinase to degrade both anticoagulants with equal facility.

Whatever the mechanism involved, it is clear that the cumulative action of dextran sulphate in man confers upon this drug certain immediate practical advantages over heparin for anticoagulant therapy. These advantages include lessened cost, reduced discomfort to the patient, and reduction in the number of man-hours of skilled medical attention necessary for the actual administration of the anticoagulant, all of which accrue from the longer spacing of injections which is possible once the patient is stabilized at the selected level of response. These advantages become more marked where treatment is given for prolonged periods.

On the other hand, prolonged therapy with dextran sulphate, as with heparin, appears to be accompanied by the occurrence of transient alopecia as a late sequel in some patients. A survey of 105 cases known to us to have been

treated with dextran sulphate suggests that this side-effect occurs in about 10% of cases, affecting males and females alike. However, in cases treated early in the series, since we were unaware of the time-lag that may occur before the alopecia develops, it is possible that cases were overlooked because the follow-up was not long enough. Estimates of the incidence of alopecia following treatment with other polysaccharide sulphates vary from 19% ("treburon"—Hirschboeck *et al.*, 1954) and 70% ("thrombocid"—May, 1951) to 54–66% for heparin (Merz, 1950) and 78% for heparin or thrombocid given in conjunction with dicoumarol (Fischer *et al.*, 1953).

In addition to its use as an anticoagulant for established cases of thrombosis, heparin has been advocated recently for prophylaxis and treatment in conditions associated with atheromatosis and accompanied by abnormally high plasma cholesterol and lipoprotein levels (Graham *et al.*, 1951). The biochemical abnormalities are said to be corrected and the clinical condition is improved thereby.

Preliminary observations suggest that dextran sulphate is similarly effective in "clearing" lipaemic plasma, altering the distribution of molecular species of lipoproteins and their electrophoretic mobilities, and lowering the plasma cholesterol, but that these effects occur with greater intensity and for a longer duration than the changes occurring with similar doses of heparin. Further work on this aspect of the clinical use of dextran sulphate will be reported later.

Although, in this series, alopecia was the only side-effect encountered which appeared to be directly related to dextran sulphate therapy, it must be emphasized that the accumulated experience with this anticoagulant is still small compared with that accruing from the extensive use of heparin. It is therefore still necessary to advocate careful clinical and pathological investigation of all cases in which dextran sulphate is used.

Moreover, although the overall anticoagulant effect of dextran sulphate resembles that of heparin, there is evidence that these two anticoagulants show both quantitative and qualitative differences when compared by a variety of methods (Mussett and Perry, 1955; Grasset and Schwartz, 1955; Astrup *et al.*, 1955; Soulier, 1955), due to differences in the nature of their interventions in the blood-coagulation mechanism (Forwell and Ingram, 1956). This suggests that further clinical experience will be necessary before a final evaluation can be made of the place of dextran sulphate in the treatment of thrombo-embolic disease.

Summary

Dextran sulphate, administered by intermittent intravenous injections to five patients suffering from thrombo-embolic disease, was found to have a marked cumulative effect when treatment was prolonged beyond three to five days. As a result reduction in the size of dosage and/or lengthened spacing of injections could be effected without materially affecting the clinical efficacy of dextran sulphate as an anticoagulant.

The cumulative effect in man could not be accounted for on the basis of the urinary excretion of a smaller percentage of the injected dose than that of heparin, the naturally occurring analogue of dextran sulphate.

A dosage schedule of dextran sulphate, similar in spacing of injections but larger in relation to body weight, did not produce a cumulative effect in rabbits. In this species a slightly larger proportion of the injected dose was excreted in the urine than the proportion found in man.

It is suggested that in man dextran sulphate differs from heparin in duration of effect because of a slower rate of metabolic breakdown in the body and consequent accumulation, probably in extravascular fluid.

In addition to its direct effect upon the blood-coagulation mechanism, dextran sulphate relieved oedema in cases of thrombophlebitis and produced effects similar to those of heparin on the plasma lipoproteins and plasma cholesterol.

Our thanks are due to Professor A. P. Thomson for his interest in this study, to Drs. E. Bulmer, C. F. Hawkins, G. M. Holme, and Clifford Parsons for permission to treat and publish details of cases under their care at the General Hospital and Queen Elizabeth Hospital, Birmingham. We are indebted to Dr. M. J. Meynell for determination of the prothrombin time and other pathological investigations and to Dr. H. A. Ellis for clinical assistance. The dexalate used in this investigation was generously supplied by Messrs. Glaxo Ltd. This work was carried out while one of us (S. M. J.) was in receipt of a grant from the Medical Research Committee, United Birmingham Hospitals Endowment Fund.

"Whatever the cause, it has been remarked at post-natal clinics how women at this stage [the early post-natal months] may indulge in very acrimonious comments about their husbands, especially in relation to their sexual demands. But this hostility, though virulent, is transient. Surely at this stage there is much conflict in the wives' minds, and they and their husbands need both support and comfort from society, rather than a demand that they should evince a bliss which theory and tradition expect. 'She's got everything she wants . . . a husband, a baby, a new home. She must be in her seventh heaven. What more can she want?' This style of comment only adds to the burden of guilt, when discontent arises. It may also induce the girl to wonder if she is abnormal, in that she cannot throw off anxiety and tension, and assume the glow which is the *sine qua non* of young mothers in magazines! Possibly now the first bitterness is sown. Certainly by the time the first child is 3 or so, it is quite common for the parents to need matrimonial guidance."—Mrs. HEIGER writing in the October issue of *Marriage Guidance*.

DEXTRAN SULPHATE: USE AS AN ANTICOAGULANT, AND ACTION IN LOWERING SERUM CHOLESTEROL

The sulphuric esters of several polysaccharides of high molecular weight possess an anticoagulant action similar to that of heparin (Chargaff *et al.*, 1936; Astrup *et al.*, 1944). Many of these compounds cause precipitation of fibrinogen (Astrup and Piper, 1946) and agglutination of platelets (Piper, 1945), and when injected into animals lead to intractable bleeding (Astrup *et al.*, 1944). Walton (1951, 1952, 1953, 1954) showed that dextran sulphates of high molecular weight had similar biological actions but that compounds of smaller molecular weight (about 7,500) caused no such toxic effects. Ricketts (1952) prepared and studied the properties of a series of sulphuric esters of dextran which differed in molecular weight and sulphur content. Dextran sulphate of molecular weight of about 7,500 was non-toxic, but toxicity developed with increasing molecular weight. Anticoagulant activity was independent of molecular weight but depended on the number of sulphate groups for each glucose unit. Ricketts and Walton (1953) prepared a dextran sulphate which had anticoagulant action but was not toxic.

A clinical trial of dextran sulphate of optimum molecular weight and sulphur content showed that this substance was an effective anticoagulant and had an action similar to but more prolonged than that of heparin (Ricketts *et al.*, 1953).

We report the effect on the clotting-time of single and repeated intravenous injections of dextran sulphate sodium ("dexalate") and describe the use of this drug in the treatment of thrombotic disease. The change in serum total cholesterol during prolonged treatment with dextran sulphate is also described.

Methods

Measurement of Clotting-time.—By venepuncture 2 ml. of blood was withdrawn, using a sterile dry syringe, and approximately 0.5 ml. of blood was added to each of three clean, dry test-tubes, 0.75 cm. internal diameter. The test was timed from the entry of blood into the syringe. The tubes were at once placed in a water-bath at 37° C., and at intervals of one minute each tube was lifted and tilted through 90 degrees. When the blood did not flow on tilting, the tube was inverted and gently shaken, to break the film of clot on the surface of the blood. The end-point was reached when no blood flow occurred with this manoeuvre. The average of the results from the three tubes was taken as the clotting-time. In the control of dextran sulphate therapy this method of estimating clotting-time was more satisfactory than determining the end-point of clotting by tilting to 90 degrees only. By the latter method lower values were obtained, which did not give a reliable guide to the control of dosage. In two patients an attempt was made to control therapy by clotting-times measured without inversion

and shaking of the tubes, but this led to overdosage with the development of toxic effects.

Estimation of Serum Total Cholesterol.—To 24 ml. of a mixture of equal parts of acetone and ethyl alcohol was added 1 ml. of serum and the mixture allowed to stand for 18 hours. It was then centrifuged and 5 ml. of the supernatant was evaporated to dryness. The residue was dissolved in 5 ml. of chloroform, and 3 ml. of a reagent prepared by mixing one part concentrated H_2SO_4 and 10 parts acetic anhydride was added to the solution. The mixture was placed in the dark at 20° C. for 20 minutes, and then the intensity of green colour was measured in a colorimeter (EEL), using Ilford 204 tricolor red filter. A standard solution of cholesterol in chloroform was estimated with each batch of sera. To exclude physico-chemical interference with the estimation, samples of blood from untreated patients were divided into two portions. To one portion was added dextran sulphate to produce a concentration of 1% (three samples) and 0.1% (one sample), and to the other an equal volume of saline. The serum total cholesterol was then estimated. On no occasion was there a difference greater than 5 mg./100 ml. between the serum total cholesterol of each pair. Thus dextran sulphate in concentrations of 0.1 and 1% did not interfere with the method by which serum total cholesterol was estimated.

Standardization of Dextran Sulphate.—The anticoagulant activity of dextran sulphate was at first assayed in terms of international standard heparin units. This was unsatisfactory, and a new unit of dextran sulphate has been defined as the activity of 0.04 mg. of a standard preparation of dextran sulphate kept in the Department of Biological Standards, National Institute for Medical Research, London (Mussett and Perry, 1956). One dextran sulphate unit is approximately equivalent in anticoagulant activity to one international unit of heparin. We have expressed all doses of dextran sulphate in terms of standard dextran sulphate units.

Effect on Clotting-time of a Single Intravenous Injection of Dextran Sulphate

A single intravenous injection of 7,500 units of dextran sulphate was given to each of six volunteers, and the clotting-time was measured during the following eight hours. The initial clotting-time before the injection was the average of three separate estimations.

Table I shows that in four of the six cases the clotting-time was prolonged to more than twice the initial level for six hours. In the other two cases the corresponding periods of prolongation were about three and five hours respectively.

TABLE I.—Effect on Clotting-time of Single Intravenous Injection of 7,500 Units of Dextran Sulphate

Patient	Patient's Weight (Kg.)	Initial Clotting-Time (Min.) (Mean of Three)	Clotting-time (Min.) at Intervals After Dextran Sulphate				
			30 min.	2 hr.	4 hr.	6 hr.	8 hr.
1	43.2	5	23	22	16	14	10
2	67.8	8	64	25	21	20	14
3	67.6	5	20	12	12	10	8
4	61.0	6	22	13	7	7	—
5	72.2	6	26	29	20	12	10
6	81.2	8	77	33	24	8	—

Effect on Clotting-time of Repeated Intravenous Injections of Dextran Sulphate

Repeated intravenous injections of dextran sulphate were given to 11 patients, of whom seven had acute myocardial infarction, three had persistent angina following a previous myocardial infarction, and one had thrombosis of the inferior vena cava. In each case the clotting-time before starting treatment was the average of three separate estimations. An attempt was made to prevent the clotting-time falling below twice the level before treatment. The dose of dextran sulphate was kept constant at 5,000 units, and the frequency of dose was varied, depending on the clotting-time, which was measured at intervals during each day.

It was found that injections were required eight-hourly during the first 24 hours. Thereafter the frequency could be reduced, and after 48 hours the clotting-time could be maintained at a minimum of twice the pre-treatment level with injections every 12 hours. In all patients who continued treatment long enough, one injection every 24 hours was sufficient from the eleventh day onwards, and in most patients this dosage was sufficient much earlier. In nine courses of treatment with dextran sulphate lasting 14 days or longer the average dose on each day is shown in Fig. 1. Illustrative cases showing the control of the clotting-time by repeated doses of dextran sulphate are shown in Figs. 2 and 3. The clotting-times recorded were measured immediately before the next injection was given—that is, they are minimum values.

FIG. 1.—Average dose of dextran sulphate on each day of treatment in nine cases.

FIG. 2.—Control of clotting-time during treatment with dextran sulphate in a patient with persistent angina following myocardial infarction. Twice the clotting-time before treatment is indicated by the broken line.

At the end of treatment the return of the clotting-time to normal was gradual, taking three to four days.

The variation in clotting-time during 24 hours after an injection of 5,000 units of dextran sulphate was studied in one patient on the first and fourteenth days of treatment.

FIG. 3.—Control of clotting-time during treatment with dextran sulphate in a patient with acute myocardial infarction. Twice the clotting-time before treatment is indicated by the broken line.

Following this there was an abrupt initial rise followed by a steady fall, to reach twice the patient's normal value in five hours (Fig. 4). In the second series of observations, made when the patient had been stabilized on one injection of dextran sulphate daily, there was a similar initial rise, but the fall was much more gradual, and a satisfactory

anticoagulant effect persisted for over 24 hours (Fig. 4). It should be noted that in both series of observations the clotting-time immediately before the injection was prolonged to approximately the same extent.

FIG. 4.—Change in clotting-time following an intravenous injection of 5,000 units of dextran sulphate on the first day of treatment (first observation) and the fourteenth day of treatment (second observation) in the same patient.

Effect of Dextran Sulphate on Serum Total Cholesterol

In nine cases the serum total cholesterol was measured before and at intervals during treatment with dextran sulphate; the results are shown in Fig. 5. The value for serum cholesterol before treatment is the average of at least two separate estimations, and in each case not less than four subsequent values were obtained and expressed as percentages of the initial value. There was a marked fall in serum total cholesterol in all cases, reaching 50–60% of the initial level after 6–12 days of continuous treatment. The average value of serum total cholesterol before treatment, the lowest level recorded, and the day of treatment on which this occurred are shown in Table II.

FIG. 5.—Change in serum total cholesterol during treatment with dextran sulphate in nine cases.

FIG. 6.—Change in serum total cholesterol in a patient with familial hypercholesterolaemia (1) during and after continuous treatment with dextran sulphate (upper curve), and (2) during a second course of continuous treatment followed by weekly injections (lower curve).

began to revert towards the original level. In six of these patients it was noted that the rise corresponded with the reduction in dosage from 10,000 to 5,000 units daily.

A patient with familial hypercholesterolaemia was given two courses of dextran sulphate, and a profound fall in serum total cholesterol occurred on both occasions (Fig. 6).

Thirteen days after the first course of treatment had been stopped the serum total cholesterol was still only 76% of the original value. After the second course of treatment weekly intravenous injections of 5,000 units of dextran sulphate were given, and at first the reduction in serum cholesterol appeared to be maintained; but these weekly injections did not prevent the return of serum total cholesterol to its original level within 28 days (Fig. 6).

TABLE II.—Maximum Fall in Serum Total Cholesterol During Dextran Sulphate Treatment

Patient	Average Serum Total Cholesterol Before Treatment (mg./100 ml.)	Lowest Serum Total Cholesterol (mg./100 ml.)	Day of Treatment on which Serum Total Cholesterol was Lowest
1	486	287	11
2	486	254	7
3	258	115	22
4	320	190	10
5	230	125	12
6	207	115	9
7	180	105	9
8	292	180	7
9	435	205	10

Patient 1 received two separate courses of treatment.

One patient, whose serum total cholesterol at the end of continuous treatment was approximately 60% of the original level, was given weekly intravenous injections of 5,000 units of dextran sulphate. With this dosage the reduction in serum total cholesterol persisted for only seven days. Another patient, whose serum total cholesterol at the end of continuous treatment was 78% of the value before treatment, was given weekly injections of 10,000 units of dextran sulphate. In this case the cholesterol had returned to its original level in nine days and thereafter did not fall.

Toxic Effects

A mild degree of alopecia was observed in three male patients, occurring after 14–21 days of continuous treatment. No other toxic effects were noted in this series of patients when the dosage of dextran sulphate was controlled as described above. Two additional patients, not included in the present study, developed diarrhoea, with the passage of blood in the stools after 14 days of treatment. The dosage in these two cases was controlled by clotting-times measured by simply tilting the tubes, without inverting and shaking, with the result that lower values of clotting-time were recorded. In an attempt to maintain prolongation of the clotting-time, a higher dosage of dextran sulphate was given to these two patients than to any of the other patients. There was a profound fall in serum total cholesterol in both these cases, from 230 to 65 mg. and from 340 to 130 mg. per 100 ml. respectively.

Discussion

At present the regime of anticoagulant therapy most frequently employed is intravenous injections of heparin, usually given at six-hourly intervals for two days, followed by oral administration of ethyl biscoumacetate or phenindione. A serious drawback to the use of heparin is that frequent intravenous injections are required to maintain an adequate prolongation of the clotting-time.

We have shown that following a single intravenous injection of 7,500 units of dextran sulphate, the clotting-time was prolonged to more than twice the normal for four to six hours. Duff *et al.* (1951) reported that an intravenous injection of 7,500 units of heparin resulted in lengthening of the clotting-time to twice normal for only three to four hours. The response of different subjects to a single dose of dextran sulphate was variable, as with heparin (de Takats, 1943).

A more important finding is the cumulative effect of dextran sulphate. Three injections, each of 5,000 units, were required in the first 24 hours, but thereafter the frequency of dosage decreased, so that with most patients injections at

12-hourly intervals were sufficient to maintain suitably prolonged clotting-times from the third or fourth day of treatment onwards. The frequency of dosage could be further reduced to once daily after 5 to 11 days of treatment.

We have tried to keep the clotting-time continuously greater than twice normal and have not allowed it to fall to an almost normal level between injections, as is often permitted during heparin treatment.

In all patients cumulation has proceeded until eventually one injection of 5,000 units every 24 hours was sufficient. Thereafter no further cumulation appeared to occur, although two patients were treated for a further period of over two weeks with 5,000 units every 24 hours. Ricketts *et al.* (1953) also obtained evidence of an additive effect after several injections of dextran sulphate.

Dextran sulphate appears to be a suitable substitute for heparin in initial anticoagulant treatment. Heparin is commonly used only for 48 hours until ethyl biscoumacetate or phenindione has become effective; for this purpose the present results suggest that 5,000 units of dextran sulphate given eight-hourly for 24 hours and then 12-hourly for a further 24 hours would be safe and effective in prolonging the clotting-time.

Continuous treatment over a period of several weeks is a practical procedure with dextran sulphate, as with many patients one injection daily sufficed after the first week. This has some advantages over the combination of heparin and oral anticoagulant. One venepuncture daily for the injection of dextran sulphate is not any more arduous than the daily venepuncture required to obtain blood for estimating the prothrombin time. Our results suggest that, once the period of maintenance treatment is reached, estimations of clotting-time are necessary only every two or three days. As with heparin, the anticoagulant effect of dextran sulphate can be quickly neutralized with protamine sulphate (Walton, 1951).

Reports have appeared of certain other sulphated polysaccharides—the polysulphuric esters of polyanhydromannuronic acid, polyhexuronic acid, and polygalacturonic acid—which have been found to have clinical value as anticoagulants (Seifter and Begany, 1948; Hirschboeck and Madison, 1950; Mangieri *et al.*, 1951; Scholz and Barker, 1951). There have been several reports of undesirable side-effects following the use of these compounds; the commonest toxic manifestations appear to have been alopecia and diarrhoea (Hirschboeck *et al.*, 1954), but generalized vasomotor collapse has also occurred (Sorenson and Wright, 1950).

Since Hahn (1943) showed that an injection of heparin cleared the turbidity of lipaemic plasma in dogs, many workers have confirmed this in man (Anderson and Fawcett, 1950; Block *et al.*, 1951; Utz *et al.*, 1953). There is evidence that the degree of clearing of turbidity of alimentary lipaemia by heparin is less in coronary artery disease than in normal persons (Block *et al.*, 1951; Oliver and Boyd, 1953). It has been shown that transient changes in the distribution of the lipoprotein fractions occur after the injection of heparin (Graham *et al.*, 1951; Rosenberg, 1952; Chandler *et al.*, 1953), but most workers have noted no effect on the total amount of cholesterol in the blood following a single injection of heparin (Anderson and Fawcett, 1950; Block *et al.*, 1951; Eder and Russ, 1952; Chandler *et al.*, 1953; Herzstein *et al.*, 1954; Soffer and Murray, 1954).

Repeated doses of heparin at intervals of 2 to 14 days kept the lipoprotein pattern altered in some patients but had little or no effect on the serum cholesterol (Graham *et al.*, 1951). However, Basu and Stewart (1950) reported that heparin in therapeutic doses produced a fall in the level of serum cholesterol after 24 hours, and Hollister and Kanter (1955) found that in two patients with essential hyperlipaemia intravenous injections of 100 mg. of heparin three times weekly produced a fall in all fractions of the blood lipids. Daily intramuscular injections of heparin in chicks produced a small decrease in total plasma cholesterol and other lipid fractions after four weeks (Opdyke *et al.*, 1955).

W. D. Brown (1952) reported that dextran sulphate had similar effects to heparin in clearing alimentary lipaemia, and single doses of other polysulphated esters of polysaccharides—"treburon" and "paritol"—have also been shown to clear alimentary lipaemia (Brown *et al.*, 1952; Ackerman and Zilversmit, 1953) without influencing serum cholesterol levels (Zinn *et al.*, 1952). On the other hand, Chandler *et al.* (1953) found that treburon given by buccal absorption produced a significant reduction in serum cholesterol and serum phospholipids five to seven hours after administration. Treburon given under these conditions had no effect on the clotting-time.

We have shown that intravenous injections of 5,000 units of dextran sulphate two or three times daily consistently produced a profound fall in serum total cholesterol. This reduction in cholesterol was not maintained when the dosage was reduced to 5,000 units daily in response to the lengthened clotting-time. With the methods of administration investigated so far, it has not been found possible to produce a sustained fall in the serum total cholesterol without an excessive prolongation of the clotting-time.

Summary

A single intravenous injection of 7,500 units of dextran sulphate produced an increase in the clotting-time to more than twice normal for four to six hours.

With repeated injections of dextran sulphate, cumulation occurred so that the clotting-time could be maintained at more than twice normal by a dosage of 15,000 units in the first 24 hours, 10,000 units daily for the next 4 to 10 days, and thereafter 5,000 units daily.

During treatment with dextran sulphate there was at first a profound fall in serum total cholesterol. This reduction persisted only while the dosage was 10,000–15,000 units daily.

It is suggested that dextran sulphate is an effective anticoagulant for clinical use and provides a possible alternative to the usual combination of heparin and oral anticoagulant. However, toxic effects may occur, particularly if the dose is not carefully controlled.

The development of a mild degree of alopecia was observed in three male patients. Overdosage in two cases resulted in diarrhoea, with the passage of blood in the stools.

We wish to express our thanks to Professor G. M. Wilson for much helpful advice and criticism; to Dr. A. Jordan and the staff of the Department of Chemical Pathology, Royal Infirmary, Sheffield, who performed all the estimations of serum total cholesterol; to Dr. H. Swan, for assistance with the early part of the work; and to Glaxo Laboratories Ltd., who supplied the dextran sulphate used in this work.

PLACE OF DIRECT SURGERY IN TREATMENT OF OBLITERATIVE ARTERIAL DISEASE*

BY

CHARLES ROB, M.Chir., F.R.C.S.

Professor of Surgery, St. Mary's Hospital, London

Obliterative arterial disease may be due to a variety of causes, including thrombosis after an injury, coarctation of the aorta, thromboangiitis obliterans, an embolus, or the condition of so-called primary arterial thrombosis. I shall not discuss the place of direct surgery in the treatment of these lesions beyond mentioning that it is the best treatment for coarctation of the aorta and for thrombosis of a major artery after an injury, a good treatment for primary thrombosis and some emboli, but only occasionally possible in patients with thromboangiitis obliterans. I am concerned mainly with atherosclerosis and the place of arterial reconstruction operations in the treatment of this all too common disease.

Atherosclerosis is a general disease which affects the arteries of the whole body, and it is an important principle that an arterial reconstruction operation can have only a local effect. Therefore this type of surgery is justified only when the local manifestations of this general disease predominate to an unusual extent. In many patients symptoms arise from the occlusion of several arteries, and it is obviously a mistake to reconstruct the femoral artery of a patient who suffers from angina pectoris and intermittent claudication. On the other hand, it is justifiable to reconstruct the femoral artery of a patient who suffers from angina pectoris and gangrene of a toe; from the patient's point of view an arterial reconstruction operation is a smaller procedure than a major amputation (Rob, Eastcott, and Owen, 1956). Fortunately, in a fair proportion of patients atherosclerosis remains relatively localized. This is particularly so in patients with occlusion of the abdominal aorta or iliac arteries, and sometimes so in those with thrombosis of the popliteal, femoral, carotid, mesenteric, renal, and subclavian vessels. In my view, at least 50% of patients with occlusion of the abdominal aorta and iliac arteries are suitable for a reconstruction operation, about 25% of those with femoro-popliteal thromboses, and probably about 5% of those with an internal carotid thrombosis, although this latter figure is merely a rough estimate.

*Carbutt Memorial Lecture delivered at Guy's Hospital on May 29, 1956.

Thrombosis of Abdominal Aorta and Iliac Arteries

The symptoms produced by this lesion are variable. One patient may be able to walk slowly for half a mile before the onset of the pain of intermittent claudication, and another with an almost identical thrombosis may have gangrene; the symptoms depend upon the efficiency of the collateral circulation. From a surgical point of view this lesion may be divided into two types—the extensive occlusion extending from the iliac arteries below to the renal arteries above (Fig. 1), and the localized occlusion usually confined to the region of the bifurcation of the abdominal aorta (Fig. 2).

FIG. 1.—Thrombosis of the abdominal aorta in a man aged 36. The occlusion has reached the renal arteries and there is a partial occlusion of the left renal artery. The patient had grade IV hypertension with a blood pressure of 210/110.

FIG. 2.—Thrombosis localized to the region of the aortic bifurcation. This patient, a woman aged 34, had gangrene of her right foot. An arterial reconstruction was successful.

It is a relatively simple matter to restore the blood flow in most of the patients with the localized type of occlusion. We have had only one death out of 28 such operations and only two recurrent thromboses, and each of these affected only one iliac artery. On the other hand, those with high occlusions present a major problem and require a major operation. For these patients it is necessary to clamp the aorta above the renal arteries and insert a plastic prosthesis or homologous arterial transplant from this level to the iliac arteries. Two of our seven patients with this lesion have died as a result of the operation, both from renal failure, but the risk of this has been reduced by using hypothermia. Because of the good results obtained with surgery in those patients with localized occlusions and the high mortality of conservative care in those with an occlusion which has

reached the mouths of the renal arteries, we now advise operation in the majority of patients with thrombosis of the abdominal aorta, exceptions being those with clinical coronary artery disease and those with evidence of active generalized atherosclerosis. It may be only after inspection of the arteries at operation that this latter group can be diagnosed.

The high mortality of occlusions which have reached the renal arteries is due to renal failure or hypertension. The former is due to occlusion of both renal arteries, with infarction of the kidneys, but the latter is of special interest. Thrombosis of the abdominal aorta at the level of the renal arteries does not cause hypertension. Fig. 3 is the blood-

FIG. 3.—Blood-pressure chart of the patient whose aortogram is shown in Fig. 1. When he was first seen his blood pressure was normal, but following the partial occlusion of the left renal artery severe hypertension developed. This was relieved by surgery.

pressure chart of the patient whose aortogram is shown in Fig. 1. When first seen in 1953 at the age of 35 he had a normal blood pressure and an occlusion of the abdominal aorta in the region of its bifurcation. Operation was advised but refused. He was kept under observation, and in 1954 his blood pressure rose to 220/110; he still refused operation, but by late 1955 he was crippled by hypertensive headaches and his vision was failing, with papilloedema and retinal haemorrhages. The aortogram (Fig. 1) now showed a partial occlusion of the left renal artery. Reconstruction of the aorta and removal of this kidney lowered his blood pressure to normal (Fig. 3) and cured his symptoms. We have had two patients of this type; the other was successfully operated on in 1952 and is well to-day. These patients raise the interesting point of the place of atherosclerosis of the renal arteries in the production of hypertension (Howard, Berthrong, Gould, and Yendt, 1954). A partial occlusion of this type may produce a Goldblatt type of renal lesion, and in my view it is worth doing aortograms on a proportion of patients with severe essential hypertension to see if one cannot detect a localized lesion of this type.

Femoro-Popliteal Artery

Patients with occlusion of this artery present either with the symptom of intermittent claudication as their main complaint or with rest pain and gangrene. For those with rest pain and gangrene an arterial reconstruction operation is the treatment of choice, because the alternative is usually a major amputation. It is surprising how often it is possible to save the limb of such a patient. In our experience such a procedure is possible for about 20% of patients with gangrene of the toes and feet; we have saved twenty such limbs, and two were diabetics. A patient with gangrene and clinical evidence of an aortic, iliac, or femoro-popliteal thrombosis should have an arteriogram to see if his limb could be saved. While this may well mean four or five arteriograms for each successful arterial reconstruction, the

results, particularly in patients below 65 years of age, should be worth the trouble.

On the other hand, the symptom of intermittent claudication presents quite a different problem. Fully 80% of such patients have a lesion, usually of the femoro-popliteal artery, which is anatomically suitable for arterial reconstruction, but only about 25% or less should be treated surgically, and this applies to both the end-to-end and the by-pass types of operation. This latter method is the best, but in my view the selection of patients should not be relaxed, chiefly because of the general nature of this disease. Patients with femoro-popliteal thromboses often have coronary atherosclerosis. We have one simple rule: a patient with intermittent claudication due to a femoro-popliteal thrombosis should have an arterial reconstruction operation only if he is unable to work. The business man who can do his work but who cannot play golf should be treated conservatively.

Table I shows the results we have obtained with direct surgical operations in patients with obliterative arterial disease, the procedures being either thrombo-endarterectomies or arterial reconstructions by the end-to-end or by-pass technique. The follow-up is between one and six years.

TABLE I.—Follow-up. Arterial Reconstruction Operations in 109 Patients with Obliterative Arterial Disease

Artery	No. of Patients	Thrombosed in Hospital	Thrombosed Later	Now Patent
Aorta and iliacs	35 (3 died in hospital)	1	1 (+ 1 dead since discharge)	29
Femoral	48	11	15 (+ 2 dead since discharge)	20
Popliteal	17	1	5	11
Others	9	2	3	4

It is of interest that patients with popliteal occlusions have done a little better than those with femoral blocks, because this is against the general trend, where the larger the vessel is the better are the results. A possible explanation of this may be that the collateral circulation is very much better around a femoral than around a popliteal thrombosis. This means that occlusion of the popliteal artery produces major symptoms early in its course, whilst a similar occlusion of the femoral artery may produce little disturbance, and so surgery becomes necessary only in those patients with marked atherosclerosis. In my view, the state of the host artery is a major factor in the late recurrence rate in these patients; in general, those with severe atherosclerosis do badly.

Carotid Arteries

Occlusion of the internal carotid artery often begins as a plaque of atheroma situated just above the carotid bifurcation. In most patients the occlusion is complete and direct surgery cannot do any good, but in a minority the occlusion is partial and the patient can be cured by surgery (Eastcott, Pickering, and Rob, 1954). These nearly complete occlusions may produce intermittent cerebral symptoms or the effects may be continuous; in either case the results of surgery may be dramatic. In one of our patients the continuous neurological abnormalities included a partial right-sided hemiplegia and the patient was unable to sign his own name; an arterial reconstruction operation has removed all his abnormal physical signs and he has returned to work in a responsible position with a shipping company. It is important to stress that many cerebral arteriograms fail to include the carotid bifurcation on the x-ray film, and this will fail to demonstrate such a lesion. Carotid arteriograms, in common with all other arteriograms, must show the site of needle puncture on at least one of the films.

Arteries of the Upper Limb

It is most unusual for thrombosis of one of these vessels to need a reconstruction operation, because the collateral

circulation is usually so good. However, on four occasions we have reconstructed such vessels (subclavian and axillary) in patients who were unable to work because of the symptoms of ischaemia, and the results have been worth while.

Type of Reconstruction Operation

Table II gives our results with the various arterial reconstruction operations in all our patients over the last six years irrespective of the reason for the operation, and Table III lists the disease for which the artery was reconstructed.

For patients with obliterative arterial disease it is only occasionally possible to resect the occluded segment and restore continuity by a direct end-to-end anastomosis, but when this can be done it is the best procedure. In my view the next most satisfactory operation is thrombo-endarterectomy. This is of particular value in localized occlusions of the aorta and iliac arteries, but it is sometimes of value in vessels as small as the popliteal. Two important

TABLE II.—Method Used in 228 Arterial Reconstruction Operations

Operation	No. of Patients	Thrombosed Early and Late	Dead (including Operation Deaths)	Now Patent
Direct suture	25	1	3	21
Thrombo-endarterectomy	24	5	1	18
Autogenous vein	25	15	4	6
Homologous artery	109	34	10	65
Plastic cloth	19	0	5	14
Polyvinyl alcohol	26	9	5	12

TABLE III.—Reason for Operation in the 228 Patients Listed in Table II

Reason	No. of Patients	Thrombosed Early and Late	Dead (including Operation Deaths)	Now Patent
Injury	17	5	4	8
Congenital abnormality	12	0	0	12
Aneurysm or A-V fistula	85	19	16	50
Obliterative disease	109	39	6	64
Malignancy	5	1	2	2

points in choosing patients for this procedure are the size of the thrombosed segment and the state of the vessel wall of the proximal and distal to the occlusion, but, as the tables show, with careful selection the results have been very good. In our hands autogenous vein grafts have given good results. The disappointing results in patients with atherosclerosis. The tables show that homologous arteries have been satisfactory, and most of the thromboses in this group have been in patients with obliterative disease of the femoral and popliteal arteries; but the maintenance of an artery bank is by no means easy, and so we use a plastic prosthesis, either of plastic cloth or of polyvinyl alcohol sponge, for the reconstruction of the aorta and iliac arteries.

Anticoagulants

We use anticoagulants locally during the operation, and then from the third or fourth post-operative day as a long-term measure in patients with obliterative arterial disease. The idea is that these patients are likely to thrombose their arteries, either the one which has been reconstructed or another such as the coronary. Long-term anticoagulant therapy possibly reduces the incidence of this. Since 1952 we have kept many of our patients on phenindione ("dind-evan") in sufficient dosage to prolong the prothrombin time to just less than twice the patient's control level. It has caused little trouble beyond the need for regular control, and we now do not even stop the drug for such procedures as another surgical operation. With the prothrombin time at this level one can operate and fail to notice any change in the patient's bleeding. The value of this measure is still unproved.

Conclusion

Our follow-up shows that with careful selection the results of direct surgery in the treatment of obliterative arterial disease can be good. They are best in patients with occlusions of the aorta and iliac arteries and they are most gratifying in patients with gangrene of the toes and feet, cerebral symptoms due to partial internal carotid occlusion, or hypertension. Good results also follow the reconstruction of the femoro-popliteal artery in patients with intermittent claudication, but here selection is particularly important. In my view the by-pass type of operation is the best procedure for occlusions of this vessel, but its reintroduction has not widened the indications for surgery in patients with this general disease, unless the reason for operating is gangrene or rest pain.

SOME DELAYED COMPLICATIONS OF INOCULATION

BY

PHILIP W. ROBERTSON, M.D., M.R.C.P.
Wing Commander, Medical Specialist, R.A.F.

AND

BRIAN J. LEONARD, M.D.
Late Squadron Leader, R.A.F.

For several years we have been aware of a number of curious disturbances which may occur during the first or second week after inoculation or vaccination. This paper is based upon a large number of clinical observations; no attempt is made to offer a detailed explanation of these disturbances, but rather to consider in what way they fit into the disease pattern of other syndromes and what is their long-term significance.

It has long been known that reactions could follow various inoculation procedures, and such reactions have usually been considered under "immediate reactions," as the delayed "serum sickness" type of reaction, or as anaphylactic reactions. We have not been particularly concerned with immediate reactions and have not met with any true anaphylactic reactions, but in the group of conditions related to serum sickness we have found the greatest variety of disease syndromes.

Present Investigation

With few exceptions, our observations were made upon young healthy adult recruits between the ages of 18 and 20. Within the first few weeks in the Service these recruits received various inoculations and all were vaccinated. As a rule, the first T.A.B.T. injection was given at the same time as the vaccination, and most of our observations were made in the period one to two weeks after this double procedure. A second T.A.B.T. injection was given six weeks after the first, following which only occasional reactions were seen. This can be attributed to various factors, but chiefly to the fact that those who reacted to the first injection were not usually subjected to a second, while those who did

not react to a first injection rarely experienced trouble with injections given subsequently. Isolated cases have occurred after other procedures, and are mentioned later.

A large number of recruits pass through the region in which our group of four hospitals is situated, and approximately 200,000 have been inoculated and vaccinated during the past few years. We therefore had an excellent opportunity of studying a number of relatively rare occurrences in addition to the more frequent and minor disturbances. We have no accurate means of determining the actual incidence of major delayed reactions, but can give a rough estimate of some 0.25 to 0.3% of all those inoculated.

The delayed reactions usually occurred some seven to ten days after inoculation and, as already stated, corresponded approximately to the serum-sickness group. It is interesting to note that the great majority of delayed reactors experienced no immediate local reaction; and conversely, those who suffered immediate reaction did not have these delayed disturbances. The delayed reactions appear to affect chiefly the joints and the reticulo-endothelial system, though other tissues and systems may become involved.

No major neurological sequelae of the type described by Miller and Stanton (1954) were noted to follow inoculation. However, a number of patients developed headaches, meningism, and even stupor as a transitory symptom-complex, associated with the appearance of a few lymphocytes and a slight rise in protein in the cerebrospinal fluid. These cases were usually of too short duration (24-48 hours) to allow of detailed investigation, and none, so far as we know, has subsequently developed neurological trouble.

Very occasionally the reaction seems to have started off an irreversible cycle of events leading to the appearance of a syndrome resembling the collagen disorders.

Arthropathies

Such a wide variation in these joint manifestations occurred that to present a typical case would be misleading. A single large joint may be swollen and painful; a number of joints may be involved in succession; or there may be stiffness and pain only, without obvious swelling. Marked constitutional upset with high fever, sweating, tachycardia, and the like may be present or there may be little or no general upset.

Joint symptoms may subside rapidly and spontaneously or persist for long periods and respond to treatment with difficulty. In many cases it has proved difficult or impossible, on clinical grounds, to differentiate a delayed allergic arthropathy from a "rheumatic fever"; similarly, syndromes resembling acute rheumatoid arthritis and acute rheumatic carditis have followed an inoculation reaction. It would appear to be of great importance to establish a connexion between these artificially induced syndromes and those which occur spontaneously; for their differentiation is in some cases difficult because the disease process is identical.

So far as the arthropathies are concerned, the clinical differentiation is usually a matter of degree; thus, in typical "acute rheumatic fever" in this age group the E.S.R. is usually higher, the joint symptoms are more severe, and the constitutional disturbance is greater than in the allergic arthropathies. In many cases, however, these extremes are not present and there are no satisfactory criteria other than the history of recent inoculation. The early therapeutic trial of salicylates is not to be recommended. Whether they are used or not, the symptoms may subside rapidly; in the case of the allergic reactions because of spontaneous remission, and in the rheumatic fevers because of the specific therapeutic effect. Thus, if the patient be rendered symptomless at too early a date the whole picture becomes obscure and it is never entirely clear what the original disease was. This, of course, is of tremendous long-term significance to the patient, for a past history of rheumatic fever might be held

against him medically for the rest of his life, whereas a transient allergic arthropathy would usually be entirely disregarded.

The picture is made more confusing by the apparent risk of precipitating a "true rheumatic fever" in patients who have a history of rheumatic fever in childhood or who give a strong family history of rheumatic disorders. We have in many cases noted a history of joint pains in childhood, but such a history must be accepted with caution, for it is quite possible that some of these patients were experiencing an allergic arthropathy from some other antigen. The risk of inducing an irreversible rheumatic syndrome following T.A.B.T. inoculation is greatly increased when there is a strong constitutional tendency to such trouble; therefore great care should be taken in the administration of any allergy-provoking substances in such cases.

We have seen several cases in which an apparently allergic syndrome followed ten days after inoculation and developed into a typical acute rheumatoid picture, although starting with just the same large-joint involvement as any rheumatic fever. In one such case, of great severity, spindling in the fingers and wasting of the small muscles of the hand developed, and nodules were noted in the limbs. Biopsy of the latter proved them to be recent rheumatic nodules. This patient responded only to cortisone, rapidly and dramatically improving to an apparently complete "cure," and did not relapse after treatment was stopped. He has remained well during the subsequent few months that we have seen him. In his case there had been no previous rheumatic trouble, but his mother had suffered from a severe rheumatoid arthritis.

We originally intended to regard any patient who developed a carditis as a case of true rheumatic fever, but we were forced to change our view up to a point, because several cases developed cardiac involvement, confirmed by E.C.G., in the course of a febrile rheumatic illness occurring in the second week after inoculation. In two such instances an aortic leak was heard during the course of the illness, though no clinical evidence of valvular damage remained after recovery. Cortisone was again found to be effective when salicylates had failed to control the illness. In three other cases originally regarded as simple allergic arthropathies a transient heart-block was noted, and two of them showed a Wenckebach phenomenon.

Those with monarticular lesions may be referred to hospital as suffering from a traumatic or other orthopaedic condition. It is interesting to note that trauma may, in fact, play a part in the appearance of a delayed joint reaction, just as it may in other rheumatic or gouty conditions, whether the trauma be old or recent.

Collagen Disorders

We have so far commented chiefly upon the arthropathies, these forming the group most often seen. However, at least one case developed a generalized "collagen disorder" strongly suggestive of periarteritis nodosa, though histological proof was lacking. This patient was admitted seven days after vaccination and T.A.B.T. inoculation; he had a gross purpuric eruption over the ankles and lower limbs, and there was swelling of the ankle- and knee-joints. He had a high swinging fever and appeared to be very ill; he developed a number of curious necrotic skin lesions, and later a perforation of the nasal septum about a quarter of an inch (6 mm.) in diameter. No evidence of septicaemia could be obtained from a blood culture or by other means, and none of the skin lesions became infected. There was marked albuminuria with microscopic haematuria and some elevation of the blood pressure. During the first few days no specific therapy was given, but when it became apparent that the condition would not spontaneously subside salicylates were administered in full dosage, and, as these had proved ineffective in doses of 240 gr. (16 g.) a day, cortisone was given, with immediate and lasting effect. There was no relapse, and the patient has remained well, though there was slight residual albuminuria.

Reticulo-endothelial Disturbances

Splenic enlargement was noted so often in subjects who had received T.A.B.T. and vaccination that it is now regarded as a common finding in the few weeks subsequent to inoculation. It may appear without any other evidence of a delayed reaction, and sometimes occurred in association with slight enlargement of the liver, and occasionally with a more generalized lymph-node enlargement. Two or three cases were seen with a mild transient jaundice occurring ten to fourteen days after inoculation, but there was no evidence of haemolysis to account for the jaundice. Another occasional finding was abdominal pain, particularly in the right iliac fossa, which may well be almost indistinguishable from acute appendicitis. A number of such patients were operated on, and the only findings were enlarged ileo-caecal lymph nodes which histologically showed a non-specific inflammatory reaction. These various findings in the spleen, liver, and abdominal glands all suggest a reticulo-endothelial disturbance, and one would therefore expect to find bone-marrow and probably peripheral blood changes in addition. This, in fact, is so. Many bone-marrow smears were examined, and frequently a slight preponderance of reticulum cells was present. In peripheral blood there was often an unexplained increase in abnormal mononuclear cells in the seven to ten days after inoculation, whether or not the patient had had a reaction.

Disturbances associated with purpura were a most important group. Twenty-two cases were studied in detail, and, in addition, large numbers of transient mild purpuric eruptions were seen. The connexion between these cases following inoculation and the syndrome of "idiopathic purpura" seems to us to be extremely close, and this clinical impression is substantiated by much previous published work on acute vascular purpura. Thus Whitby and Britton (1953) stated: "The aetiology [of acute vascular purpura] is ill-understood, but there is evidence to suggest that the acute vascular purpura may be the result of an immunological disturbance affecting the small blood vessels throughout the body."

In the anaphylactoid group of purpuras the process is regarded as immuno-allergic, affecting the epithelium of the blood vessels, joints, intestinal tract, and renal glomeruli; and relapse in the so-called essential thrombocytopenic purpura is thought by many to be of a similar nature.

Tocantins (1936) showed that platelets are antigenic and that they are antigenically similar to capillary endothelium. Clark and Jacobs (1950) prepared an antiserum from vascular endothelium, and after injection haemorrhages into the skin and internal organs were seen which did not cause any reduction in the platelets.

Whitby and Britton (1953) have summarized existing knowledge by suggesting that: "In principle, the antigen, an infection, a drug, or a toxin for example, may be regarded as forming a complex with capillary endothelium or platelets, thereby initiating active immunization. The resulting antibodies may have a potentiality for damaging endothelium or destroying platelets, or both. There is little doubt that many cases, at one time thought to be essential thrombocytopenia, have in fact been immuno-allergic vascular phenomena arising from the sensitization of some foreign or noxious substance."

Many of our cases of purpuric eruptions following inoculation were severe and bleeding occurred into the skin, into the bowel, and into the genito-urinary tract.

Typical Cases

The findings in some typical cases are here briefly described.

A youth of 18 complained of swollen, painful ankles ten days after T.A.B.T. and vaccination. Both ankles were grossly swollen, tender, and painful, and a petechial rash was present over the lower limbs. Hess's test was strongly positive. Blood findings: haemoglobin, 12.4 g./100 ml.; P.C.V., 39%; E.S.R.,

87 mm. in one hour; W.B.C., 10,200 per c.mm.; platelets, 350,000 per c.mm.; bleeding-time, clotting-time, blood films, and marrow films, normal. After four days the swelling and rash subsided and within four to five weeks the E.S.R. and haemoglobin had resumed normal levels and the patient was entirely symptomless.

In the following case an apparently pre-existent bleeding tendency was brought to light by inoculation and produced a severe episode.

A girl of 18 had a widespread and well-marked petechial rash ten days after T.A.B.T. inoculation; she gave a history of always bruising extremely easily and having had repeated small epistaxes. The skin rash became confluent in parts to form ecchymoses, and blood was found in the urine and stools. The liver and spleen were not palpable. Blood findings: bleeding-time, 30 minutes; clotting-time, 6 minutes; platelets, under 10,000 per c.mm. on several estimations; E.S.R., 18 mm. in one hour; W.B.C., 8,000 per c.mm. (polymorphs 56%, lymphocytes 40%, monocytes 2%, eosinophils 2%); sternal marrow, hyperplastic with considerable normoblastic hyperplasia; megakaryocytes, normal in appearance and number. After her admission the next menstrual period was excessive and persisted for ten days. There had been no previous menorrhagia. After six weeks the rash had partly subsided, but she continued to produce fresh crops of petechiae and the platelets were still under 10,000 per c.mm. In view of the age and sex of the patient, splenectomy was advised and undertaken by Mr. Simmons at the Manchester Royal Infirmary. The post-operative period was uneventful and there has been no relapse.

From time to time patients were seen with a symptom-complex closely resembling a Henoch-Schönlein syndrome. The following is an example.

A male patient was admitted with a well-marked purpuric rash limited to the legs below the knee-joints and associated with swollen and tender ankle-joints. On the second day he experienced colicky central abdominal pain, accompanied by the passage of bright-red blood in the stools and frank haematuria. The blood and marrow findings were completely normal. The condition resolved spontaneously, and within two to three weeks had entirely subsided.

Discussion

We have described a few examples of the types of purpura seen following T.A.B.T. injections. As a rule the petechial rash is limited to the lower limbs and there is swelling in or around the ankle-joint, but usually this is not very painful. The blood findings are often negative, except for a transitory fall in haemoglobin and a rise in the E.S.R., and these minimal blood findings are characteristic of the allergic purpura group.

In the case of the girl who had thrombocytopenia there seems little doubt that the acute relapse was related or entirely due to an immuno-allergic vascular phenomenon arising from sensitization to her inoculation. We believe that this case of thrombocytopenia provides some support to the contention that many of the so-called acute essential thrombocytopenias have, in fact, been immuno-allergic phenomena arising from sensitization to some foreign substance. In this respect we should compare that case with the production of an allergic arthritis in a patient who has previously had a rheumatic disorder and who therefore presumably has a rheumatic diathesis.

The question of the aetiology of rheumatic syndromes as a whole is obviously relevant to this discussion. We make no attempt to review accepted theories except to note that the most widely held view is that acute rheumatic fever is almost certainly due to an allergic reaction to streptococcal infection. We wonder whether exactly the same process, but on a much less severe scale, may not have occurred in the cases we saw. Obviously, where a streptococcal infection is present there is a constant source of antigen to provide a continuous allergic process, and this would be expected to be far more damaging than one isolated injection of antigen. It seems to us that in those cases where the patient has an extreme degree of sensitivity, or where there is a strong family background of rheumatism or a past history of rheumatic disorder, one isolated injection of antigen is

sufficient to set up a continuous clinical syndrome which is indistinguishable from that occurring "naturally."

The experimental work of Rich (1945) is of special interest. He demonstrated changes in cardiac muscle and skin tissues seemingly identical to those of rheumatic fever when repeated injections of antigenic horse serum were given. However, it has not been possible to reproduce the whole clinical syndrome of a self-perpetuating rheumatic fever syndrome by these or any other means (Holbrook, 1953). We believe that under certain circumstances such a syndrome very occasionally follows inoculation procedures.

Whilst it is noted that the majority of delayed reactions of all types have followed a combined T.A.B.T. and vaccination procedure, similar disturbances have often been seen after either has been given separately. The reactions to vaccination are too well known to require description, but as these generally occur after about the same time interval—that is, seven to ten days—many of the cases have presented a rather confused pattern owing to the fever and malaise from the vaccination becoming superimposed upon the allergic reaction. In point of fact, it is quite possible that many of the delayed symptoms from vaccination are actually allergic.

A further clinical observation, though not statistically substantiated, is that infective conditions of all kinds, including upper respiratory infections, segmental pneumonias, and skin and tissue infections, are more common during the seven to ten days following inoculation, and this may help to make recognition of an underlying cause rather difficult. A possible explanation of this observation is that all the immunological processes are disturbed at this time, giving rise to a general lowering of resistance to infection.

We have, so far, mentioned only T.A.B.T. and vaccination reactions, but we do not believe that these are in any way due to specific antigens; it is merely that we have been able to observe so many delayed reactions because of the enormous scale of the procedures. We have seen occasional rheumatic syndromes after Mantoux-testing and also during the course of a delayed pulmonary reaction to lipiodol bronchography. It is interesting to note, in this connexion, that one of us has, in fact, suffered both a delayed pulmonary reaction to lipiodol (Robertson and Morle, 1951) and also a delayed allergic arthropathy to a Mantoux test.

Summary

Clinical observations have been made upon the reactions occurring one to two weeks after T.A.B.T. injection and vaccination and certain other procedures. These may involve the joints, closely resembling acute rheumatic fever or acute rheumatoid arthritis. There may actually be an apparent rheumatic carditis. A syndrome resembling periarteritis nodosa following inoculation is described. Various purpuric manifestations, identical with the so-called immuno-allergic vascular purpuras, are discussed. Changes in the reticulo-endothelial system, including spleen, liver, lymph nodes, and bone marrow, are described.

The significance of these delayed reactions is discussed, especially in connexion with the aetiology of the rheumatic and purpuric disorders.

We wish to thank the Director-General of Medical Services for permission to publish this article.

QUANTITATIVE EXAMINATION OF BONE MARROW IN GUINEA-PIGS AFTER GAMMA IRRADIATION

A PRELIMINARY NOTE

BY

P. F. HARRIS, M.B., Ch.B.

Department of Anatomy, University of Bristol

Previous work on the quantitative study of the bone marrow of the guinea-pig has shown that there are three main cell groups—myeloid, erythroid, and lymphocytic. The lymphocytes were found to constitute an unexpectedly high proportion of the total nucleated cells (Harris *et al.*, 1954). In a recent series of 10 normal animals (Harris and Harris, 1956), out of a total nucleated count of 1,814,000 ($\pm 86,000$) per c.mm. marrow there were about 430,000 ($\pm 42,000$) lymphocytes, or just under 25%, a figure which agrees closely with that of Sawitsky and Meyer (1948). So large a number of lymphocytes cannot possibly be due to contamination of the marrow with blood (Yoffey, 1954).

The question at once arises whether the presence of all these lymphocytes in the marrow is a purely incidental phenomenon, or whether they may function as stem cells for the myeloid and erythroid series. On this, perhaps the most controversial of all problems in haematology, it was felt that a quantitative analysis of marrow changes in conditions of severe marrow damage and subsequent regeneration should yield more precise information than has hitherto been available. If lymphocytes really can function as stem cells, then under these circumstances the course of the recovery should be associated with significant changes in the marrow lymphocytes.

Despite the very extensive investigations which have already been made upon the effect of irradiation on the haemopoietic system, some initial experiments indicated that a quantitative technique would make possible a much more precise analysis of the changes occurring. This communication presents the results of further investigations along these lines.

Material and Method

The dose of irradiation chosen was such that it produced marked changes in the haemopoietic organs, but at the same time involved as small a mortality rate as possible. For the guinea-pig, the minimum lethal dose for 50% of animals within 30 days of irradiation is said to be approximately 200–250 r (Ellinger, 1945). A dose of 150–170 r was ultimately selected as the dose that best fulfilled the above requirements. Marked changes in the bone marrow have occurred when using this dose, and in addition distinct cellular simplification has been achieved at a certain stage in recovery.

All animals used were males of a standard strain (Dunklin-Hartley) and about 400 g. in weight at the time of irradiation. A preliminary blood count was made, using blood obtained from an ear vein. Total R.B.C., W.B.C., and reticulocyte counts were made, together with a differential white cell count and haemoglobin estimation. An interval of about 10 days then elapsed, after which the animal was irradiated. Total-body irradiation was given, a cobalt-60 unit being the source of irradiation. It was performed under general anaesthesia (intraperitoneal pentobarbitone sodium) to ensure uniform dosage.

In each animal at a certain period after the time of irradiation a second blood investigation was made, followed immediately by quantitative examination of the bone marrow, using the technique described in previous papers from this department (Yoffey, 1955; Harris, 1956). Differential marrow cell counts were made upon smears fixed in methyl alcohol and stained by MacNeal's tetrachrome stain. One thousand cells were counted in each experiment.

Observations were made at daily intervals after irradiation until the fourth day and thereafter on alternate days up to the 28th day, with final observations on the 35th day.

Results

The results given are based upon 79 experiments, and further work is proceeding. The number of experiments in each group is shown in the accompanying Table. Comparison is made with the mean values obtained by quantitative examination of the bone marrow in ten normal animals whose mean weight was about 400 g.

Table Showing Number of Experiments and Time of Observation

Days: ..	1	2	3	4	6	8	10	12	14	16	18	20	22	24	26	28	35
No. ..	5	4	4	4	3	5	5	4	6	6	4	6	2	4	6	5	

Total Nucleated Cells

Our experiments show that the count is already reduced below normal by the first day after irradiation. The lowest level is reached by the sixth day, being 674,000 per c.mm. marrow, which is approximately one-third of normal. This is followed by a gradual return to normal by the 20th day. However, though the number of cells is approximately back to normal, differential counts reveal that there is a far from normal distribution of the main cell groups at, and for some days after, this stage.

Myeloid Cells

The vast majority of cells in this group are neutrophils. Twenty-four hours after irradiation there is initially a slight increase in the total myeloid cells which is due to the presence of increased numbers of mature or nearly mature cells (562,000 band and mature neutrophils per c.mm. marrow, compared with 431,000 per c.mm. in the controls). The more immature cells are decreased at this time. After this the number of cells decreases, reaching a very low figure by the 14th day, being 47,000 per c.mm. marrow. By the 18th day granulocytes are beginning to reappear in the marrow in large numbers, and have reached almost normal levels by the 20th day after irradiation. The increase continues, and reaches well above normal by the 22nd and 24th days (1,130,000 and 1,146,000 per c.mm. respectively). Thereafter there is a decrease to more normal values.

Subdivision of the neutrophils into two groups—immature (that is, metamyelocyte or earlier forms) and mature (that is, band and segmented cells)—shows that the great majority of cells present up to the 14th day are of the mature variety. In the interval between the 12th and the 14th day after irradiation there is a rather sharp fall, reaching as low as 6,000 cells per c.mm. It is of interest that a marked neutropenia occurs in the blood from the 14th to the 18th day after irradiation.

A rapid re-population of the marrow with immature neutrophils begins on the 16th day, and within a period of two days they have risen to well above normal. A peak level is reached on the 20th day after irradiation, when the number of immature cells is approximately double that of the normal. After this time the level of immature cells gradually returns towards normal.

The more mature forms of neutrophils begin to reappear in the marrow between 18 and 20 days after irradiation, reaching their maximum between the 22nd and 24th days.

At this time their level in the marrow is about twice normal. Subsequently the mature neutrophils return to more normal figures over a period of four days.

Erythroid Cells

The erythroid precursors would appear to be very sensitive to irradiation, and even by 24 hours there is a low content of these cells, which at this time are less than one-third of normal. Low levels (less than 100,000 per c.mm.) persist until the 12th day, after which they rise to normal within a period of four days. A continued elevation of these cells occurs, reaching a maximum (about twice normal) by the 20th day. There then follows a decline to normal levels.

Lymphocytes

These cells, like the erythroblasts, are very sensitive to irradiation, and after 24 hours their number in the marrow is less than one-third of the normal value. A low level persists until the 4th day, but after this time the marrow lymphocytes tend to rise gradually, and have exceeded the normal figure by the 10th day. They continue to increase until by the 16th day their numbers have approximately doubled in comparison with the controls. After the 16th day the lymphocytes fall quite rapidly to subnormal values, minimal levels being reached on the 22nd and 24th days after irradiation (approximately one-third of normal). However, by the 28th day the number of lymphocytes in the bone marrow has again returned to normal.

Discussion

There have been two outstanding findings in these experiments. Firstly, the lymphocyte, although very sensitive to irradiation, recovers quickly relative to the erythroid and myeloid series. A level well above normal is reached between the 14th and the 16th day after irradiation, and this

FIG. 1.—Erythroid, myeloid, and lymphocyte changes in guinea-pig marrow after gamma irradiation.

marked accumulation of lymphocytes precedes the regeneration of cells in both the erythroid and the myeloid groups (Fig. 1). Furthermore, at this time of high lymphocyte content in the marrow numerous lymphocyte-like cells appear with a characteristic morphology. These we describe as transitional cells (Yoffey and Courtice, 1956). The observations appear to confirm those of Brecher *et al.* (1948),

who investigated the effects of x rays on the lymphoid and haemopoietic tissues of albino mice. These authors noted that lymphocytopenia appeared to be normal by the 7th and 10th day after irradiation, and even to be raised above normal by the 14th day. An abrupt temporary rise in marrow lymphocytes occurred on the 10th day and accompanied a persistent blood lymphopenia. A similar relationship between blood and marrow lymphocytes has been noted in these experiments. Brecher *et al.* also describe the appearance of a distinct cell type, a lymphocytic-like cell (resembling the lymphoidocyte of Pappenheim) which they suggest is a stem cell of the granulocytic series.

The second finding is that the great decline in marrow lymphocytes occurring after the 18th day corresponds closely with the presence of large numbers of both erythroid and myeloid cells in the marrow (Fig. 2). An inverse relationship between the levels of mature neutrophils and lymphocytes in the bone marrow has been noted in a quantitative study of the effect of leucocytosis-promoting factor on guinea-pig bone marrow (Harris *et al.*, 1956).

A remarkable increase in the immature forms of both myeloid and erythroid cells occurs over the short period of two to four days. Since there is no obvious increase in the number of mitotic figures, and in view of the marked decline (following a peak) in lymphocyte content of the marrow, it is reasonable to postulate a direct relationship between the accumulation of lymphocytes and the recovery of the other cell series. The appearance of forms of cell having a transitional appearance between a typical small lymphocyte and the blast precursors of myeloid and erythroid cells further supports this hypothesis.

The low level of erythroid precursors in the bone marrow 24 hours after irradiation is identical with that of the lymphocytes. This is in agreement with the findings of Bloom and Bloom (1947), who investigated the effects of

Fig. 2.—Changes in guinea-pig marrow after gamma irradiation: showing decline in marrow lymphocytes after the 18th day, corresponding closely with the presence of large numbers of myeloid cells.

irradiation on haemopoietic tissues in various animals. They conclude that the erythroblast is as sensitive to irradiation as the small lymphocyte. Recovery of the erythroid series in the present experiments precedes that of the myeloid series by an interval of between two and four days. Rosenthal *et al.* (1951) in a semi-quantitative study of bone marrow in rats following total-body x-irradiation, noted that there was evidence of erythroid regeneration 12 days after irradiation, compared with 15 days for the myeloid series. They also remarked that from the 12th day onwards the bone-marrow lymphocyte count increased more than the blood level. Valentine and Pearce (1952) investigated the relative sensitivity of erythroid and myeloid elements in cats after total-body irradiation. They concluded that erythroid tissue is less sensitive to irradiation than myelopoietic tissue, as gauged by recovery times.

The initial rise of mature and nearly mature neutrophils in the marrow occurring 24 hours after irradiation has been noted by other workers (Aubertin and Beaujard, 1908;

Rosenthal *et al.*, 1951; Latta and Waggener, 1954). Rosenthal *et al.* remarked that the fall in myeloid elements of the rat bone marrow occurring 24 hours after irradiation involves the more immature cells, there being a slight rise in the more mature, segmented, cells at this stage. The sharp fall in the level of mature neutrophils occurring in the interval between 12 and 14 days after irradiation suggests that the duration of life for immature neutrophils within

Fig. 3.—Changes in mature and immature neutrophils in guinea-pig marrows after gamma irradiation.

guinea-pig bone marrow is at least 14 days. Restoration of granulocytes occurs with such remarkable rapidity that within four days they have increased from 47,000 per c.mm. to 482,000 per c.mm. Comparison between the peaks of immature and mature neutrophils in the marrow (Fig. 3) shows that they are separated by an interval of between two and four days. It therefore appears that the time taken under these conditions for immature neutrophils to mature in the bone marrow is from two to four days.

Summary

Quantitative examinations of bone marrow in the 400-g. male guinea-pig have been made at varying intervals up to five weeks after total-body irradiation.

The results confirm the well-known fact that the lymphocyte is very sensitive to radiation, but also indicate that there is a marked accumulation of these cells in the bone marrow between 10 and 18 days after irradiation. This accumulation occurs at the same time as a lymphocytopenia in the blood. The presence of a large number of lymphocytes in the marrow precedes the recovery of the stem cells in both the myeloid and the erythroid series. Accompanying the accumulation of lymphocytes, numerous cells are seen which morphologically appear to be transitional between the lymphocyte and the typical blast precursors of the myeloid and erythroid series. The significance of the findings is discussed.

During the marrow regeneration, erythropoiesis seems to reach a peak at about the 20th day, and myelopoiesis between the 22nd and 24th days. At the period of sustained erythropoiesis and myelopoiesis the inverse relation to the marrow lymphocytes, which fall precipitously, is very striking.

Regeneration of cells in the myeloid group begins two to four days after that of the erythroid group. Evidence suggests that the time taken for immature neutrophils to mature in guinea-pig bone marrow in the recovery from irradiation is in the region of two to four days.

I wish to thank Professor J. M. Yoffey for suggesting this research subject and for his encouragement throughout the work.

I am also grateful to Dr. R. C. Tudway, who has allowed me to use the facilities of the Radiotherapy Department of the United Bristol Hospitals and to the physicists at Bristol General Hospital for their ready co-operation. Miss J. A. Drury has been of great technical assistance in these experiments. The work reported in this communication has been aided by a grant from Messrs. Reckitt and Colman, Ltd., Hull.

BLOOD PYRUVATE AND α-KETOGLUTARATE IN NORMAL AND DIABETIC SUBJECTS

BY

M. J. H. SMITH, M.Pharm., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology

AND

K. W. TAYLOR, M.B.

From the Department of Chemical Pathology, King's
College Hospital Medical School, Denmark Hill, London

The blood concentrations of α-keto acids in patients with diabetes mellitus have been the subject of conflicting reports. Thus Gey (1953) observed raised blood pyruvate levels in some diabetic patients, and α-ketoglutarate levels in some diabetic patients, and Villano (1952) and Seligson and Shapiro (1952) stated that the blood concentrations of both pyruvate and α-ketoglutarate were increased in diabetes. Other workers (Bueding *et al.*, 1942b; Klein, 1942) reported that the fasting blood pyruvate was normal in diabetic patients, and Lestrade and Guest (1951) and van Marken Lichtenbelt and Florijn (1952, 1955) found normal blood pyruvate values in diabetic acidosis and normal blood pyruvate communication (Smith and Taylor, 1955) we reported that the blood concentrations of pyruvate and α-ketoglutarate, measured by a specific paper chromatographic method, were normal in a group of ambulant diabetic patients. This work has now been extended to a larger number of diabetic patients, including those with more severe grades of the disease.

The fluctuations in the blood pyruvate after the administration of glucose to diabetic patients have been studied by several workers. Most of them (Himwich and Himwich, 1946; Klein, 1942; Bueding *et al.*, 1942a; Miller *et al.*, 1952) reported that diabetics showed little change in blood pyruvate after glucose, but the results of Root *et al.* (1946) and Amatuzio *et al.* (1952) suggested that diabetic patients did not respond as a uniform group in this test. In general, patients with a mild form of the disease showed a rise in blood pyruvate, whereas in patients with severe diabetes this rise was either delayed or absent. It is now generally accepted that diabetes mellitus is not a single disease entity, and Lawrence (1951) has distinguished two main clinical

types—the obese patients not requiring insulin and the thin insulin-requiring patients. It therefore seemed of interest to investigate the effect of the administration of glucose on the blood concentrations of pyruvate and α-ketoglutarate in these two clinical types of diabetic patients.

Experimental

Analytical Methods.—The blood concentrations of pyruvic and α-ketoglutaric acids were measured by the method of Taylor and Smith (1955), except that tungstic acid, in the amounts used by Seligson and Shapiro (1952), was substituted for metaphosphoric acid as the protein precipitant. This modification reduced emulsion formation during the extraction procedure and slightly improved the recoveries of the α-keto acids. All the blood specimens were obtained from arm veins, no clenching or unclenching of the fist being allowed before or during collection. Blood glucose was estimated by the method of Nelson (1944) on the same venous blood samples.

Clinical Material.—Single blood samples were obtained from 12 normal subjects and 17 ambulant diabetic patients attending the out-patient clinic. The blood specimens were collected approximately three hours after breakfast, and a sample of urine was also obtained from each diabetic patient at the same time and tested for ketone bodies. The diabetic patients were taken at random and were free from disease apart from their diabetes.

Oral Glucose Test.—Twelve normal subjects and 16 diabetic patients were fasted overnight and urine samples were obtained from the diabetic patients and tested for ketone bodies. Each subject was allowed to rest on a bed for one hour before the first (0 hour) specimen of blood was collected. A 25% (w/v) solution of glucose (equivalent to 1.75 g. of glucose per kg. body weight) was then given by mouth and blood specimens were collected at intervals of one, two, and three hours. Thirteen of the diabetic patients were divided into two main groups according to Lawrence (1951), and the details of the patients are given in Table I. The first group ("obese" group) comprised six patients who gave a history of recent gain in weight or who had maintained weight on a low-calorie diet and were not ketosed.

TABLE I.—Classification and Details of the Diabetic Patients
Used for Oral Glucose Test

Case No.	Sex	Age	Recent Weight Change	Treatment	Urine Test	
					Rothera	Gerhardt
<i>Obese Group</i>						
1	F	23	Gain	New patient	0	0
2	M	59	Maintained	Diet	0	0
3	F	53	"	New patient	0	0
4	F	46	Gain	" "	0	0
5	F	52	Maintained	" "	0	0
6	F	62	"	Diet	0	0
<i>Thin Group</i>						
7	M	26	Loss	Insulin	0	0
8	M	33	"	"	0	0
9	M	34	"	New patient	+++	0
10	F	55	"	Insulin	+	0
11	M	30	"	New patient	+++	++
12	M	46	"	" "	+++	++
13	M	33	"	" "	+++	+

The second group of seven patients ("thin" group) gave a history of great loss of weight and severe ketosis before insulin therapy; four patients in this group were new untreated patients and the remainder were under treatment, their insulin being stopped for 24 hours before the test. A further small group of three obese diabetic patients showing a recent significant loss of weight was also studied.

Results

The blood pyruvate, α-ketoglutarate, glucose, and urine ketone results for the individual diabetic patients, together with the mean results for the normal subjects, are given in Table II. In all the following tables the significances of

the differences between the means have been analysed by Student's *t* test and values of *P* are included. The minimum acceptable level of significance has been taken as *P*=0.02.

The results show that there were no significant differences between the means of the blood concentrations of the α -keto acids in both groups. In the diabetic group there was no correlation between the blood concentrations of pyruvic and α -ketoglutaric acids and either the blood glucose concentration or the presence of ketosis.

Blood Pyruvate and α -Ketoglutarate after Oral Glucose

Normal Subjects.—Table III gives the blood glucose, pyruvate, and α -ketoglutarate results in 12 normal subjects before and at intervals of 1, 2, and 3 hours after the oral administration of glucose. The blood pyruvate concentration was significantly increased one and two hours after the glucose had been given, and the blood α -ketoglutarate tended to reach a peak value at two hours, although the differences were not significant.

3	67	F	0	0	New patient	226	390	405	410	249	194	304	365	48	59	91	122

Diabetic Patients.—Obese Group: The results (Table IV) show that the blood pyruvate increased significantly one hour after the glucose was given; the one-hour pyruvate value was not significantly different (*P*=0.2) from that found in the normal subjects. **Thin Group:** Table V shows that, unlike the findings in the normal subjects and obese diabetic patients, the blood pyruvate did not rise either one hour or subsequently after the administration of glucose. The decrease observed at one hour was not statistically significant (*P*=0.3). Comparison of the one-hour pyruvate values between the three groups showed a highly significant difference (*P*<0.001) between the thin diabetics and normal subjects, and between the thin and obese diabetics. The blood α -ketoglutarate increased steadily and in contrast to the other group of patients was still significantly raised after three hours.

Obese Diabetics with Recent Loss of Weight.—The clinical details and results of the three obese patients with a history of recent weight loss are given in Table VI. The blood pyruvate failed to rise one hour after the glucose, and in all cases showed a slight fall comparable to that observed in the thin diabetic group.

Discussion

The results in Table II confirm the conclusions of our earlier report (Smith and Taylor, 1955) that the blood concentrations of pyruvate and α -ketoglutarate are normal in ambulant diabetic patients exhibiting a wide range of blood glucose concentrations. In the diabetic patients there was no correlation between the blood concentrations of the α -keto acids and the presence or absence of ketosis. Additional evidence in favour of these conclusions is provided

TABLE IV.—Blood Concentrations of Glucose, Pyruvate, and α -Ketoglutarate in Six Obese Diabetics after Oral Glucose. Results Given as Means $\pm$ Standard Deviation and Ranges

Estimation	Time (Hours)			
	0	1	2	3
Glucose (mg./100 ml.)	222 $\pm$ 42 177-300	335 $\pm$ 52 273-408	350 $\pm$ 65 271-415	329 $\pm$ 63 245-407
Pyruvate (μ g./100 g.)	287 $\pm$ 52 213-326	387 $\pm$ 65 244-458	282 $\pm$ 83 165-384	286 $\pm$ 88 161-390
α -Ketoglutarate (μ g./100 g.)	102 $\pm$ 30 63-139	107 $\pm$ 26 66-136	137 $\pm$ 58 75-249	116 $\pm$ 33 77-160

Statistical significance of difference between results:—Pyruvate: 1 and 0 hour, *P*=0.02; 0 and 2 hours, *P*=0.9; 0 and 3 hours, *P*=0.9. α -Ketoglutarate: 0 and 1 hour, *P*=0.8; 0 and 2 hours, *P*=0.3; 0 and 3 hours, *P*=0.5.

TABLE V.—Blood Concentrations of Glucose, Pyruvate, and α -Ketoglutarate in Seven Thin Diabetics after Oral Glucose. Results Given as Means $\pm$ Standard Deviations and Ranges

Estimation	Time (Hours)			
	0	1	2	3
Glucose (mg./100 ml.)	272 $\pm$ 102 148-470	471 $\pm$ 79 370-580	563 $\pm$ 89 425-680	478 $\pm$ 47 435-525
Pyruvate (μ g./100 g.)	281 $\pm$ 150 168-554	193 $\pm$ 87 129-333	233 $\pm$ 123 139-475	260 $\pm$ 202 103-557
α -Ketoglutarate (μ g./100 g.)	69 $\pm$ 7 58-74	102 $\pm$ 47 51-171	122 $\pm$ 30 89-155	122 $\pm$ 24 100-151

Statistical significance of differences between results:—Pyruvate, 0 and 1 hour, *P*=0.3; 0 and 2 hours, *P*=0.6; 0 and 3 hours, *P*=0.8. α -Ketoglutarate: 0 and 1 hour, *P*=0.1; 0 and 2 hours, *P*=0.01; 0 and 3 hours, *P*=0.001.

by comparison of the fasting levels (0-hour specimens in the oral glucose test) of the α -keto acids from normal subjects and the selected diabetic patients, considered as a group (Table VII). Again there were no significant differences in the blood α -keto acid concentrations between the normal subjects and diabetic patients. Similar results have been described by Klein (1942) and Bueding *et al.* (1942b). However, when the diabetic patients were divided into the two main clinical types the blood pyruvate levels of the "obese" group were found to be significantly higher than those of the normal subjects (Table VII).

TABLE VII.—Fasting Blood Levels of Pyruvate, α -Ketoglutarate, and Glucose in Normal Subjects and Diabetic Patients. (Figures in Parentheses are the Number of Patients in Each Group; Results Given as Means $\pm$ Standard Deviation and Ranges)

Estimation	Normal Subjects (12)	All Diabetic Patients (16)	Obese Diabetics (6)	Thin Diabetics (7)
Glucose (mg./100 ml.)	84 $\pm$ 9 66-93	242 $\pm$ 75 148-470	222 $\pm$ 42 177-300	272 $\pm$ 102 148-470
Pyruvate (μ g./100 g.)	225 $\pm$ 41 159-361	294 $\pm$ 109 168-554	287 $\pm$ 52 213-326	281 $\pm$ 156 168-554
α -Ketoglutarate (μ g./100 g.)	90 $\pm$ 30 50-120	85 $\pm$ 28 48-139	102 $\pm$ 30 63-139	69 $\pm$ 7 58-74

Statistical significance of differences between results:—Pyruvate: normal and all diabetics, *P*=0.1; normals and obese diabetics, *P*=0.02; normals and thin diabetics, *P*=0.3. α -Ketoglutarate: normals and all diabetics, *P*=0.7; normals and obese diabetics, *P*=0.5; normals and thin diabetics, *P*=0.2.

A more striking difference was the blood pyruvate concentration measured one hour after the oral administration of glucose (see Chart). Both the normal subjects and "obese" diabetics showed a significant rise in blood pyruvate at one hour, whereas the "thin" diabetics failed to show this rise, the blood pyruvate tending to fall at one hour. The majority of previous workers (Klein, 1942; Bueding *et al.*, 1942a; Himwich and Himwich, 1946; Miller *et al.*, 1952) have studied insulin-requiring diabetics and

Mean values of blood concentrations of glucose, pyruvate, and α -ketoglutarate after the oral administration of glucose to normal subjects and to "obese" and "thin" diabetic patients. Δ =Glucose. $\blacksquare$ =Pyruvate. $\bullet$ =Ketoglutarate.

found there was either no change or a slight delayed increase in blood pyruvate after glucose or a high carbohydrate meal. However, Root *et al.* (1946) observed that a rise in blood pyruvate after oral glucose occurred in two patients with "mild" diabetes not receiving insulin, and that this rise was absent or delayed in more severely diabetic patients. Amatuzio *et al.* (1952) gave intravenous glucose and noted that a rise in blood pyruvate, which was not statistically significant, occurred at one hour in "mild" diabetics, not receiving insulin, whereas in "severe"

diabetics receiving insulin a significant fall in blood pyruvate occurred at 30 minutes followed by a delayed rise after two hours.

The present results are of interest because the diabetic patients were selected and divided into two groups according to the clinical criteria of Lawrence (1951), and Bornstein and Lawrence (1951) have shown that plasma insulin activity could be demonstrated in the "obese" type but not in the "thin" type. This finding has been confirmed by Vallance-Owen *et al.* (1955), who used an independent method of assay for plasma insulin-like activity. The possible correlation between the one-hour pyruvate response and the presence or absence of plasma insulin activity after the administration of glucose in these two groups of diabetic out-patients merits further investigation.

One of the possible explanations of the rise in blood pyruvate in the normal subjects and "obese" diabetic patients is that the administered glucose was actively metabolized. Lynen (1954) and Glock and McLean (1955) have stressed the dependence of lipogenesis on the presence of active glycolysis, and it may be postulated that the occurrence and maintenance of obesity in the "obese" diabetic group is due to their ability to metabolize glucose without added insulin. Similarly, the absence of an increase in the blood pyruvate at one hour in the "thin" diabetic group may be a reflection of their comparative inability to utilize glucose. It is of interest that Miller *et al.* (1955) have demonstrated that "stable" diabetics convert more 14 C glucose to 14 CO₂ than "labile" ketotic diabetics.

An alternative explanation of the pyruvate results is that the production of a larger glucose diuresis in the "thin" diabetic group may have caused an increased renal excretion of pyruvate, which would explain the absence of a rise in the blood pyruvate at one hour. However, this possibility appeared unlikely because the one-hour blood pyruvate did not rise in the three obese diabetics with a recent history of weight loss, in whom the glucose-tolerance curves, and hence presumably the extent of the glycosuria, were similar to the "obese" group showing a rise in blood pyruvate. These three patients, although obese, resembled the "thin" diabetic type in the recent loss of weight and failure to show a rise in blood pyruvate one hour after glucose, and may represent an intermediate type of the disease, but this must remain speculative until larger numbers of such patients have been studied.

In contrast to the behaviour of the blood pyruvate after the administration of glucose, the blood α -ketoglutarate followed a similar pattern in the normal subjects, and the "obese" and "thin" diabetics (see Chart). The values tended to reach a maximum at two hours and then declined during the following hour in the normal subjects and "obese" diabetics, but remained significantly raised in the "thin" diabetics at three hours. No explanation of these results can be offered at present.

Summary

Normal blood concentrations of pyruvate and α -ketoglutarate were found in ambulant diabetic patients in blood specimens collected either three hours after a meal or after an overnight fast.

When diabetic patients were divided into two main clinical types, the administration of oral glucose caused a significant rise in blood pyruvate in the "obese" group at one hour, similar to that found to occur in normal subjects, but not in the "thin" group.

Some of the implications of these results are discussed.

We wish to thank the normal subjects and diabetic patients for their willing co-operation; the medical and nursing staff of the diabetic clinic, King's College Hospital, for their help with the patients; and Dr. R. D. Lawrence and Professor C. H. Gray for their encouragement during the work. We are grateful to

Miss E. Quilley for technical assistance and to the Board of Governors of King's College Hospital for grants towards the cost of the work from their endowment funds.

THROMBOSING ARTERIOSCLEROSIS RESULT OF LONG-TERM ANTICOAGULANT THERAPY

BY

JENS DEDICHEN, M.D.
Oslo, Norway

Man lives with arteriosclerosis, and dies of the complicating thrombosis. The combination represents a disease entity which should be called "thrombosing arteriosclerosis." The symptoms depend on the seat of thrombosis—giving angina pectoris or coronary infarction, cerebral accidents, or intermittent claudication—and the prognosis is first and foremost the prognosis of arteriosclerotic heart disease.

Thrombosing arteriosclerosis is confined to man alone. We are not able therefore to produce the disease in experimental animals, because they cannot achieve thrombosis spontaneously even if some part of the coagulation system may be influenced during experiments with hypercholesterolaemia in animals (Dedichen, 1950).

Since 1950 I have been giving long-term anticoagulant therapy to out-patients with arteriosclerosis, 149 of whom have been under constant treatment for one year or more (Table I). This report gives the results of treatment with phenindione ("phenylindanedione"), using a method described elsewhere (Dedichen, 1953).

TABLE I.—Number of Cases and Duration of Treatment

	No. of Patients	Months of Treatment	Average Length of Treatment
Coronary thrombosis or angina pectoris	86	2,693	31 months
Intermittent claudication	63	2,016	32 "
Total	149	4,709	31.6 "

Results and Treatment

Of 86 patients with coronary disease, 12 died during the period of observation (Table II), giving a mortality rate of 5% a year. This is in conformity with the results of Owren

(1954, 1955), who since 1949 has been treating coronary thrombosis and angina pectoris with long-term anticoagulant therapy, and whose results have been confirmed by Bjerkelund (1956). Among the 63 patients with intermittent claudication in this series eight deaths occurred during the period of observation—that is, 5% a year.

TABLE II.—Cause of Death

	Coronary Thrombosis or Angina Pectoris	Intermittent Claudication
Sudden death	5	6*
Coronary thrombosis	2	
Heart failure	2	
Cancer	1	1
Other causes	2†	1 (suicide)
Total	12	8

* One died fourteen days after cessation of two years' therapy.
† One died fourteen days after cessation of therapy, owing to bleeding from gastric ulcer.

The main cause of death was arteriosclerotic heart disease. Of the patients with intermittent claudication, 54% had clinical signs or symptoms of arteriosclerotic heart disease when treatment was started, or developed such signs during the period of observation. It is therefore difficult to establish the group to which the particular patient belongs. I have followed the rule that the symptoms which bring the patient to the clinic for treatment have been definite. The two groups correspond closely as regards mean age, blood pressure, and cholesterol values (Table III); but there is a greater frequency of women in the coronary group. Diabetes occurred in only three of the 149 cases.

Complications.—Severe haemorrhage necessitating admission to hospital occurred six times: haematemesis, twice (once gastric ulcer); gross haematuria, three times; and haemoperitoneum once (from regional ileitis). Nose bleeding was also a complication. Slight haematuria has not been of importance and is not recorded. Six patients out of a total of 200 treated have shown signs of sensitization to phenindione, with rash, and have been switched over to dicoumarol.

TABLE III*

	No. of Patients			Cholesterol (mg./100 ml.)	B.P.	Average Age
	M	F	Total			
Coronary thrombosis or angina pectoris	86	15	106	280	150/90	57.5
Intermittent claudication	63	4	80	278	160/90	58.3

* This includes 37 cases on long-term treatment.

Comments

The prognosis of intermittent claudication is difficult to establish with certainty. The selection of material will of course influence the mortality, and here the percentage of complicating diseases, such as diabetes, is of great importance. Of 280 patients at the Mayo Clinic (Allen, Barker, and Hines, 1946), 116 were followed up after three years and showed a mortality of 54.6%, 20% had diabetes, and 70 had undergone amputation. Six of my patients had chronic ulcers—five being healed during treatment—and one underwent amputation.

The beneficial effect of anticoagulant therapy is thought to be due to the prevention of further intravascular thrombosis, giving time for development of collaterals. Other pharmacological effects of the anticoagulants have not been recorded.

Other factors which may influence the course of the disease are exercise, diet, and smoking habits.

Exercise.—The modern treatment of arteriosclerosis is a more active concept, the patient being encouraged to take exercise. This view is probably to some degree due to

observations on London Transport workers made by Morris *et al.* (1953)—which showed that the mortality of coronary thrombosis is higher in the group of employees with less activity (drivers in comparison with conductors)—and on London postmen. Our patients are instructed to take daily exercise, if possible one hour's walking a day, and to try to accelerate the speed up to (but not beyond) the point where they are forced to stop or slow down.

A 52-year-old officer was able to walk at a speed of 30 steps a minute at the start of treatment. After two years' treatment he could walk at 110 steps a minute.

Diet.—The patients have been encouraged to reduce their weight and avoid heavy meals, particularly fatty ones. The following case illustrates the role of fat and of exercise in arteriosclerosis.

A 36-year-old man spent his holidays in the mountains (Hardangervidda) the year after the liberation. There he met friends from the resistance movement—farmers who had assisted in taking care of sabotage groups during the war. He was overwhelmed with all sorts of dairy produce, which had been so scarce for years. During his three weeks' stay (taking long hikes almost every day and getting a lot of exercise) he developed thrombosis of the abdominal aorta, which was almost completely obliterated. He has since got coronary disease as well. There are no signs of Buerger's disease or of familial cholesterolaemia.

The role of the diet as compared with the importance of exercise has been commented on in another observation (Dedichen *et al.*, 1951). The frequency of thromboembolism after operation declined during the war and rose again afterwards. Here exercise must be left out of the picture.

Tobacco.—Many patients have been heavy smokers, but their smoking habits have not been recorded with such consistency as to form a background for further comment. About half the patients have stopped smoking. There have been difficulties in persuading patients to stop smoking, particularly in the elder group. Some have stopped for more than a year without showing any improvement in the condition.

Summary

The mortality rate in a series of 149 out-patients with thrombosing arteriosclerosis on long-term treatment with anticoagulants has been shown to be 5% a year.

It makes no difference whether the process is localized to the heart or to the arteries of the limbs.

I thank Nyegaard and Co., Ltd., of Oslo, for supplies of phenylindanedione.

The advances made during the last decade in educating blind, deaf, epileptic, and similarly handicapped children are reported in *Education of the Handicapped Pupil* (Ministry of Education Pamphlet No. 30, price 2s., H.M.S.O.). "Between January, 1946, and January, 1955," the pamphlet reports, "the number of special schools increased from 528 to 743, the number of pupils in them from 38,499 to 58,034, and the number of full-time teachers from 2,434 to 4,381." One-year training courses for teachers of educationally sub-normal children are held by London, Birmingham, and Leeds Universities: Manchester University's Department of Education of the Deaf can now take 65 students yearly; and Birmingham hopes to open a training course for teachers of the blind in 1956-7.

EYE INJURIES DUE TO FIREWORKS

BY

W. MAY, M.B., B.S., D.O.

Ophthalmic Registrar, King's College Hospital, London

In an attempt to ascertain the number of eye injuries due to fireworks on November 5, 1955, seventy hospitals with eye out-patient departments in the London postal area were circularized. The ophthalmic registrar or deputy was asked to give details of patients who, as a result of accidents with fireworks, sustained eye injuries which necessitated their admission to hospital. Forty-four replies were received, which included those from all the London teaching and ophthalmic hospitals. It was felt that details of minor injuries not requiring in-patient treatment would be difficult to obtain, but the replies contained information relating to 25 such injuries, including the case of a man whose cornea was scratched while rescuing a cat frightened by fireworks.

Details of Injuries

Fourteen people, all male, between the ages of 3 and 46 suffered major eye injuries (see Table). These can be divided into two groups—that is, those due to flash burns and those due to direct injury by the firework.

Summary of Eye Injuries Due to Fireworks on November 5, 1955, in the London Postal Area

Case	Age	Sex	Type of Injury	Mode of Injury	Result
1	7	M	Superficial burns of right eye and lids	Exploding firework	No permanent damage
2	14	M	Superficial burns around eyes and lids	Making fireworks at home	" "
3	7	M	Severe contusion of globe. Iridodialysis, hyphaema	Struck in eye by firework	Permanent damage
4	11	M	Superficial burns of lids and cornea	Exploding firework	No permanent damage
5	14	M	Corneal staining, commotio retinae	" "	" "
6	37	M	Perforated cornea. Prolapsed uveal tissue and vitreous (previous retinal detachments)	? Hit by rocket	No perception of light in injured eye
7	12	M	Hyphaema, commotio retinae, small vitreous haemorrhage	Lighting one firework from another	No permanent damage
8	14	M	Bilateral, superficial corneal abrasions. Corneal F.B.s	Firework blew back into face	" "
9	46	M	Ruptured globe with prolapsed tissue, laceration of lid	Hit by falling rocket stick	Excision of eye
10	3	M	Superficial burns of face, corneal abrasions and F.B.s	Firework exploded in face	No permanent damage
11	11	M	Superficial burns of face, large corneal abrasions	Exploding firework	" "
12	20	M	Burns to lids and conjunctiva, corneal abrasions and F.B.s	Making fireworks with red phosphorus, pot. chlorate, and flour	" "
13	7	M	Superficial burns to lids and corneal abrasions	Exploding firework	" "
14	13	M	Superficial burns to both lids, superficial burns to right cornea, deep burns to left cornea	" "	Right eye normal. Permanent damage to left eye

Flash Burns.—Ten patients were admitted to hospital with flash injuries involving the eye and the skin around the eye. This is a similar type of injury to that suffered by gunners in the last war. There were superficial burns involving skin, cornea, and conjunctiva with singeing of the eyelashes, eyebrows, and hair. At the same time multiple minute foreign bodies were blown into the face, speckling

the cornea and conjunctiva of the palpebral opening and causing corneal abrasions. Nine of these injuries settled rapidly on local treatment and were left without permanent damage. One boy (Case 14) suffered burns to both corneae, the left cornea being severely damaged, leaving a deep vascularized opacity which limits vision to counting fingers.

Direct Injuries.—These more unfortunate victims were struck by a larger portion of the firework. Case 9 illustrates this type of injury. This man, aged 46, was standing outside his front door watching the fireworks in the surrounding gardens, when he was struck in the eye by a falling rocket stick. When seen in the casualty department he had a laceration of the upper lid, and when the lids were opened it was found that there was a large transverse split in the cornea through which extruded the lens, uveal tissue, and vitreous. Three days after toilet and suturing of the wound the blind painful eye was excised. Three other similar injuries (Cases 3, 6, and 7) occurred, one resulting in a blind eye, another in severe damage with impaired vision, and the third with no permanent damage.

Discussion

The only records in the medical literature concerning eye injuries due to fireworks were published in the United States of America. Between 1937 and 1946 the six annual summaries of the Fourth of July injuries show a decreasing incidence of firework accidents involving the eye. In 1937 there were 16 patients who lost the vision of one or both eyes and 294 who received eye injuries of a less serious nature; the figures for 1946² were 1 and 44 respectively in the two groups.

Large quantities of fireworks were ignited in London last year on November 5, which was a fine Saturday evening, and it is perhaps gratifying to note that only 14 eye injuries were serious enough to require in-patient hospital treatment. Eleven patients (78.5%) were boys aged 3 to 14 years. Most injuries were of a minor character, and the problem does not seem to be serious enough to urge for legislation about the sale of fireworks. However, four injuries were of a serious nature, one eye being lost. It is of special interest that the lost eye was due to a falling rocket stick, and another severe injury was thought to be due to a rocket. This might suggest that further efforts be made to ensure that all the falling parts of rockets disintegrate before reaching the ground.

Summary

On November 5, 1955, 14 eye injuries due to fireworks occurred in the London postal area, and required admission of the patient to hospital.

A review of the literature shows that no figures are available for previous years in this country.

I wish to thank the many ophthalmic surgeons who replied to my letter, and especially those surgeons at King's College, Moorfields, Royal Eye, St. Alfege's, St. James', Western Ophthalmic, and Whipps Cross Hospitals whose cases are mentioned above. My thanks are also due to Mr. L. H. Savin and Mr. T. Keith Lyle for their help and encouragement in preparing this report.

King Edward's Hospital Fund for London have issued a pamphlet entitled *Notes on Diets for Old People in Homes and Institutions*, which is obtainable from the Fund at 10, Old Jewry, London, E.C.2, price 1s. The pamphlet stresses that "many old people on entering hospital are undoubtedly suffering from malnutrition," and the need for protein foods does not become less with age but perhaps even increases. Small meals at frequent intervals are recommended, with special emphasis on a milk drink at bedtime to prevent insomnia due to hunger. Daily menus are suggested, and the twenty pages of recipes, allowing enough for 30 portions, cover all meals.

Medical Memoranda

An Unusual Cause of Obstructed Labour

A case of obstructed labour due to an unusual abnormality is reported.

OBSTETRIC DETAILS

A para-1 was first seen when 34 weeks pregnant. On examination twins were presenting as breeches; this was confirmed by x-ray examination.

Seven weeks later one of us (D.J.) was called to a general-practitioner maternity home. The legs and trunk

of the first twin had been delivered, but two doctors had failed to bring down the arms. We brought down the arms without difficulty, noting that the cord had stopped pulsating, but attempts to extract the foetus failed. What was apparently part of the second twin could be felt, but there was no actual obstruction and there was plenty of room for one head to come through.

The uterus was becoming increasingly irritable, and the patient was transferred to the main hospital, where an x-ray examination showed a double-headed monster. It was decided to endeavour to decapitate one head by the abdominal route and then deliver the remaining head vaginally.

On opening the abdomen by a low transverse incision, longitudinal rupture of the lower segment was seen to have occurred. Amputation of one head presented some difficulty, as the other head obstructed proper access to the neck. The whole foetus was therefore delivered abdominally. Closure of the uterus was difficult owing to the paper-thinness of the lower segment. The uterus retracted well, but moderate bleeding from the vagina persisted, presumably from the site of the uterine rupture, which ceased spontaneously after three hours. Nine pints (5.1 litres) of blood and 2 pints (1.1 litres) of plasma were administered in seven hours.

Fig. 1.—Photograph of monster.

Fig. 2.—X-ray photograph of monster.

Penicillin and streptomycin were given as a prophylactic. Apart from a rise of temperature to 100.2° F. (37.9° C.) on the second day, the temperature remained normal throughout the patient's convalescence.

DESCRIPTION OF FOETUS

The foetus, as can be seen in Figs. 1 and 2, was a dicephalic monster. The two heads and necks were of normal size, but the contiguous surfaces of the heads were slightly flattened from pressure. The trunk, arms, and legs

Fig. 3.—Diagram of viscera in thoracic and abdominal cavities.

Fig. 4.—Diagram of twin oesophagus and stomach.

of the left lobe of the liver, and some of the small intestine. A separate oesophagus and stomach were associated with each head, but the duodenum fused just beyond the pylorus and thereafter there was a single intestinal tract.

As the specimen was required for preservation the spine was not dissected, but radiographs showed the fusing of the two spinal columns in the mid-dorsal region.

Schizophrenia in Uniovular Twins: Recovery

The study of uniovular twins is of great value in establishing a genetic element in schizophrenia. Two fallacies must be excluded. Firstly, one must remember that twins occupy the same place in the family hierarchy and are apt to have very similar conditioning factors in upbringing and education; secondly, one must exclude the possibility of *folie à deux*, of infection between two persons who live in close association. Both these were fully excluded in the unique case recorded by Craike and Eliot Slater (1945), in which the twins were separated at the early age of 9 months and were brought up in completely different environments. Nevertheless, they both developed paranoid schizophrenic disorders with similar symptomatology.

The pair recorded below were not completely separated until the age of 17, when each went to study in distant

separated universities. But even before that time there had been a number of differences in environmental stresses; yet they both developed schizophrenic illnesses with similar symptomatology within a year of each other. Both made good recoveries with insulin shock treatment and resumed their studies.

CASE REPORT

Twin B, born one hour later than twin A, suffered a severe scalding of her legs with shock at the age of 2½. Up to about the age of 10 (I.Q. then recorded as 137) the twins did not show significant differences, but differentiation became marked after B developed an eye ulcer which kept her away from school for a while, and she had to be moved to a lower form. Twin A began to forge ahead. Twin B became frustrated in the competition with A; however hard she tried, A always came first. Finding she could not beat her sister in arts, she took up science, entering a university in October, 1950. She had an attack of shingles in December, 1952, but some weeks earlier had become excessively religious. The acute breakdown occurred in March, 1953, at the age of 20. She began to pray for the conversion of her parents, was alternately elated and depressed. On admission to hospital she exhibited an ambivalence of mood and thought: at times she would describe herself as the Virgin Mary or Queen of the Realm, talked of opening up the Kingdom of Heaven, wanted to get married to the Lord Jesus; at other times she called herself Judas Iscariot, thought she had sold herself to the devil and ought to be crucified. After undergoing a course of E.S.T. (9 shocks) and I.S.T. (30 comas) she made an excellent recovery. In October, 1953, she resumed her studies, and took her B.Sc. in August, 1954.

Twin A developed the first signs of schizophrenia about a year later. In December, 1953, she became intensely self-critical, accused herself of laziness and apathy, maintained that she had led a deplorable life, described herself as despicable and a menace to everybody. On admission to hospital about a month later she claimed that she had seen God in the form of a light, was told that she would give birth to a child who would be called "Love," and thought that she had a special mission on earth. A Wechsler-Bellevue II gave her an I.Q. of 137. The Rorschach, M.M.P.I., and Szondi tests all pointed to a schizophrenic illness. After a course of I.S.T. (50 comas) she made a good recovery. Early in 1955 she obtained an honours degree.

COMMENT

Folie à deux can be excluded because the twins studied at far-separated universities for over three years. Moreover, in the earlier years, twin A was the more dominant and stronger character, but it was twin B who first developed schizophrenia; also, twin A informed me that she had no sympathy with B's religious ideas. Though as children they were often confused because of similarities, as time passed differences of environmental strains and stresses determined differences in their personalities, and they soon grew away from each other. Nevertheless, a strong genetic factor doomed each of them to schizophrenic breakdowns with similar psychic patterns and subsequent recoveries.

Of the 41 uniovular twins reported by Eliot Slater (1953), in which one member was schizophrenic, there was concordance in 28 instances, and in only 9 of these did the ages of onset differ by one year. This indicates that environmental factors are also of importance in the development of schizophrenia. In the pair reported here environmental differences were not strikingly marked, and this no doubt helps to account for the similarity of onset and clinical picture.

Reviews

"STARLING"

Principles of Human Physiology. Originally written by E. H. Starling, M.D., F.R.C.P., C.M.G., F.R.S. Twelfth edition by Sir Charles Lovatt Evans, D.Sc., F.R.C.P., F.R.S., LL.D., with chapters on the special senses by H. Hartridge, M.A., M.D., Sc.D., F.R.S. (Pp. 1,233+xii; illustrated. 65s.) London: J. and A. Churchill Ltd. 1956.

This volume possibly represents the last edition of this book. It is at the same time in many respects the best. To compare it with the earlier editions as written by Starling and the later editions as written by Sir Charles Lovatt Evans has been an interesting and fruitful study and is the basis of the statement that it is the best of the twelve. Each has in its generation been outstanding, and the comparison has been of interest to see the way the two authors measured up to the task. Starling had the easier task in a way: he initiated the book; he told of the physiology of his time as it appeared to him as he wrote each edition, and he spoke from his heart as one of the best teachers and most brilliant lecturers and one of the great originators of the subject. Evans, his pupil, took up where Starling relinquished at the time when the fission of physiology into the different disciplines of biochemistry, pharmacology, biophysics, and experimental medicine was well under way. Each was still adding new facts and new interpretations to biology; it alone could integrate these new findings in terms of the newer physiology. In so doing Evans has succeeded in preserving the unity of the book, aided in the section on the special senses by Professor Hamilton Hartridge and in the excellent index by Dr. Grace Eggleton.

The size of the book has been unaltered since the eleventh edition. The new material includes sections on the adrenal hormones, fat metabolism, intracellular and end-plate potentials, and conduction in the spinal cord. The volume has become very compact in the process and is essentially a standard of reference for the research worker and advanced student. This aspect of "Starling," which is due to Evans, is well shown by two particular points: the historical introduction to each section, and the arrangement of references to original papers as footnotes with reviews and monographs at the ends of the chapters. It may well be that no book should exist for more than 30 or 40 years. After that its basic plan needs scrapping and a new book to be written with a new balance between the different disciplines and aspects. In this case "Starling" would appear to be an exception in that its adaptation to modern developments in the subject is outstanding.

THE DISEASES OF DICKENS

Charles Dickens and his Family: A Sympathetic Study. By W. H. Bowen. (Pp. 182. No price.) Privately printed by W. Heffer and Sons Ltd., Cambridge. 1956.

Mr. W. H. Bowen, in his foreword to this book, tells us that it developed first out of his interest in the medical history of Charles Dickens, but that it gradually expanded into a series of studies of the novelist and some members of his family, including his father, his mother, and his wife. For medical readers the chapter on the medical history of Charles Dickens will hold the most interest. Dickens died at 58 years of age, and Mr. Bowen, out of his surgical knowledge, makes the retrospective diagnoses of renal calculi, chronic renal disease, gout, anal fistula, and cerebral atheroma.

Sir Henry Thompson, first consulted in 1867 about the novelist's great toe, decided that the trouble was due to an inflamed bunion associated with erysipelas. In 1869 he may have altered the diagnosis to gout, but, if he did, Syme, seen a week later in Edinburgh, ridiculed the notion that gout was the cause of the inflammation and supported the original bunion hypothesis. The many mistakes made by

Victorian consultants, unfortified as they were by our diagnostic advantages, are matters of history; their diagnostic triumphs are forgotten. Moreover, Dickens's later consultation with Sir Thomas Watson, when the first symptoms of cerebral arteriosclerosis appeared, shows that the Victorians did not escape our prognostic perplexities. The question to be decided by the great man was: Should the Readings (those histrionic triumphs made familiar to us in this generation by Emyln Williams) be resumed? Sir Thomas Watson, after Dickens's death, defending his agreement that they should be continued, wrote: "I expressed some apprehension that he might fancy we had been too peremptory in our injunctions of mental and bodily repose in April, and I quoted the following remark, which occurs somewhere in one of Captain Cook's voyages, 'Preventive measures are always invidious, for when most successful, the necessity for them is least apparent.'"

This book is well written and it is an interesting supplement to existing biographies. It has no index and no bibliography.

D. V. HUBBLE.

DERMATOLOGY AND MYCOLOGY

Clinical Selections in Dermatology and Mycology. By Frederick Rehm Schmidt, A.B., M.D. Contributions by thirty-six specialists from various lands. (Pp. 505+xx. 80s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This is a most attractive and interesting volume which will entertain and stimulate the dermatologist and mycologist. It contains a collection of essays written in uninhibited fashion by some 36 physicians and scientists, mostly from those countries which "comprise the Americas." The essays are founded upon experience in very differing climates and among different races and peoples, and express the opinions which the specialists have built upon that experience—opinions which do not necessarily coincide with those of the usual textbooks. How different from our own is the experience of some of the contributors is indicated by the following observation: "The incidence of pyogenic disorders would be greatly reduced in countries where the cost of the antibiotic drugs is high, if good soap were available at a price that everyone could pay. This would put an end to ineffective cleansing with wood ashes and alkaline fruit juices."

Some early papers are devoted to spasm of the smallest arteries and arterioles as an important aetiological factor in disease, and treatment with vasodilating agents is recommended for affections as diverse as herpes simplex, allergic dermatoses, pityriasis rosea, and leprosy. Riehl contributes an excellent paper on tuberculosis of the skin, Hailey on familial benign pemphigus, and Becker on the melanoma. A most instructive chapter on sunlight and skin diseases in the Tropics is written by Corrales-Padilla, and another on deficiency dermatoses by Schmidt. There is much to be learnt about nutritional disorders, pigmentary disturbances of the skin, and the effects of light from this study of their behaviour in the various American countries. Lichen simplex was seen much more frequently in the Japanese and Chinese than in the Caucasian, and more often in the Filipino than in either. A large part of the work is devoted to fungous and infective diseases not met with in Britain, but the general contribution to knowledge made by these studies is of value to the whole field of medicine. The authors are to be congratulated upon a pleasing and valuable work.

J. T. INGRAM.

In revising *Bellows' German Dictionary* for its third edition (Longmans, Green and Co., 15s.) the compilers have separated the German-English from the English-German section instead of showing both on the same page. The new type and format make it a clear and handy volume. Features of the dictionary are a short section on German grammar, a glossary of German motoring terms, and the inclusion of translated phrases where their key words appear in the text.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 3 1956

SPENS AND PRESENT DISCONTENTS

At last a further stage has been reached in the long-drawn-out negotiations between the profession and the Government over the fulfilment of the Spens recommendations by the latter. When the profession's Negotiating Committee met the Ministers in August Mr. R. H. Turton, giving ground a little, invited the Committee to provide a legal report on what it believed to be a contractual obligation of the Government to carry out the recommendations of the Spens Committees; and this necessitated an examination of the meaning of the recommendations. A document published in this week's *Supplement* presents the results of this examination by the Association's legal advisers, under Sir James Millard Tucker.

The substance of the obligation is, in the words of this week's document, "that the rates of remuneration that would thereafter become payable to the individual serving members of the profession would at all times conform with the requirements involved in the recommendations of the Spens Committees." The obligation is a general overriding one to the profession as a whole. Personal contracts relating to pay are merely the formal agreement with individuals of rates of pay which were fixed as in accord with the Spens recommendations at a given date of review. But, if the scales of pay recommended require periodical adjustment when certain events occur, individual personal contracts would have to be amended. "This," the document states, "follows from the fact that continuing compliance with those requirements still remains as an overriding contractual obligation of the Government to both branches of the profession as a whole. In short, the requirements of the Spens recommendations, whatever they may be, remain at all times the paramount and governing consideration in relation to remuneration." The legal verdict is that of common sense, and in line with the interpretation consistently given for years past in these columns.

It is then asked whether the Spens recommendations "envisage and require periodical adjustments" of remuneration in the light of changes in the value of money or increases in other professional incomes, "at any rate where these changes are of a substantial character." The Minister of Health in August this

year asserted that the Spens recommendations applied only to remuneration at the time of entry into the Service. The document effectively deals with these contentions of the Minister by reference to the wording of the Spens Reports, to what has hitherto been accepted by Ministers of Health, and to the construction put on the recommendations by Mr. Justice Danckwerts in making his award in 1952. In brief, the matter is governed by the terms of reference which required the Spens Committee, in 1945, "to frame their recommendations with due regard to the desirability of maintaining in the future" the proper social and economic status of doctors in a public service, and its power to attract suitable recruits. No limitation was put upon the duration of the future. Clearly the Committee's task was to produce a long-term policy. The base line for the recommendations was the year 1939. And the Committee determined what should have been the proper scales of net remuneration in 1939 to maintain the proper social and economic status of the medical profession and its power to attract suitable recruits. They found that the actual total net remuneration of general practitioners in 1939 fell short by some £3m. of the desired total. This revised "what-should-have-been" in 1939 became the standard to which all future adjustments should be referred—adjustments related to the changed value of money and to the increases in other professional incomes. Ministers have recognized the need for periodical adjustment of practice expenses: "It would be an odd result if one factor is clearly to take account of all subsequent changes in the value of money, and the other is not." Perhaps the most convincing evidence that the Government know very well that the Spens recommendations envisaged continuing adjustments is given in the observation by the Ministry's Deputy Accountant-General quoted in the document, and by the fact that the adjudicator, Mr. Justice Danckwerts, made his award in relation to two betterment factors calculated for different periods.

The closely knit and—so it would seem—unanswerable argument is there for all to read in this week's *Supplement*; but no one can feel otherwise than cynical and weary in reflecting that Minister after Minister has resorted to every trick of evasion in order to escape honouring a bond entered into by Government and profession in 1948. Our correspondence columns during the past weeks show that the present and mounting discontent is as much with the National Health Service as a whole as with the Minister's procrastination and prevarication over pay. There is something fundamentally wrong, it is felt, in a sickness scheme which gives everyone everything, or almost everything, apparently free of charge. Such a scheme, it is thought, puts a premium on irresponsibility. The report of the World Medical Association

tion on medical aspects of social security¹ expressed anxiety on this score in a conclusion which contained the following observations: "Doctors are interested in and welcome plans for medical care which enable them to look after their patients more efficiently. . . . While they recognize that society has an obligation to help those who . . . are handicapped in the struggle to survive, they fear the demoralizing effects of State paternalism exercised on adults. . . . In what is called the Welfare State social security schemes loom large, and in these schemes the provision of (apparently) free medical services is important. . . . The more the State does for the individual in this direction, the less is the individual sense of obligation and responsibility."

Several recent correspondents have looked inquiringly at what is being done elsewhere, especially in the Dominions. The medical services, for example, organized under the guidance of the British Medical Association in Australia have features which are growingly attractive to many who are disillusioned by the British scene. In Australia the essential drugs, "the life-savers," are free to everyone without discrimination, and everyone has to pay for the simple household remedies, the total cost of which so grossly inflates the drug bill of the N.H.S. in Britain. To put a tax on all prescriptions, as both Labour and Conservative administrations have done, is to make the worst of all worlds. In Britain the private patient, who helps to pay for the public service through taxation, is not allowed to take advantage of only one set of its provisions—the pharmaceutical services—though he was promised that this should be possible. In Britain the general practitioner is paid according to the number of "heads" he collects on a list. In Australia, as in many other countries, the reward is in direct relation to the service given. These differences in running medical services in other countries, so the argument seems to run, may well be improvements. Certainly in Australia the public and the profession appear to be content.

The discontent expressed in recent letters in the *Supplement* cannot be lightly dismissed, nor is it by any means related solely to the present dispute with the Ministers about pay. Our correspondence columns give voice to a disquieting sense of frustration and almost apathy. If this spirit becomes widespread, then no amount of extra money in doctors' pockets will attract suitable recruits to the profession of medicine. The Spens Reports were rightly concerned that pay in a publicly organized service should be such as to attract suitable recruits and to maintain the proper social and economic status of the practitioner in it. And the profession is going to insist that the Government shall keep to its bargain, stick to its

word, honour its bond. But, once this battle is over, all concerned might well look at the N.H.S. as a whole, and at its many particulars, to see if indeed it is such as to attract suitable recruits, is such as to give Britons the best possible medical service and British doctors the best possible chances of providing it. It is evident that many doctors do not believe it does in the conditions of to-day.

SURVIVAL AT SEA

Those looking for the sensational in the report¹ from the Medical Research Council on "The Hazards to Men in Ships Lost at Sea" will be disappointed. Professor R. A. McCance and his co-authors have an unemotional approach to the subject, but their final report makes absorbing reading. They collate the information obtained from the survivors of 448 wartime (1940-4) sinkings, involving 27,000 men and women. The main question the authors asked themselves was, "How many failed to survive, and why?" first in the actual sinking, then in the sea waiting to be picked up, and finally, while on lifeboat or raft, until eventual rescue. Nearly all possible factors are considered, and the influence of each on the survival rate is brought out clearly in numerous tables and histograms; factors not discussed, presumably for lack of reliable information, are age, sex, injury, and the all-important intangible, morale.

Seventy per cent. of the ships sank within fifteen minutes of being hit; nevertheless in this time 48% of the boats and 45% of the rafts were launched. When ships stayed afloat for thirty minutes or more 72% of boats were launched. More than a quarter of those at risk either died in the sinking or were never picked up. The authors consider this initial mortality needlessly high; alternatives to lifeboats should, they suggest, be capable of being manned and got away under all conditions, and some should be manoeuvrable against wind and sea to pick up men helpless in the water. Only an experienced seaman could say whether this is a valid criticism. Eight per cent. of those who reached lifecraft subsequently died. Thus only two-thirds of all the men and women from the stricken ships survived, and then not unscathed. "Immersion foot" took its toll, often with eventual amputation, whenever the sea temperatures

were below 20° C. An additional hazard, numerically unimportant, was attack by sharks or other fish, which could be fatal. According to this report fuel oil, even when swallowed, was not the danger it was reputed to be.

The chances of being picked up were, of course, reduced by darkness and bad weather, but cold was not quite as lethal as others had predicted.² Many men survived prolonged immersion in cold water: 31 out of 40 men picked up after sixty minutes in water at -1° C. survived. With sea temperatures below 10° C. 17% of the survivors died within 24 hours of rescue, but no man died within 24 hours of being picked up from warmer water. In the cold high latitudes the men had protective clothing, and this seemed to help even during immersion. All but 1,587 of those who reached the lifecraft were eventually rescued; one-third of these losses were accounted for by the 4% of lifecraft which were never found again. The chances of being rescued within ten days were good, 80% of lifeboats launched, and about the same proportion of rafts, being picked up within this time, half of them within 48 hours.

The report first examines sea temperature as a factor associated with the 1,000-odd deaths in the boats that were rescued. Below 10° C. the mortality rate in the boats was 20%, and in warmer waters it was between 6 and 7%. Deaths from cold occurred with sea temperatures up to 20° C., and even in warmer waters cold at night was sometimes complained of and protective suits were generally appreciated. Men became injured to heat and sunburn within the first few days, and there was no special call for the shade and protection from the breeze suggested by J. L. Gamble.³ The mortality rate among 12,340 survivors adrift for two days or less was only 2%, but 25% of 905 who were in the boats for 15 days or more died. Some long voyages were successful; only one man out of 23 was lost on a 49-day voyage which began in mid-Atlantic in the region of the doldrums; but on a 77-day voyage, starting from almost the same area, only one man survived out of 20. The causes of death could not be determined, but lack of food and water was undoubtedly contributory; on 11 out of 175 voyages no food at all was available, and on some of the voyages there was no water. Some may remember hearing stories of food and water containers being so rusted up that it was impossible to open them when required, but there is no mention of this in the report. The Board of Trade ration of biscuits, milk tablets, pemmican, and chocolate seems to have been the standard; on only eight voyages were fish and birds caught. The food available provided 300 to 400 calories per man per day. Pemmican, physiologically undesirable in any case,⁴ was disliked; but tinned fruit and sweets were much

appreciated—evidence in favour of the suggested carbohydrate diet for castaways.⁵ Fat provided one-third of the calories.

Water is essential to the castaway. Of 113 men on voyages lasting from 3 to 15 days with no water available, 57 died—53 in less than 6 days. On voyages of more than 32 days with 4 oz. (114 ml.) of water or less per man per day, 90% died. With 4 to 8 oz. (114 to 228 ml.) per day survival rates were excellent, for only one man died out of 62 adrift for at least 37 days, and the overall survival rate for voyages of three days or more was 92%. Increasing the water supply to more than 8 oz. (228 ml.) daily raised the survival rate to 98% for any length of voyage. These survival rates are higher than would have been predicted from laboratory trials⁶—for instance, in one experiment a 3% loss of body weight occurred in 48 hours with a daily water intake of 8 oz. (228 ml.). This apparent discrepancy was caused by unmeasured supplements of rain water. But as rain cannot be relied upon it is surely unwise to suggest that, provided there is a daily minimum of 4 oz. (114 ml.) of water, there is little to worry about. Uncritical acceptance of this might imply that the present lifeboat ration of 110 oz. (3.2 l.) per man could be reduced and discourage crews from accepting the earlier recommendation⁷ of the Medical Research Council to take as much extra water as possible. The report makes no mention of attempts to supplement water supplies by fish juice—a practice of questionable value⁸ recommended by A. Bombard⁹—but sea water was drunk in unspecified quantities on some voyages. The mortality of the sea-water drinkers was 38.8%, ten times that of those who drank only fresh water, but, contrary to theoretical expectation,¹⁰ their mortality was less, instead of more, marked at higher temperatures. There are physiological reasons why it is dangerous to drink sea water, even in small amounts,¹¹ but recent American work suggests that it may be physiologically permissible to eke out fresh water with limited amounts of sea water.⁵ According to the figures in the report the mortality of the sea-water drinkers did diminish as the fresh-water supplies increased, but with so many other factors involved this theory can be neither proved nor disproved from the information available.

POSTGRADUATE MEDICAL SCHOOL OF LONDON

Thirty-five years ago the first Minister of Health, Dr. Christopher Addison (later Lord Addison) appointed a committee under the chairmanship of the Earl of Athlone to investigate the needs of medical practitioners for further education in medicine in London. With commendable promptness the committee issued its report in June, 1921, and one of its

recommendations was the "institution of a post-graduate medical school attached to a large and well-equipped hospital." Thereafter the pace became slower. It was not until 1930 that a "practicable" scheme was finally arrived at and approved by the Government. This made provision for the conversion of the Hammersmith Hospital (then under the control of the London County Council) into a post-graduate teaching hospital of 400 beds and a medical school with residential accommodation. The Athlone Committee had regarded it as essential that the post-graduate medical school should be part of the University of London, and this was accepted by the Government.

In 1931 a Royal Charter was granted to the school, and Sir Austen Chamberlain, who was also taking an active part in the management of the London School of Hygiene and Tropical Medicine, was appointed the first chairman of the governing body. One of the more serious financial crises to which we have since become accustomed was then approaching its climax, and only £200,000 was made available to start the scheme instead of the expected £500,000. The foundation stone was laid by Mr. Neville Chamberlain, then Chancellor of the Exchequer, in 1933, and two years later the school was officially opened by King George V. Though seriously handicapped by the drastic curtailment of the original plans, the school established itself firmly in the years before the second world war, being staffed as four professorial units. The professors, readers, and assistants were whole time, but help was given with teaching by members of the staff of other London hospitals.

The outbreak of the second world war put a stop to the expansion of the school, but much good work was done during the war in acclimatizing refugee doctors, in training undergraduates, in holding courses for serving medical officers in the medicine and surgery of war, and in the undertaking of special research work. Since the end of the war there have been some structural changes: the war-damaged hospital has been repaired (there are now 694 beds), a building for the Medical Research Council's cyclotron has been opened, and new laboratories have been provided on top of the existing school buildings. Last year a new unit for the investigation of metabolic disorders was opened. In an attempt to make more room for students the library was taken over as a laboratory in 1947, and the books were housed in a prefabricated hut as a temporary measure: they still remain there. Under the National Health Service Act the Hammersmith Hospital was joined with the West London Hospital in Hammersmith Broadway

and St. Mark's Hospital, City Road, to serve as a teaching unit under the same board of governors, and with the creation of the British Postgraduate Medical Federation in 1945 the organization of postgraduate medical education in London was put on a much more satisfactory basis. Along with the various specialist institutes in London, the British Postgraduate Medical School at Hammersmith—renamed the Postgraduate Medical School of London—became an institute of the Federation, of which Sir Francis Fraser is the director.

In spite of the difficulties caused by inadequate accommodation the Postgraduate Medical School has more than fulfilled the high expectations of its founders. King George V, when opening the school in 1935, said that he hoped it would "play an imperial role in the winning and dissemination of medical knowledge, in the relief of suffering among my people in this country and overseas, and in enabling the doctors of all lands to come together in a task where all must be allies and helpers." Thanks to the brilliance and eagerness of the staff of the school it has indeed played an "imperial role," for it is the only medical school in Great Britain and the Commonwealth devoted wholly to postgraduate education in medicine, surgery, and pathology. The work of the school is directed primarily to the training of teachers and specialists, and at the present time thirty-three professorships in the Commonwealth and elsewhere are held by former members of the staff or of students of the school. Since it came into existence the school has contributed to the further education of about 12,000 qualified doctors, of whom over 5,000 have come from outside the United Kingdom. In research, too, the school has been outstandingly successful: in fact, few medical institutions in the world have so consistent a record. Among methods of investigation which the Postgraduate School has played a leading part in developing are cardiac catheterization and liver biopsy, and workers at the school have made many important contributions to the knowledge of renal disorders, hypertension, anaemia, silicosis, besides exploring such new fields as the relationship between blood groups and disease and the use of heart-lung machines in cardiac surgery.

The success of the school has had the natural consequence of attracting to it an ever-increasing number of medical graduates wishing to take advantage of its unique facilities, and the time has now come for putting into effect the plans which have been made for an orderly expansion of the school buildings. The school's financial grant from London University can be used only for maintenance expenses, and therefore a public appeal is being made for the £750,000 which

is the estimated cost of the extensions. Details of this appeal and of the impressive buildings which have been designed are given elsewhere in this issue (p. 1052). The achievements of the Postgraduate Medical School in the past twenty years have enhanced the reputation of British medicine, and medical men and women all over the Commonwealth will hope that the organizers of the appeal will soon be able to hand over the sum which is needed to give the school the buildings it deserves.

THE DIABETIC FOOT

The higher incidence of atherosclerosis in diabetics is still a matter of some dispute, largely because the criteria of diagnosis of arterial disease have varied with different investigators. This problem is further complicated by the occurrence of diabetic neuropathy, which can produce pain and coldness in the foot and also tissue loss leading to chronic ulceration and gangrene. Apart from neuropathy and ischaemia, the increased susceptibility of the poorly controlled diabetic to staphylococcal sepsis has also to be kept in mind. Moreover, in many cases all three disorders will be present in varying degree. Their proper assessment is important in planning treatment and considering prognosis. In a paper published in last week's *Journal* Drs. Wilfrid Oakley, R. C. F. Catterall, and M. M. Martin¹ have helped to throw some new light on the problem.

In neuropathic lesions loss of appreciation of pain is the important sign. Areas of pressure necrosis occur on the toes and bony points, favoured by the characteristic deformity of dorsal dislocation of the toes, which makes any normal shoe ill-fitting. If the trauma is allowed to continue ulceration will result, and this may be complicated at any time by sepsis. In many of these cases the blood supply is adequate, and suitable treatment, including avoidance of pressure, good control of the diabetes, and possibly surgery, usually results in normal healing. Arterial disease in diabetics often presents with gangrene. In the majority of patients this is confined to one or more toes and is due to thrombosis of the digital artery. When the foot is involved, with the development of severe pain of a burning nature while at rest, the anterior and posterior tibial arteries are the site of the thrombosis. The foot is discoloured, is hyperaesthetic, and cold, and the ankle pulses are absent. In the diabetic, in contrast to the non-diabetic, occlusion of one of the main trunks is uncommon, but it does occur. In such cases a prior history of pain in the calf on exercise will be forthcoming. Speaking on this subject recently at the Royal Society of Medicine, Professor C. G. Rob² emphasized that, when gangrene of a main vessel is suspected, arteriography is an essential investigation, so that the feasibility of arterial reconstruction, either by endarterectomy or by the insertion of a by-pass graft, can be considered.

¹ Oakley, W., Catterall, R. C. F., and Martin, M. M., *British Medical Journal*, 1956, 2, 953.
² See *British Medical Journal*, 1956, 2, 880.
³ *New Engl. J. Med.*, 1955, 283, 685.

Dr. Oakley and his colleagues rightly recommend a more urgent approach when the question of amputation arises. The use of antibiotics has tended to postpone surgical removal of the dead part in the expectation that the infection will subside. Because drainage is inadequate, the reverse is more often true. The gangrenous toe should be disarticulated at an early stage and the wound left open to granulate. When gangrene has spread beyond the toes amputation below the knee is necessary. The most important single precaution in such an operation is the avoidance of tension. Again the wound is better left open and secondary suture carried out later.

If treatment is to be effective a proper understanding of foot lesions in the diabetic is essential. Neuropathy seems to be a more frequent cause of such lesions than arterial occlusion; because their development is insidious they may remain unrecognized and unattended for some time, perhaps until sepsis complicates the picture. In a review³ of 502 diabetic patients with surgical abnormalities of the feet the Committee on Diabetes of the Massachusetts Medical Society found that the great majority had had a lesion for one or two months before entering hospital. This delay was largely responsible for the average hospital stay exceeding 30 days. One-fifth of the patients were in hospital for 60 to 100 days. These findings underline the need for early recognition of foot lesions in diabetics and for their early treatment. Patients are often allowed to be up and about for too long; and to rely on the use of antibiotics in the face of unresolved infection or of deficiency in the blood supply is to take a serious risk. Furthermore, many diabetic patients are unaware of the dangers of the painless foot and of the need for regular medical supervision, with early care of what may seem to be a trivial lesion.

WORLD POPULATION

The population of the world has more than doubled itself in the last hundred years, and the United Nations Statistical Office estimates the 1954 figure as 2,652 million.¹ More than half (1,451 million) live in Asia. Europe contributes a total of 404 million, America 357 million, Africa 210 million, Oceania 14 million, and the U.S.S.R. (not included in Europe or Asia) 214 million. The most densely populated continent is Europe, with 82 persons per square kilometre. Asia comes next, with 54 persons per square kilometre, and other continents are more sparsely populated with fewer than 10 persons per square kilometre. In the past four years an increase of 148,000,000 has meant that every day there have been an additional 100,000 mouths to feed. By 1980 world population will exceed 3,500 million if the present tendency continues²; by 2056 it will have reached 6,000 million.³ The present rate of increase varies in the

⁴ *Ibid.*, July 27, 1956.
⁵ *Manchester Guardian*, July 27, 1956.
⁶ *P.E.F. World Population and Resources*, 1955, London.

different continents. Oceania has the highest rate of over 2.5% per year, owing in part to the large amount of immigration. Contrary to what is often popularly supposed, the U.S.A. has the next highest annual rate of increase with 2.0%. Asia, Africa, and the U.S.S.R. have an annual increase of about 1.5% and Europe one of 0.7%.

There are widely divergent views in different countries on the treatment of this problem. This is typified by recent newspaper articles^{4,5} which discussed the present position in China and Japan respectively. At the present time the population of China is probably more than 600 million, or about a quarter of the world's total. Its rate of increase has been variously estimated, but may be as high as 2%. The density of the population is low by comparison with many countries, being only 60 persons per square kilometre (that of England and Wales is 293 per square kilometre). However, owing to climatic conditions it is unevenly distributed, nearly one-half of the area being inhabited by only one-twentieth of the population. Nevertheless, official Chinese policy says that she can provide room for a further 600 million people. In Japan, on the other hand, the population has almost reached 90 million. Before the war this figure was regarded as "explosion point," and the Japanese Government is treating the problem as one of great seriousness. It was recently estimated that there are 1,500,000 legal or illegal abortions annually, almost equal to the number of live births, and this high abortion rate keeps the Japanese birth rate down to 19.4 per 1,000. The difficulties of getting Western methods of birth control generally adopted in the Orient seem to be almost insuperable, at least at present. Moreover, we still know little of the potential resources for increasing world food production whether on land or in the sea.

The Food and Agriculture Organization of the United Nations has estimated that world output of food has increased by about 1% per annum since 1938.⁶ The present increase in world population is of the order of 1.5% per annum. However, the position is more serious than this global estimate may lead us to believe. Outside China the population in the Far East is increasing at about 1.3% per annum, while the increase in food supply is only about 0.04%. This problem certainly presents "a challenge to which the generation which has penetrated the secrets of the atom should be capable of finding a constructive reply."⁷

CHLORPROMAZINE JAUNDICE

It has long been recognized that jaundice can occasionally develop as a result of exposure to various drugs or chemicals. Cinchophen, carbon tetrachloride, and trinitrotoluene are well-known examples. The jaundice in the majority of these patients has developed as a result of severe injury to the parenchymal cells of the liver. Some substances—arsine, for example—cause jaundice as a result of intense haemolytic action on the erythrocytes. During the recent war a third and exceed-

ingly important mechanism of iatrogenic jaundice was discovered—namely, the transmission of the virus of homologous serum jaundice by incompletely sterilized needles or syringes. More recently yet a fourth variety of jaundice has been recognized, which is seriously limiting the use of some otherwise beneficial drugs. The therapeutic agents that have been most frequently blamed are chlorpromazine¹ and methyl testosterone,² though some cases have been attributed to arsenic³ and to manganese.⁴ The clinical and laboratory findings in this fourth group are quite distinct from the others in that the jaundice is typically obstructive in character and the degree of parenchymal damage is negligible.

Since the illness induced by chlorpromazine and methyl testosterone is usually mild, and the lesion apparently reversible when the drug is withdrawn, opportunities of studying the morbid anatomical changes are few. A. A. Stein and A. W. Wright,⁵ however, have recently had four cases, of which three came to necropsy as a result of their non-hepatic disease; from the fourth a biopsy specimen was obtained during laparotomy for suspected extrahepatic biliary obstruction. The lesions, although at different stages in the different specimens, were all of the same type.

In the earliest stage the centrilobular liver cells showed a slight degenerative change and were deeply stained with bile. The adjacent Kupffer cells were similarly stained, and the bile canaliculi in the central zones were distended with plugs of bile. The more peripherally situated canaliculi and the bile ducts in the portal tracts were normal. Cellular infiltration of the portal tracts, which in cases of viral hepatitis is usually severe, was slight and mostly lymphocytic. Clinical improvement of the jaundice was associated with reduction of bile staining of parenchymal and Kupffer cells and the disappearance of the biliary plugs in the canaliculi.

The pathogenesis of this form of jaundice is not at present understood. The most widely held view, with which Stein and Wright agree, is that an increase in the viscosity of the bile impedes its flow along the narrow bile canaliculi. In consequence bile accumulates upstream—that is, in the centrilobular zones. The mild degenerative changes seen in the liver cells could then be regarded as a consequence of the obstruction of outflow of their secretion. Alternatively, the stagnation of bile in the centrilobular capillaries might well result from the lack of secretion pressure by the functionally impaired parenchymal cells, and, since the centrally situated cells have the furthest distance along which to propel their secretion, this tends to accumulate in the centrally situated canaliculi. The final decision must obviously await the development of a technique for determining the viscosity of freshly secreted bile. In either event some impairment of function of the parenchymal cells is implied, despite the present lack of laboratory or histological confirmation.

THE B.M.A. VISIT TO THE U.S.S.R.

BY

J. G. M. HAMILTON, M.B., F.R.C.P.Ed.

Physician, Royal Infirmary, Edinburgh

At the invitation of the Ministry of Health of the U.S.S.R. and the Academy of Medical Sciences a party of seven, representing the British Medical Association, visited the Soviet Union from August 4 to 26, 1956. The party consisted of Sir Geoffrey Jefferson, who acted as leader, Dr. Mary Esslemont, Mr. Ian Fraser, Professor G. W. Pickering, Dr. Ralston Paterson, and myself, with Dr. Alexander Duddington as interpreter. It will be recalled that in 1955 a party of six Soviet medical men and women visited Great Britain as guests of the B.M.A.

Members of a delegation such as ours must receive impressions as medical visitors, as guests, and as tourists in the country visited, and these impressions are likely to have varied from member to member, since our experience and our spheres of work were all different. The following is an account of some of my impressions.

The Academy of Medical Sciences

In our capacity as medical visitors with varying interests we naturally tended to break up into two and sometimes three groups, though on a number of occasions we paid visits as a whole group. We were received at the Academy of Medical Sciences of the U.S.S.R. in Moscow by the President, Professor Bakulev, and some of his colleagues, who discussed with us the organization of the Academy. The Academy carries out its function of promoting and organizing medical research through three divisions—of Medical Biological Sciences; of Clinical Sciences; and of Hygiene, Microbiology, and Epidemiology. In each division are a group of institutes, as, for example, the Institutes of Pharmacology, Virology, Nutrition, Surgery, Chest Surgery, Neurosurgery, Therapy (Internal Medicine), and the Brain Institute. There are twenty-one institutes in the three divisions. Many are situated in Moscow, some in Leningrad, and the remainder in other cities of the Union. The Academy has 110 full members and 150 associate members. Full and associate members are elected by secret ballot by the Academy in full meeting from amongst the most prominent people working in the various fields, on the proposals of the institutes, the merit of the work done having been assessed by the Presidium of the Academy through an advisory committee.

Alongside the Academy with its institutes is the Ministry of Health, which also controls a series of institutes throughout the country. The Presidium of the Academy and the Scientific Committee of the Ministry of Health combine to draw up a five-year plan of research, laying down the main problems to be tackled and apportioning these between the two groups of institutes.

Atherosclerosis and Hypertension

Much active work is evidently going on of which we were able to see only a fraction, owing solely to limitations of time and place and in no way from any reluctance on the part of our hosts. Whatever we asked to see was open to us. In one laboratory after another we saw work going on on the experimental production of atherosclerosis by cholesterol feeding and similar means. The three who visited him in his laboratory in Leningrad were greatly impressed by Professor Anitchkov, who described experimental cholesterol-induced atherosclerosis as early as 1912 and has been working on the problem ever since. This fine

FIG. 1.—Professor Anitchkov in conversation with Professor Pickering in Leningrad.

old man, who, as he said, had survived two major wars and two revolutions, is evidently a first-class experimental pathologist and a teacher of the highest standard with whom it must be a privilege to work.

In the Institute of Therapy in Moscow Professors Mesnikov and Speranski are concerned with two lines of approach, amongst others, to problems of atherosclerosis and hypertension; in the former, the preventive or mitigating effect on experimental atherosclerosis of ascorbic acid and of sedatives such as phenobarbitone and chloral hydrate, and the aggravating effects of vitamin D, of cerebral stimulants, and of hypertension; in the case of hypertension, the production of stable hypertension in dogs by the induction of Pavlovian neuroses. They are developing their view that human hypertension in the initial stages represents a neurosis in the Pavlovian sense. This view is also the basis of work proceeding in the Medico-Biological Research Station at Sukhumi in Georgia (director, Professor Yudkin), which we were enabled to visit. Here a large colony of experimental monkeys is kept in which spontaneous stable hypertension is attributed to the spontaneous occurrence of neuroses and in which the experimental production of Pavlovian neurosis is followed in a proportion (unspecified) of cases by stable hypertension, and in others by what is claimed, less convincingly, to be myocardial infarction without coronary atherosclerosis.

FIG. 2.—Pavlov's study.

At the Pavlov Institute of Physiology in Leningrad active work is going on in following up Pavlov's concepts of higher nervous activity, cortico-visceral relations, and the inheritance of acquired characteristics. Pavlov's own laboratory at the Institute of Experimental Medicine of the First Leningrad Medical Institute, where he worked till his death in 1936, is preserved as a museum of the great man, his study still containing the furniture and articles (even his breakfast dishes and mail) which were there on his last morning.

At the Brain Institute, under Professor Sarkisov, who broke his holiday in the Crimea to meet us in Moscow, there is interesting work on cerebral function and localization in dogs by means of electrodes implanted at different levels and maintained *in situ*.

Hospitals

We visited hospitals and saw work in operating theatres and wards. The hospitals we visited in Moscow, Leningrad, and Kiev were all 50 to 150 years old, though scheduled for replacement. The façades of some are handsome, others have little architectural merit. Many are designed on the sprawling multi-pavilion plan with rather unkempt grounds. The wards and their associated rooms—laboratories and offices—are clean, tidy, and brightly decorated with flowers and plants in greater profusion than we are accustomed to.

The wards—the biggest I saw had 20 beds—are more crowded than in British hospitals, but most have more accommodation for up-patients, who, for instance, have their meals at tables in the spacious central corridor of the ward unit. Ward furniture appears to be adequate without being lavish or specially modern.

Hospital staffing seemed to be on a generous scale so far as medical staff is concerned, but at the Botkin Hospital (a Moscow municipal teaching hospital of 2,400 beds in 28

units) the ratio of patients to nurses was said to be 15–20 to 1. We formed the impression that many of the duties carried out by nurses in British hospitals fall to doctors in Soviet hospitals. We found it impossible to distinguish between women doctors, nurses, and orderlies in the hospital wards because no distinctive uniforms are worn.

The hospital patient population in general medical and surgical wards was similar, in respect of types of illness, to ours except for the almost total absence of elderly people with degenerative vascular disease and its consequences. True, there were many cases of myocardial infarction, but I doubt if we saw a single case of cerebral thrombosis. A home-nursing service based on the district polyclinics is available, and use may be made of this in regard to geriatric cases.

The general approach to treatment of the common medical and surgical conditions was similar to our own.

Anticoagulants are used for myocardial infarction, though figures illustrating results were not forthcoming; parenteral hexamethonium is used for hypertension but is in short supply, and the newer oral hypotensive agents are not available; emergency gastrectomy is carried out for severe bleeding peptic ulcers, and some surgeons, but not all, carry out immediate gastrectomy for perforation of peptic ulcers except in young patients; thyrotoxicosis is treated by thyroidectomy or by radio-iodine according to the preferences of the physicians or surgeons into whose care the patients happen to come.

We inquired and were freely told about the use of cadaver blood for transfusion. This is virtually confined to the Sklifosovski Hospital in Moscow, where it was introduced for human use by Yudin in 1932. Yudin's first patient, a suicide, is alive to-day. Blood is withdrawn up to six hours after death and stored for up to a month. This hospital uses more cadaver blood than blood from living donors, but there is still much objection to its use on the part of medical men generally, and most hospitals use blood from living donors supplied through the institutes of blood transfusion.

Undergraduate and Postgraduate Education

In learning about medical education in the U.S.S.R. we were somewhat handicapped by the fact that universities and medical schools were on vacation at the time of our visit. Medical delegations would in future be well advised to avoid the holiday month of August. In Moscow the medical schools were divorced from the university in 1930, and this separation has, I think, taken place in all the cities. The medical schools are under the direction and financial control of the Ministry of Health, as are many of the institutes of postgraduate education, though postgraduate education and training is conducted also in the institutes of medical research of the Academy of Medical Sciences. Great emphasis is laid on postgraduate medical education and each doctor must attend for three to six months at a postgraduate institute on the completion of his first three years' work after qualification, years spent under supervision. He is encouraged to specialize at this stage. If he does so his period of postgraduate work will be longer. If he does not specialize, or only in a broad field, he will take refresher courses after further periods of three, five, or seven years. Attendance at postgraduate courses does not entitle a doctor to an increase in salary, but it does facilitate appointment to higher posts. The pattern of postgraduate education is planned by the Central Postgraduate Institute in Moscow, with which the independent postgraduate institutes of the various constituent republics of the Union co-operate.

In Moscow the two undergraduate medical schools have an annual intake now of 500 students each, of whom 250 are in each of the two faculties of medicine and hygiene. The medical course is one of six years. About 10% of the students leave the school for one reason or another at

the end of the first year, but each school expects to graduate about 450 annually. Examinations are all oral, though "plenty of written case records are required." The Moscow hospitals seem to provide 1,400 beds for undergraduate medical teaching. About 65% of the 300,000 fully qualified medical practitioners throughout the Union are women, and the proportion amongst medical students is even higher and is rising.

Courteous and Hospitable Reception

The impressions gained in our capacity as guests were of the most pleasant. We were treated with the greatest possible courtesy, consideration, and respect. Everything possible was done to make our visit comfortable and profitable, and our own wishes were met whenever possible. We were received on the day after arrival by the Deputy Minister of Health, Professor Zhdanov, himself an associate member of the Academy of Medical Sciences, who gave in English a most concise and succinct account of the organization of medical services and education in the U.S.S.R., and who gave a cocktail party (at 2 p.m.) for us on the day before our departure. The opportunity of this latter occasion was taken to present to the Deputy Minister a small gift in the form of an old map of Russia of the time of Peter the Great. Our party were received at the Academy of Medical Sciences of the U.S.S.R. by the President, Professor Bakulev, and nine of his fellow-academicians, who, besides giving us an account of the structure and functions of the Academy and its associated institutes, entertained us to lunch when the official B.M.A. gift was presented—a chairman's hammer and block made from the wood of a mulberry tree which grew in the garden of Charles Dickens's house in Tavistock Square on the site of which B.M.A. House now stands. The gift evoked much interest and some amusement, but at the Deputy Minister's farewell cocktail party Professor Bakulev told me that in the interval he had already been able to quell a disputatious meeting of the Academy with its aid.

The meal with which we were regaled by our hosts at 11 a.m. on the Sunday morning of our arrival in Leningrad was probably the most extraordinary Sunday breakfast any of us has ever had. It was a five-course meal more allied to dinner than breakfast, with wine, vodka, and brandy, though we were expected to have the ordinary hotel lunch about two hours later. Throughout the visit, however, there were no formal evening banquets. We regarded this designed omission as a kindness on the part of our hosts, for we were thereby able to avoid much of the fatigue which this form of entertainment entails and which so exhausted the Soviet guests of the B.M.A. in 1955.

We were accommodated most comfortably in good hotels and our city journeys were all made in large limousines which were at our disposal at all times. We travelled from Moscow to Leningrad by first-class night sleeper train, and from Leningrad to Kiev, to Sochi on the Black Sea coast, and back to Moscow by scheduled air-line planes. We expressed great keenness to visit the Medico-Biological Research Station at Sukhumi in Georgia in order to see the experimental work on monkeys. In order to spare us a night in the moist heat of Sukhumi and a very tiring double journey over tortuous roads, a special plane was chartered for us. At Sochi we were given ample opportunity of basking in the hot sunshine and bathing in the warm sea. Sochi is a resort, one of many, with 59 "sanatoria," which are combinations of convalescent establishments and holiday hotels. They are medically staffed and equipped with provision for physiotherapy, etc., together with laboratories for clinical investigation. The laboratories did not seem to be very actively employed, though they were proudly displayed. We lived in privacy and luxury in the Metal Workers' Sanatorium, which could take 350 "patients." Many of the other sanatoria are of comparable size. The patients, apparently selected on the recommendation of the medical authorities at their homes, come from all parts of

the Union, and the normal stay is 28 days, during which time they become tanned to the colour of mahogany. The Soviet citizen is a great sun-worshipper.

A Few General Impressions

So much has been written recently about the tourist impressions of the U.S.S.R. that little fresh can be added. Moscow as a city did not attract me. Apart from the varied and, from some angles, breath-taking beauty of the buildings of the Kremlin and a few other handsome buildings of more modern construction, the general style is utilitarian. The main streets are enormously wide and the traffic is not yet dense enough to fill them. The traffic is sufficient, however, to make the crossing of these wide streets a considerable adventure. Taxis and private cars travel fast, and, as all use of horns was forbidden in Moscow from August 1, a sharp look-out was necessary. The usual metropolitan story was told that the only people knocked down in the streets are visitors from outside Moscow.

Leningrad, on the other hand, is a most handsome city. The many fine buildings of its two hundred years as a capital are preserved and cared for. The Nevski Prospect is one of the finest streets in the world, sign-posted by the beautiful golden needle spire of the Admiralty. The art galleries and museums in Moscow and Leningrad are full of priceless treasures on full display and are crowded with eager visitors of all ages.

The citizens' pride in their country and its "achievements" is evident on all sides. Streets and public places (but not lavatories) are kept scrupulously clean and free from litter by women street-cleaners using fan-shaped brooms which are often short-handled and require the user to bend double. The smoker does not tread his cigarette stub on to the pavement. Receptacles for litter are numerous and are assiduously used so that there is little or no trash to be swept up.

Back streets, however, tend to be narrow and mean, though also clean. The housing problem is still immense in spite of a vast amount of new domestic building in the form of blocks of workers' flats ranging in style from four- to six-story concrete masses to ornate multi-story towers. People still live in wooden shacks resembling hen-houses. Building, however, is going on everywhere we visited.

I have already been asked the question many times, "Are the people happy?" This, of course, is impossible to answer. The street crowds are not vivacious and the impression of stolid drabness is accentuated by the poor design of both men's and women's clothes and shoes. In spite of the very high place held by artists in the scale of values, and in spite of the magnificent and brilliant use of colour in public spectacles such as sports and physical culture displays, there is little evidence of interest in and use of colour in women's clothing. Conversation with ordinary people was free, animated, and serious, and we found no sign of fear on their part in talking to foreigners. We were all struck by the evident health and well-being of the children, who, however, were shy and unresponsive to our doubtless elephantine overtures. Since nearly all married women have jobs outside their homes their young children are of necessity cared for during the working-day from a very early age by strangers in crèches, where no doubt their appropriate education is begun. We saw no evidence of the supposedly harmful effects of separation of the infant from its parents, although admittedly we had no opportunity for a close study of the psychological balance of the children.

The overall impression remains of a courteous, hospitable, and very friendly reception by people, of all types, who were interested and active, devoted individually and collectively to peace and the development of their country and its life, avid for education, interested in the arts, proud of their technological and scientific progress, but withal slightly bemused by the complications of this age of technology.

The illustrations are from photographs taken by Dr. Alexander Duddington.

FIG. 3.—Members of the B.M.A. Party with a monk at the monastery of Pecherski Lavra at Kiev. Left to right: Mr. Ian Fraser, Dr. Mary Esslemont, Dr. J. G. M. Hamilton, Dr. Ralston Paterson, and Sir Geoffrey Jefferson.

POSTGRADUATE MEDICAL SCHOOL OF LONDON

EXTENSION APPEAL FOR FUNDS

The Postgraduate Medical School, the only medical school in the Commonwealth devoted wholly to the further education of doctors, is appealing for £750,000 to extend its accommodation. On this page we reproduce an architect's drawing of what is proposed. On the left of the picture can be seen part of the existing school building, in the centre a new block which is to contain laboratories, the library, and administrative offices, and on the right the new lecture theatres and common-rooms. The buildings are described more fully below in a note by the architects, Messrs. E. D. Lyons, L. Israel, and T. B. H. Ellis.

Urgent Need for More Space

The appeal is launched under the patronage of the Earl of Athlone, and is sponsored by Viscount Bruce of Melbourne, Viscount Malvern, Mr. R. G. Menzies, Sir Ernest Oppenheimer, Mrs. R. C. Pandit, Viscount Waverley, and H.H. the Aga Khan. The appeal committee, under the chairmanship of Mr. W. W. Watt, includes among its members Dr. Charles Newman, the dean of the Postgraduate Medical School, Professor Ian Aird, Professor J. H. Dible, Dr. Charles Fletcher, Professor E. J. King, Professor J. McMichael, and Professor Lord Stamp. An attractive brochure about the school and its present urgent need has been prepared for the appeal. The brochure contains these words:

"The school's accommodation was cramped in the beginning: it is many times more so now, with the expansion which increasing reputation and the growth of medical science have caused. Every shift and every plan that could be thought of and tried have been used to increase the accommodation required for students, for investigation, and for medical research; but there is a limit to what can be accomplished by makeshift measures, and that limit has now been reached, so that important work is held up and doctors from home and overseas wishing to work in the school have to be turned away.

"The school is therefore faced with a large programme of expansion to provide the lecture theatres and classrooms, laboratories and research rooms, library and common-rooms, which it requires to accommodate its students and the many research workers who, attracted by its reputation and facilities, wish to use it as a place of work.

"Unlike the famous undergraduate medical schools of ancient lineage, the Postgraduate Medical School—born into a period of rapidly changing values—has neither endowments nor subscribers. Its finance is derived almost wholly from a University grant which has to be spread over many claimants in different fields. This source, which provides nearly £200,000 each year for revenue requirements, cannot provide for a capital expenditure of the order now envisaged. It has therefore become necessary for the school to appeal to the wider public, which has at heart the advance of

medical science and the alleviation of suffering, for the funds which it requires to extend its work.

"Believing profoundly in its mission as a training ground for future specialists in the profession of medicine, and as a centre for postgraduate teaching and research paramount throughout Great Britain and the Commonwealth—and in the standard of its work challenging comparison with any medical centre in the world—the Postgraduate Medical School appeals to all who have these objects at heart to give generously and to do their utmost to promote this great ideal."

Contributions to the Appeal Fund should be made payable to the "Postgraduate Medical School Extension Fund," and sent to the Appeal Treasurer, Postgraduate Medical School, Ducane Road, London, W.12.

Architects' Note on the Buildings

The purpose of the new buildings is to provide space for the expansion of the existing school and to concentrate those departments at present dispersed in inadequate

accommodation; to provide an up-to-date core of laboratories and lecture theatres which later can be expanded in an organized way. To the architects the crux of the problem seems the need to separate those activities involving large bodies of people (e.g., postgraduate students and medical staff) from those involving small study and research groups. The former require large halls with uninterrupted spans, the latter a series of

smaller rooms with specialized equipment and services. To this end two separate buildings have been suggested: one of nine floors containing seven floors of laboratories, the other of two stories containing the lecture theatres and common-rooms for the staff and students. The first two floors of the larger building are planned to contain interdepartmental accommodation as well as a spacious two-story entrance hall with generous lavatory accommodation off it.

Since the site demands that the two new buildings should be placed on either side of a road, it is necessary to connect them by a bridge at first-floor level. This level thus becomes the main circulation level of the two buildings, and on it are located the library, the dean's suite of administrative offices, and the three lecture theatres. The bridge between the two buildings forms the key to the scheme and provides protection for the main entrance doors underneath it. On entering the double-height hall, the visitor will immediately be aware of a wide staircase leading up to the first floor and main level; and also of the lifts leading to the laboratories above; for one of the architects' main considerations has been to make the way to the various departments easy and clear from the moment of entry. The research laboratories begin from the second floor, and each level has been planned so far as possible as a self-contained department. Each floor has a service core containing lifts, staircases, lavatories (mechanically ventilated), service rooms, and ducts. The separate elements of this core form islands in a long rectangular circulation space round which are wrapped the laboratories. This arrangement allows for uninterrupted laboratory space which can be divided up as required by the various departments.

The second and third floors—i.e., the first two floors of laboratory accommodation—will consist of the departments of medicine (Professor J. McMichael) and chemical microbiology (Professor Lord Stamp). The second floor will also contain a new department of virology and the school's electron microscope. Both these floors will be linked by bridges to the existing buildings, where some of the work of the departments of medicine and bacteriology will still be done. Professor E. J. King's biochemistry department will occupy the fourth floor. The fifth and sixth floors will be largely occupied by Professor J. H. Dible's departments—clinical pathology, histochemistry, and the museum—but will also house the departments of haematology (Dr. J. V. Dacie) and biophysics (Mr. D. K. Hill). The two top floors are for the department of surgery (Professor Ian Aird) and the department of anaesthetics (Dr. J. P. Payne).

All supplies to the school will be brought down a ramp to the lower ground floor, where the school stores occupy the whole floor. The animal cages have been placed in the basement, and are isolated from the remainder of the building.

Lecture Theatre Block

The route over the bridge to the two-story building divides to form a foyer which goes round three sides of the group of lecture theatres. On the fourth side are the medical staff common-rooms and dining-room. The demonstration and lecture theatres will seat respectively 500, 150, and 80. Under the rake of the small lecture theatres is a staircase leading down to the common-rooms and canteen for the postgraduate students, technicians, and secretarial staff. Under this block are to be the school workshops and garages, the former being connected to the lower ground floor of the main building by a subway.

AMERICAN ACADEMY OF PEDIATRICS

ANNUAL MEETING IN NEW YORK

[FROM A SPECIAL CORRESPONDENT]

The 25th annual meeting of the American Academy of Pediatrics was held in New York, from October 8 to 11, under the chairmanship of its president, Dr. HARRY BAKWIN. The Academy is composed of paediatricians from all parts of the United States, of whom only a few are consulting, hospital, or academic paediatricians of the type found in Britain. By far the majority are more of the nature of the general practitioner, although their practice is confined to a particular and limited age group. In America the obstetrician usually relinquishes care of the baby at birth to the paediatrician, who thereafter looks after the child up to the age of about 16.

Conference Arrangements

Over 2,000 paediatricians from the States, together with many from Canada and other countries, attended the meeting. Most of them look on it as an opportunity to meet old friends and to refresh their knowledge, and they are less interested in detailed papers on recent research. Catering for this bias, a series of seminars, limited to 35-50 participants, are arranged for the two days preceding the general meeting. Each of these is on a single subject and lasts two days, and is given by one or several experts in the particular subject. In addition, during the meeting itself and concurrently with the general sessions, a series of round-table conferences are held, lasting two to three hours, at which an expert discusses a subject and answers questions. Both the seminars and round-table conferences attract full attendances, and might usefully be copied at similar meetings in Britain.

The papers read at the general sessions are similarly designed to meet the needs of the attending practitioners: the papers bring their knowledge up to date rather than

report the results of recent research. Most of the speakers sketched in the background of their subject before describing the results of new work, and in the panel discussions there was always a clinician as well as experts in specialized fields. The panel discussions consisted in fact of three or more speakers who gave short papers on different aspects of a problem, with a chairman, or moderator, who opened the subject and who sometimes commented on the points raised in any paper. The manner in which the speakers almost always completed their subject within the allotted time was remarkable.

Obesity and the Adenoviruses

The general sessions opened with a panel discussion on obesity, in which Professor BARTON CHILDS, of Johns Hopkins University, commented on the difficulty of defining obesity. He said also that, although some studies showed an increased amount of obesity among the children of obese parents, no study indicated that a single gene could be responsible in human beings. In animals, however, a single gene might be responsible for obesity in certain species, and in his opinion this was an indication of primary metabolic differences in different strains of these species. Professor JOHN BROBECK, of the University of Pennsylvania, discussed the role of the hypothalamus in controlling appetite and satiety, and suggested that there were two hypothalamic centres responsible—the lateral or appetite centre, which initiates appetite, and the medial or satiety centre, which inhibits appetite. He further suggested that the hypothalamus is affected by reflexes, either sensory or behavioural, and that the appetite is inhibited by reflexes initiated by increase in the body's production of heat, a full stomach, diminished gastric secretion, and hyperglycaemia, while it is whetted by the reflex effect of the converse factors.

Dr. ROBERT HUEBNER, National Institute of Health, Bethesda, Maryland, spoke on the adenoviruses (A.P.C. viruses) as a cause of ill-health in childhood. There were at least 12 distinct types, he said, of which types II and V occurred chiefly in early childhood. Type III occurred in both childhood and adult life, sporadically and in epidemics. These viruses produced enlargement of the regional lymph nodes and inflammation of the mucous membranes of the respiratory system and sometimes of the conjunctivae. Type III produced a febrile illness with conjunctivitis and pharyngitis, and formed a distinctive clinical entity which was now well recognized. Swimming in lakes and rivers, as well as in swimming-pools, seemed to increase the risk of infection by these viruses, but the manner in which it did so was not certain. Dr. Huebner added that the possibility of using prophylactic vaccines was being studied. Preliminary results suggested that a neutralizing antibody could be produced in susceptible persons.

Hereditary Diseases

An exceptionally interesting and well-delivered symposium was that on genetics and disease, in which Professor BARTON CHILDS acted as moderator. He paid a very generous tribute to the work of Sir Archibald Garrod, who was the first to suppose that there is some genetic control over all the chemical processes in the body. Dr. JAMES SIDBURY, of Johns Hopkins Hospital, emphasized that in effect genetic control means chemical control. He then gave a clear description of the way in which the genes were thought to act in controlling chemical processes within the cell, and gave examples of the way in which a piling up of metabolic products could produce toxic effects in diseases such as phenylketonuria and galactosaemia, as a result of the absence of an enzyme following genetic abnormality, and the consequent breakage in the chain of metabolic processes. Dr. LYTT I. GARDNER, State University of New York, discussed the difficult problem of genetic heterogeneity in endocrine disease. He explained that by this was meant a similar phenotype resulting from various types of genetic abnormality. Dr. EUGENE KAPLAN, Sinai Hospital, Baltimore, discussed various types of haemoglobin

and their genetic transmission, and showed how physico-chemical properties differed in various types and how this enabled a differentiation between hetero- and homo-zygosity to be made in sickle-celled anaemia, thalassaemia, and similar conditions. He finally emphasized that physico-chemical studies alone were inadequate to differentiate the various genetic patterns because of their complexity.

Dr. JAMES V. NEEL, Institute of Human Biology, Ann Arbor, Michigan, gave a description of the work of the Heredity Clinic at Ann Arbor. He said that it was now possible to give a considerable amount of help by advising those who suffered from an inheritable disease on the risks their offspring might run; and, in some cases, those who had found there was an inheritable condition in their own forebears of the risks they themselves ran. In many instances such information was a real help to these people in arranging their lives. He emphasized that the work of the clinic did not end at genetic prognosis. The help must be offered to the patient, or the parent coming for advice, in such a way that he could be assisted to adapt his life to the best advantage, or to live within the limits indicated. Dr. Neel thought that the value of the Heredity Clinic was being rapidly and increasingly appreciated by both doctors and their patients.

Visitors who gave papers included Professor ARGYZLO, University of Toronto, who discussed lupus erythematosus and the many conditions it might resemble; Dr. PAUL SWYER, the Hospital for Sick Children, Toronto, who discussed hiatus hernia and partial thoracic stomach; and Dr. SEYMOUR HEYMANN, Johannesburg, who reviewed the medical treatment of congenital pyloric stenosis. The growing interest in the United States concerning the physical and emotional problems of the adolescent was mirrored in the panel discussion on the "Emotional and Psychiatric Disturbances of Adolescence" and in a two-day seminar on "Problems of the Adolescent."

Preparations and Appliances

OCCLUSION CLAMP FOR INTRATHORACIC INTESTINAL ANASTOMOSES

Mr. KENNETH S. MULLARD, F.R.C.S.Ed., writes: The usual patterns of intestinal occlusion clamps are rarely of use in the performance of intrathoracic anastomoses of the oesophagus and stomach or jejunum, following operations such as resection of the oesophagus for carcinoma. The blades are too long to allow proper application of the instrument to structures lying in the mediastinum, and the handles lie awkwardly in the thoracotomy wound.

The Genito-Urinary Manufacturing Company have made for me the clamps illustrated, which overcome these difficulties. The clamps are 3 in. (7.5 cm.) in length, and the blades are entirely detachable from each other. There are no handles. The clamps are satisfactory in use on the oesophagus, stomach, or jejunum, and control both spillage of bowel contents and haemorrhage from the cut ends without trauma to the organs.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Neostigmine-resistant Curarization

SIR,—I was interested to read the article by Dr. A. R. Hunter on neostigmine-resistant curarization (*Journal*, October 20, p. 919). Recently Drs. Hamer Hodges and Foldes¹ drew attention to the fact that the combination of large doses of depolarizing relaxants with normal doses of non-depolarizing relaxants administered during the same anaesthetic often led to prolonged apnoea. Later I stated² that in my experience small initial doses of succinylcholine chloride followed by normal doses of curare or "flaxedil" sometimes led to prolonged apnoea.

I note that all the cases reported in Dr. Hunter's article had been intubated with the aid of a depolarizing relaxant. Could this small initial dose combined with the normal dose of a non-depolarizing relaxant given later in the anaesthetic be the cause of the apnoea he reports?—I am, etc.,

London, W.1.

JOHN GORDON.

- ² Gordon, J., *ibid.*, 1956, 2, 842.

SIR,—I read Dr. A. R. Hunter's article on neostigmine-resistant curarization (*Journal*, October 20, p. 919) with great interest, as I have also been collecting a similar series of cases. A full report of four cases will, I hope, appear elsewhere shortly.

These cases are of elderly patients with intestinal obstruction treated in a similar way to Dr. Hunter's cases and presenting the same syndrome.

The reason for the failure of neostigmine is, in my opinion, a depression of the cholinesterase acetylcholine system. A low level of cholinesterase has been shown in similar types of patients, and an anti-cholinesterase cannot be expected to have much effect in the absence of cholinesterase.

The important thing is, however, that if Dr. Hunter and myself can collect ten cases of patients dying through the irreversibility of curare, then very many more must have occurred in this country. Most of these cases are anaesthetized by resident anaesthetists and it is imperative that the existence of this syndrome is brought to their notice. Of equal importance, it must be the duty of all senior anaesthetists to instruct their juniors in alternative methods of anaesthesia. Unless they receive adequate instruction they will lack the confidence to use alternative methods and these tragedies will continue.—I am, etc.,

Leeds, 4.

GEOFFREY B. BURCHELL.

SIR,—Dr. A. R. Hunter (*Journal*, October 20, p. 919) has drawn attention to a disquieting complication following the use of competitive myoneural blocking agents. I was interested to note that in each of the cases quoted by him intubation was carried out with the aid of suxamethonium, and that after the onset of spontaneous respiration subsequent relaxation was obtained by the use of D-tubocurarine or gallamine triethiodide. May it be that, although respiration returned after the administration of suxamethonium, it would not have been adequate, but that, before this was apparent, relaxation and depression of respiration were produced by myoneural blocking agents acting by competitive inhibition?

At the end of each procedure some improvement in respiration followed the administration of neostigmine, which presumably reversed the competitive block produced by D-tubocurarine or gallamine triethiodide. It may be that the residual depression of respiration was due to a prolonged depolarization of myoneural junctions, produced

by the suxamethonium given in the early stages of each case. This depolarization would be prolonged by neostigmine.

Each patient was elderly and dilapidated, and may well have had a low plasma pseudo-cholinesterase level. The improvement in one patient following the transfusion of stored blood may have been due to its content of pseudo-cholinesterase rather than its potassium level. The effect of transfusing fresh blood, or the administration of concentrated human pseudo-cholinesterase, would have been of interest.

A variety of factors has been shown to influence conduction at the myoneural junction. The exhibition of two myoneural blocking agents, each acting in a different way, must unnecessarily complicate the problem. In the type of case described relaxation, both for intubation and operation, would be more simply obtained by the use of either D-tubocurarine or gallamine triethiodide, preceded in each case by a test dose of the drug.—I am, etc.,

St. Athan.

P. J. VERRILL.

SIR,—Dr. A. R. Hunter's article (*Journal*, October 20, p. 919) is of great interest and considerable importance to all anaesthetists.

The elderly toxic case forms a good proportion of emergency work. They are normally the province of the junior anaesthetist, a fair prognosis is given, but, as the facts show, should this syndrome develop, death is the rule. Although not previously described in the literature, one has the feeling that occasional cases of this type may not be as uncommon as would otherwise be anticipated. One feature of these cases, mentioned in passing but surprisingly not discussed in the article, must surely be given more prominence. I refer to the fact that suxamethonium was used in addition to curare during the course of the anaesthetic in all the cases. Although some spontaneous respiration may have recommenced before curare was given, the possibility that suxamethonium may in some as yet unexplained way be implicated in the resulting hypoventilation must be considered. Viewed in this light the syndrome may be apnoea following the use of a depolarizing and competitive inhibitor.

Indeed, many anaesthetists refuse to give such mixtures even to fit patients on general principles. Put more positively, can anyone cite a case similar to those described in which suxamethonium was not used at all? Such a case would be a true neostigmine-resistant curarization.

A case identical in all points to those described occurred in King's College Hospital recently, again following suxamethonium-curare sequence. Treatment followed Dr. Hunter's lines, the hypotensive episode being controlled by noradrenaline with the restoration of normal respiration and recovery in about eight hours. The serum electrolytes were normal. The practical point arising out of this surely would be not to ban curare in such cases but forfeit the convenience of suxamethonium for the original intubation.

—I am, etc.,

B. S. BEARDSWORTH.

London, S.E.5.

Cerebral Abscess and Tetralogy of Fallot

SIR—In connexion with correspondence published by your *Journal* on the subject of Fallot's tetralogy and abscesses of the brain, we would like to add some of our experiences, which we summarized in a paper read at the March session, 1955, of the Paediatric Society in Prague under the heading "Neurological Complications in Heart Diseases."

In the second children's clinic of the Charles University we have observed 21 children with neurological complications among the children hospitalized with heart diseases. Thirteen children suffered from a congenital heart disease. All but one died and had a post-mortem examination. Interstitial myocarditis was further diagnosed histologically in two children, and a child with myocarditis recovered and the neurological signs disappeared. In three children a diagnosis of bacterial endocarditis was established and one child

had a rheumatic pancarditis. The diagnosis of lupus erythematosus disseminatus with a Libmann-Sachs type of endocarditis was confirmed after post-mortem examination in a 12-year-old boy.

Among the affected children congenital heart diseases were prevalent. Except for a 14-year-old girl with coarctation of the aorta who is still alive, all the other children were suffering from a cyanotic malformation of the heart. Two children with Fallot's tetralogy reached an age of 12 years. This was at a time when preparations for surgery were in progress and the children were hospitalized in different departments. In all the deceased children the malformation was of the type with an inadequate blood flow to the lungs. We underline this observation, because from a far bigger number of children who died in infancy with transposition of the great vessels not a single one succumbed as a result of neurological complications.

Among the cyanotic malformations four children were mongoloids. Not a single one had a Fallot's tetralogy, although we have observed such a combination. If we compare the percentage of neurological complications in congenital heart diseases without mongolism with those where it is present, we find that central lesions occurred in mongoloids incomparably more often. Bacterial endocarditis was found in three children with cyanotic heart diseases, and in every case it led to the formation of an abscess of the brain. In all others we presumed thrombus formation in the cerebral vessels. The marked polyglobuly and increased viscosity of the blood may be considered as factors supporting the thrombus formation. For prevention of neurological complications in those children a good hydration and well-balanced way of life should be aimed at, and this should be maintained even after surgery has been performed. Postponement of surgery should be avoided.

The neurological symptomatology was quite evident clinically, but revealed very little of the pathological substrate of the lesion, although this is of great importance for therapy and the prognosis. In the first instance the basic cardiological diagnoses should be made and the evolution of the disease and the circumstances under which the neurological lesions developed established. The pathological findings reveal that the neurological complications arise basically from four different processes. It is necessary to decide whether it happens to be thrombosis, embolus, haemorrhage, or abscess in the brain tissue.

In cyanotic malformations thrombosis is in the first instance the underlying cause, followed in the second place by embolization of the cerebral vessels. In secondary bacterial endocarditis the existence of a brain abscess should be suspected first. The clinical picture according to our experiences depends rather on the extensiveness of the lesion than on its nature. The usual signs of a brain abscess—namely, elevated temperature, at least in some phase of the disease, leucocytosis with a shift to the left, and an increased erythrocyte sedimentation rate and slowly developing signs of intracranial hypertension—are usually absent. In some instances they may be due to the presence of another infectious process. The brain abscess usually manifests itself by progressively increasing neurological symptoms, which may be very bizarre, or, on the other hand, the abscess may be a surprise finding at necropsy.

Therapeutically massive doses of antibiotics should be given, and if the patient does not improve surgical intervention should be considered. Some authors even recommend early surgical intervention in congenital heart disease. The indications for a detailed examination are persistent headache and lethargy.

It remains undecided whether it would be appropriate to protect our patients with continuous small doses of anticoagulant drugs, especially those with cyanotic malformations of the heart, where the danger of thrombosis is most acute.—We are, etc.,

Apomorphine Treatment for Alcoholism

SIR,—Dr. Denis Parr (*Journal*, October 13, p. 860) states that apomorphine treatment for alcoholism was introduced by Dent in 1934, but this is not so. The treatment was first described in the *Practitioners Encyclopaedia of Medical Treatment* in 1915,¹ a copy of which has been in my possession since that date. From that date until the present the treatment has been employed successfully by myself and others.—I am, etc.,

Belfast.

GEORGE G. LYTTLE.

Tests for Drunkenness

SIR,—With regard to Mr. G. F. Rowbotham's letter on medical examination for drunken driving (*Journal*, October 20, p. 941), I cannot agree that the verdict of the courts is substantially influenced by the medical evidence, and this is particularly so in trial by jury. Over 50% are found not guilty at quarter sessions, and the evidence of the doctor called by the police is very often the only medical evidence. Our present method of testing for co-ordination does not seem to carry the weight one might expect, and a more widespread use of the urine alcohol test is needed. This test could show a jury that a motorist is lying about the amount he has had to drink, but it will prove nothing else.

I do not think that examination in hospital by three doctors is the answer. Hospitals are not handy ways to the police station and disagreement by the panel would provide an absolute field day for defending counsel, and three doctors for the prosecution and perhaps one for the defence all giving evidence in court would certainly confuse the jury and not help them. Also would three doctors of senior status have the time to give to this? It is possible to spend a day or two in court before being asked to give evidence and then to spend half an hour or more in the witness box under close cross-examination.—I am, etc.,

Worsborough Dale, Yorks.

D. W. MAYMAN.

SIR,—Mr. G. F. Rowbotham's letter (*Journal*, October 20, p. 941) on the subject of the examination of persons suspected of being incapable of having proper control of a motor vehicle through the influence of drink will arouse interest without, one imagines, securing a wide measure of agreement. His final sentence conveys that even he has misgivings.

To try to set up and operate a sufficient number of "three wise men" panels throughout the country would be to raise a multitude of questions. What omniscient being is to nominate "medical men of senior status" to serve on these panels? What kind of area is each to cover? This is a facet of diagnosis in which experience is of prime importance; can many areas outside the larger cities muster a number of senior practitioners who have a considerable experience of this type of examination? Again, having secured a panel capable of being assembled at short notice at any hour of the 24, and they having drawn up their report, how is it to be put before the court? Presumably each member must give evidence and be cross-examined; the vision which this conjures up when there is a majority decision only is one of fine forensic confusion, and one doubts if the court would be enlightened by it.

Finally, why should this examination be carried out in hospital? The suspect is under police detention, suspected of a serious offence; what is to be gained by a pretence that it is entirely a medical matter, in which the police should be relegated to the background? Surely Mr. Rowbotham will not insist that a decision is never to be made in this field without the full battery of accessory diagnostic apparatus being brought to bear.

At present, the burden of decision falls squarely on the police surgeon, and the quality of his examination and deduction from it may vary, but these are capable of improvement. A uniform scheme of examination adopted

by all would be of advantage; many police surgeons have already discovered the value (and the limitations) of urine alcohol estimations. In the end it is the court which must make the decision, and the function of a court is to distinguish sound evidence from unsound; technical competence is recognizable even to the layman. The police surgeon would welcome some relief from the weight of his responsibility, but to turn him into a committee would not make individual responsibility less, and could well further complicate the matter for the court.—I am, etc.,

Wigan.

F. G. INCE.

SIR,—I quite agree with Mr. G. F. Rowbotham (*Journal*, October 20, p. 941) that the diagnosis of being "drunk in charge" is such a heavy responsibility that it is most important to have the examination placed in experienced hands. I cannot, however, agree with his conclusions, but consider his letter rather as a strong argument in favour of appointing regular police surgeons all over the country.

Mr. Rowbotham, excluding all arguments against practicability of his proposals, forbids detailed discussion of them. One point, however, remains for comment even so: the fact of holding a senior appointment at a hospital—usually the result of eminence in some special field—would not necessarily qualify to deal specially with these questions, while the particular studies and accumulating experience make the police surgeon a specialist in this and related fields.—I am, etc.,

Gillingham, Kent.

K. F. M. POLE.

Troublesome Staphylococci

SIR,—Your leading article (*Journal*, October 13, p. 867) records various views about the staphylococcus and the changing frequency of staphylococcal pneumonia. May I suggest that the significant word has been omitted in reference to the 122 cases of pneumonia treated in Reading? The word is "hospitals."

I cherish the remark of the physician whose beds were occupied by a considerable proportion of the cases which Drs. W. Hausmann and A. J. Karlish discuss (p. 845). He lamented that a general practitioner had filled one of his hospital beds with a straightforward case of pneumonia who could have been treated at home with a few shots of penicillin. The comment, even in its anonymity, should not be taken too literally, but it did indicate a changing attitude to certain infections. Perhaps the majority of general practitioners approach cases of pneumonia with sulphonamides and antibiotics, considering hospital admission only if resolution is delayed or another pathological process is present. Our scale of values has changed. The pneumococcus has ceased to be the killer and the staphylococcus has assumed considerable relative importance.

The present and future nuisance value of the staphylococcus is not to be minimized. It is probably public enemy No. 1, deployed to suppress any tendency to surgical abandon. But is it not so because other bacteria have been mastered while the same bolt has been loosed at staphylococci without producing much thinning in their ranks?—I am, etc.,

Henley-on-Thames.

HARLEY STEVENS.

SIR,—The pros and cons of antibiotic therapies will have a thorough airing in these columns. Will the protagonists pause to consider whether the bacteria cause the diseases with which they are associated? By a happy coincidence a prominent American professor of public health has confessed in this *Journal* recently that we do not know (Professor Walsh McDermott, "The Problem of Staphylococcal Infection," *Journal*, October 13, p. 837). He critically examines the staphylococci as an initiator of disease and concludes that only in such closed systems as blood-borne osteomyelitis and bacteraemia can we be fairly certain of its pathogenicity. He concludes with the advice that we should study the major problem of resistance in the host and search for the factors which cause it to vary.

Nov. 3, 1956

Professor R. Hare and Dr. C. G. A. Thomas (p. 840) report that nasal carriers of *Staphylococcus aureus* can freely disseminate organisms in the vicinity clothed or unclothed, and even when gowned, masked, and scrubbed up. In view of this it is surprising that modern aseptic techniques have been successful in preventing the spread of sepsis, either in hospital or within the waiting- and consulting-room of a doctor. According to Hare and Thomas such places must be knee-deep in pathogenic bacteria. It points to the conclusion that our relative immunity from staphylococcal disasters in widespread epidemics must be due to a superior host resistance and/or an inability of the staphylococcus to invade intact hosts. Indeed, it has never been proved that such an organism satisfies the postulates of Koch.

It is so easy to hammer the staphylococcus with powerful antibiotics in order to relieve the patient and thus save him the inconvenience and discomfort of an illness. But unless we know what caused his defensive system to fail we may be creating a more serious medical problem later—perhaps years later—which cannot be dealt with by capsules and syrupy suspensions. Professor McDermott has spoken with accuracy, honesty, and insight on this subject, and it is the writer's hope that others in the vanguard of medicine will follow his suggestion to study the major problem of host resistance instead of hurling wider and wider spectrum antibiotics at the ubiquitous staphylococci. Let us leave the laboratories and pharmacies and return to the bedside to learn by observation and reflection what makes a patient sick.—I am, etc.,

Hornchurch, Essex.

P. D. MULKERN.

SIR,—I was very interested to read your leading article (*Journal*, October 13, p. 867) on troublesome staphylococci, in which you stress the importance of the treatment of the in which you stress the importance of the treatment of the nasal carrier state. You mention that A. F. MacCabe and J. C. Gould¹ have cleared up two carriers with 1% "hibitane" cream. I have treated ten nasal carriers for two weeks with 1% hibi-tane cream. After seven days' treatment six were still carrying staphylococci, and on the fourteenth day of treatment staphylococci were isolated from the nasal swabs of eight of the ten. I should be interested to hear if others have had better results with this treatment.—I am, etc.,

London, N.19.

Anaesthetic Deaths

SIR,—May I seek to draw attention to your important leading article on this subject (*Journal*, October 13, p. 868)? You point out that inhalation of vomit is the commonest single cause of death in general anaesthesia. You go on to say, significantly, that in operative obstetrics anaesthesia *has now become* (the italics are mine) the commonest cause of maternal death. This indicates, correctly, that it is a new feature in the vital statistics of this country, and, of course, it is aspiration of vomit rather than the anaesthetic which is chiefly responsible for the deaths in forceps delivery.

There is clearly now a consensus of opinion that this shocking state of affairs is due almost entirely to two factors: (1) that for a whole generation students have been taught to use the lithotomy position for forceps delivery, which ensures that, if a patient vomits during anaesthesia, she will be exposed to a period of mortal peril; (2) grave suspicion exists that the modern anaesthetic machine may increase the risk of the patient as compared with the simple mask and drop bottle (R. B. Parker, *Journal*, July 7, p. 16).

Many a full-time anaesthetist in giving anaesthetics for experience considerable disquiet in the lithotomy position, forceps delivery with the patient in the lithotomy position, but he is expected to do so because many obstetricians nowadays will not, or cannot, use the lateral position.

Opinions differ somewhat as to the relative importance of the two factors mentioned above, but of one thing we

can, unfortunately, be quite certain—as long as the lithotomy position is taught and practised for forceps delivery under general anaesthesia, so long will there continue to be, here and there, fatalities from aspiration of vomit. On the other hand, in all probability the patient will survive the most up-to-date anaesthetic apparatus, provided she is delivered in the lateral position, in which inhalation of vomit is virtually impossible.—I am, etc.,

London, N.W.7.

A. H. MORLEY.

Abuse of Antibiotics

SIR,—May I add a short comment to the correspondence on the subject of abuse of antibiotics? I am a regimental medical officer in Cyprus and frequently have the opportunity of doing clinics in remote villages when a curfew is imposed. A doctor is seldom, if ever, seen in these villages. There is sometimes a nurse-cum-midwife who does what she can with very meagre medical supplies. I have been surprised to see in these supplies crystalline penicillin and the wherewithal to give it. On numerous occasions I have heard of this being given for uncomplicated coryza, osteoarthritis, headache of unknown origin, and many other miscellaneous complaints. And, as if this were not bad enough, I have seen it given in totally inadequate dosage—for example, 200,000 units on alternate days. The villagers here regard penicillin as a universal panacea, and it seems that some of their medical attendants share this view.—I am, etc.,

Cyprus.

T. M. TIBBETTS.

Medical Education

SIR,—Dr. H. Stewart Moore's patient (*Journal*, October 20, p. 940) must undergo hospitalization before he is laparotomized and never anaesthetized with both depolarizing and non-polarizing narcotizing agents. At the operation the peccant parts must be visualized. It helps if they can be exteriorized before being excised.—I am, etc.,

London, W.1.

ALECK BOURNE.

Medical Evidence at Inquests

SIR,—I am surprised that certain coroners are so sensitive in their reaction to the suggestion that some of their number may exercise economy when calling medical evidence, and that this economy tends to eliminate the clinician in favour of the pathologists. Dr. A. C. Sommerville (*Journal*, October 13, p. 886) prefers the pathologist, not from reasons of economy but because he considers his evidence more reliable. My point is that there are occasions when the pathologist's evidence would be still more valuable if it were reinforced by the clinical picture as supplied by the deceased person's doctor. This is seen in the case when no clearly defined cause of death is found at necropsy, or when two or three pathological processes are present, any one of which could be regarded as the cause of death.

Dr. Sommerville is "only too willing to hear the point of view of the general practitioner—that is, if he has something material to say." I think that few practitioners would be prepared to waste time and volunteer evidence when it is received in such a patronizing manner. Apparently, it is quite uncertain whether or not he will be paid for his trouble. As it happens they seldom have an opportunity, for their first notice of the inquest is usually the report published in the press.

The pathologist's difficulty is that, in this area at any rate, he is not informed of the name of the deceased person's doctor when he is asked by the coroner to perform the necropsy. It would surely be easy in most cases to supply this information if the coroner so instructed. Unfortunately, neither the coroner nor the pathologist seem to think they would obtain additional information of value in this way. This complacency, in my opinion, is the most disturbing factor.—I am, etc.,

Preston.

F. M. ROSE.

Diesel Fumes

SIR,—It is encouraging to read the balanced letter from Dr. F. G. Tomlins (*Journal*, October 20, p. 939). One cannot but heartily agree with all his statements. The report on toxicity of some atmospheric pollutants by Mr. R. E. Pattle and Dr. H. Cullumbine (p. 913) is also of very great importance.

Recently it has been my privilege to present a paper on this subject at the Annual Conference of the National Smoke Abatement Society at Southport (October 3, 1956). On the same day Dr. P. J. Lawther also presented a paper based on the report on smoke in a London diesel bus garage (*Journal*, September 29, p. 753). Following this, unfortunately, some of the press emphasized the fact that diesel fumes were proved harmless (*Bristol Evening Post*, October 3, and *Manchester Guardian*, October 4). This, of course, is an altogether misleading and erroneous finding. It must be stated in fair play that Dr. Lawther indicated his report to be a preliminary one. However, the conduct of these investigations seems to me to be invalid. One should not expect to find a rise in 3:4-benzpyrene or any appreciable concentration of other untoward pollutants to be emitted from 10% derated diesel engines in perfect mechanical condition and under no load.

Let us be sensible over this matter. We must put aside the question as to whether it be benzpyrene, sulphurous, nitrous fumes, aldehydes, or unburnt olefins; in fact, whether it be a question of one or a combination of several pollutants; or again whether it is a question of high concentration, with occasional exposure, or constant repetitive doses of low concentration. Whatever the answer, the proved conclusion of present research indicates that these fumes are pathologically dangerous. Therefore, without waiting for a final pin-pointing by research workers of what is or are the exact dangerous pollutants, it seems only reasonable that the engineers concerned, including oil combustion specialists, engine designers, and operatives, should get together urgently in an endeavour to rectify this menace. Surely this is now a problem for the engineers and not the medical profession, but it is high time the latter and the public pressed hard for them to achieve it. Meanwhile the conversion of electrically propelled public transport to oil-powered vehicles cannot be too harshly condemned.—I am, etc.,

Bristol, 8.

HANDLEY HOWELL.

Enzyme Test for Glycosuria

SIR,—Surely Dr. B. M. D. Rosten (*Journal*, October 20, p. 940) is in error over Benedict's excellent qualitative test for urine sugar. Its proper operation requires 5 c.cm. (or ml.), not 2.5 ml., for 8 drops of added urine.—I am, etc.,

London, W.1.

R. D. LAWRENCE.

Glycyrrhetic Acid

SIR,—Dr. F. Ray Bettley (*Journal*, October 13, p. 882) suggests that drugs should not be prescribed at public expense "before a single clinical trial has been published." Surely, the great majority of drugs in common use are accepted without published controlled trials. Even when extensive trials are made and published it does not follow that the drugs will be used wisely by some of our profession. For example, first, the adverse reports of the Joint Committee of the Medical Research Council on cortisone orally in comparison with aspirin did not prevent the continued use of cortisone in vast numbers of cases. Secondly, in spite of the excellent circular from manufacturers on the use of hydrocortisone topically, I am sure that Dr. Ray Bettley will have seen scores of cases sent to his out-patients' clinic who had the most unlikely skin conditions previously treated with hydrocortisone preparations without benefit.

In suitable cases I agree that hydrocortisone topically is "astonishing" in its effect. Dr. Brian Russell *et al.*,¹ in their excellently controlled trial, found a distinct or com-

plete relief in only 50 out of 132 cases. Dr. E. Colin-Jones (*Journal*, September 8, p. 604) out of 38 cases treated with glycyrrhetic acid ointment had only six failures. I have been using and assessing glycyrrhetic acid preparations since February, 1956, with, so far, many more than 20 cases, and I am continuing these trials, but at this stage I feel justified in saying that glycyrrhetic acid is a valuable anti-inflammatory agent, comparable with hydrocortisone at a fraction of the cost.—I am, etc.,

Twopenny-halfpenny Advertising

SIR,—While fully recognizing the tremendous amount of highly valuable work that is done by the great drug houses, I feel that many doctors must, like myself, get a bit irritated by their advertisement techniques. It has, it seems, become common practice for a considerable portion of their literature to go straight into the waste-paper basket unopened. Presumably in an effort to overcome this, a number of firms are now sending out literature carefully disguised as personal letters. I find this offensive. Again, while some travelling representatives are both helpful and courteous, others spare no efforts to plug their new products and even seek to lecture us on how to treat our cases. All this I believe to be unfortunate.

It is highly desirable that commerce should be kept out of medical practice. At the same time, it is right that the great drug houses should have a proper reward for their efforts and have a proper opportunity to present their new products to the profession. I would like, therefore, to put forward a suggestion. It is that the B.M.A. should set up a committee of experts who would be asked to report on new products sent to them by the manufacturers. The nature of the report might vary with the importance of the product, but would, I suggest, include such items as: (1) specific indications and/or general usefulness; (2) side-effects; (3) comparison with standard and accepted remedies and equivalents; and (4) price to N.H.S. when prescribed on E.C.10.

I believe all reputable drug houses would welcome such an independent assessment, and I believe they would gladly accept the cost of the service. I am sure it would be of great value (particularly) to general practitioners, who are at present befogged with the multiplicity of available alternatives and in consequence the more easily influenced by skilful advertisement.—I am, etc.,

Stratford-on-Avon.

E. O. EVANS.

Speech Therapy

SIR,—Miss J. H. van Thal (*Journal*, October 13, p. 884), in reading my letter (*Journal*, September 29, p. 768), jumped to conclusions—"comparative values" did not refer to the values of patients to speech therapists, but to the community. In my opinion to correct a lisp is not as valuable as to correct a stammer, especially in view of the number of lispers employed by the B.B.C., but Miss van Thal does not agree with me, so that what to me would be waste of public money, to her is money well spent. She goes on to write of the "misapprehensions of an old gentleman." I do not think my fifty years of experience and study of the voice, including my time at Guy's, is a disadvantage to my work, nor, I have reason to believe, does the medical profession, and surely most misapprehensions are due to too little study, not to too much.

Miss van Thal sounds an almost facetious note when she suggests that I have never heard of the speech defects on her list, nevertheless many of these are of more interest, in my opinion, to the speech therapist than to the community, which judges every profession by the value of its achievements and would be likely to set a higher value on the correction of a stammer in a boy of marked ability than on teaching a laryngectomized patient to convey his thoughts

through a succession of specialized belches. To show in a few minutes to a parent that an incorrect consonant can be formed correctly does not break the habit, it merely shows the parent that the correct sound is within the child's powers. Experienced teachers will agree with me that children should be taught to teach themselves rather than be spoon-fed indefinitely.

Miss Peggy Carter of the College of Speech Therapists (p. 884) informs me about difficulties of case selection at a clinic; I had been in charge of the clinic at Guy's for 21 years before the College was formed. She writes with great assurance when she states that the reluctance of a youth to take orders from a woman is due to "very faulty technique"; she is ignoring fundamentals; but perhaps she would like to see our boys' schools staffed by mistresses. Miss Carter accuses me of generalizing, whereas every case of stammering is individual. Measles involves different ages, sexes, and personalities, but that does not prevent generalizations about the illness. Surely, after fifty years' experience, it is my duty to generalize, since it is only those with long experience who can do so. She also states that men will not become speech therapists because they are not paid enough; she has forgotten that Cortlandt MacMahon at Bart's and I at Guy's worked without any salary and depended on our results for our patients at hospital and in private practice.

Dr. R. Macdonald Ladell and Miss R. Bennett (*Journal*, October 27, p. 1000) both rightly stress the importance of the psychological factor, without which correction of stammering would be too easy to be interesting. Both these writers quote faulty enunciation as the faulty physical factor. This is such an important point that I must correct it at once; the physical fault is in phonation, as is proved conclusively by the stammerer's ability to sing. Enunciation is identical in speech and song; it is in phonation that the contrast lies; in song phonation is controlled, but not in normal speech, and it is lack of control that makes the stammer possible physically. Solution of the psychological problems involved is easier at hospital than in private practice, but in the last analysis it is the work of the speech therapist to show the stammerer how to overcome his defect in spite of difficulties in the home, office, or school.

Dr. Ladell agrees about the need for male speech therapists, but to bring them back into the profession is not as easy as it sounds. Men would have to be included in the organization which Mr. MacMahon joined and left three times, nor was he ever given the fellowship, and when I offered to join I was ordered to send copies of all my books (seven at the time), and I was warned not to assume that I should be successful in fulfilling their requirements—this after contributing to the *Index of Treatment* for nearly twenty years.

One other matter needs ventilation. Until the National Health Service came into being no visiting specialist was allowed to attend more than one teaching hospital; as a result I had the speech cases from three teaching hospitals referred to me at Guy's. This was the rule when very few speech therapists were available; to-day there are about a hundred in the London area, but these appointments are held in plurality. The old rule was better, if only to give more people a chance to show what they could do and to set up healthy competition. Thanks to the pioneer work of Cortlandt MacMahon, speech therapy is recognized by the medical profession and it has great possibilities, but at present a small group is responsible for organization, training, and examining, and holds all the key posts; as a result it has become a closed shop.—I am, etc.,

London, N.W.1.

H. ST. JOHN RUMSEY.

Arteriosclerosis and the McNaughton Rules

SIR,—I am interested in your report in the case of Kemp before Mr. Justice Devlin at the Bristol Assizes (*Journal*, October 20, p. 947). In a similar case of Chapman before Mr. Justice Diplock at the Hertfordshire Assizes it was decided by the defence that the wiser procedure was to plead guilty to the assault charge and not invoke the McNaughton rules, because these rules would inevitably result in the patient being detained at the Queen's pleasure. The legal approach to this type of problem is that a charge must be brought, in order to avoid a negligence counter charge on the part of the Crown in the event of a repetition of the event. The case of Chapman illustrates

two types of problems on which the law requires medical help: first, the duration and degree of the disease process and thus the prognosis of the disease and the possibility of a recurrence; secondly, perhaps more important at present, any accentuating factors to the confusional state, such as inadequate doses of hypnotics, particularly barbiturates or hypotensive agents such as reserpine, which itself causes water retention and maniacal confusional states, apart from the arteriosclerosis. In effect the therapy (normally designed to relieve the mental symptoms of cerebral arteriosclerosis) may stimulate a period of clouding of consciousness, with the typical unfortunate nocturnal episode of violence, and thus commit the patient to Her Majesty's pleasure within the present legal framework. Surely we must ask for a revision of the law in this matter.—I am, etc.,

St. Albans.

JOHN H. PRICE.

Children Handicapped by Maternal Rubella

SIR,—I think your readers would like to know of the existence of a group which was formed in 1955 to assist parents with the upbringing and education of children affected by rubella in pregnancy, particularly those with two or more handicaps. For children who are only deaf or blind, a great deal is already being done; but for those who are doubly affected, deaf and blind with perhaps a cardiac lesion as well, the opportunities for schooling are very limited indeed. While the primary object of the group is educational, the collective records and experience being gained have also a research value. For example, little if anything is known about the number, age, or geographical distribution of these children.

The organizer and secretary of the group, Mrs. Peggy Freeman, of "Rowland Lodge," 33, Parrock Road, Gravesend, Kent, would be grateful if as many parents as possible from all over the country, especially those with doubly handicapped children, would get in touch with her. A newsletter is published within the group, by which contact is maintained and information and progress reports are exchanged.—I am, etc.,

Peaslake, Surrey.

G. I. WATSON.

Clinical Psychologist in the Mental Hospital

SIR,—With reference to my letter (*Journal*, October 6, p. 826), it has been pointed out to me that the official instrument (report of a working party of the Committee of Professional Psychologists (Mental Health) which deals with the functions, policy, etc., of clinical psychologists within the N.H.S.) I was referring to is, unfortunately, not fully printed in the P.T.A. Circular No. 27. This report, however, is fully published in the *Bulletin of the British Psychological Society*.¹ I apologize for overlooking this point in my previous letter.—I am, etc.,

Chester.

LEON J. DRASPA.

History of Medicine in Medical Education

SIR,—There has been much correspondence on the subject of medical education, mainly criticizing its suitability for general practice. I wonder how many family doctors are dissatisfied with the training they received? To my mind, training does not end with the finals but must include medical and surgical house jobs, together with midwifery, to say nothing of a course of lifemanship outside medical circles to be taken before qualification.

The letter from Dr. A. P. Cawadias (*Journal*, October 13, p. 883) advocates the history of medicine as a tutor, and I must write to support this. In my teaching hospital, from the beginning of the introductory course to the end of one's stay, the emphasis was always on the patient's history—"Listen to him, he's telling you the diagnosis" is a proved adage. The history of medicine, too, was all important, and any who had the good fortune to listen to Dr. Donald Hunter will never forget the lineage, say, of Turnbull or the homely discovery of digitalis.

Obituary

A. E. BARNES, M.B., F.R.C.P.

The death occurred on October 23 at Helensburgh, Dunbartonshire, of Dr. A. E. Barnes, formerly professor of medicine in the University of Sheffield. He was 75 years of age.

Alfred Edward Barnes was born in Sheffield on June 3, 1881, the eldest son of a solicitor's clerk. From the Sheffield Grammar School he entered University College, Sheffield, in 1897 with an entrance scholarship and graduated M.B., B.S. (London) in 1903. Later, after the charter of a university had been granted to University College in 1905, he proceeded to the M.B., Ch.B. of Sheffield University. After graduation he was house-physician at the Royal Infirmary from 1905 to 1907, and was then appointed its first medical registrar. He took the M.R.C.P. in 1907 and was elected F.R.C.P. in 1921. At the Royal Infirmary he became honorary physician in 1911 and senior physician in 1920, holding that position for many years.

Although his early professional years were fully occupied in hospital routine and in widening his experience in clinical medicine, Dr. Barnes was always interested in and realized the importance of clinical research, in which he took an active part. He held a B.M.A. research scholarship in his early years. In the University of Sheffield he was in turn tutor in medicine, lecturer in therapeutics, lecturer in medicine, and, finally, from 1936 to 1946, professor of medicine. During the first world war he was on the staff of the 3rd Northern General Hospital and later in charge of the medical division of the 37th General Hospital in Salonika. He remained on the staff of the Royal Infirmary all his professional life. As a consultant he was a tower of strength to practitioners over a wide area in and around Sheffield. He was a valued and prominent member of the B.M.A., being honorary secretary of the Yorkshire Branch from 1922 to 1928, and he also served on a number of central committees, including the Pharmacopoeia and Joint Formulary Committees.

A man of great energy and strong character and convictions, he could not fail to play a prominent part in shaping the course of medicine in Sheffield. Inspired with the idea of clinical science, and ahead of his time in this respect, he was largely responsible together with friends for the establishment at the Royal Infirmary of a unit of the department of pharmacology, with Professor Edward Mellanby (later Sir Edward Mellanby) at its head—the prototype of many similar departments throughout the country. Indeed, he was willing to sacrifice some of his own beds for the purpose in the conviction that the combination of clinical and laboratory medicine was of paramount importance. His wisdom and foresight in this as in many other things earned him the gratitude of a growing university and of its teachers and students. Professors of preclinical

The type of training at the London was directed all along the line towards general practice, and as students we were frequently told of the differences in hospital and general practice. We were encouraged to go and spend a day with a family doctor as part of our training, but obviously there are not enough doctors to cater for all the students. A local G.P. I remember gave lectures to us in a packed theatre—a popular item, no doubt. After three very enjoyable years in general practice I can only uphold the training which aimed at producing the frame of mind to inquire, examine, diagnose, and treat. May I therefore respectfully suggest that those who decry our training might do well to peruse the methods of education which, to my mind, in the hands of Professor Clifford Wilson functions so admirably?—I am, etc.,

Cradley Heath, Staffs.

G. A. AMES.

Gorleston Holiday Camp for the Physically Handicapped

SIR,—Once again I should like to thank the many doctors whose patients came to our fourth annual holiday camp at Gorleston between September 15 and 29 for the medical and nursing details they kindly sent me. This information was invaluable to the camp medical and nursing staff and enabled us to make special provision in advance for those who needed it.

The camp itself was a great success and 400 disabled people, some very helpless indeed, had a very happy week's holiday. Everyone played their part well, even the clerk of the weather, who gave us the two best weeks of the summer with plenty of warm sunshine. The only difficulty I had was in reading some of my colleagues' writing. Some signatures were quite undecipherable, and, alas, some certificates were unsigned. Apart from these minor points I was again struck by the great admiration so many doctors have for their handicapped patients, and, now that I have seen them, I am not surprised. They were really magnificent and always anxious to lend a hand to those a little more helpless than themselves. Again, most of the nursing assistance came from voluntary workers, both resident and part-time, and the ordinary camp entertainments were augmented by organized outings suitable to our special type of guests.

Our only regret is that we are still the only association doing this work. We sincerely trust that other camps will see their way to providing similar holidays, because the demand for Gorleston is now so great that very many deserving people have to be disappointed. I should be glad to hear comments on, or criticisms of, our arrangements this year, so that we can be guided in our preparations for 1957.—I am, etc.,

Norwich.

IRENE B. M. GREEN,
Vice-chairman,
Norfolk Voluntary Association for
the Welfare of the Physically Handicapped.

Books for Christian Medical College

SIR,—While in this country on a brief furlough I am writing to ask the courtesy of your columns in the interests of the Christian Medical College, Ludhiana, Punjab, India, of which I am principal.

The Christian Medical College, founded in 1894 as the first medical school for women in India, now trains men and women medical students, who come to us from all parts of India and further afield. We are building up a good medical library, and I would like to ask, through these columns, authors and publishers of medical books whether they would send a copy of each book published to Ludhiana. American authors are very kindly doing this for us, and I am anxious that British medical thought should be well represented. We should be very grateful indeed for any such volumes donated.

These may be sent to the College direct, or to the Secretary, Ludhiana British Fellowship, 12, Queen Anne's Gate, London, S.W.1, who will acknowledge and forward them.—I am, etc.,

London, S.W.1.

EILEEN R. BARTER SNOW,
Principal.

subjects, surprised and delighted at his enthusiasm, constantly sought his help and advice. As an ally in a somewhat poor and very young university he was invaluable in obtaining financial and other assistance, and enabled many who later became famous in older universities to initiate and pursue important research.

Dr. Barnes wrote little, but as a clinician and teacher he was unsurpassed. His boundless energy and enthusiasm could not fail to communicate itself to the students, house-physicians, and registrars. His scrupulously recorded histories, careful examinations, and balanced judgment set a standard difficult to emulate. Perhaps the most important characteristic he was able to convey was the spirit of adventure which he always sought in medicine. A voracious reader and with a mind scintillating with the newest ideas to the end of his days, he led his juniors in one bold clinical experiment after another, though never losing sight of the patient as a human being.

Unsparring to himself, as a colleague he was sometimes critical and, with his fearless mind, often controversial, but always loyal and devoted to his profession, his hospital, and his university, and utterly honest. He was particularly kind and helpful to the struggling youngster, and many a junior colleague will remember with gratitude his support in the first difficult years of consultant life. It was characteristic of him that on his retirement, determined to give his younger colleagues more scope, he left with regret his many friends and his home town. It is pleasant to know that his last years were spent in happiness and contentment in his beloved garden in Scotland.

Dr. Barnes married Miss Jessie Morrison in 1911 and there were two sons of the marriage, one of whom is Dr. J. M. Barnes, director of the Medical Research Council's Toxicology Research Unit.—H. P. B.

J. C. CRUICKSHANK, M.D., D.T.M.

We record with regret the death on October 30 of Professor J. C. Cruickshank, who held the chair of bacteriology as applied to hygiene at the London School of Hygiene and Tropical Medicine. He was 57 years of age.

John Cecil Cruickshank was born on October 14, 1899, and educated at George Watson's College, Edinburgh. Before going on to Edinburgh University to study medicine he served for over a year with the Gordon Highlanders at the end of the first world war. In spite of this interruption in his studies he graduated M.B., Ch.B. just after his 22nd birthday, and thereafter held the posts of house-surgeon at Sheffield Royal Infirmary and house-physician at Chesterfield Royal Hospital. After taking the Diploma in Tropical Medicine in 1923 at Liverpool, where he gained the Alan H. Milne Memorial Medal, he was appointed a member of the West African Medical Staff in the Gambia, where he remained until 1930.

On his return to Britain Dr. Cruickshank went into general practice near Glasgow for a year or two, but by this time he had decided on a career as a bacteriologist, and after taking the Diploma in Bacteriology of London University he was appointed demonstrator of bacteriology at the London School of Hygiene and Tropical Medicine. He was promoted lecturer in 1937, reader in 1945, and professor of bacteriology as applied to hygiene in 1947. During the second world war he served in the Emergency Public Health Laboratory

Service, being director of laboratories first at Horsham and later at Exeter. In 1952 he proceeded to the M.D. of the University of Edinburgh, being awarded a gold medal for his thesis.

During his early years at the London School of Hygiene Professor Cruickshank was one of a team investigating the immunizing fractions isolated from bacteria by chemical means, and with G. G. Freeman he was successful in obtaining fractions from the whooping-cough bacillus effective in the prophylaxis of infections in mice. He had also investigated the antigenic components of salmonellae and the chemotherapy of experimental pertussis, anthrax, and brucella infections. After the second world war he published a useful paper on the value of Vi-phage typing in the investigation of typhoid fever in a rural area. He obtained the material for this paper while he was in charge of the public health laboratories at Exeter, where he will be remembered for his excellent work during the war. Several of the epidemiological and bacteriological investigations he carried out in those years were published in this *Journal*.

As a teacher Professor Cruickshank was quiet and thorough. He took great pains to clear up the perplexities of his students, and earned the respect and affection of all those who passed through his department.

He married Miss Mabel Margaret Elizabeth Harvey in 1928, and had two sons and one daughter.

Sir WILBERFORCE NEWTON, M.D., F.R.A.C.P.

Sir Wilberforce Newton, consulting physician to the Royal Australian Navy, died at Melbourne on October 4 at the age of 65.

Wilberforce Stephen Newton was born on December 27, 1890, and was educated at Haileybury College, Melbourne, and at Melbourne University, where he graduated M.B., B.S. in 1915. He proceeded to the M.D. in 1920, and in 1937 was elected a foundation Fellow of the Royal Australasian College of Physicians. Soon after graduation he entered the R.A.M.C. for service in the first world war. After the war he held the post of medical superintendent of the Alfred Hospital, Melbourne, in 1918–19, and thereafter held a succession of appointments at the hospital. He was medical clinical assistant to out-patients in 1920–1, honorary physician to out-patients from 1923 to 1933, and honorary physician to in-patients from 1933 to 1948, when he was appointed to the honorary consulting staff. Since 1937 he had been a member of the board of management of the hospital. From 1935 to 1944 and again in 1945–6 he was Stewart lecturer in medicine in Melbourne University. A member of the council of the Royal Australasian College of Physicians from 1944 to 1954, he held office as a vice-president of the College from 1950 to 1952. He was a member of the Faculty of Medicine of Melbourne University from 1932 to 1948.

In his later years Newton became consulting physician to the Royal Australian Navy. He was also a member of the Consultative Council on Tuberculosis of Victoria and, for a time, a member of the executive committee of the Anti-Cancer Council of Victoria. During the second world war he was a member of the final medical board of the Southern Command. From 1947 to 1953 he was chairman of the Melbourne Permanent Postgraduate Committee. He received a knighthood in the 1950 Birthday Honours for public services in the State of Victoria. He married Margaret, daughter of the late

Dr. William Macansh, and had four sons. His elder brother, the late Sir Alan Newton, who died in 1949, was one of Australia's leading surgeons.

The tragic death on September 21 of Dr. D. R. EDWARDS, of Bath, came as a great shock to all who knew him. Appointed only three months previously to a vacant practice in Bath, he was shot dead while conducting his surgery. Dennis Raymond Edwards, although born in England on March 2, 1926, spent his youth in Kirkmaiden, Wigtownshire. He had a fine record at Stranraer High School, where he was dux, at St. Andrews University, where he graduated M.B., Ch.B. in 1948, as a houseman at Arbroath Infirmary, and in the R.A.M.C., with which he served in Malaya in 1950-1. Before going to Bath he had been for three years a partner with Dr. H. S. Kent in Darlington, where he was also deputy police surgeon, and honorary secretary of the Darlington Division of the British Medical Association in 1955-6. While a student he gained the premier award at Perth Festival for his tenor voice, and his singing was only one of the gifts with which he enriched the community in which he lived. On moving to Bath in July he made his mark immediately in the medical life of the city, and his professional skill was quickly recognized by patients and consultants alike.

A. S. writes: Although young in years, Raymond Edwards showed by his kindness, humanity, and devotion to work that the National Health Service can produce the kind of family doctor that in the past has been the glory of British medicine. The local medical committee at Bath, knowing of his fine work for the B.M.A. in Darlington, elected him to a vacancy on the committee, and here also the loss of a man with his integrity, ability, and industry is a serious one to the profession. His radiant and lovable personality was the expression of a life dedicated to his work and to the Master whom he humbly and consistently served. Struck down at the threshold of a life full of high hope and promise, these lines of R.L.S. might well be said of him:

"Doomed to know not Winter, only Spring, a being
Trod the flowery April blithely for a while,
Took his fill of music, joy of thought, and seeing
Came and stayed and went, nor ever ceased to smile."

He leaves a widow and a son of three years, and to them and to his widowed mother has gone out the sympathy of a whole city and of many far afield.

H. S. K. writes: Raymond Edwards came to Darlington five years ago to assist me in general practice. He was recommended to me by a medical colleague with whom he had been acting as a trainee assistant in Harrogate, and it was evident at once that he had already reached a high standard of efficiency as a doctor. He very soon became endeared to us all, and possessed all the attributes of a successful and most respected professional man. He was a sound and most painstaking clinician, and by his kind and sympathetic approach to, and in the treatment of, his patients there was no wonder that he gained the popularity and respect which he richly deserved. He was equally popular with his medical colleagues, and latterly undertook the secretaryship of the Darlington Division of the B.M.A. He immediately infused fresh enthusiasm among our members, as he did in fact with all his undertakings. He was a gifted lecturer, mainly on medical subjects, and was ever ready to lecture and examine in first aid. He was a man with strong religious principles, and from the first became attached to St. George's Presbyterian Church, where he took an active part in arranging the forum and its rota of speakers. As deputy police surgeon he was most respected and was known for his fairness in judgment and exactness in detail. He often was asked to lead in debates between doctors and the clergy to improve the relationship between the two professions, for the physical and spiritual betterment of patients. It was a great loss to me as his partner and to the practice when he was offered a practice at Bath, but we all felt that it was going to be in his best interests

to accept the position, for which he was so admirably equipped. This terrible tragedy has stunned all of us who loved and respected him so much, and our thoughts are very deep for his wife, his young son, and his mother in their irreparable loss. Raymond Edwards's character, which was of the highest order, reflected the perfect happiness of his family life, and enriched the lives of us all.

Dr. J. M. A. WILLOX writes: Having been a close friend for nearly twenty years, I would like to pay a personal tribute to the late Dr. D. R. Edwards. The full tragedy of his death and of the loss of his outstanding personality is felt by all who knew him. My earliest recollection of him is of a boy who seemed older than he really was, then of a friend at whose home in the picturesque village of Drummore I spent many happy days, often also in the company of the charming girl who was later to become his wife. I remember particularly the happiness in the home of his ever-welcoming parents, and I recall that wherever he went he was always greeted with pleasure and affection. Raymond Edwards was the most brilliant pupil of his school. The principal prize-winner in every year, he was also a keen sportsman, and possessed a very fine tenor voice which later earned him a soloist medal at the Perth Music Festival. As a boy and as a man he was brilliant, modest, and always popular. A well-integrated personality, he had also a rare gift which inspired complete trust and confidence in all who knew him, whether as patients, friends, or colleagues. His approach to all problems, whether professional or personal, was always constructive, never complaining or critical, and in all he did he showed tremendous enthusiasm and vitality coupled with a very genuine love for his fellow man. His death has deprived the medical profession of a truly outstanding practitioner. For those who loved him there are no words to describe adequately how great is their loss.

Dr. R. H. TITCOMBE, who practised at Disley, near Stockport, died on October 3 at the age of 73. Roland Hereward Titcombe was born on March 12, 1883, in the Cotswolds. He was the son of a solicitor, who later practised in Colne, Lancashire, and it was in this district that he received his early education at the local grammar school. His mind turned to medicine, and he became a student at the medical school of the University of Manchester, graduating M.B., Ch.B. in 1909. He was then appointed house-surgeon at Ancoats Hospital, and later became the resident surgical officer. Later he joined the pathological department of the Christie Cancer Hospital, where he came under the influence of Professor R. B. Wild, Professor James Lorrain Smith, and Dr. C. Powell White. In 1911 he wrote his M.D. thesis on the relation of the anterior pituitary gland and other ductless glands to cancer. This was an advanced thesis, for which he was awarded the gold medal for the best thesis of the year. In the same year he passed the examination for the D.P.H. Thus was laid an excellent and unusual foundation for the life of a general practitioner. In 1913 he moved to Disley, in Cheshire, to become the partner of the late Dr. Alan Boyle, and quickly gained a fine reputation as a doctor. He was kindly and sympathetic—one of the old school—and well versed in the art of general practice. He was recognized by his consultant friends as a man who had a wide knowledge, not only of medicine, but of life in general. A man of culture, he was widely read, with a great interest in music. In his early days he was a church organist and he also played the harp. Ecclesiastical architecture was one of his interests. In the first world war he served in Mesopotamia, in the 33rd British General Hospital. On his return to practice he entered fully into the activities of his district, becoming president of the Disley branch of the British Legion. He was for many years medical officer of health of the New Mills Urban District Council. In 1952 he was elected chairman of the Stockport Division of the British Medical Association, and in 1954 president of the General Practice Section of the Manchester Medical Society. At the time of his death he was a member

of the Cheshire Local Medical Committee. He was keenly interested in the training of young doctors, and his trainees had a high opinion of his sage advice. Roland Titcombe will be sadly missed by his wide circle of friends. He leaves a wife and two sons, who are both doctors.—W. R. D.

By the death of Dr. G. DRU DRURY on October 12 Corfe Castle and the Isle of Purbeck have lost a well-loved general practitioner, who had lived for fifty years under the shadow of the old castle. He was 76 years of age. Godfrey Dru Drury was born on March 16, 1880, and was educated at Monkton Combe School and at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1904. After holding the appointments of house-surgeon and house-physician at the Seamen's Hospital, Greenwich, he settled in practice at Corfe Castle. There he became a well-known and much-loved figure, and his work as a general practitioner took him all over the Isle of Purbeck. For many years he was on the staff of the Cottage Hospital at Swanage and the Children's Hospital. A Fellow of the Society of Antiquaries for twenty-eight years, he also served at one time as president of the Dorset Natural History and Archaeological Society. An expert on the history of Corfe Castle, he was always keen and willing to impart his knowledge to others at medical meetings and to groups of ordinary sightseers. In his younger days he led the Corfe Castle cricket team. He had been chairman of the Salisbury Diocesan Advisory Committee and was also a member of the Dorset Church Building and Restoration Committee. He was a churchwarden for twenty-five years in the parish church, and was entirely responsible for the tidiness of the churchyard. The church of St. Edward, Corfe Castle, was crowded for the memorial service, at which the address was given by the Bishop of Sherborne. He leaves a daughter and a son.

Dr. H. S. BAKER died in London on October 13 after a long illness and many years of poor health. He was 63 years of age. Henry Searle Baker was born at Lewisham on January 25, 1893. Educated at Colfe's Grammar School, Lewisham, he then went to St. Bartholomew's Hospital, where he enjoyed life to the full. He excelled at cricket and also enjoyed playing Rugby football. The outbreak of the first world war found him just ending his fourth year, and by much hard work he qualified L.M.S.S.A. in 1914 at the age of 21. He joined the R.A.M.C. and was posted to the Royal Sussex Regiment, and while in France was severely wounded in the abdomen and was thought to be dying. His fiancée, then a nursing sister in the Q.A.I.M.N.S., travelled to the forward clearing station and nursed him back to health. This wound was a cause of much ill-health in later life. After the war he went back to his studies and took the London Conjoint diploma in 1920. He settled in Camden Town and soon acquired a name as a skilled practitioner. All his patients were personal friends, and he worked untiringly in their interests. From 1930 to 1935 he devoted much time to research and had several papers published on the treatment of cancer by connective-tissue extracts. He also became deputy medical officer to Holloway Prison. He remained in general practice until soon after the outbreak of the second world war, when he joined the R.A.F. For most of the war he was stationed at aerodromes in England and Ulster, but also spent much time in the *Queen Elizabeth* and the *Scythia* in convoys. On demobilization he returned to general practice, but ill-health eventually forced his retirement from active work. Journalism had always been his other love, and from time to time many articles of his had appeared in the lay press. He now devoted all his energy to both journalism and medical boards. He became a close friend of a large number of Fleet Street personalities, wrote for many newspapers, and felt especially honoured by his election to the Press Club. He became chairman and deputy chairman respectively of Ministry of Pensions and Ministry of Labour medical boards. In 1950 he underwent his first operation, and immediately realized his ultimate prognosis, but neither courage nor wit

deserted him over the next six years. He lived his life to the full, enjoying every minute and giving much. He leaves a widow and two sons, one a doctor. The sympathy of his many friends is extended to his family in their great loss.

Dr. H. J. A. POLLARD died suddenly at his home at Eastbourne on October 17 in his 62nd year. He had been in apparent good health, and his sudden death came as a great shock not only to his family but also to many others, both in his own profession and among his friends. The son of Sir George Pollard, doctor, barrister, and M.P., Harold James Alexander Pollard was born at Southport on January 18, 1894. Educated at Harrow, Clare College, Cambridge, and at St. Bartholomew's Hospital, he qualified M.R.C.S., L.R.C.P. in 1920. After holding the appointment of house-physician at St. Bartholomew's Hospital and at the David Lewis Northern Hospital, Liverpool, he went into practice at Eastbourne in 1923. Then began what was to be a long connexion with the local hospitals. He was a member of the staff of the Leaf Hospital from his early days at Eastbourne and was intimately associated with the management of the hospital until it was taken over under the National Health Service Act in 1948. He was appointed anaesthetist to the Eastbourne Hospital Group in that year and medical officer to the Merlynn Convalescent Home. He was a hard-working, conscientious family doctor, whose sense of humour and invariable good nature endeared him to patients and friends alike. His recreations were golf, bridge, and photography, but in recent years he had found less and less time to devote to them. "Alec" Pollard will be sorely missed by his friends, and the sympathy of these friends goes to his widow and daughter, for above all he loved his family and his home.—D. A. C.

Medical Notes in Parliament

NEW CHARGES ON PRESCRIPTIONS

An explosion about Health Service charges marked the resumption of the Parliamentary session when on October 25 the CHANCELLOR OF THE EXCHEQUER announced the second instalment of his efforts to find £100m. savings in Government expenditure.* These amounted to £17,500,000, and he confined his comments to two of the individual items which made up the total.

First, he said, it was proposed to alter, as from December 1, 1956, the method of charging for National Health Service prescriptions, the cost of which was running at nearly 5s. an item. From that date the charge would be 1s. per item instead of 1s. per form. Existing arrangements for refunds would be continued. The saving would be £4m. this year and £5m. in a full year.

Secondly, it was proposed to make a seasonal increase, from 7½d. to 8d. a pint, in the retail price of milk as from January 1, 1957, for the remainder of the winter. The net saving this year would be £4,500,000. The charge for welfare milk would not be affected by this change.

*The B.M.A. issued to the press the following statement: The B.M.A. is not concerned with the politics of charges within the National Health Service. It is, however, vitally concerned with the effect on patients. We are just as anxious as the Government to get the size of the drug bill reduced, but we think that the decision to charge a shilling for every item of medicine is bound to have medical repercussions. It discriminates unfairly between different classes of patient. One patient requires only one bottle of medicine: another must have drugs in several different forms. Take diabetes. Sufferers from diabetes require not only insulin but syringes, needles, spirit, and all these at regular intervals for the rest of their lives. A varicose ulcer needs dressings of various sorts, and again for a considerable period. Worst of all, patients dying of ulcerating carcinoma requiring large amounts of dressings and sedatives will have to pay five or six shillings a time for their prescriptions. Doctors will be concerned about the medical repercussions of this decision.

The other savings included a further £9m. on defence, but—as his statement appeared to anticipate—these were the items which roused the Opposition to noisy wrath. He was assailed with cries of "Scrooge," "Cheap," "Brute," "Shame," and a mounting chorus of "Resign." Mr. HAROLD WILSON (Huyten, Lab.), who was the chief Opposition spokesman, demanded to know why the economies always fell on those least able to afford them, in this case the sick, and how the increases could be reconciled with all the preaching about "a plateau of price stability." Mr. MACMILLAN told him that the effect of the seasonal change in the price of milk on the cost-of-living index was estimated to amount to 0.22, which was negligible. As for the prescriptions change, the Government had to thank the former Labour Government in 1949 for providing the powers in the National Health Service (Amendment) Act. He recalled the claim of the then Government, in introducing that Bill, that not merely was economy the reason but also the need "to reduce excessive and unnecessary resort to doctors and chemists"—and added that this had led to some difficulties between Mr. Gaitskell and Mr. Aneurin Bevan.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked if the Chancellor had fully considered what his proposal would mean in the next few months to the five million old-age pensioners, who must of necessity have recourse to doctors. It was customary to prescribe on one form for medicine, lotion, and liniment, but in future the pensioners would have to pay 2s. or 3s. Mr. MACMILLAN explained that the arrangements for reimbursement covered all war pensioners requiring treatment, all persons in receipt of National Assistance, and all old-age pensioners and others who could not meet the charges without hardship. Miss M. HERBISON (Lanarkshire, North, Lab.), who charged him with a "despicable attack" on the sick and disabled, was also told that the reimbursement arrangements, which the Chancellor thought to be satisfactory, would continue. Dame IRENE WARD (Wallsend, Con.) asked for an assurance that this would be made clear in the notices in chemists' shops, and Mr. MACMILLAN promised to consult the Minister of Health to see that this was done. In answer to another question by Mr. JAMES GRIFFITHS (Llanelli, Lab.) he included among those who could claim reimbursement "those drawing industrial injury benefits." Dr. SUMMERSKILL pressed him to say how a poor person having recourse to a doctor could prove inability to afford the charges. Mr. MACMILLAN: Exactly in the same way as hitherto.

Epileptics in Prison

Mrs. E. BRADDOCK (Liverpool, Exchange, Lab.) questioned the Home Secretary on October 25 about the numbers of epileptic prisoners, the numbers of specially equipped cells in prisons, and the arrangements made to attend to epileptic prisoners and prevent them from injuring themselves. Major G. LLOYD-GEORGE told her that the most recent available annual total figures showed that 192 epileptics were received into custody in 1954 and that a further 209 prisoners were recorded as possibly having epilepsy. With two exceptions, in prisons where prisoners with severe epilepsy were detained the number of specially equipped cells for their use ranged from one to seven. In the two such prisons where there was no permanent provision special *ad hoc* arrangements were made as necessary. Prisoners suffering from epilepsy received anticonvulsant drugs and other medicinal treatment; where necessary they were lodged in cells equipped to reduce the likelihood of injury.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked him to consider permitting epileptic prisoners to be detained only in prisons which had all the facilities necessary for dealing with them, including what amounted to a padded cell. Major LLOYD-GEORGE said that in many cases where a padded cell was provided it was hardly ever used, but he would look into the matter.

Poliomyelitis This Year

Mr. S. P. VIANI (Willesden, West, Lab.) asked the Minister of Health how many of the 2,538 cases of poliomyelitis recorded this year occurred in the age classes 2 and 9 years; how many of them and at what ages occurred after April 30; in which areas the 2,538 cases were notified; in how many of the 2,538 cases the diagnosis of poliomyelitis was confirmed; how many of the cases developed paralysis, and at what ages; and how many proved fatal, and at what ages. Mr. R. TURTON, replying on October 26, said that figures of corrected notifications, ages, and deaths for the September quarter were not yet available. In the first six months of the year the uncorrected notifications numbered 848 (paralytic 536, non-paralytic 312), while statistics for corrected notifications were as follows:

Age	Corrected Notifications			Registered Deaths*	
	Total	Paralytic	Non-paralytic	Age	Deaths
0	12	11	1	0	4
1	25	20	5	1	1
2	37	31	6	2	1
3	36	24	12	3	0
4	59	35	24	4	0
5	196	106	90	5	4
10	80	46	34	10	6
15	91	65	26	15	2
25+	106	82	24	20	2
				25	8
				30	6
				35	3
				40	2
				45	1
				50-4	2
Total	642	420	222		42

* Number of deaths registered where the interval between onset of the disease and death was less than twelve months.

Mr. HECTOR HUGHES (Aberdeen, North, Lab.) asked the Secretary of State for Scotland for a comprehensive statement on the incidence in Scotland of poliomyelitis, indicating age groups and areas, and on the results which had followed the tests and application of the new anti-poliomyelitis vaccine recommended by the Department of Health for Scotland, to the latest convenient date.

Mr. J. STUART stated on October 24 that in the four weeks to October 13 there were 57 provisional notifications of poliomyelitis. About 34,000 children were vaccinated during May and June, but it was too early to assess the results of these vaccinations. A detailed assessment was being made by the Medical Research Council, and the results would be made known in due course.

Drug Sales Investigation

Mr. DAVID LLEWELLYN (Cardiff, North, Con.) asked the Home Secretary on October 25 about the sale by some Cardiff chemists of a certain drug without the signature of a dental surgeon, and if he was aware that the drug was being sold as confidence pills without purchasers signing the poisons book or producing a doctor's or dentist's prescription. Major LLOYD-GEORGE replied that his attention had been drawn to recent allegations about the indiscriminate sale of a drug which was added to the Poisons List from August 15. He understood that the matter was being investigated by the Pharmaceutical Society, which was responsible for the enforcement of the Pharmacy and Poisons Act.

Reports in Progress

The MINISTER OF HEALTH informed Mr. N. DODDS (Erith and Crayford, Lab.) on October 25 that since it last received evidence in public on July 27, 1955, the Royal Commission on Mental Laws had been pursuing inquiries and preparing its report. He did not know when this work would be completed.

He told Mr. B. JANNER (Leicester, North-west, Lab.) that he was studying the report of the McNair Committee on the recruitment of dentists, with a view to discussion with the profession and others concerned.

The HOME SECRETARY stated in answer to Mr. K. ROBINSON (St. Pancras, North, Lab.) that the Wolfenden Committee on homosexuality and prostitution was engaged in drafting its report. It was aware of his anxiety that this should be presented as soon as possible, and, while he could not give any firm date, he was hoping that the committee would complete its work early in the new year.

Hospital Doctors' Emoluments

Mr. ERIC JOHNSON (Manchester, Blackley, Con.) asked the Minister of Health on October 29 if he was aware that in many hospitals the new scale in emolument charges would result in a substantial reduction in the net salaries of resident doctors; and if he would give instructions that these charges should not be implemented in retrospect or until the negotiations in regard to the standard of accommodation, which were in progress, had been completed. He also said there was still a shortage of junior hospital medical staff; and asked if the Minister would ameliorate this situation by abolishing emolument charges for those who were compelled to reside in hospital, by improving the standard of accommodation for doctors, and by providing married quarters.

Mr. R. H. TURTON replied that, while the charges payable by house officers, who were the most numerous class of resident doctors, were not altered, he was aware that for many doctors in the more senior grades the new charges were higher than those previously paid. They took effect on August 1 in accordance with a Whitley agreement, and he saw no justification for suspending the operation of that agreement, much less for abolishing charges altogether. He answered the other points by reference to a 1954 circular on residential accommodation issued to hospital authorities (Supplement, January 15, 1955, p. 16).

Mr. JOHNSON.—Is the Minister aware that resident doctors have to sign contracts which do not state the amount of the emoluments charged; that they have no redress if they are increased; and that they have to pay income tax on their gross salary before the charges are deducted? Is he also aware that the standard of accommodation in some hospitals is still extremely poor? Is it not wrong that doctors, who might have to get up in the middle of the night to perform difficult operations, should have only a bedroom and no sitting-room at their disposal, even after six or seven years' service? Mr. TURTON.—These charges were agreed under the Whitley agreement, and I think the matter must be left there. I am sure the hospital authorities are as anxious as I am to see that the accommodation provided for resident staff is as satisfactory as possible.

Mrs. LENA JEGGER (Holborn and St. Pancras, South, Lab.) asked whether the Minister had been able to give any special consideration to married doctors required to be resident. Mr. TURTON.—All these factors were taken into account by the Whitley committee.

Junior Medical Staff

Mr. ERIC JOHNSON asked the Minister if he was aware that junior hospital medical staff had no direct access to, nor negotiating powers with, his department; and if he would arrange for them to be represented on the Joint Negotiating Committee. Mr. TURTON.—There is a joint negotiating body for all grades of hospital medical staff. The composition of the staff side of this body is a matter for the profession itself. Mr. JOHNSON invited him to agree that it was grossly unfair that this group of doctors, who represented more than 50% of the hospital service and probably did the bulk of the work, should not be represented on the committee, and their voice could not be heard. Mr. TURTON said it would be most improper if he were to interfere with the composition of the staff side.

Practice Expenses

Mr. W. W. HAMILTON (Fife, West, Lab.) asked the Minister of Health what was the latest date on which doctors' practice expenses were reassessed; what was the

total increase resulting from that reassessment; and how much it represented per doctor per year. Mr. TURTON.—The latest year for which doctors' practice expenses have been reassessed is that ending on March 31, 1955, when for Great Britain they are estimated to have been £23,549,227, or £1,114 per doctor, an increase of £2,891,797, or £114 per doctor, over the preceding year.

P.P.S.

The Minister of Health, Mr. R. H. TURTON, has appointed Mr. JOHN ARBUTHNOT (Dover, Con.) as his Parliamentary Private Secretary.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in September was 93, compared with 86 in the previous month and 136 in September, 1955.

The numbers of cases of industrial diseases in the United Kingdom reported during September, 1956, were as follows: lead poisoning 7, aniline poisoning 5, epitheliomatous ulceration 23, chrome ulceration 14; total 51. There was one death from epitheliomatous ulceration due to pitch and tar.—*Ministry of Labour Gazette*, October, 1956.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest rises in the notifications of infectious diseases in England and Wales during the week ending October 13 were 178 for measles, from 1,968 to 2,146, 103 for dysentery, from 421 to 524, and 74 for scarlet fever, from 458 to 532; the only large fall was 94 for whooping-cough, from 1,487 to 1,393.

The largest rises in the incidence of measles were 48 in Middlesex, from 65 to 113, 45 in Lancashire, from 455 to 500, and 43 in Northumberland, from 73 to 116; the only large fall was 43 in Derbyshire, from 75 to 32. The only rise of any size in the notifications of scarlet fever was 27 in Lancashire, from 54 to 81. The largest fluctuation in the returns of whooping-cough was a fall of 26 in Surrey, from 41 to 15. 10 cases of diphtheria were notified, being 8 more than in the preceding week and the largest total for 36 weeks. The multiple cases of diphtheria were Warwickshire 4 (Birmingham C.B. 3), Lancashire 2, and London 2.

150 cases of acute poliomyelitis were notified. The number of paralytic cases was the same as in the preceding week and the non-paralytic cases were 5 fewer. The largest returns were Lancashire 32 (Manchester C.B. 12, Liverpool C.B. 8, Blackpool C.B. 2, Urmston U.D. 2), Cheshire 21 (Stockport C.B. 12, Wirral U.D. 3, Sale M.B. 2), Hertfordshire 9 (Elstree R.D. 7, Watford M.B. 2), London 8 (Lambeth 2, St. Pancras 2), Durham 8 (West Hartlepool C.B. 3, Sunderland C.B. 2, Hartlepool M.B. 2).

The rise in the incidence of dysentery was mainly contributed by rises of 55 in Yorkshire West Riding and 24 in Lancashire. The largest returns were Yorkshire West Riding 149 (Leeds C.B. 29, Thorne R.D. 23, Colne Valley U.D. 19, Tadcaster R.D. 15, Sheffield C.B. 11), Lancashire 103 (Liverpool C.B. 31, Rawtenstall M.B. 18, Blackpool C.B. 11), London 50 (Southwark 8), Warwickshire 37 (Coventry C.B. 29, Birmingham C.B. 8), Durham 27 (South Shields C.B. 12, Stanley U.D. 9), Yorkshire East Riding 18 (Haltemprice U.D. 10, Kingston-upon-Hull C.B. 8).

Week Ending October 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 600, whooping-cough 1,469, diphtheria 6, measles 2,790, acute pneumonia 284, acute poliomyelitis 140, dysentery 636, paratyphoid fever 7, and typhoid fever 1.

INFECTIOUS DISEASES AND VITAL STATISTICS
Summary for British Isles for week ending October 13 (No. 41) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Professor Charles Singer, 80.—Dr. Charles Singer professor emeritus of the history of medicine in the University of London, celebrated his 80th birthday on November 2. For many years he has held a pre-eminent place among medical historians. His contributions to the literature of his subject number more than 500, among them being his *Studies in the History and Method of Science* (1917 and 1921) and *A Short History of Medicine* (1928), and more recently he has been editing *A History of Technology*, the second volume of which is soon to appear. Though confined to his house at Par, Cornwall, by illness during part of the summer, Professor Singer is out and about again now and fully occupied with the preparation of the later volumes of the history of technology. Many who have been led by his writing and teaching to a permanent interest in medical history will be anxious to add their good wishes to those which Professor Singer will have received on his birthday.

Welsh National School of Medicine.—Mr. L. P. THOMAS has been appointed senior lecturer in surgery, and Dr. H. E. F. DAVIES lecturer in medicine. Mr. Thomas graduated in science and medicine at Cardiff. After resident appointments at the Cardiff Royal Infirmary he held a research fellowship in surgery at Harvard University and was assistant in surgery at the Peter Bent Brigham Hospital, Boston. Dr. Davies was formerly medical registrar at the miners' chest diseases treatment centre and pneumoconiosis research unit, Llandough Hospital.

British Medical Help for the Argentine.—Following an invitation from the Argentine Government and a request from the British Foreign Office, Mr. H. J. SEDDON, clinical director of the Royal National Orthopaedic Hospital, will visit Buenos Aires later this month. He will advise on the treatment and rehabilitation of those incapacitated in the serious outbreak of poliomyelitis which occurred in the Argentine earlier this year. Since June five British physiotherapists and one occupational therapist have been working in Buenos Aires under the rehabilitation commission.

Mercury in Teething Powders.—The council of the Pharmaceutical Society states that teething powders containing mercury or mercury compounds are still being sold. It therefore draws attention to the danger of such preparations, and strongly urges that they should not be supplied (*Pharmaceutical Journal*, October 27, p. 335).

Board of Control for Scotland.—Dr. PATRICIA O'KANE has been appointed a deputy commissioner of the General Board of Control for Scotland.

Postgraduate Travelling Fellowships.—Details of the travelling fellowships offered by the British Postgraduate Medical Federation to medical and dental practitioners in training as specialists at schools or institutes of London University are to be found at p. 48 of our advertisement columns this week. The fellowships are tenable for one year.

Cardiovascular Research in Australasia.—The Life Insurance Medical Research Fund of Australia and New Zealand announces grants in aid of research on diseases of the heart and blood vessels to the value of £25,000 for the current year. Grants have been awarded to the departments of pharmacology and physiology at Sydney University; the cardiac department of the Royal Melbourne Hospital; and the clinical research unit, Alfred Hospital, Melbourne; and the department of medicine, Otago University. A senior research fellowship has also been renewed. The Fund's address is 13, Bond Street, Sydney, New South Wales.

Bequests of Bodies and Eyes.—A pamphlet describing the procedure for those who wish to leave their bodies for dissection or their eyes for corneal grafting is available from the section or their eyes for corneal grafting is available from the B.M.A.'s public relations department. Copies are obtainable on request.

Royal College of Physicians of London.—At the quarterly comitia on October 25 Dr. D. H. BRINTON, Dr. R. M. B. MACKENNA, Dr. K. ROBSON, and Professor J. McMICAL were elected councillors. Dr. S. R. F. WHITTAKER was elected to the Standing Joint Committee of the three Royal Colleges, and Sir RUSSELL BRAIN, P.R.C.P., Sir HAROLD BOLDEO, Professor W. G. BARNARD, and Sir ALLEN DALEY were re-elected to it. The president and the president of the Royal Society (Sir CYRIL HINSHELWOOD) presented the Conway Evans Prize to Lord ADRIAN. A message of greeting was sent to the College of Physicians and Surgeons of South Africa on the occasion of its inauguration. Dr. CICYLY D. WILLIAMS has been appointed Milroy Lecturer for 1958.

U.N.I.C.E.F. Greetings Cards.—The United Nations Children's Fund offers sets of Christmas cards of new design this year, as well as the earlier set "Holiday Bound" designed by Edy Legrand. The three new sets on sale are "Festive Times in Many Lands" designed by Joseph Low (10 cards assorted, 2 each of 5 designs), "Indian Cards" by Jamini Roy (10 cards: 5 each of 2 designs), and "Bridge to Peace" by Saul Steinberg (10 cards, all the same design). The cards are supplied with or without a greeting in the five official languages of the United Nations, and each set of 10 cards with envelopes, costing 7s. 6d., may be obtained from U.N.I.C.E.F. Greeting Card Fund, 14/15, Stratford Place, London, W.1. The profit made from the sale of these cards enables U.N.I.C.E.F. to carry on its work of raising the standard of health and welfare of children throughout the world.

Grenfell Association's Christmas Cards.—The Grenfell Association's Christmas cards this year are to raise funds for the building of a nursing station in Northern Labrador, which is ice-bound for more than half the year. Here many of the Eskimos suffer from tuberculosis and extreme poverty. An illustrated leaflet of the Grenfell cards may be obtained, on receipt of 2d., from the Grenfell Association, 66, Victoria Street, London, S.W.1.

Association of Clinical Biochemists.—At the annual general meeting on October 6 the following officers were elected: President, Professor E. J. KING; chairman, Dr. R. GADDIE; treasurer, Dr. I. MACINTYRE; and secretary, Dr. A. L. TARNOKY, Royal Berkshire Hospital, Reading.

"Physics in Medicine and Biology."—The Hospital Physicists' Association has launched a journal called *Physics in Medicine and Biology*, under the editorship of Professor J. E. ROBERTS, of the Middlesex Hospital Medical School. It will record original research on the physical properties and constitution of living matter, and on the application of physical techniques to medical, biological, and physiological problems. From time to time review articles will be published. The journal includes a section devoted to abstracts of relevant papers appearing in the medical and scientific literature of the world. *Physics in Medicine and Biology* will appear quarterly, at an annual subscription of £3 10s. (\$10.50) and is obtainable from Taylor and Francis, Ltd., Red Lion Court, Fleet Street, London, E.C.4.

Prize for Registrars in Anaesthetics.—The Section of Anaesthetics of the Royal Society of Medicine offers a £30 prize for the best paper on a subject connected with anaesthesia by an N.H.S. registrar (or senior registrar) in anaesthetics. Details from the hon. secretary of the Section, 1, Wimpole Street, London, W.1.

Reading Pathological Society.—The annual oration of this, the oldest pathological society in Britain, was given at the Royal Berkshire Hospital in Reading on October 25 by Mr. A. DICKSON WRIGHT on diseases of blood vessels. Before the oration the outgoing president of the Society, Mr. S. F. LOGAN DAHNE, invested the new President, Dr. H. R. FOSBERY, with the insignia of his office. At the annual dinner on the same evening the health of the Society was proposed by Sir JOHN WOLFENDEN, vice-chancellor of the University of Reading.

COMING EVENTS

Institute of Dermatology.—Second semi-permanent exhibition, November 5–26. Dr. A. TICKNER: "Protein in Relation to Dermatology."

Training of Mental Defectives.—A meeting to discuss the training of mental defectives will be held at the Fountain Hospital, Tooting Grove, London, S.W.17, on November 7 at 5.30 p.m. All interested are invited.

Occupational Dermatitis.—The Joint Advisory Council for Occupational Health is holding a conference on the "Prevention of Occupational Dermatitis" at 3 p.m. on November 7 at the Royal Pavilion, Brighton. Admission by ticket (2s. 6d., including tea). Details from the hon. secretary of the council, Health Department, Royal York Buildings, Brighton, 1.

Fellowship for Freedom in Medicine.—Annual meeting will be held at Caxton Hall, Westminster, November 10 at 2 p.m. Details from the honorary secretary, 45, Nottingham Place, London, W.1.

London Medical Orchestra.—A concert will be given at B.M.A. House on November 24 at 8 p.m. in aid of the Cancer Relief Fund. Tickets (10s., 7s. 6d., and 5s.) from the hon. secretary, 6, Oxford Court, London, W.3, or at the door.

Research Defence Society.—Professor A. A. MILES will deliver the Stephen Paget memorial lecture on November 27 at 5.30 p.m. at the physiology lecture theatre, University College, London. His subject will be "Resistance to Infection: The Experimental Approach." The annual meeting of the society will be held after the lecture.

Bethlem Royal Hospital and the Maudsley Hospital.—The biennial ball for past and present medical staff will be held on November 30 at the Connaught Rooms, Great Queen Street, London, W.C.2. Tickets from Dr. BRIAN ACKNER, the Maudsley Hospital, London, S.E.5.

Radioisotope Techniques.—Four-week courses on radioisotopes and their uses will begin on January 14, 1957, at the Sir John Cass College, London, E.C.3. Details will be found in our advertisement columns (p. 3 of cover).

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 5

DENTAL AND MEDICAL SOCIETY FOR THE STUDY OF HYPNOSIS.—At Medical Society of London, 8 p.m., Mr. L. Becker: Hypnosis and the Psychosomatic Approach in Dentistry.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. O. W. S. Fitz-Gerald: A Few New Ideas in Mental Hospital Administration.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. S. Banks: Recent Advances in Infectious Fevers.

Tuesday, November 6

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Mr. W. J. Dempster: Homotransplantation of Organs.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Role of Viruses in Dermatology.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. R. F. Tredgold: Preventive Psychiatry.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Professor R. J. Last: Form and Function in Muscles.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. D. H. MacLeod: Differential Diagnosis in Gynaecology.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. C. C. Edwards: neurological demonstration.

Wednesday, November 7

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Role of Viruses in Dermatology.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. I. S. Longmuir: Application of Polarographic Analysis to the Study of Cellular Respiration.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. W. N. Mascall: Gonococcal Urethritis.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Medical School, Manchester University, 4.30 p.m., Dr. E. L. Peel: Plasma Cells and Plasma Proteins.
MIDLAND MEDICAL SOCIETY.—At General Hospital, Birmingham, 8.15 p.m., clinical meeting.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor G. M. Bull: Quantitative Assessment of Renal Function.
ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Professor W. E. Adams: Some Hazards and Corresponding Safety Measures in Thoracic Surgery for Elderly People.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Frank Wokes, Ph.D.: Human Vitamin Needs and Sources (illustrated).

Thursday, November 8

ALFRED APTER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Mr. P. Rom: Vaihinger's Fictionalism and Individual Psychology.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor C. G. Rob: Arterial Substitutes.
HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Professor G. A. Smart: The Nephrotic Syndrome.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Role of Fungi in Skin Disease.
LIVERPOOL MEDICAL INSTITUTION.—At Sefton General Hospital, 2.30 p.m., afternoon clinical demonstration.
MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Medical School, Manchester University, 4.30 p.m., University Lecture on the History of Medicine by Dr. A. Morgan Jones: Dogma and Experiment in Harvey's Time.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. J. Charnley: Arthrodesis of the Hip in Three Weeks.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Bradshaw Lecture by Dr. W. Phillips: Disintegrative Action of the Nervous System.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Robert Jones Lecture by Mr. S. A. S. Malkin: Conquest of Disability.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Aspects of Refraction Work—(5) Myopia, and Myopic Patients.
ROYAL MEDICAL SOCIETY, EDINBURGH.—At Royal College of Surgeons of Edinburgh, 7.15 for 7.30 p.m., presidents' annual dinner.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Queen's College, Dundee, 5 p.m., Dr. Joan Taylor: Infective Bacterial Diarrhoea of Infants.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatry demonstration.
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Dr. G. S. Wilson: B.C.G. Vaccination; 6.15 p.m., Dr. W. R. S. Doll: Present Knowledge of Causation of Cancer of the Lung.

Friday, November 9

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Mitchell-Heags: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. N. Pattinson: radiological demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—3.30 p.m., clinical meeting for general practitioners. Dr. C. H. Edwards: Neuralgias and Headaches.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. I. E. A. O'Connell: Surgery of Intractable Pain; 9 a.m., Professor G. M. Bull: How to Pass Examinations Without Actually Cheating.
ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—5 p.m., John Matheson Shaw Lecture by Dr. W. Ferguson Anderson: Care of the Elderly Sick in General Practice.
●ROYAL INSTITUTION.—9 p.m., Sir Charles Dodds, F.R.S.: Chemical Substances Influencing Mental and Physical Development.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. T. R. McCall: medical education.
SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At Chemistry Lecture Theatre, King's College, W.C., 7 p.m., Dr. F. Sanger: Chemistry of Insulin.
UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—At No. 1 Lecture Theatre, 5.30 p.m., contraceptive technique. Lecture and film demonstration for final-year students from London Medical Schools.
WEST KENT MEDICO-CHIRURGICAL SOCIETY.—At Miller General Hospital, Greenwich, 8.30 p.m., Dr. B. A. Young: The New Diabetic Treatments.

Saturday, November 10

●SOCIALIST MEDICAL ASSOCIATION.—At Conway Hall, Red Lion Square, W.C., 2 p.m. to 5 p.m., London Delegate Conference on Air Pollution. Smog—or Clean Air? Speakers include Dr. H. Joules, Dr. H. Price, and Dr. B. Stross.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Herriott.—On October 15, 1956, to Mary, wife of Dr. T. Dunn Herriott, of 2, Maidstone Road, London, N., a daughter, Janice Claire.
Menzies.—On October 8, 1956, at Vancouver, B.C., Canada, to Dr. Nanette Menzies (formerly Braster), wife of Dr. Albert Menzies, a sister for Heather and Anthea—Michele Margaret.
Oldham.—On October 21, 1956, at the Carmarthen Maternity Unit, to Valerie (formerly Williams), wife of Dr. William Oldham, a sister for Catherine and Robert.

DEATHS

Baker.—On October 13, 1956, at the King Edward VII Hospital for Officers, Henry Searle Baker, M.R.C.S., L.R.C.P., of 75, Lyttelton Road, London, N.
Cairns.—On October 15, 1956, at Albury House, Berwick-on-Tweed, Alexander Cairns, M.B., Ch.B.
Christie.—On October 10, 1956, at 15, Hill View Road, Cheltenham, Glos, Anaple Frances Mary Christie, M.B., B.S.
Drury.—On October 12, 1956, Godfrey Dru Drury, M.R.C.S., L.R.C.P., of Corfe Castle, Dorset, aged 76.
Langmead.—On October 8, 1956, at the Lido Wing, St. Mary's Hospital, London, W., Olive Gertrude Mary Langmead, M.B., B.S.
Monroe.—On October 18, 1956, at The Elms, Davyhulme Road, Davyhulme, Lancs, James Monroe, M.B., Ch.B.
Pollard.—On October 17, 1956, at his home, Milner Down, Selwyn Road, Eastbourne, Sussex, Harold James Alexander Pollard, M.R.C.S., L.R.C.P.
Rushbrook.—On October 19, 1956, at Redruth, Cornwall, Henry Martin Rushbrook, M.B., B.S.
Thoseby.—On October 18, 1956, at Kirkley, Crantock, Newquay, Cornwall, John Norman Lonsdale Thoseby, M.B., Ch.B.
White.—On September 26, 1956, at Queen Alexandra's Military Hospital, Millbank, London, S.W., Michael White, M.C., M.B., B.Ch., Lieutenant-Colonel, R.A.M.C., retired, of 17, Clarendon Road, Jersey, Channel Islands.
Whitehead.—On October 3, 1956, in hospital, Eleanor Murrian Whitehead, M.B., Ch.B., of "Moorrate," Oxford Road, Gomersal, Leeds.
Wooler.—On October 3, 1956, in hospital, Ernest William Nowell Wooler, M.B., Ch.B., of Linden Lea, Plane Tree Road, Hale, Cheshire, formerly of Cleckheaton, Yorks.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Belated Completion of Polio Vaccination

Q.—My daughter, aged 9, was one of the last children chosen for poliomyelitis vaccination last May. After she had received her first injection, the supply of vaccine ran out and the appointment for her second injection was cancelled. We were told that such children would receive priority when vaccination begins again. Is the long interval between the injections—probably six months—likely to affect the immunity conferred or predispose to reactions?

A.—An interval of approximately six months is not a contraindication to further immunization: in fact, the antibody response to the second injection at six months may be even better than with an interval of three to six weeks. Reactions are unlikely.

Malignant Disease in the Foetus

Q.—Does malignant disease ever occur in the human foetus? If so, what varieties have been reported?

A.—Malignant disease does occur in the human foetus, but fortunately only rarely in the ordinary sense of an evident tumour. A number of neoplasms are, however, foetal in origin and therefore present from an early stage of development, although they may not become obvious until much later in life. The teratomata are foetal tumours which are of embryonic origin and are occasionally malignant. Retinoblastoma occurs in the foetus and seems to be the only foetal tumour in which heredity plays a large part in causation. Environmental influences, such as foetal irradiation with x rays and radium, are occasionally responsible for congenital sarcoma, and are suspected to be a causative factor in leukaemia appearing in later infancy. Congenital leukaemia has also been reported. Direct transmission of malignant disease from mother to foetus is very rare, but has been proved in malignant melanoma, lymphosarcoma, and perhaps in a few cases of carcinoma. Chorion epithelioma may also be considered a prenatal foetal tumour.

The largest group of foetal tumours are sarcomata of all types. Neuroblastomata come next, and Wilms's tumours of the kidney third.

Alkalis and the Kidneys

Q.—Is there any danger of prolonged and quite heavy dosage with magnesium hydroxide for the relief of constipation damaging the kidneys? A patient has been taking 20–50 gr. (1.3–3.3 g.) of magnesium hydroxide nightly for the last ten years.

A.—Although it has been shown that very high doses of soluble alkali can be taken without harm, there is equally no doubt that renal calcification with progressive damage to function has often occurred in patients who have taken large amounts of milk and alkalis over a number of years. This "milk-alkali syndrome" is apparently commoner in America, but definite cases have been found in this country; the Americans are more prone to drinking large amounts of milk than adult Britons. These cases have mainly involved the consumers of soluble alkalis (MacLean's powder and the like). One would expect the danger of renal damage to be less with magnesium hydroxide, which is not indeed insoluble, but is much more poorly absorbed than sodium bicarbonate. I do not think anyone would be prepared to rule out

"danger," but my view would be that there was very little danger of renal damage. If renal damage should occur from this cause, it would be expected to be associated with calcification of the renal substance, possibly detectable by plain x-ray films; but not with calculus formation. If tests of renal excretory function should show impairment, it would be worth stopping the alkali intake, and keeping the bowels regular by other means. It would be hard to prove the complicity in causing renal damage of an amount of magnesium hydroxide which must be consumed by many patients with peptic ulcer.

Alternating Nasal Obstruction

Q.—Why is it that during an attack of rhinitis first one nostril and then the other commonly becomes blocked?

A.—Obstruction of the nasal airway which alternates from side to side is a common symptom in rhinitis, including that due to a non-specific hypersensitivity—for example, vasomotor rhinitis. The obstruction results from engorgement of the inferior turbinates.

Position is one of the factors which influences the side of the obstruction. When recumbent on one side it is often found that the lower nasal airway becomes occluded, but on turning over to the opposite side the previously obstructed nasal airway becomes patent and the one previously patent becomes occluded. The swelling of the turbinate is dependent on engorgement of the venous lakes in the erectile tissue of the inferior turbinate. This vascular tissue appears to be reflexly controlled, but the exact nature of its reflex response to changes in position has not been clearly demonstrated.

Depilation

Q.—What treatment is advised for removing a few hairs on a young woman's chin? She has been unsuccessful with a home electrolysis outfit, which in her hands causes only "pain and some pit marks," but no loosening of the hairs. Are abrasives or chemical depilatories satisfactory, and is endocrine therapy advised?

A.—Presumably the failure of electrolysis is due to the lack of skill of the operator. In carrying out electrolysis it is essential for the needle to be carefully and accurately placed into the hair follicle and for the operator to avoid undue force which would lead to the needle entering the tissues; otherwise the treatment will cause slight scarring without affecting the hair. Properly carried out, electrolysis is probably the best treatment if the hairs are sufficiently well developed for the follicle to be seen and exactly entered by the needle.

Abrasive material no doubt refers to sandpaper or pumice stone. In the writer's opinion this kind of treatment is more suited to the limbs than to the face, but an ordinary pumice stone may be found suitable for the chin. Chemical depilatories are sold in most chemists' shops. It is impossible to avoid some tendency to irritation to the skin, but in practice it seems very uncommon for any serious trouble to arise: it is very unusual in dermatological clinics to see ill effects arising from the use of chemical depilatories. No particular brand is recommended. They are simply applied to the skin and washed off after a suitable interval according to the makers' instructions.

It is rational to suppose that hirsuties in women is the result of endocrine upset. If this is so, then treatment to rectify such an abnormality is the rational treatment. In practice, however, it most often happens that women with hirsuties show no endocrine abnormality even after the most searching clinical and biochemical examination. For this reason a rational endocrine treatment cannot be chosen, and in fact treatment of this nature is seldom successful. The writer believes that endocrine investigation should be made when possible and that if abnormalities are found they should be corrected; otherwise endocrine treatment is not indicated.

Agonal Twitching

Q.—What is the explanation of the momentary generalized spasms sometimes observed just before death when respiration and the circulation have ceased?

A.—Asphyxial convulsions are well-studied phenomena in experimental animals. It is also well known that death of body tissues is not simultaneous. When the circulation has stopped, some central nervous system activity may continue for a few more minutes, and this commonly gives rise to twitching or spasms as described.

Protective Value of Washing the Hands

Q.—How effective is ordinary "social" washing in removing bacteria from the hands and reducing the risk of transmitting infections by this route?

A.—It is easy to study the effect of washing on the "transient" flora of the hands by heavily contaminating them with a readily recognizable organism such as *Chromobacterium prodigiosum* and taking cultures from them before and after washing. It is advisable to include such tests in practical instruction in bacteriology and hygiene for nurses, and in my experience scrubbing for about one minute always removes the organism completely: simple washing with soap and water reduces the numbers recovered from thousands in the first culture to a few scattered colonies in the second. Organisms which have only just been picked up by the skin are very easily removed mechanically, and soap assists the process both by its cleansing action and by its capacity actually to kill bacteria. Simple social washing, therefore, has a substantial value, reducing the risk of transmitting infection by the hands by at least 99%. Thorough scrubbing—and, it may be added, other precautions—should be undertaken by anyone who knows or suspects that his hands are contaminated by specific pathogenic organisms, whether after defaecation or in other ways.

Schools for Mentally Backward Children

Q.—Where may information about schools for mentally backward children be obtained?

A.—Schools for educationally subnormal (E.S.N.) children are run by the local education authorities. Information about these may be obtained from the education officer of the appropriate county council. It is usually best, however, for the doctor concerned with a case to consult with the school medical officer or county medical officer. Most of the accommodation available is for the day pupils, but there are some residential schools. There is a long waiting-list in many cases for such schools, particularly for the residential ones. A great many children are waiting either in ordinary schools or at home for admission to E.S.N. schools.

In addition to the schools for children of E.S.N. level there are also day occupation centres which are run by the medical officer of health for children of lower mental levels, that is to say, for imbeciles who are deemed ineducable. Information about these may be obtained from the county health department. In addition to this the mental deficiency hospitals, about which information can be obtained from the respective regional hospital boards, make provision for occupation centres for children residing in these hospitals. The regional psychiatrist may be consulted about such cases or a direct approach may be made to the mental deficiency hospital in the area.

Some ordinary small private schools are willing to keep backward children, though this will vary with the school and with the particular teacher concerned. It will also depend on the degree of defect. Very few private schools are willing to retain imbeciles, although they may be able to cope with children of E.S.N. level. Some provision for short-stay accommodation for children of imbecile level is made by the National Society for Mentally Handicapped

Children. Information about this and some other types of provision for mentally handicapped children may be obtained either from that society at 162a, Strand, London, W.C.2, or from the National Association for Mental Health, 39, Queen Anne Street, London, W.1.

NOTES AND COMMENTS

Pica in a Child.—Dr. J. H. C. WALKER (Maidstone) writes: Your answer ("Any Questions?" October 13, p. 893) says "perverted appetites very commonly symbolize a need for love." Time marches on! When I was a small boy I used to eat garden soil. My mother took me to a very sensible old G.P. who suggested that I had a need for salt. This was added to my diet and I then stopped eating soil.

Dr. IAN G. WICKES (Ballards Croft, Stock, Essex) writes: In the query about pica, I strongly suspect that the practitioner and respondent have overlooked the possibility that this is an inherited familial disorder. I am beginning to collect family trees in which several members show pica in infancy and childhood, and I would be most grateful for information about any such families.

Nocturnal Angina.—Dr. A. PINEY (London, W.1) writes: In reply to the question, "What are the possible causes of nocturnal precordial angina?" ("Any Questions?" October 13, p. 894) nothing is said about prevention. There appears to be no doubt that hyperlipaemia may precipitate an attack of precordial pain in persons with coronary atheroma; and Barritt,¹ among others, has shown that post-prandial lipaemia is greater and more prolonged in males with coronary infarction than in normal males of the same age group. Further, it is well known that a heavy meal before retiring is likely to precipitate an attack in predisposed people. Emphasis on the prophylactic value of taking only a very light meal in the evening and, in many cases, the administration of substances tending to diminish post-prandial hyperlipaemia would be of great practical use.

Severe Reaction to Penicillin.—Dr. E. M. COCHRANE (Omagh) writes: Your correspondent described dry gangrene of the feet in an infant of 10 months following the injection of 900,000 units of procaine penicillin for bronchopneumonia ("Any Questions?" September 22, p. 722). This dose of penicillin appears to be rather large and might have aggravated a reaction in so small a child. Gaisford and Lightwood recommend 150,000–300,000 units of penicillin for this complaint combined with a sulphonamide if necessary.

OUR EXPERT replies: While I agree with Dr. Cochrane that the dose in this case was large for a child of 10 months, I do not think the size of the dose conditions in any way the intensity of these sensitivity responses. Death has occurred within a few minutes of ordinary doses of intramuscular procaine penicillin when the amount of penicillin circulating in the blood could have been only minimal.

Preparation of Benzocaine and Urethane Solution.—In a reply to a question ("Any Questions?" October 20, p. 951) it was stated that this preparation did not seem to be on the market in Great Britain. We have since been informed that this is incorrect. At least two pharmaceutical houses provide it.

LUNG CANCER AND OTHER CAUSES OF DEATH IN RELATION TO SMOKING

A SECOND REPORT ON THE MORTALITY OF BRITISH DOCTORS

BY

RICHARD DOLL, M.D., M.R.C.P.

Member of the Statistical Research Unit of the Medical Research Council

AND

A. BRADFORD HILL, C.B.E., F.R.S.

Professor of Medical Statistics, London School of Hygiene and Tropical Medicine; Honorary Director of the Statistical Research Unit of the Medical Research Council

On October 31, 1951, we sent a simple questionnaire to all members of the medical profession in the United Kingdom. In addition to giving their name, address, and age, they were asked to classify themselves into one of three groups—namely, (a) whether they were, at that time, smokers of tobacco; (b) whether they had smoked but had given up; or (c) whether they had never smoked regularly (which we defined as having never smoked as much as one cigarette a day, or its equivalent in pipe tobacco or cigars, for as long as one year). All smokers and ex-smokers were asked additional questions. The smokers were asked the ages at which they had started smoking and the amount of tobacco that they were smoking, and the method of smoking it, at the time of replying to the questionnaire. The ex-smokers were asked similar questions but relating to the time at which they had last given up smoking.

On the basis of their replies to the questionnaire, we classified the doctors in a few broad groups according to their sex and age, the amount of tobacco they smoked, to their method of smoking, and whether smoking had been continued or abandoned. Subsequently we have recorded the deaths occurring in each of these groups. To ensure a high proportion of replies we intentionally made the questionnaire extremely short and simple. In particular, we did not ask for a life-history of smoking habits, although in studying the incidence of lung cancer, with a long induction period, we realized that the habits of early adult life might be more relevant than the most recent habits. In addition, we have made no further inquiry into any change of habits that may have taken place since October, 1951. In short, we have related the deaths of doctors that have occurred since October, 1951, to the non-smoking, present smoking, and ex-smoking groups as constituted at that date.

It follows that, while we can make an accurate comparison between life-long non-smokers and all smokers past or present, any gradient of mortality that we may observe in relation to the amount of smoking will be an understatement of the true relationship. We shall, for instance, have included in the group of "light" smokers persons who had previously smoked "heavily" but at November 1, 1951, had reduced their consumption. Similarly, a "heavy" smoker at November 1, 1951, may

previously have been a light smoker or may since then have given up smoking altogether; we shall have continued to count him, or her, as a heavy smoker. If there is a differential death rate with smoking, we must by such errors tend to inflate the mortality among the light smokers and to reduce the mortality among the heavy smokers. In other words, the gradients we present in this paper may be understatements but (apart from sampling errors due to the play of chance) cannot be overstatements.

In 1954 we published a preliminary report on the results of this inquiry (Doll and Hill, 1954a). The number of deaths from lung cancer was then small (36) and standing alone they would not have justified a firm conclusion. In showing a steadily rising mortality from lung cancer as the amount of smoking increased, they were, however, in close conformity with the figures we had previously found in our extensive retrospective inquiries into the smoking histories of patients with cancer of the lung and other diseases. With the passage of another two years we are now able to present from this prospective inquiry a considerably increased body of data, and, in consequence, a more exhaustive analysis. The four main questions to which we have sought answers are: (1) What are the relative risks of lung cancer associated with the smoking of different amounts of tobacco by different methods? (2) Is there a reduction in the risk if smoking is given up? (3) What is the most likely explanation of the observed association? (4) Is there a relationship between smoking and any other cause of death?

The Exposed to Risk

The questionnaire was sent out to 59,600 men and women on the *Medical Register*. Of the 41,024 replies received 40,701 were sufficiently complete to be utilized; 34,494 of these were received from men and 6,207 from women.* For the purposes of the present report the doctors concerned have been followed until March 31, 1956—that is, for four years and five months. No new additions have been made to the population and the total

*These numbers are slightly different from those given in our preliminary report, as a re-examination of the forms enabled an additional 137 to be utilized, while in a few cases it was found that the age group had been allocated incorrectly.

number of survivors exposed to risk at the beginning of each new period of twelve months has therefore steadily diminished. At the same time each of the survivors has grown older and mortality has, of course, fallen more heavily on the older age groups; as a result, the age distribution of the population has altered. These changes are shown for men in Table I as well as the total numbers of years of exposure in each age group during

TABLE I.—Number of Men Living in Each Age Group at the Beginning of Each Year of the Study and the Total Number of Years of Exposure

Age in Years	No. of Men Living at:						Total No. of Years of Exposure
	1/11/51	1/11/52	1/11/53	1/11/54	1/11/55	1/4/56	
Under 35	10,140	9,145	8,232	7,389	6,281	5,779	35,489
35-44	8,886	9,149	9,287	9,414	9,710	9,796	41,211
45-54	7,117	7,257	7,381	7,351	7,215	7,191	32,156
55-64	4,094	4,212	4,375	4,601	5,057	5,243	19,909
65-74	2,694	2,754	2,823	2,873	2,902	2,928	12,462
75-84	1,382	1,433	1,457	1,485	1,483	1,513	6,431
85 and over	181	200	223	256	278	296	1,028
All ages	34,494	34,150	33,778	33,369	32,926	32,746	148,686

the course of the study. The total number of years for all age groups is 148,686 for men and 27,187 for women. (These figures have been obtained by taking the average of the numbers of survivors at the beginning and at the end of each year and summing for the four years and five months of the study. For example, the number of male doctors aged 45-54 was 7,117 on November 1, 1951, and 7,257 on November 1, 1952; on average, therefore, there were 7,187 male doctors alive in that age group throughout that year. Similarly there were 7,319 male doctors alive in the same age group throughout the second year, 7,366 throughout the third year, 7,283 throughout the fourth year, and 7,203 throughout the first five months of the fifth year. The total number of years lived by male doctors in that age group is therefore calculated to be $7,187 + 7,319 + 7,366 + 7,283 + 5/12$ of 7,203, or 32,156 years.)

Figures for the number of years of exposure of men and women with different smoking habits have been obtained in the same way. Table II shows the figures

TABLE II.—Total Number of Man-Years of Exposure by Non-smokers and Smokers of Different Amounts of Tobacco; Men Only, Divided by Age

Age in Years	Non-Smokers*	All Smokers	Men Smoking a Daily Average of:		
			1-14 g.†	15-24 g.	25 g. or More
Under 35	10,143	25,346	12,548	10,002	2,796
35-44	7,130	34,081	13,625	13,380	7,076
45-54	4,136	28,020	9,477	10,371	8,172
55-64	1,907	18,002	6,333	6,514	5,155
65-74	1,078	11,384	5,201	3,893	2,290
75-84	720	5,711	3,334	1,701	676
85 and over	136	892	616	230	46
All ages	25,250	123,436	51,134	46,091	26,211

* A non-smoker is defined as a person who has never consistently smoked as much as 1 g. of tobacco a day for as long as one year.
† 1 cigarette is equivalent to 1 g. of tobacco.

for men, divided according to the daily amount of tobacco stated to have been smoked at the time of the inquiry in 1951, or immediately before smoking had last been given up. It will be seen that the distribution of smoking habits varies considerably from one age group to another, and it will therefore be necessary to use death rates at specific ages, or a rate standardized for age, in comparing the mortality experiences of men in the different smoking categories.

The Deaths

Through the courtesy of the Registrars-General in the United Kingdom a form showing particulars of the cause of death has been provided, since the questionnaire was sent out, for every death identified as referring to a medically qualified person. Lists of the deaths of doctors notified to them since October 31, 1951, have also been obtained from the General Medical Council and the British Medical Association. These extra sources of information have proved necessary since it is not always possible for the Registrars-General to determine at registration of death that the deceased person was, in fact, a doctor. For example, occasionally the occupation of a doctor who had served in the Army, or who had held a university appointment, may be described at the time of death merely as "Colonel (retired)" or "University teacher." Similarly with a married woman who has ceased to practise medicine there may well be no reference at registration of death to the fact that she possessed a medical qualification. It must also be noted that the deaths of civilians occurring abroad do not form part of the records of the Registrars-General. It has therefore been necessary to seek information about them, and their cause of death, from other sources—from the records of the Service departments, from the Registrars' offices of Commonwealth countries, and, in a few instances, from relatives. For all deaths occurring in the United Kingdom, irrespective of the source of our information, we have ascertained the certified cause of death.

In the 53 months covered by the present study (November, 1951, to March, 1956) 1,854 deaths have been reported. Table III, in which they are set out by age and sex, shows that

TABLE III.—Number of Deaths of Doctors Reported as Occurring Between November 1, 1951, and March 31, 1956, Inclusive

Age in Years	Males	Females
Under 35	34	3
35-44	68	10
45-54	189	8
55-64	311	26
65-74	417	24
75-84	543	23
85 and over	186	12
All ages	1,748	106

their numbers are small for women and for men under 35 years of age. Our principal analyses in this paper have therefore been confined to the mortality experience of men aged 35 years and above, involving 1,714 deaths from all causes.

We first classified these 1,714 deaths according to the underlying cause as certified. The eight cases in which we obtained the cause of death only from the other sources mentioned above we classified according to the reported cause; in a further 12 cases we have not yet obtained any statement of cause. Of the total 1,714 deaths among men aged 35 years or more, 82 were certified as due to lung cancer, while in three others lung cancer was mentioned as having contributed to death without being the primary cause. No deaths from lung cancer were reported in men under the age of 35 years and only three such deaths at all ages have been reported among women.

For every one of these 88 deaths we sought confirmation of the diagnosis by writing to the doctor who certified the death and also, when necessary, to the hospital or consultant to whom the patient had been referred. Additional information on the nature of the evidence was thus obtained in every case and is summarized in Table IV. In two cases, one male and one female, we have not accepted the cause of death as established. With the man, histological examination of the operation specimen had failed to confirm the presence of a carcinoma. With the woman, the histological report was "sarcoma of lung." In 7 of the remaining 86 cases the site of the primary growth had been diagnosed by

TABLE IV.—Criteria on Which Diagnosis of Primary Lung Cancer was Based

Diagnostic Criteria	Male Cases		Female Cases
	No.	% of Total	
I. Necropsy evidence, with or without histological examination; or histological evidence plus evidence of the site of the primary tumour from operation, bronchoscopy, or radiological examination	39*	46	1†
II. Evidence of the site of the primary tumour from operation and/or bronchoscopy and/or radiological examination, but without histological evidence	38	45	1
III. Evidence from clinical examination only	7	8	0
All cases, diagnosis accepted	84	99	2
Diagnosis not regarded as established	1	—	1

* 16 squamous-cell carcinoma, 16 oat-cell or anaplastic carcinoma, 3 adenocarcinoma, 3 cell-type undetermined, and 1 not examined histologically.
† Squamous-cell carcinoma.

clinical examination only. In 79 the site of the primary growth had been confirmed at necropsy or by operation, bronchoscopy, or radiological examination. Clearly the diagnosis may have been incorrect in some of the cases, but the evidence suggests that it is not likely to have been wrong in more than a small proportion. In making comparisons between the mortality of different groups within the investigation, we have therefore used the 84 male cases in which the additional information did not throw doubt upon the diagnosis of lung cancer.

RESULTS

The Amount Smoked

The complete data for the present 53 months of the follow-up have been used, and the death rates per annum from all causes of death and from five groups of diseases have been calculated for four categories of men—namely, non-smokers and smokers of small, moderate, or large amounts of tobacco. These rates have been standardized for age (by the direct method), using the total male population of the United Kingdom aged 35 years or above on December 31, 1951, as the standard population.† The results are shown in Table V and in the Figure.

If all causes of death are taken first, it will be seen that the mortality is highest among men who smoked 25 g. or more of tobacco a day (18.84 per 1,000), and that the rates for light smokers (14.92 per 1,000) and moderate smokers (14.49 per 1,000) are 10 to 13% above the rate for non-smokers (13.25 per 1,000). Of the five groups of diseases separately considered, lung cancer is the only one to show a marked and steady increase with the amount smoked. Its death rate rises from 0.07 per 1,000 among non-smokers to 1.66 per 1,000 among heavy smokers—that is, an increase of approximately twentyfold. Other respiratory diseases and coronary thrombosis also show some increase with rising tobacco consumption, particularly the former. But in both instances the difference between the extreme rates is, compared with lung cancer, relatively small. For other respiratory diseases the rate for heavy smokers (1.41) is 74% above the rate of non-smokers (0.81), while for coronary thrombosis the corresponding figure is 42% (5.99 to 4.22). The equality of non-smokers and smokers in cancer of other sites is striking and no trend with the amount of smoking is apparent. (These death rates from diseases other than cancer of the lung are considered in more detail in a later section.)

† Thus death rates for each cause of death were calculated separately for each age group for each of the smoking categories shown in Table II. These age rates for a smoking category were then applied to the corresponding U.K. populations in 1951 to obtain the death rate at all ages that would have prevailed in the U.K. population if it had experienced the rates at specific ages of the particular smoking group.

TABLE V.—Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More, in Relation to the Most Recent Amount Smoked*

Cause of Death	No. of Deaths	Death Rate Among:					
		All Men	Non-smokers	All Smokers	Men Smoking a Daily Average of		
					1-14 g.	15-24 g.	25 g. or More
Lung cancer ..	84†	0.81	0.07	0.90	0.47	0.86	1.66
Other cancer ..	220	2.02	2.04	2.02	2.01	1.56	2.63
Other respiratory diseases ..	126	1.10	0.81	1.13	1.00	1.11	1.41
Coronary thrombosis ..	508	4.78	4.22	4.87	4.64	4.60	5.99
Other causes ..	779	6.79	6.11	6.89	6.82	6.38	7.10
All causes ..	1,714	15.48	13.25	15.78	14.92	14.49	18.84

* That is, at November 1, 1951, for those smoking at that time and at the date of giving up for those who had given up at November 1, 1951.

† The three cases in which lung cancer was recorded as a contributory but not a direct cause of death are included under both lung cancer and the cause to which death was assigned by the Registrar-General.

Relationship between death rate, expressed as a percentage of the rate for all men, and the amount smoked, for five disease groups.

The statistical significance of the differences in the death rates is best assessed from the actual numbers of deaths recorded—that is, by comparing them with the numbers which would have been expected to occur in each smoking category if smoking were unrelated to the cause of death under inquiry. For example, 31 men aged 65-74 died with lung cancer. The man-years of exposure in this age group of men who had always been non-smokers (at the time the questionnaire was completed) formed 8.65% of the total exposure of all men (Table II). If the mortality from lung cancer is quite unrelated to smoking, then the proportion of non-smokers among the 31 lung cancer deaths should also be 8.65%. A similar calculation has been made for the numbers of men dying with lung cancer in the other age groups—namely, 1 at ages 35-44, 9 at ages 45-54, 24 at ages 55-64, 16 at ages 75-84, and 3 at ages 85 and above. The total number of deaths expected among non-smokers of all ages was then obtained by adding the numbers for the separate age groups. Corresponding calculations were made to obtain the number of deaths which would be expected to have occurred in men who smoked small, moderate, or large amounts, and likewise for the other principal disease groups of Table V. The results are shown in Table VI.

If non-smokers are compared with smokers it is found that for all causes of death the observed difference is not quite statistically significant ($P=0.06$). Division by cause shows that it is highly significant for lung cancer ($P<0.01$) but not significant for any of the other four diseases or

TABLE VI.—Observed Deaths From All Causes, and From Particular Causes, in Non-smokers and Smokers Compared With the Number of Deaths that Would Have Been Expected to Occur in Each Such Group if There Were No Association Whatever Between Smoking and Mortality

	Non-smokers	All Smokers	Test of Significance* P	Men Smoking a Daily Average of:			Test of Significance† P
				1-14 g.	15-24 g.	25 g. or More	
All causes: Observed deaths	163	1,551	0.06	727	468	356	Less than 0.01
Expected deaths	187.4	1,526.6		751.2	510.2	289.6	
Lung cancer: Observed deaths	1	83	Less than 0.01	22	27	34	Less than 0.001
Expected deaths	8.5	75.5		36.9	28.3	17.9	
Other cancer: Observed deaths	25	195	Between 0.8 and 0.9	95	51	49	Between 0.3 and 0.5
Expected deaths	23.9	196.1		92.8	64.9	37.3	
Other respiratory diseases: Observed deaths	11	115	Between 0.3 and 0.5	55	36	24	Between 0.2 and 0.3
Expected deaths	13.8	112.2		59.8	36.5	18.7	
Coronary thrombosis: Observed deaths	44	464	Between 0.1 and 0.2	200	148	116	0.06
Expected deaths	53.9	454.1		211.2	156.7	96.1	
Other diseases: Observed deaths	82	697	Between 0.5 and 0.7	356	207	134	Between 0.7 and 0.8
Expected deaths	87.6	691.4		351.9	224.9	120.2	

* Based on χ^2 test with $n=1$.† Based on χ^2 test applied to the trend with $n=1$.

groups of diseases. (The numbers of deaths of non-smokers are still small in some of these groups and it is quite possible that significant differences may be obtained with more extensive data.)

When comparisons are made between the different grades of smokers, it is proper to take account not only of the actual extent of the differences but also of the order in which they occur. The statistical test which has been applied to the results is therefore a test of the significance of the trend of the differences between the observed and expected numbers of deaths as the amount smoked increases (Armitage, 1955). It is thus found that there is a significant trend, with an excess of deaths among heavy smokers, for all causes of death ($P<0.01$) and a highly significant trend for cancer of the lung ($P<0.001$). Other forms of cancer and other diseases reveal no significant change with smoking, and the observed rise in other respiratory diseases and in coronary thrombosis is not, on present numbers, more than might quite easily be due to chance. (With the latter the rise is significant if the non-smokers are brought into the test of gradient along with the smokers of different amounts.)

TABLE VII.—Mortality From Lung Cancer in Relation to the Amount Smoked at Different Ages Above 35 Years: Annual Rates Per 1,000 Men

Age in Years	No. of Deaths	Death Rate Among:			
		Non-smokers	Men Smoking a Daily Average of:		
			1-14 g.	15-24 g.	25 g. or More
35-54 ..	10	0.00	0.09	0.17	0.26
55-64 ..	24	0.00	0.32	0.52	3.10
65-74 ..	31	0.00	1.35	3.34	4.81
75 and over	19	0.70	2.78	2.07	4.16
All ages ..	84	0.07	0.47	0.86	1.66

We may also note, at this point, that a finer analysis of the lung cancer data has shown a marked gradient at each stage of life. The mortality rates for four age groups above 35 years are shown in Table VII.

Method of Smoking

For classifying our population into cigarette smokers, pipe smokers, or smokers by both methods our data are certainly faulty. As pointed out above, the questionnaire asked for smoking habits at a particular point of time (November 1, 1951) and not for a life-history. In a covering letter we invited doctors to add any information on their smoking habits or histories which they thought might be of interest to us, and a number of them did so. In those instances we have, of course, used all the information given. For example, if a man stated that in November, 1951, he was smoking 2 ounces of tobacco weekly in a pipe but added in a footnote that previously he had, in addition, smoked 20 cigarettes a day, we classified him as a "mixed" smoker. But we can be sure that some, and perhaps many, men who had changed their habits did not volunteer this extra information. It follows that some whom we have classified as "pure" cigarette smokers or as "pure" pipe smokers really belong to the mixed class. The rates we give in Table VIII cannot therefore indicate the full extent of

TABLE VIII.—Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More, in Relation to the Method of Smoking

Cause of Death	No. of Deaths Among Smokers	Death Rate Among Men Smoking:			Test of Significance† P
		Pipes	Pipes and Cigarettes*	Cigarettes	
Lung cancer	83†	0.38	0.68	1.25	Less than 0.001

* Including men who smoked cigars.

† Based on χ^2 test applied to the trend from pipes to cigarettes; $n=1$.

‡ See second footnote to Table V.

the difference in risk associated with the two methods of smoking; the difference must be blurred by this inclusion in each "pure" group of men who belong to the "mixed" group. (In the mixed group we have included the few men who smoked cigars.)

However, in spite of this blurring of the picture, we find an excess mortality among cigarette smokers compared with pipe smokers for all causes of death and for three of the specific groups. For all causes of death the trend of the differences is highly significant ($P<0.001$) though the mortality of the "mixed" group is not in step. For lung cancer the trend is continuous and also highly significant ($P<0.001$); the death rate among the cigarette smokers is over three times as great as the rate among the pipe smokers. The death rate among cigarette smokers is also higher than that among pipe smokers for other respiratory diseases, coronary thrombosis, and the miscellaneous group of other diseases. The excess is less marked than for lung cancer, but it is sufficiently great for the trend to be statistically significant for other respiratory diseases and for the miscellaneous group. The mortality from these diseases among mixed cigarette and pipe smokers is, however, either lower or inappreciably higher than that among pipe smokers. For cancer of other sites no relationship is apparent.

The pronounced differences of Table VIII for persons dying of lung cancer can be explained, to some extent, by the fact that pipe smokers use, on the average, less tobacco than cigarette smokers (in the present study the average was 12 g. a day for pipe smokers against 20 g. a day for cigarette

smokers). This difference in consumption can be allowed for by calculating at each different level the distribution of the observed deaths that would have been expected to occur if the method of smoking bore no relationship at all to the rate of mortality. The resulting figures still show a significant difference between the categories ($P<0.01$). The same conclusion can also be reached by calculating separately, for each level of smoking, the standardized death rate for pipe smokers and cigarette smokers. It is then found that the death rate of pipe smokers is less than that of cigarette smokers at each level. We may repeat, too, that the contrasts obtained must almost certainly be an understatement of the true difference.

Effects of Giving up Smoking

To measure any effects that might follow the giving up of smoking, we divided the doctors into three groups: (1) those who, on replying to the questionnaire, reported that they had given up smoking for at least 10 years; (2) those who reported that they had given up within the previous 10 years; and (3) those who, at November 1, 1951, reported that they were then smokers. We know nothing of any subsequent changes in habits, so again any contrasts we find between these groups will be minimal. The mortality rates for the three groups are shown in Table IX. It will be

TABLE IX.—Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More, in Relation to Giving Up of Smoking

Cause of Death	Total No. of Deaths Among Smokers and Ex-smokers	Death Rate Among:			Test of Significance* P
		Ex-smokers, who had given up 10 Years or More at 1/11/51	Ex-smokers, who had given up Less than 10 Years at 1/11/51	Smokers at 1/11/51	
Lung cancer	83†	0.35	0.59†	1.03	0.02
Other cancer	195	1.31	1.79	2.15	Between 0.1 and 0.2
Other respiratory diseases	115	1.17	1.28	1.11	Between 0.9 and 0.95
Coronary thrombosis	464	3.98	5.23	4.88	Between 0.3 and 0.5
Other causes	697	7.24	7.22	6.71	Between 0.2 and 0.3
All causes	1,551	14.04	16.11	15.84	Between 0.5 and 0.7

* Based on χ^2 test applied to the trend, $n=1$.

† See second footnote to Table V.

seen that only for cancer of the lung is there a progressive and statistically significant reduction in mortality with the increase in the length of time over which smoking has been given up. Cancer of all other sites shows the same trend, but the observed differences are relatively small, and, with the numbers involved, might be due to chance. On the other hand, for cancer of the lung the mortality among the present smokers at November 1, 1951, has been three times as great as that among men who at that date had stopped smoking for 10 years or more, and 76% greater than the rate for men who had given up within the previous 10 years.

These differences cannot be accounted for by differences between the three groups in the amount smoked or in the method of smoking. The average amount smoked (at November 1, 1951, for the smokers and at the date of giving up for the ex-smokers) was practically the same—namely, men who had given up for 10 years or more, 18 g. a day; men who had given up within the previous 10 years, 19 g. a day; men who were still smoking, 18 g. a day. In regard to method, the proportion of "pure" cigarette smokers was also almost the same amongst those who had given up and amongst the continuing smokers—88% in men who had given up for 10 years or more; 87% in men who had given up within the previous 10 years; 84% in men who were still smoking.

We may also note at this point that the average age at which men had given up smoking was 44 years for those

who had given up within the last 10 years and 42 years for those who had given up for 10 years or longer.

In spite of these equalities the three groups are, of course, self-selected, and it seems not unlikely that selective factors may play some part in the contrasts of mortality between continuing smokers and ex-smokers of different durations. Thus, amongst those who have more recently given up smoking there are likely to be some who have given up on grounds of ill-health. Such persons are likely to have a higher-than-average mortality in the ensuing years. There is in the figures for all causes of death given in Table IX a slight suggestion of such an effect—the death rate is 16.11 per 1,000, compared with 15.84 per 1,000 for those who were continuing to smoke. On the other hand, we would not expect such a selective influence to be very pronounced in our data, since many seriously ill persons would not have returned our questionnaire at all. In the course of time those with a higher-than-average mortality will have been eliminated and the death rate among the group of persons who gave up smoking many years ago may be expected to fall—the actual figure is 14.04.

While such selective factors might, we think, contribute to the observed trend of mortality from all causes (and from coronary thrombosis in particular), they will not explain the continuous trend of the lung cancer mortality to its highest point in those who were continuing to smoke.

Mortality Among Present Cigarette Smokers

Since the mortality from lung cancer has been shown to be greater (a) among cigarette smokers than among pipe smokers, and (b) among present smokers than among past smokers, it is clear that the highest rates of mortality must have been recorded among those doctors who were continuing to smoke cigarettes at the time of the inquiry (November 1, 1951). In fact, the mortalities among men in this group are substantially higher than the corresponding mortalities among all smokers—past and present, pipe, cigarette, and mixed (as shown in Table V). Thus, for men aged 35 years and over who at November 1, 1951, smoked 1-14 g. a day in cigarettes the subsequent annual mortality from lung cancer has been 0.95 per 1,000; for those similarly smoking 15-24 g. a day it has been 1.67 per 1,000; and for those similarly smoking 25 g. or more a day it has been 2.76 per 1,000. The corresponding rates for all smokers are 0.47, 0.86, and 1.66. In other words, the rates for the continuing cigarette smokers have been 102%, 67%, and 66% higher than the corresponding rates for all smokers, past or present. While remembering that the numbers involved are small, we may note that the rate for men who were continuing to smoke 25 or more cigarettes a day at the time of the inquiry (2.76 per 1,000) was almost 40 times the rate observed among non-smokers (0.07 per 1,000).

Histological Type

There is now evidence to suggest that the relationship holds only for epidermoid and anaplastic cancers (including oat-cell cancer) and that it applies to a less marked degree (if it applies at all) to adenocarcinoma (Wynder and Graham, 1950; Wynder, 1954; Kreyberg, 1955). In the present study only three of the histologically proved cases were diagnosed as adenocarcinoma. This is too few for rates to be calculated for different smoking categories, but it may, perhaps, be noted that the amount smoked by the three patients (3 cigarettes a day, 20 cigarettes a day, and 14 g. daily in a pipe) was, on average, somewhat less than the amount smoked by men of the same ages (12.3 against 16.3 g. a day), whereas the average amount smoked by men dying of epidermoid or anaplastic cancer was substantially greater (23.6 against 16.4 g. a day).

Mortality Among Women

The total number of deaths recorded among women (106) is still too small for reliable estimates to be made of the mortality from different causes among different categories of

smokers. Two deaths were attributed to carcinoma of the lung—one of a woman of 66 years who smoked 15 cigarettes a day at November 1, 1951, and the other of a woman of 55 years who smoked 30 cigarettes a day. A third woman, aged 44, was certified as having died of sarcoma of the lung; she had started smoking at the age of 27 years, and smoked 30 cigarettes daily.

The total mortality from all causes of death recorded among women aged 35 years and over has been much less than that recorded among men. Thus their standardized death rate is 7.82 per 1,000 for non-smokers, 7.87 per 1,000 for all smokers, and 16.90 per 1,000 for smokers of 25 or more cigarettes a day (a small group). The corresponding figures for men are 13.25, 15.78, and 18.84 per 1,000. It is very probable that these lower rates for women are not wholly due to a lower actual mortality but partly to a less complete recording. Deaths in women are likely to be certified according to the married name, whereas a number of the women are recorded in our series only under the name that they used professionally and which they entered upon our questionnaire. This has created considerable difficulty in identifying the women doctors who replied to the questionnaire and who have subsequently died. A number of deaths have certainly been missed. A more complete identification is in progress and the further analysis of female mortality in relation to smoking habits is therefore postponed to a subsequent report.

QUESTIONS OF BIAS

Diagnosis of Cause of Death

It might perhaps be argued that doctors have more readily diagnosed lung cancer in heavy smokers than in light smokers or in non-smokers, and have thus produced the gradient of mortality recorded here. As one means of investigating this possibility we wrote in the last two years of the inquiry to all the doctors who signed the death certificates referring to cancer of the lung. We asked them whether they knew the patient's smoking habits when they diagnosed the cause of death, and, if so, whether they thought their diagnosis was influenced by that knowledge. Of the 47 doctors involved, 40 replied that they had some knowledge of their patients' smoking habits and seven that they were ignorant of them. Of the 40 with some knowledge, 36 did not believe that it had in any way influenced their judgment, one thought that it had (the patient was a man of 68 years who smoked 18 cigarettes a day), another that it might have done so subconsciously (the patient was a man of 68 years who smoked 15 cigarettes a day), and two did not express an opinion.

A second, and perhaps more convincing, test of this possible bias can be made by comparing the mortality gradient with smoking for those cases in which the diagnosis was firmly established (category I in Table IV) with that observed for the cases in which the diagnosis contains a

TABLE X.—Standardized Death Rates From Lung Cancer in Relation to the Amount Smoked, Divided According to the Basis of the Diagnosis

Basis of Diagnosis		Standardized Death Rate per 1,000 Men Aged 35 Years and Above per Year			
		Non-smokers	Men Smoking a Daily Average of:		
			1-14 g.	15-24 g.	25 g. or More
Category I.* Firm diagnosis based on necropsy, histological evidence, etc. (39 cases)	Rate as % of rate for all men	0.00	0.22	0.31	0.94
		0	58	80	244
Categories II and III.* Less well established diagnosis lacking histological confirmation (45 cases)	Rate as % of rate for all men	0.07	0.24	0.55	0.71
		18	56	129	166

* For full definitions see Table IV.

greater element of doubt (categories II and III in Table IV). The figures are given in Table X, from which it will be seen that with the firmly established cases the trend of mortality with smoking is certainly no less steep, and possibly steeper, than that shown by the remaining deaths.

In view of these results it seems to us most improbable that the relationship we have observed between smoking and lung cancer can be attributed merely to a biased attitude among the medical profession.

The Population at Risk

In our preliminary report on this inquiry (Doll and Hill, 1954a) we pointed out that the mortality we had recorded amongst doctors in the 29 months of follow-up was considerably less than that which we would have expected to occur at the death rates of the general population. We suggested that the main reason for this—and one which would apply to all causes of death and not only to lung cancer—was that doctors who were already ill of a disease, likely to prove fatal within a foreseeable space of time, would have been disinclined, or indeed unable, to answer our questionnaire. In other words, we should learn of their deaths but we would have no corresponding completed questionnaire on our files. The question we had to consider was whether such a bias in the population at risk would differentially affect the mortality of the non-smoking and smoking groups. Could it have artificially produced the gradient with smoking that we had observed with cancer of the lung whilst not producing any such gradient with other causes of death (excepting, possibly, coronary thrombosis)? Not only did that seem to us very unlikely on general grounds, but we noted two specific pieces of evidence in support of our view: (a) although the number of deaths from cancer of the lung was small we had not seen any obvious change in its gradient with smoking over the 29 months of inquiry; (b) the gradient we had observed in this prospective inquiry closely resembled that which we had already obtained in our earlier retrospective inquiry.

The preliminary results of the large-scale inquiry conducted by the American Cancer Society (Hammond and Horn, 1954) showed the same characteristic—namely, a low death rate from all causes in the subjects of the inquiry compared with that of the general population. Further, contrary to our own observations, Hammond and Horn reported an appreciably heavier mortality in smokers than in non-smokers for every disease group examined—for cancer of other sites, for coronary thrombosis, and for other diseases—though the gradient with lung cancer, we may note, was very much sharper than that shown by the other causes.

These results led Berkson (1955) to suggest that not only is the total population in these studies biased, by the absence of the seriously ill at the time of initial inquiry into smoking habits, but that the component smoking and non-smoking groups may be differentially biased to the advantage of the latter in the subsequent mortality experience. He points out that this would be the effect if non-smokers in good health came more readily into the study than smokers in good health—for example, because answering the questionnaire is a simpler task for the non-smoker—whereas the chances of inclusion in the study were low for men seriously ill and unrelated to the smoking habits. In such circumstances the already seriously ill component would be artificially low, but still representative of the parent population; the component in good health would be large but unrepresentative. It would contain proportionately too many healthy non-smokers. It follows that the total mortality would be lower than that anticipated from general population rates, and the mortality among non-smokers would be less than that amongst smokers—and for all causes of death.

The final test of Berkson's thesis lies with the passage of time. For as time passes it becomes progressively less likely that the shadow of death could have been foreseen at the start of the inquiry, less likely that such pre-knowledge could have influenced response to our questionnaire. As

stated in our preliminary report, and quoted above, we had seen over the first 29 months no signs of a change in the gradient of lung cancer mortality to suggest an initial selective bias. We are now able to analyse the observations over four complete years. The figures are given in Table XI.

TABLE XI.—Standardized Death Rates From Lung Cancer in Each Year of the Inquiry by Amount Smoked

Year of Inquiry (and No. of Deaths)	Standardized Death Rate per 1,000 Men Aged 35 Years and Above per Year				
	Non-smokers	Men Smoking a Daily Average of:			All Men
		1-14 g.	15-24 g.	25 g. or More	
1st (12) ..	0.00	0.29	0.60	0.86	0.53
2nd (14) ..	0.00	0.26	0.43	1.80	0.57
3rd (31) ..	0.33	0.82	1.51	2.44	1.31
4th (21) ..	0.00	0.54	0.98	1.67	0.92
As percentages of rate for all men					
1st ..	0	54	112	161	100
2nd ..	0	45	75	315	100
3rd ..	25	62	115	187	100
4th ..	0	59	107	182	100

and show, as expected, death rates in the third and fourth years of the inquiry substantially greater than those of the first and second years. (With the relatively small population at risk we think the steep rise in the third year and the fall in the fourth year are no more than chance fluctuations.) On the other hand, the gradient of mortality in relation to amount smoked has been remarkably constant in the first, third, and fourth years—that is, irrespective of the absolute levels of mortality. The second year shows a much steeper gradient, but with only 14 deaths involved we think no emphasis can be placed upon this. In short, it would seem that the association between death rate and amount smoked has shown very little change between the beginning of the inquiry and the later years. It certainly has not become any less pronounced with more representative death rates. The observations do not seem to us to support Berkson's thesis.

As regards the total mortality of our population of doctors we can also make a check as to how far it has been unrepresentative of the rate for all doctors. For this purpose we have accumulated details of the mortality that has occurred year by year amongst a 10% sample (randomly drawn) of all the doctors who did not reply to our questionnaire. This population of "non-answers" was not obtained until several months after the start of the inquiry, when the names of doctors who had died in the first few months had already been erased. We cannot, therefore, reconstruct the total population nor measure the first year's mortality among those who did not reply. In the subsequent years, however, we can estimate the mortality rate of all doctors by combining the figures for those who did reply to the questionnaire with the figures for those who did not reply (multiplying the sample by ten). In the second year of the inquiry we thus reach a standardized death rate at all ages of 20.4 per 1,000 for all doctors, compared with a rate of 14.7 for those who replied to us. The latter is only 72% of the former, revealing, as we previously recognized, the initial effects of selection through the absence of the seriously ill. In the third year of observation the rate for all doctors is calculated to be 18.6 per 1,000; for those who replied it was 16.1; the ratio is 87%. In the fourth year the rates are respectively 18.4 and 17.0 per 1,000, and the ratio is 92%.

We see, therefore, that though the effect of self-selection initially present may still not have entirely worn off, it is certainly no longer large. Conceivably it may be rather larger than 92% suggests, since it is possible that we are able to trace the deaths of those who replied to us more fully than the deaths of those who did not reply. But we have no evidence to that effect. On the other hand, the difference may never wholly vanish. If non-smokers answered us proportionately more frequently than did smokers, then our population will always contain a higher

proportion of the persons who suffer a relatively low mortality rate. In other words, we should always have a population which—in total—has a relatively favourable mortality experience. But it does not follow that its components (smokers and non-smokers) cannot be validly contrasted. That very marked contrast is not, as we have shown above, diminishing with the passage of years.

In this analysis we have compared the mortality observed amongst the doctors who answered us with our estimate of the mortality of all doctors whether they answered us or not. This latter figure is, in our view, the proper standard of comparison, to reveal how far our group is representative of the total. If, however, we compare our rate for all doctors with the corresponding figure for the general population of the whole country, we find that the doctors' rate in the last two years of the inquiry has been 83% of the national mortality. We cannot from this result deduce that the deaths of doctors have been incompletely recorded in our inquiry. It may well be that in these years the medical profession was experiencing lower death rates than the general population of all social classes. Unfortunately, in the absence of the national occupational mortality analysis since 1930-2 there is no evidence available.

ASSOCIATION, DIRECT OR INDIRECT

Site of Growth

In relation to the observed association between lung cancer and smoking it has been suggested that smoking does not produce cancer in a person in whom cancer would not otherwise have occurred at all, but merely determines the primary site of a growth that is destined to appear in some part of the body (Fairweather, 1954; Goodhart, 1956). In short, a man predestined to have cancer increases his chance of having it in the lung if he smokes and increases his chances of having it elsewhere in the body if he does not smoke. If he is not predestined to have cancer, smoking and other environmental factors obviously have no relevance. This hypothesis is in line with the general theory discussed by Cramer (1934) that cancer susceptibility is pre-determined by heredity, that the effect of environmental stimuli is merely to elicit the response in particular tissues, and that, as a result, the total cancer incidence in a given population is a fixed sum uninfluenced by changes in the stimulus. The primary sites may change, the total does not. The final test of the theory will require accurate observations of cancer morbidity, but several recent studies of cancer mortality seem to us to provide strong evidence that the theory is untrue.

Thus Case (1954) has shown that among certain chemical workers exposed to β -naphthylamine mortality from bladder cancer has been almost double that expected for cancer of all sites; the excess in the particular site is certainly not balanced by a reduction in other sites. Similarly Doll (1952, 1955) has shown that the raised death rate from lung cancer among gas workers and asbestos workers is not compensated for by a reduction in mortality from other types of cancer, and Brinton, Frasier, and Koven (1952) have made a similar observation among chromate workers. Case and Lea (1955) have obtained a similar result in another field. They studied 1914-18 war pensioners with chronic bronchitis and found a substantial excess of cancer of the lung, while the mortality from cancer of other sites was normal and unreduced.

Specific to the present issue, Doll and Hill (1954b), in their retrospective study of patients' smoking habits, found no evidence that tobacco produced an effect by the mechanism postulated. While a large excess of heavy smokers was a feature of their lung-cancer group there was no deficit of heavy smokers in patients with cancer in other sites—that is, in comparison with patients with other diseases. The data from the present investigation are also inconsistent with the theory. If tobacco merely determines the site of the cancer without affecting the total incidence of the disease, then the mortality from all forms of cancer should be similar among non-smokers and smokers and

among the different grades of smokers. In fact it is seen from Table V that the annual death rate from all cancer rose from 2.11 per 1,000 among non-smokers to 2.91 per 1,000 among smokers.* The rise in lung cancer from 0.07 to 0.90 is not balanced by a reduction in cancer of other sites, the rates for which are almost identical—2.04 and 2.02 per 1,000 in non-smokers and smokers respectively. In the smoking grades the total cancer rates are almost the same in the 1-14 g. and 15-24 g. groups—namely, 2.48 and 2.42—but the substantial rise in lung cancer in the heavy smoking group (1.66) is certainly not balanced by any fall in cancer of other sites. The total incidence of 4.25 per 1,000 is significantly higher than that of the other two groups of smokers and of the non-smokers.* In short, our data, both retrospective and prospective, indicate a total incidence of cancer in the smoking groups in excess of the incidence that would have prevailed in the absence of smoking.

Constitutional Type

The observed association between the mortality from lung cancer and the amount of smoking could conceivably be explained in terms of some common factor which produced lung cancer and was also associated (directly or indirectly) with cigarette smoking. For example, it has been suggested that constitutional and psychological factors might have such an effect—that is, that persons of a certain "make-up" are peculiarly liable to lung cancer and to smoke. We know of no published evidence to this effect. It is difficult, too, to see how such an indirect association could explain the rise in lung cancer mortality of recent years.

Atmospheric Pollution

It has been argued that, since cigarette smoking is, in general, more prevalent in towns than in country districts, the comparison of different smoking groups is, in part, merely a comparison of urban and rural residents, the former being exposed to an atmospheric pollution which the latter escape. On the other hand, if the difference between the smoking habits of town and country were somewhat greater 20 to 30 years ago than it is to-day, there may be no reason at all to invoke atmospheric pollution as the explanation of the higher mortality from lung cancer in urban areas. Cigarette smoking could, in that event, be the answer. However that may be, atmospheric pollution could not account for the pronounced gradient in mortality that we record here. For example, the national figures record that the lung-cancer death rate among men in Greater London is about twice that among men in rural districts. Our data, prospective and retrospective (Doll and Hill, 1952) give a mortality among the heavy smokers more than twenty times the mortality among non-smokers. Further, the association with smoking has been shown to persist when the observations are limited to men living within a particular type of area. We ourselves found it for male patients resident in Greater London (Doll and Hill, 1952); Stocks and Campbell (1955) have reported a most marked gradient within two wholly rural counties of North Wales and a slighter gradient in the City of Liverpool; Hammond and Horn (1955) have found consistently higher death rates for smokers compared with non-smokers within specific types of areas in the U.S.A.

Finally, in this present study we have analysed the smoking habits of doctors resident in different types of areas (using a 10% sample randomly drawn from the questionnaires returned by doctors aged 35 years and over). The results show (Table XII) that within this occupationally relatively homogeneous population there is remarkably little difference between the smoking habits of the residents in the specified areas. The tendency is for more non-smokers and fewer heavy smokers to be found in the large urban communities.

*The death rates for all cancer shown for smokers (2.91 per 1,000) and for heavy smokers (4.25 per 1,000) are slightly lower than the sum of the rates for lung cancer and for other cancer, since one doctor suffered from primary cancer in both lung and larynx and his death was included in both categories in Table V.

TABLE XII.—Numbers of Doctors Aged 35 Years or Over Smoking Different Amounts of Tobacco (Most Recent Amount Smoked) According to Place of Residence at November 1, 1951

Amount Smoked Daily	Percentage Smoking given Amount in:			
	Greater London (525 Doctors)	Large Towns in the U.K.* (716 Doctors)	Elsewhere in the U.K. (1,147 Doctors)	Abroad or Unspecified Place (46 Doctors)
Nil	16	13	11	13
1-14 g.	31	32	35	35
15-24 g.	34	38	31	33
25 g. or more	19	17	23	19
Total	100	100	100	100

* County boroughs in England and Wales together with Belfast, Edinburgh, and Glasgow.

It follows that the contrasts in lung cancer mortality that we have observed between smokers and non-smokers, and between light, medium, and heavy smokers, cannot be explained in terms of a differential exposure to atmospheric pollution which happens to be associated with smoking habits.

SMOKING IN RELATION TO DISEASES OTHER THAN LUNG CANCER

For the large number of deaths attributed to other causes further information was not specially sought from the certifying doctors, and these deaths have therefore been classified according to the cause of death as certified (or by the informant in the few cases where no such information was available). In the main the Registrar-General's rules for the classification of causes of death have been followed, but occasionally some other classification seemed more appropriate and was adopted. The observed death rates for individual diseases other than lung cancer are not, therefore, strictly comparable with the national rates.

Cancer of Other Sites

Deaths attributed to cancer of sites other than the lung are shown in Table XIII. In none of the groups is the difference between smokers and non-smokers significant, and

TABLE XIII.—Standardized Death Rate Per 1,000 Men Aged 35 Years and Over Per Year, for Cancer of Sites Other than the Lung

Site of Primary Cancer	No. of Deaths	Death Rate Among:					
		All Men	Non-smokers	All Smokers	Men Smoking a Daily Average of:		
					1-14 g.	15-24 g.	25 g. or More
Upper respiratory and upper digestive tracts	13	0.12	0.00	0.14	0.13	0.09	0.21
Stomach	32	0.29	0.41	0.28	0.36	0.10	0.31
Colon and rectum	57	0.52	0.44	0.53	0.54	0.37	0.74
Prostate	30	0.28	0.55	0.25	0.26	0.22	0.34
Other sites (excluding lung)*	88	0.81	0.64	0.83	0.72	0.76	1.02
All cancer, other than cancer of the lung	220	2.02	2.04	2.02	2.01	1.56	2.63

* Including 7 of unspecified primary site.

in none is there a steady—or significant—increase in death rate with the amount smoked. One group consists of deaths attributed to cancer of the upper respiratory or upper digestive tracts, types of cancer which, it has been suggested, may also be related to smoking. It will be seen that no death occurred among non-smokers and the highest death rate occurred among heavy smokers, but the total number of cases is at present too small to give reliable results. The 13 deaths include one from cancer of the buccal cavity, eight from cancer of the oesophagus, and four from cancer of the larynx; the average amount smoked by these men was 17.3 g. a day, against an average of 15.1 g. for all men of corresponding ages in the inquiry.

Coronary Thrombosis

The data for deaths from coronary thrombosis have already been given in Tables V, VI, VIII, and IX, and in the Figure. The increase in mortality with the amount smoked (from 4.22 per 1,000 non-smokers to 4.64 for men smoking 1-14 g., 4.60 for men smoking 15-24 g. a day, and to 5.99 per 1,000 men smoking 25 or more g. a day) is consistent with the existence of a slight relationship, and this, as noted previously, is not very likely to be due to chance ($P = 0.02$). To test whether this result might, however, be due to a selective bias on the part of the doctors replying to the questionnaire (as previously discussed) the data obtained in the first two and a half years of the inquiry have been compared with those obtained in the subsequent 23 months. Table XIV shows that in the second period the increase

TABLE XIV.—Death Rates From Coronary Thrombosis in Relation to the Amount Smoked, Recorded During the Earlier and Later Parts of the Inquiry

Period	Rate as % of rate for all men	Standardized Death Rate per 1,000 Men Aged 35 Years and Above per Year			
		Non-smokers	Men Smoking a Daily Average of:		
			1-14 g.	15-24 g.	25 g. or More
First 30 months (278 cases)	89	4.20	4.46	4.83	5.59
Subsequent 23 months (230 cases)	89	4.32	4.85	4.33	6.37

in mortality is certainly less regular than that observed in the first period, though in both periods the highest rate falls on heavy smokers. It does not seem likely that the trend is entirely due to bias arising from the method of investigation.

Our findings agree broadly with those of Hammond and Horn (1954), in that both sets of data show an increase in mortality with smoking. But in our experience the increase is distinctly less marked. These different results might, we thought, be due to the difference in the age of the subjects, our population of doctors being of all ages over 35 and our population of doctors being limited to 50-69 years. Hammond and Horn's men being limited to 50-69 years. Analysis of our death rates from coronary thrombosis by age, however, reveals an even greater discrepancy. We find a distinct gradient of mortality with amount of smoking at ages under 55 and a rather less distinct gradient at ages 75 and above. We observe none at ages 55-74 (see Table XV).

TABLE XV.—Relationship at Different Ages Between Mortality From Coronary Thrombosis and Most Recent Amount Smoked: Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More

Age in Years	No. of Deaths	Death Rate Among:			
		Non-smokers	Men Smoking a Daily Average of:		
			1-14 g.	15-24 g.	25 g. or More
35-54	90	0.44	0.95	1.47	1.84
55-64	122	7.34	6.79	4.45	6.98
65-74	143	11.13	10.77	10.53	14.85
75 and over	153	15.18	20.00	22.27	24.95
All ages 35 and over	508	4.22	4.64	4.60	5.99

A possible explanation of this paradox may lie in the fact that we have classified men as dying of coronary thrombosis solely on the basis of the certified cause. It is, perhaps, reasonable to suppose that, for this group of deaths, the diagnosis is most likely to be accurate at the youngest ages.

Other Causes of Death

The results for other causes of death are shown in Table XVI. They reveal a steady increase in mortality from non-smokers to heavy smokers in three instances—pulmonary tuberculosis, chronic bronchitis, and peptic ulcer.

TABLE XVI.—Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More, in Relation to the Most Recent Amount Smoked: Diseases Other than Cancer and Coronary Thrombosis

Cause of Death	No. of Deaths	Death Rate Among:					
		All Men	Non-smokers	All Smokers	Men Smoking a Daily Average of:		
					1-14 g.	15-24 g.	25 g. or More
Pulmonary tuberculosis	19	0.18	0.00	0.20	0.16	0.18	0.29
Chronic bronchitis	42	0.37	0.12	0.39	0.29	0.39	0.72
Other respiratory diseases	65	0.56	0.69	0.54	0.55	0.54	0.40
Cardiovascular diseases other than coronary thrombosis	279	2.36	2.23	2.37	2.15	2.47	2.25
Cerebral haemorrhage or thrombosis	227	2.03	2.01	2.02	1.94	1.86	2.33
Peptic ulcer	18*	0.17	0.00	0.19	0.14	0.16	0.22
Violence	77	0.68	0.42	0.73	0.82	0.45	0.90
Other diseases (including 12 of unspecified nature)	183	1.60	1.45	1.63	1.81	1.47	1.57

* Including 5 cases in which peptic ulcer was referred to as a contributory cause, but not the direct cause of death.

For chronic bronchitis the increase is sixfold (from 0.12 per 1,000 among non-smokers to 0.72 per 1,000 among smokers of 25 g. or more a day) and the trend is statistically significant ($P < 0.01$). Further analysis shows that the death rate is higher among cigarette smokers (0.61 per 1,000) than among mixed pipe and cigarette smokers (0.21 per 1,000) or pure pipe smokers (0.21 per 1,000), and these differences are significant ($P < 0.01$). With such a chronic disease it is obvious that the disease itself may influence the amount smoked and thus obscure any relationship. It may also be that the presence of a "smoker's cough" may influence the physician to attribute death to chronic bronchitis when, in its absence, he would have diagnosed some other respiratory (or cardiovascular) condition. Table XVI does, in fact, show some fall in the mortality from "other respiratory diseases" as smoking increases, suggesting a transference from one label to another. But this fall does not wholly compensate for the rise in chronic bronchitis mortality.

The differences observed between the various categories of smokers dying with pulmonary tuberculosis or peptic ulcer are not statistically significant; but the numbers of deaths are so small that strong relationships with smoking might exist, without significant results being obtained. The average amount smoked by the 19 men who died of pulmonary tuberculosis was 19.5 g. a day, against an average of 15.2 g. for all men in the inquiry of corresponding ages; for the 18 men who died with a peptic ulcer the average was 18.8 g. a day, against an expected average of 15.3 g.

Possibly Related and Unrelated Causes

In the causes of death that we have analysed there are six which have from time to time been regarded as possibly related to smoking—namely, cancer of the lung, cancer of the upper respiratory and upper digestive tract, coronary thrombosis, chronic bronchitis, peptic ulcer, and, recently (Lowe, 1956), pulmonary tuberculosis. In the present study 676 doctors died of these causes—nearly 40% of all the deaths in the doctors aged 35 years and over. We have set out the death rates from these causes in Table XVII. Alongside them we give the rates derived from all other causes of death. The relative stability of these other rates (based upon over 1,000 deaths) is, we think, striking. They provide, we suggest, a further answer to the question of selective bias.

TABLE XVII.—Standardized Death Rates Per Year Per 1,000 Men Aged 35 Years or More in Relation to Amount Smoked; a Summation of Groups of Causes of Death

Causes of Death	No. of Deaths	Death Rate Among:			
		Non-smokers	Men Smoking a Daily Average of:		
			1-14 g.	15-24 g.	25 g. or More
Lung cancer					
Cancer of upper respiratory and upper digestive tracts	168	0.19	1.13	1.62	2.99
Pulmonary tuberculosis					
Chronic bronchitis					
Peptic ulcer					
Coronary thrombosis	508	4.22	4.64	4.60	5.99
Diseases possibly related to smoking	676	4.41	5.77	6.22	8.98
All other diseases	1,038	8.84	9.15	8.26	9.87

* The figures given are lower than those obtained by summing the figures for the five individual groups of diseases, because 8 deaths included in Tables V and XVI under lung cancer and peptic ulcer have been excluded. For these deaths, lung cancer and peptic ulcer were certified only as associated causes; they are included here in the disease group to which death was primarily attributed.

If the association suggested by the upper part of the table were due merely to a bias in our method of investigation, we would expect to see that bias operating to some extent in all, or nearly all, causes of death. It does not appear to do so. Secondly, if the effect of smoking were merely to influence the apparent cause of death, without in any way determining the occurrence of death, the second group of diseases should show a negative association complementary to the positive association of the first group. They do not do so.

SUMMARY AND CONCLUSIONS

1. In reply to a questionnaire sent out at the end of 1951, over 40,000 men and women on the *British Medical Register* informed us of their smoking habits at that time or, in the case of ex-smokers, when they previously gave up smoking. On the basis of these answers we classified them into a few broad groups—namely, non-smokers and smokers (or ex-smokers) of three different amounts by cigarette, pipe, or both (Tables I and II). The subsequent mortality of each of these groups has now been recorded for nearly four and half years (Table III). The present study relates to men aged 35 years and above, amongst whom there were 1,714 deaths, including 81 from lung cancer (in three others lung cancer was mentioned as a contributory cause).

2. The analysis shows that in this population there has been a marked and steady increase in the death rate from lung cancer as the amount smoked increases. Its death rate per year rises from 0.07 per 1,000 in non-smokers (based upon the observations of one death only) to 0.47 per 1,000 in "light" smokers of 1 to 14 g. a day, to 0.86 per 1,000 in "medium" smokers of 15 to 24 g. a day, and finally to 1.66 per 1,000 in smokers of 25 g. or more a day (1 g. is almost equal to one cigarette). The death rate of the heavy smokers is approximately twenty times the death rate of the non-smokers (Tables V and VI).

3. This rising mortality from lung cancer in smokers compared with non-smokers, and in heavy smokers compared with lighter smokers, has been a feature of each stage of life, 35-54 years, 55-64, 65-74, and 75 years and over (Table VII).

4. The mortality from lung cancer has been substantially and significantly greater in cigarette smokers

than in pipe smokers, with smokers by both methods falling in between (Table VIII). This difference between pipe and cigarette smokers is to be observed for each of the smoking categories, light, medium, and heavy, and therefore appears to be a function of the method of smoking irrespective of the amount.

5. Those who reported themselves as smokers at November 1, 1951, have been compared with those who had given up smoking at that time within the previous 10 years or for more than 10 years. The comparison reveals a progressive and significant reduction in mortality with the increase in the length of time over which smoking has been given up (Table IX).

6. From conclusions 4 and 5 it follows that the highest mortalities have occurred amongst those who reported themselves as continuing to smoke cigarettes at November 1, 1951. Among them the annual death rate rose from 0.95 per 1,000 for smokers of 1 to 14 cigarettes a day, to 1.67 per 1,000 for smokers of 15 to 24 cigarettes a day, and to 2.76 per 1,000 for smokers of 25 cigarettes or more a day—that is, to approximately forty times the death rate of the non-smokers.

7. For every death attributed to cancer of the lung confirmation of the diagnosis was sought from the certifying doctor and, when necessary, from hospital or consultant. Additional information was obtained in every case. The deaths can thus be divided into those quite firmly established by necropsy, histological evidence, and the like, and those less well established and lacking histological evidence (Table IV). The increased death rate associated with the increase in smoking is found to be just as great with the firmly established cases as it is with the remainder (Table X). The relationship cannot therefore be attributed to a biased attitude in the medical profession in certifying cancer of the lung as the cause of death.

8. Analysis of the deaths from lung cancer separately in each of the first four years of the inquiry shows that the increase in mortality associated with increase in smoking has been a feature of each year. On the whole, there has been a remarkably constant gradient which has become no less marked with the passage of time (Table XI). We also estimate that in the fourth year of the inquiry the mortality of the doctors who answered the questionnaire was as much as 92% of the mortality of all doctors, whether they answered us or not. On these grounds we do not believe that the gradient of mortality with smoking can be regarded as merely an artifact due to bias in those who chose to reply to the questionnaire.

9. An analysis of a random sample of the questionnaires shows that there was remarkably little difference between the smoking habits of doctors resident (at November 1, 1951) in Greater London, in large towns, or in other districts (Table XII). The contrasts in lung cancer mortality between smokers and non-smokers, and between light, medium, and heavy smokers, cannot therefore be attributed to a differential exposure to atmospheric pollution which happens to be associated with smoking habits. This observation supports those of previous investigations.

10. Study of the deaths from cancer in sites other than the lung reveals, with one possible exception, no association between mortality and smoking. The exception is cancer of the upper respiratory and upper digestive tracts, from which the number of deaths is at present insufficient to substantiate a possible trend. In total,

cancer of sites other than the lung shows a mortality of 2.04 per 1,000 in non-smokers and 2.02 per 1,000 in smokers. It reveals no gradient by amount smoked (Table XIII). In other words, the marked and steadily increasing mortality from lung cancer in association with smoking is not compensated for by a decrease in cancer of other sites. The result indicates a total mortality from cancer in the smoking groups in excess of the mortality that would have prevailed in the absence of smoking.

11. If the causes of death as certified are accepted at their face value, mortality from coronary thrombosis reveals a slight but significant relationship with smoking (Table V). Division by age, however, shows that the trend is distinct only at the youngest ages, 35-54 years (Table XV).

12. Three other causes of death show a steady increase in mortality from non-smokers to heavy smokers—chronic bronchitis, peptic ulcer, and pulmonary tuberculosis (Table XVI). Only with chronic bronchitis is the gradient statistically significant. The remaining causes of mortality reveal no trend (Table XVII).

13. From our retrospective studies of the smoking habits of nearly 1,500 patients with lung cancer and over 3,000 patients with other illnesses we concluded that if large groups of persons of different smoking habits were observed for a number of years they would reveal distinct differences in their rates of mortality from lung cancer. They would show, we believed, (1) a higher mortality in smokers than in non-smokers, (2) a higher mortality in heavy smokers than in light smokers, (3) a higher mortality in cigarette smokers than in pipe smokers, and (4) a higher mortality in those who continued to smoke than in those who gave it up. In each case the expected result has appeared in the prospective inquiry here reported. These results are evident in spite of the fact that our method of inquiry is such as constantly to underestimate the mortality differences. The reason for the underestimate is that our classifications are based, for the most part, upon a statement of the smoking habits at one point of time. We have seldom been able to take previous habits into account, and any subsequent changes have been unknown to us. As a result we shall sometimes have included in the light smoking group persons who had previously smoked heavily for a long time; we shall sometimes have included as "pure" pipe smokers persons who had previously smoked cigarettes and vice versa; we shall sometimes have continued to class as smokers persons who have given up. All such errors in classification must inevitably have reduced the, nevertheless, clear associations between the mortality from lung cancer and the smoking of cigarettes which we have observed in these British doctors.

This work was made possible by the co-operation of the thousands of doctors who completed our questionnaires. We are most grateful to them and to the many consultants who have provided us with further details of the evidence on which the diagnosis of lung cancer was made. We are deeply indebted to the British Medical Association, who dispatched the questionnaires on our behalf and who subsequently helped us in tracing the deaths of doctors; to the Registrars-General of the United Kingdom and the Registrars of the General Medical Council and its Branch Councils in Ireland and Scotland for information about the deaths of doctors; and to the Statistical Department of the Ministry of Labour for the mechanical analysis of the results. We are grateful to Dr. R. Bignall for advice on the clinical classification of some of the deaths from lung cancer. We also offer our thanks to Mrs. Joan Bodington, Mrs. Jean Gilliland, Miss Keena Jones, and Mrs. M. Lloyd for the onerous work of sorting and analysing the mass of data.

AN ASSOCIATION BETWEEN SMOKING AND RESPIRATORY TUBERCULOSIS

BY

C. R. LOWE, M.D., Ph.D., D.P.H.

From the Department of Social Medicine, University of Birmingham

In England and Wales mortality from respiratory tuberculosis has been falling for at least a century. The rate of decline has not been the same at all ages, however, and in the two sexes the pattern of mortality, which seventy-five years ago was not dissimilar, is now strikingly different (Fig. 1). During the decade 1871-80 mortality for both males and females was highest in early adult life. Seventy years later this is still true for females, but for males death rates in young adult life have fallen so much more rapidly than in middle and late life that maximum mortality now occurs at a much later age.

A number of partial explanations have been offered for this change in the age pattern of mortality, but they do not add up to a very convincing whole, and the sex difference remains an incompletely solved epidemiological

FIG. 1.—Mortality from respiratory tuberculosis in England and Wales (1861-70 and 1941-50 compared).

puzzle. The two most quoted explanations have been, first, that the difference is in part the result of a cohort or generation effect, and, second, that it is related to the degree of urbanization and the proportion of males in industrial occupations.

The cohort method of examining mortality from tuberculosis was first explored by Frost (1939) and was used again by Springett (1952), who gave a clear explanation of this rather complicated procedure. In brief, the method traces death rates experienced at successive ages by a group of persons (the "cohort") born in the same decennium (or any other convenient time interval), in contrast to the orthodox method illustrated in Fig. 1, which examines age-specific death rates of a population in a stated year (or group of years). When male death rates are examined in this way the shift of maximum mortality towards middle and late life disappears. It

FIG. 2.—Age-specific respiratory tuberculosis notification rates (Birmingham, 1951).

has been suggested, therefore, that this apparent shift is an artifact produced by the orthodox way of looking at age-specific death rates. But in a recent communication (Lowe, 1954) it was demonstrated that in Birmingham, although female age-specific notification rates followed much the same pattern as the corresponding national death rates, male notification rates were unmistakably bimodal in distribution (Fig. 2). This curious sex difference is now becoming apparent even in the four broad age groups used for notification rates in national statistics (Registrar-General, 1955), and it is difficult to believe that this is a statistical illusion which, if the data were available, cohort analysis could explain away. In any case the cohort method of looking at death rates does not explain why in middle and late life mortality has fallen at a much slower rate in males than in females, while in early adult life, if anything, the reverse is true (Table I).

TABLE I.—Mortality From Respiratory Tuberculosis in 1941-50 Expressed as a Percentage of Mortality in 1861-70

	Age					
	15-24	25-34	35-44	45-54	55-64	65-74
Males ..	12.7	14.8	17.0	26.3	35.3	39.2
Females ..	18.7	15.0	10.0	9.8	12.4	17.6

A more plausible explanation rests upon the observation that the pattern of male mortality in late adult life appears to some extent to be related to the degree of urbanization. Dahlberg (1949) examined the recent mortality from tuberculosis in many different countries. He found that for males there was an excessive mortality in middle and late life in Germany, France, Italy, and the U.S.A., as well as in England and Wales, but that the sex difference was by no means so marked in Sweden, Norway, and Denmark. He suggested that this difference might be due to "a greater measure of urbanization in the larger countries" and in particular to the much greater risk of coming into contact with persons suffering from tuberculosis to which employment in congested and highly industrialized communities exposes the male. In addition, McDonald (1952) has demonstrated that in England and Wales the sex difference in age-mortality pattern is much more marked in London and county boroughs than in small towns and rural districts, and he believes with Dahlberg that greater opportunity for contact with infection at place of work is the probable explanation.

In recent years, however, it is becoming accepted that "a large part of the tuberculosis mortality in males in later life is due to a final breakdown of disease acquired many years earlier" (Springett, 1952). It seems unlikely, therefore, that opportunity for infection or reinfection at place of work is the principal reason for the difference between the sexes. And unless there is some inherent difference between males and females in their reaction to infection, which is, of course, possible, the explanation must lie in a sex difference in middle and late life in the risk of exposure to environmental influences that can lead to breakdown of healed or quiescent lesions. In industry men are often exposed to dust, fume, smoke, and mist hazards in a bewildering variety, and it is possible that these may in part account for the difference in rate of breakdown. But one of the most profound differences between the pulmonary environment of males and females, the degree to which the lungs are exposed to tobacco smoke, has so far been overlooked as a possible explanation. In view of the established relationship between smoking habits and cancer of the lung, in which male mortality is also relatively high, it was thought worth while to investigate the smoking habits of patients with respiratory tuberculosis.

Method of Investigation

Since tuberculosis is a notifiable disease, it is an easy matter to identify large numbers of patients with respiratory infection. The problem of interviewing patients is also simplified by the fact that substantial numbers are to be found in sanatoria, while the majority of those living at home attend chest clinics at fairly regular intervals. In this investigation notification was accepted as the diagnostic criterion, and the sample of patients was drawn from sanatorium and chest clinic.

During February, March, and April, 1955, a social worker questioned about their smoking habits all patients occupying beds in the three principal sanatoria providing accommodation for Birmingham residents. During October, November, and December, 1955, the same social worker interviewed all patients attending the Birmingham Chest Clinic. Apart from one sanatorium patient who was too ill to be questioned and one clinic patient who refused to co-operate, there was no selection. For the purpose of this investigation it was decided to exclude non-Europeans, patients who were under 20 years of age at notification,

TABLE II.—Source of Patients and Controls

Place of Interview	Males	Females	Total
Patients:			
Sanatorium	255	179	434
Chest clinic	508	258	766
Total	763	437	1,200
Controls:			
Accident hospital out-patients ..	327	261	588
General hospital in-patients ..	237	154	391
Total	564	415	979

and patients who at the time of interview had not been notified. The source of the final sample of 1,200 patients is shown in Table II.

The identification of a suitable control group was more difficult. In the first place it is clear from the literature that smoking habits vary considerably with age. The advantage of an age-matched control series is, however, more than outweighed by the difficulty of collecting it, and it was decided to rely upon age-specific and age-standardized comparisons. In the second place, since a number of conditions which may lead to hospital admission are already known to be associated with smoking habits (lung cancer, chronic bronchitis, and coronary thrombosis), hospital patients, although the most accessible, are certainly not the best population from which to draw a control series. The difficulty of interviewing a large random sample of the general population is so great, however, that it was decided to use as controls certain sections of the local hospital population.

During May, 1955, the social worker interviewed all new patients attending the Birmingham Accident Hospital with minor injuries. In June and again in September of the same year she interviewed all patients occupying beds in the surgical wards of Dudley Road Hospital (a large non-teaching Birmingham hospital). Patients under 20 years of age, non-Europeans, and patients with lung cancer and of the respiratory tuberculosis were excluded. The source of the 979 controls is also given in Table II.

Smoking habits were recorded as the number of cigarettes per day (1 oz. (28 g.) of pipe tobacco a week was considered the equivalent of four cigarettes a day), and persons who had never smoked as much as one cigarette a day for as long as a year were entered as non-smokers (Doll and Hill, 1950). Smokers were asked how much they were smoking at present, the maximum amount they had ever smoked, the age at which they had begun to smoke, and, if they had given up smoking, the time that had elapsed since they last smoked. In addition, tuberculous patients were asked how much they were smoking immediately before notification (of which the date was recorded), and controls who were hospital in-patients were asked how much they were smoking immediately before their present illness.

FIG. 3.—Smoking habits of patients with respiratory tuberculosis and controls compared (aged 30 years and over).

TABLE III.—Smoking Habits of Patients and Controls Aged 30 Years and Over

	Males							Females				
	No. of Cigarettes Smoked per Day						Total	No. of Cigarettes Smoked per Day				Total

Males: $\chi^2_{10} = 3.9$; $0.7 < P < 0.5$. Females: $\chi^2_{10} = 1.3$; $0.7 < P < 0.5$. (All females smoking 10 or more cigarettes a day grouped together.)

Results

The data collected permit the smoking habits of patients and controls to be compared in a number of different ways. In the analysis which follows the number of cigarettes smoked daily by patients with tuberculosis refers to regular smoking habits immediately before notification. (In all tabular material, therefore, the age of these patients is age at notification and not age at interview.) The number of cigarettes smoked daily by controls refers, in the case of out-patients, to smoking habits at time of interview and, in the case of in-patients, to habits immediately before the present hospital illness. A small number of patients and controls had given up smoking before notification and interview (or, hospital admission) respectively. These persons were classified according to the amount they were smoking immediately before they gave it up.

The essential findings of the investigation are summarized in Table III and Fig. 3. In both sexes patients of over 30 years of age with pulmonary tuberculosis showed when compared with the controls a highly significant deficiency of non-smokers and light smokers and an excess of moderate and heavy smokers (11.7% of the tuberculous males were non-smokers or had smoked less than 10 cigarettes a day,

compared with 21.0% of the controls; 50.1% had smoked 20 or more cigarettes a day, compared with 43.4% of the controls).

This observation was confirmed when the data were examined according to place of interview (Tables IV and V). There was very little difference for either males or females between the smoking habits of sanatorium and chest clinic patients or between out-patient and in-patient controls, and both sanatorium and chest clinic patients showed the same excess of heavy smokers and deficiency of light smokers and non-smokers when compared with either of the two control groups.

It has already been mentioned that in the general population the amount smoked is known to vary considerably with age. The possibility has to be considered, therefore, that the observed difference between smoking habits of tuberculous patients and controls may be due at least in part to the fact that the two groups have different age structures. That this is not the explanation is demonstrated in Tables VI and VII. For both sexes there was in each ten-yearly age group a consistent excess of heavy smokers and deficiency of light smokers and non-smokers when compared with the corresponding control group. Age standardization of the smoking habits of patients and controls aged 30 years and over (by applying the observed smoking rates in each ten-yearly age group to a standard population with the age structure of patients and controls combined—Table VIII) indicates that in fact Table III somewhat underestimates the difference. And at this point it is of interest to note that for the age group 20-24 years there was no appreciable difference between the smoking habits of the tuberculous and their controls (Table IX).

There still remains one serious objection to be considered: we have been comparing smoking habits of controls at the present time with smoking habits of a tuberculous population at the time of notification. This might have influenced the result in two ways. First, since tobacco consumption in the United Kingdom is still rising, on the average persons of a given age are likely to be smoking a little more heavily to-day than persons of the same age a few years ago. Clearly this cannot account for the observation that tuberculous patients had smoked more than controls, since they were asked about their smoking habits at a time when tobacco consumption was on the average a little less than it is to-day. Secondly, estimates of amount smoked in the past are likely to be less reliable than estimates of amount smoked at time of interview, and it is possible that this may have resulted in exaggeration of past smoking habits. Table X suggests that this is not so. There was no appreciable difference in estimates of amount smoked at time of notification between patients notified within the twelve months preceding interview and patients notified five or more years earlier.

TABLE VI.—Smoking Habits of Male Patients and Controls in Ten-yearly Age Groups

Age		No. of Cigarettes Smoked per Day						Total
		0	1-9	10-19	20-29	30-39	40+	
20-29	Patients	13.6	16.0	39.9	20.2	4.1	6.2	100% (243)

5 and over	3.9	8.8	37.3	27.5	11.8	10.8	100% (102)

Discussion

If the control group is representative of the local population from which the tuberculous patients were drawn, and there is no reason to doubt this, there appears to be a direct association between smoking habits and respiratory tuberculosis in adults. The interpretation of this observation is another matter, and it is hardly necessary to point out that although such an association suggests that the amount of tobacco smoked may play a part in determining whether a healed or quiescent pulmonary lesion breaks down, it does not and can never prove it. We must inquire whether the hypothesis is consistent with our knowledge of respiratory tuberculosis and of the history of smoking.

In the past it has been generally accepted that the high death rate among middle-aged and elderly males indicates a high attack rate, and consequently in the search for an explanation attention had been focused upon the opportunities for infection (or reinfection) offered by working conditions in highly industrialized communities. Recently serial mass x-ray examination of a group of people has shown that in both sexes attack rates are highest in young adult life and decline rapidly with increasing age (Springett, 1951), and the discrepancy between high mortality and low attack rates in elderly males suggests that "tuberculosis deaths in later life are usually, though not always, the result of disease acquired many years earlier" (Springett, 1952). This is supported by the analysis of Birmingham notification data already referred to (Lowe, 1954). The notification peak in young adult life (shown graphically in Fig. 2) was almost entirely due to early (group I) disease, while the second peak exhibited by males in late life was predominantly made up of advanced (group III) disease. To solve the problem of the sex difference it now seems that we have to ask not what conditions are likely to provide opportunity for infection but what influences can precipitate the breakdown of healed or quiescent lesions. General influences (such as faulty nutrition and physical or mental stress) which affect the sexes more or less equally are unlikely to be of great importance, and tobacco smoke is probably the commonest lung irritant with a marked sex differential. And since tuberculosis in young adults is principally a consequence of new infection rather than of breakdown of old disease, if our hypothesis is true we should expect to find no difference between the smoking habits of young tuberculous patients and the population from which they were drawn. Table IX indicates that this is so.

If it is true that smoking can lead to the breakdown of old lesions, it is still not possible from the data available to say whether it is the principal reason for the sex difference in mortality and morbidity in middle and late life. There are, however, two indications that this may be so. First, smoking is still essentially a male habit. Not only are there far fewer non-smokers among males (over 30 years of age 8.1% of male and 51.4% of female controls were non-smokers—Table III), but also among smokers males smoke much more heavily than females (49.9% of male and 5.0% of female smokers had smoked 20 or more cigarettes a day). Second, the difference in amount smoked between patients with respiratory tuberculosis and controls in this investigation is similar to the difference between patients with cancer of the lung and their controls reported by Doll and Hill (1952). For both males and females there is a similar deficiency of non-smokers and light smokers and an excess of moderate and heavy smokers. In England and Wales during the quinquennium 1950-4 the ratio of

male to female deaths from cancer of the lung was 6:1, while for respiratory tuberculosis at age 55 years and over it was 5:1.

Finally, we must consider whether what is known about the growth of the tobacco habit in this country and the changing pattern of tuberculosis in middle life is consistent with the suggestion that there may be a causal relationship between them. Tobacco consumption in the United Kingdom began to rise steeply shortly after the 1914-18 war, and it was during the decade 1921-30 that a rapid increase in mortality attributed to cancer of the lung first began to attract attention (Doll and Hill, 1950). No great weight can be attached to this relationship, since, as has so often been pointed out, a substantial part of the increase in mortality from cancer of the lung is probably due to improved diagnosis and more accurate death certification. In the case of respiratory tuberculosis a direct comparison between mortality and tobacco consumption is even less instructive, because death rates have always provided a very unreliable measure of incidence, and in recent years therapeutic advances have profoundly altered the pattern of survival. Since our principal concern is with the change in sex pattern of tuberculosis in middle life it is possible to side-step these difficulties. In Fig. 4, which illustrates

FIG. 4.—Changes in the ratio of male to female death rates from respiratory tuberculosis in certain age groups from 1851.

changes in the ratio of male to female death rates for various age groups over the past hundred years (a method used by Springett, 1952), a rising ratio indicates that the male death rate is declining less rapidly than the corresponding female death rate, and vice-versa. It is evident that in the age group "45 years and over" male mortality has been declining less rapidly than female mortality for at least a century, but since 1911-20 (the decade in which tobacco consumption began to climb) the sex difference has become very much more pronounced.

It seems reasonable to conclude that smoking may be an important cause of the breakdown of healed or quiescent respiratory tuberculosis in middle and late life and perhaps the principal reason for the rapidly increasing sex difference in mortality at these ages.

Summary

No satisfactory explanation has been provided for the observation that in most large industrialized countries mortality from respiratory tuberculosis in middle and late life is now very much higher for males than for females. In view of the association between smoking and cancer of the lung, in which male mortality is also relatively high, it was decided to investigate the smoking habits of patients with respiratory tuberculosis.

A social worker questioned 1,200 patients with notified respiratory tuberculosis about their present and past smoking habits: 766 were interviewed at the Birmingham Chest Clinic and 434 in the three principal Birmingham sanatoria. The same worker interviewed as controls 588 patients attending the Birmingham Accident Hospital with minor injuries and 391 patients occupying beds in the surgical wards of a large non-teaching hospital in Birmingham.

In both sexes patients of over 30 years of age with respiratory tuberculosis showed a highly significant deficiency of non-smokers and light smokers and an excess of moderate and heavy smokers when compared with the controls. It seems unlikely that this difference is due to a bias in choice of patients and controls or to the method of comparison.

From this and from certain other considerations it is suggested that smoking may be an important cause of the breakdown of healed or quiescent respiratory tuberculosis in adults and may account for a considerable part of the excessive male mortality in middle and late life.

I acknowledge with pleasure my indebtedness to Dr. V. H. Springett, medical director, Birmingham Chest Services, Mr. W. C. Gissane, surgeon-in-chief of the Birmingham Accident Hospital, and Mr. K. O. Parsons, consultant surgeon to Dudley Road Hospital, for the facilities they afforded me for collecting the data used in this paper. I should also like to thank Miss Ida Giles, who interviewed all patients and controls and helped with the sorting of the data.

LATE RESULTS OF VAGOTOMY COMBINED WITH GASTRO-JEJUNOSTOMY OR PYLOROPLASTY IN THE TREATMENT OF DUODENAL ULCERATION

BY

J. A. LLOYD DAVIES, M.B., F.R.C.S.

From the Dan Mason Research Foundation, West London Hospital Medical School

Sedation, diet, antacids, and antispasmodics have long been accepted in the medical treatment of duodenal ulceration. There is, however, no equivalent unanimous surgical opinion regarding the most satisfactory operative procedure, for the functional result achieved has to be evaluated in conjunction with the incidence of recurrent or stomal ulceration.

Vagal nerve section, reintroduced by Dragstedt *et al.* (1944), soon fell into disrepute for duodenal ulceration because of the high incidence of gastric retention, with all its sequelae, which followed this operation. The addition of gastro-jejunostomy or pyloroplasty as a simultaneous procedure has materially diminished the frequency of this delay in stomach emptying. Nevertheless, both these gastric drainage procedures have complications peculiar to themselves. Particularly is this so with gastro-jejunostomy, in which both the

liability of the stomach region to peptic ulceration and also the production of symptoms by mechanical factors or by the regurgitation of duodenal juice have long been appreciated.

Present Series

In this paper are embodied the results of an analysis of 366 cases of chronic duodenal ulceration treated by vagotomy combined with either gastro-jejunostomy or pyloroplasty. The length of time post-operatively has been five years or longer in most cases. The series consists of consecutive cases drawn from several surgical centres in this country. In this way it is thought to be representative of the overall late results obtained in current surgical practice by these operations.

Out of this complete group, 22 (6%) patients had died from causes unconnected with their duodenal ulceration, and 14 (3.8%) have been lost, leaving 330 (297 males, 33 females) for study. In all cases section of the vagi was performed transabdominally, the nerves being exposed on the lower oesophagus after mobilization of the left lobe of the liver. Pyloroplasty was carried out in most cases by the method of Heineke-Mikulicz, which consists of enlargement of the pyloric opening by an incision parallel to the long axis of the stomach and closure of this by suture at right angles to the original incision. In other patients the method of combined pyloroplasty and pylorotomy advocated by Beattie (1950) was employed. All operations were elective, none being for the emergency treatment of haemorrhage or perforation. In all cases the clinical and radiological diagnosis of duodenal ulceration was confirmed at operation.

Follow-up has been by personal visit to the patient's home in 37 cases (10.2%), out-patient review of 120 cases (36.4%), and by questionnaire in 173 cases (53.4%). The questionnaire covered the following points: (a) the extent of the patient's satisfaction with the operative result; (b) any return of ulcer pain; (c) any further stomach operations; (d) any post-operative haematemesis or melaena; (e) a survey of the possible post-operative symptoms; and (f) weight gain or loss since operation. In any case where there was doubt the patient was seen or the position made clear by further correspondence.

The length of time since operation was four years in 52 (15.8%) cases, five years in 219 (66.4%), six years in 51 (15.4%), and seven years in 8 (2.4%).

The operative procedure in 198 cases (60%) was vagotomy and gastro-jejunostomy, and in 132 cases (40%) it was vagotomy and pyloroplasty.

Clinical Results

The results of the review have been classified in general accordance with the method of Visick (1948). Separation has been made into the following groups:

Grade I: Patients Who are Completely Symptom-free.—There were 167 cases (50.6%) in this grade. With the complete absence of subjective or objective troubles, the excellence of the result obtained leaves nothing to discuss.

Grade II: Patients Who Have Mild Symptoms which Cause No Disability.—There were 113 cases (34.2%) in this grade. It must be emphasized that the symptoms complained of were minor and did not detract from the good operative result, either in the patients' or the reviewer's opinion. They occurred so infrequently in the majority that it was only the rigid adherence to the complete absence of symptoms necessary for classification in grade I that prevented their inclusion in this latter grade. The complaints were of

occasional looseness of stool, attacks of weakness or faintness, flatulence, fullness, and biliary regurgitation or vomiting.

Grade III S: Patients Who Have Moderate Symptoms not Relieved by Care, but Who are Improved Symptomatically and Clinically by the Operation.—There were 19 cases (5.8%) in this grade. Their complaints were analysed as follows:

1. General physical condition poor from congestive heart failure and carcinoma of the prostate respectively, with consequent symptoms overshadowing satisfactory operative result, 2 cases.
2. Moderate dyspeptic symptoms, but no ulcer pain and no evidence of recurrent ulceration, 6 cases.
3. Moderate dyspeptic symptoms, but no ulcer pain and no evidence of recurrent ulceration, but with functional overlay and under psychiatric care, 6 cases.
4. One past attack of ulcer pain after vagotomy but no recurrent ulceration found on investigation then and symptom-free since, 5 cases.

The attack of ulcer type pain suffered by five patients was thought to have been associated with minor stomal ulceration with spontaneous healing, for in each of these patients the stomach drainage operation had been gastro-jejunostomy. The difficulty of achieving complete symptomatic cure in patients who enjoy their disabilities or who have personality disorders is well exemplified in this grade.

Grade III U: Patients Who Have Moderate Symptoms not Relieved by Care and in Whom the Clinical Result is Unsatisfactory.—There were 11 cases (3.3%) in this grade. Their complaints were analysed as follows:

1. Many severe dyspeptic symptoms but no clinical or radiological evidence of recurrent ulceration, 2 cases. These two patients had radiological evidence of gastric retention as shown by a six-hour delay in stomach emptying after a barium meal. This delay in both cases followed vagotomy and pyloroplasty.
2. Symptoms of recurrent ulceration present at all times but radiological or gastroscopic proof unobtainable, 4 cases. These four patients had had vagotomy and gastro-jejunostomy performed. Three presented with ulcer pain and the fourth had had two bouts of haematemesis and melaena. Although proof of recurrent ulceration could not be obtained, it was felt from the extent of the symptoms that sooner or later the presence of such ulceration would be confirmed in these cases.
3. Troublesome diarrhoea, 5 cases. There was barium-meal evidence of delay in stomach emptying in one of these cases.

Grade IV: Patients Not Improved by Operation.—There were 20 cases (6.1%) in this grade. They were subdivided as follows:

1. Recurrent duodenal ulceration, 4 cases. This had been proved in each case at the further operative procedure required. The primary gastric drainage operation in each case was pyloroplasty. The presenting symptom common to all was ulcer pain, and all had radiological evidence of active duodenal ulceration, with marked duodenal stenosis in two. All four cases had had a subsequent partial gastrectomy.
2. Anastomosis ulceration, 5 cases. Ulcer pain was present in all five patients. One had perforated a stomal ulcer in America and had had a simple suture performed, but has since been untraceable. One man had had repeated haematemeses, had not been operated on, and had died four years later from unconnected causes. The remaining three had each had an elective partial gastrectomy performed.
3. Gastric ulceration, 4 cases. In two of these patients, in addition to the presence of lesser-curve ulceration at the angulus, there was coexistent barium-meal evidence of delay in stomach emptying due to duodenal stenosis from pyloroplasty failure. These patients presented with ulcer pain. The third patient was averted to have had a high lesser-curve ulcer found on routine barium-meal examination. He was symptom-free at that time and had been so ever since his primary procedure of vagotomy and gastro-jejunostomy. No further operation had been undertaken in his case and no further investigation was possible. The fourth patient developed a gastric ulcer at the angulus seven years after vagotomy and short-circuit, and presented with ulcer pain.
4. "Gastric cripples," 4 cases. All these had had subsequent partial gastrectomy, but in none of them had any evidence of recurrent ulceration been found, although two had multiple adhesions. One of these patients died from peritonitis following his partial gastrectomy. No improvement in the many symptoms

of the remainder had resulted from partial gastrectomy. One had had a further entero-anastomosis performed and then a further division of adhesions, and still had multiple symptoms.

5. Successful partial gastrectomy for ulcer type of pain but ulcer not confirmed at operation, 3 cases. One patient had pain after food and was tender over the duodenum. At laparotomy he was found to have a stitch abscess associated with unabsorbable suture material used for repairing the duodenum at his original pyloroplasty. The second patient had had ulcer type of pain after food for three years following vagotomy and pyloroplasty, but the absence of active peptic ulceration was confirmed at partial gastrectomy. The third patient with pain after food had developed a stenosis at the pyloroplasty stoma, and was also treated by partial gastrectomy, no active duodenal ulceration being found at this operation. All have subsequently remained well.

Patients in grades I, II, and III S have been regarded as having a satisfactory clinical result, and patients in grades III U and IV as having an unsatisfactory clinical result. The result of this classification, when applied to the whole series, is shown in Table I.

TABLE I.—Grading of Whole Series

Grade	No. of Patients
I	167 (50.6%)
II	113 (34.2%)
III S	19 (5.8%)
Total satisfactory	299 (90.6%)
III U	11 (3.3%)
IV	20 (6.1%)
Total unsatisfactory	31 (9.4%)

Sex in Relation to Clinical Result

There is no difference between the results obtained in males and in females, for, as is shown in Table II, satisfactory results were achieved in 90.2% of males, as compared with 93.9% females, and unsatisfactory results occurred in 9.8% of males, as compared with 6% of females. Allowing for the small size of the female group (33 cases), the small differences in these findings are not significant.

TABLE II.—Sex in Relation to Clinical Result

Grade	Males	Females
I	150 (50.5%)	17 (51.5%)
II	104 (35.0%)	9 (27.3%)
III S	14 (4.7%)	5 (15.1%)
Total satisfactory	268 (90.2%)	31 (93.9%)
III U	11 (3.7%)	0 (0%)
IV	18 (6.1%)	2 (6%)
Total unsatisfactory	29 (9.8%)	2 (6%)

Post-operative Nutrition

All patients were questioned regarding any change in their weight since operation. It was clear that in the majority of patients their weight had returned to normal and had remained steady. Clinical observation confirmed this most strongly, and patients' satisfaction in their ability to eat normal-sized meals was often reflected in their resumption of heavy industrial or mining work, where high calorie intake was essential.

Thus 214 (65%) were keeping to a steady normal weight and 72 (21.8%) had gained weight well, a total of 286 (86.8%) with a satisfactory nutritional result. Minor weight loss had occurred in 27 (8.2%) and considerable loss in 5 (1.5%). This last group of five patients were all graded as unsatisfactory in the general result classification because of their post-operative symptomatology. Thus all patients with weight loss totalled only 32 (9.7%). No information was available concerning the weight of 12 patients.

It is appropriate to compare these figures with weight levels after partial gastrectomy. Ivy, Grossman, and Bachrach (1950) reviewed 864 patients, made up of six series, treated by this operation. They found that the post-

operative weights remained steady or increased in 53% and decreased in 47%. Thus even with any other relevant factors excluded, there appears to be significant evidence that weight maintenance after vagotomy and a gastric drainage operation is more generally satisfactory than after partial gastrectomy.

General Analysis of Post-operative Symptoms

Diarrhoea.—Seventy-four patients in the series complained of loose stools or diarrhoea, an incidence of 22.5%. It was not considered troublesome by 64 (19.4%), and of these 40 stated that they only passed loose stools intermittently, periods of normality of a month or more being usual. On the other hand, 10 (3%) complained of troublesome diarrhoea, but in only three of these was there radiological evidence of delay in stomach emptying.

Flatulence.—Increased flatulence compared with their pre-operative condition was complained of by 67 patients (20.4%). Of the three who found it worrying or severe, two were air swallowers. In the third case foul eructations were associated with proved gastric retention. There was radiological evidence of gastric delay in one further mild case. Thirty-three of these patients also complained of occasional diarrhoea.

Biliary Regurgitation or Vomiting.—Occasional biliary regurgitation or vomiting occurred in 44 cases (13.4%). It was generally infrequent or mild, although in nine cases it was accompanied by other post-operative symptoms to an extent sufficient for them to be classified in grade III S. In only one case, following upon a vagotomy and gastro-jejunostomy, was biliary vomiting severe enough to warrant further operation. This man was not improved by subsequent partial gastrectomy and a later entero-anastomosis.

Hypoglycaemic Attacks.—Mild occasional hypoglycaemic attacks were not uncommon following both vagotomy and gastro-jejunostomy (18 patients) and vagotomy and pyloroplasty (27 patients), making a total of 45 cases (13.6%) with this complaint. The attacks occurred typically one to three hours after food; they were characterized by a feeling of weakness or faintness, sometimes accompanied by sweating, and were rapidly relieved by food or a sweet drink. Patients stated that the frequency and severity of these attacks had diminished as time had passed following their operation, and none found them distressing at the time of review.

Other Post-operative Side-effects.—Undue fullness after food was difficult to evaluate as a subjective symptom. It occurred to a significant extent in 10 patients (3%), and only two of these had lost weight post-operatively. There was evidence of coexistent gastric stasis in 3 of these 10 cases. Only one patient complained of symptoms of a typical immediate postprandial "dumping" syndrome, and this followed vagotomy and gastro-jejunostomy.

Post-operative Gastric Retention

Barium-meal examination showed a delay of six hours or longer in stomach emptying in eight patients. They had all had vagotomy and pyloroplasty. Gastric retention did not occur among the group in which vagotomy and gastro-jejunostomy had been carried out. In five patients inadequacy of the pyloroplasty outlet was the cause of the delay in emptying. In two cases recurrent duodenal ulceration with stenosis had occurred. The last case had pylorospasm and obstruction from a gastric ulcer at the angulus with surrounding oedema.

An organic obstruction lesion was present in all these cases of delay in stomach emptying. All presented at periods longer than one year after vagal section. It may be that partial loss of stomach motor function may render almost impassable a degree of pyloro-duodenal stenosis which could be easily overcome by a stomach possessing normal motor power. Thus even if only a minor diminution in stomach tone and peristalsis is likely, the provision of a stomach outlet which remains permanently widely patent is essential.

Recurrent Peptic Ulceration

The site of a recurrent ulceration in the 13 (3.9%) proved cases is shown in Table III, together with a possible explanation for each recurrence. Six (4.5%) followed

vagotomy and pyloroplasty, four being duodenal ulcers and two being gastric ulcers, and seven (3.5%) followed vagotomy and gastro-jejunostomy, five being gastro-jejunal ulcers and two being gastric ulcers.

In addition to the proved cases there were four other patients (graded III U) whose symptoms of pain or bleeding following vagotomy and gastro-jejunostomy were such as to warrant a presumptive diagnosis of gastro-jejunal ulceration despite negative radiological or gastroscopic findings. If these patients are included, then the proved and presumed recurrence rate totals 5.1% in the whole series and 5.6% following vagotomy and gastro-jejunostomy.

The number of years after operation at which these ulcers occurred is shown in Table IV.

TABLE IV.—Time of Recurrence After Operation

Time in Years of Recurrence after Vagotomy	Site and No. of Ulcers	Total
0-1	2 G.J.U.; 1 D.U.	3
1-2	3 G.J.U.; 1 D.U.; 1 G.U.	5

3-4	1 G.U.	1
4-5	1 D.U.	1
5-6	1 G.U.	1
6-7	1 G.U.	1

The following points of importance arise: (1) Proved recurrent duodenal ulceration occurred only after vagotomy and pyloroplasty, and its incidence was evenly divided through a five-year follow-up period. (2) Proved gastro-jejunal ulceration, occurring after vagotomy and short-circuit, presented only during the first two post-operative years. (3) There was insulin-test-meal evidence of incomplete vagotomy in eight out of the nine patients with proved anastomotic or recurrent duodenal ulceration. A test-meal examination could not be performed in the remaining case. (4) Gross delay in stomach emptying occurred in two of the four cases in which gastric ulceration had taken place. (5) There is no statistical difference between the total recurrence rate of 5.6% following vagotomy and short-circuit, and that of 4.5% following vagotomy and pyloroplasty (standard error=2.4).

Operative Mortality

Table V is an analysis of the five (1.5%) deaths directly associated with the operative procedure.

One of the deaths from uncontrollable diarrhoea was proved at necropsy to be due to an enteritis severe enough to have caused sloughing of the mucosa of the small bowel. Similar cases, but occurring after partial gastrectomy, have been reported by Williams and Pullan (1953).

Comparison between Gastro-jejunostomy and Pyloroplasty as Stomach Drainage Procedures

Table VI shows the respective gradings and the extent of the post-operative complications arising in the 198 patients who had gastro-jejunostomy combined with vagotomy, and in the 132 patients who had pyloroplasty combined with

TABLE VI.—Comparison of Results and Symptoms After Vagotomy and Gastro-jejunostomy With Those After Vagotomy and Pyloroplasty

	Vagotomy and Gastro-jejunostomy	Vagotomy and Pyloroplasty	Standard Error
Total No.	198 (60%)	132 (40%)	—
Satisfactory results	183 (92.4%)	116 (87.9%)	4.5/3.2
Unsatisfactory results	15 (7.6%)	16 (12.1%)	4.5/3.2
Grade I	105 (53%)	62 (47%)	6.0/5.6
Grade II	65 (32.8%)	48 (36.4%)	3.6/5.6
Grade III S	13 (6.6%)	6 (4.5%)	2.1/2.6
Grade III U	7 (3.5%)	4 (3.0%)	0.5/2.0
Grade V	8 (4.0%)	12 (9.1%)	5.1/2.5
Recurrent ulceration	11 (5.6%)	6 (4.5%)	1.1/2.4
Gastric retention	0	8 (6.0%)	6.0/1.7
Diarrhoea	37 (19%)	37 (28%)	9.4/7
Biliary regurgitation	28 (14%)	16 (12%)	2/3.8
Flatulence	29 (15%)	24 (18%)	3/4.1
Hypoglycaemic attacks	18 (9%)	27 (20%)	9/3.8
Operative mortality	3 (1.5%)	2 (1.5%)	—

The standard error is expressed as the ratio of the difference in percentage to the standard error between proportions.

vagotomy. Allowing twice the standard error as a measure of significance, it is clear that the only definite statistically significant differences between the results of these procedures were: (1) There was a higher number of patients thus placed in grade IV, than there were after vagotomy and gastro-jejunostomy (4%). (2) There was a marked incidence of gastric retention following pyloroplasty, 8 cases (6%) occurring, as opposed to the absence of this complication following gastro-jejunostomy. (3) The incidence of hypoglycaemic attacks was higher following pyloroplasty (20%) than after gastro-jejunostomy (11%).

Insulin-test-meal Findings

Adequate records of post-vagotomy insulin test meals were available in only 87 cases. Separation into complete and incomplete vagotomy was made by the criteria of Hollander (1946, 1948). This separation revealed that no fewer than 26 (29.8%) of these 87 cases had insulin test meals showing marked response to hypoglycaemia with very high levels of free acid. These figures do not represent the correct incidence of incomplete vagotomy as a whole, since insulin test meals had sometimes been carried out only when recurrence of ulcer symptoms suggested that vagal section had not reduced free acidity down to a safe level. The seriousness of failing to achieve adequate vagal section is emphasized by anastomotic or recurrent duodenal ulceration developing in 8 (30%) of these 26 cases.

A review of the test meals from one surgical centre, where satisfactory results were available from 62 out of 102 consecutive patients, disclosed that 17 had clear evidence of incomplete vagal section. Thus the incidence of incomplete vagotomy for this hospital lies somewhere between 16.6% and 27.4%.

No case of anastomotic or recurrent duodenal ulceration was found among those patients who had insulin-test-meal evidence of complete vagal section.

Comparison with other Surgical Procedures

Recurrent Ulceration

When simple gastro-jejunostomy headed the surgical field in duodenal ulceration it was clear that pyloroplasty, as a sole procedure, had no place in operative treatment. Even in 1906 Paterson recorded a relapse rate of 54% in 22 cases reviewed. Presumably, therefore, success from vagotomy and pyloroplasty depends on the vagal nerve section. Douglas (1947) found stomal ulceration in 27.1% of 37 cases in which simple gastro-enterostomy was performed for duodenal ulceration without stenosis. Tanner (1952) thought that there was a 30% risk of stomal ulceration in such cases.

Anastomotic ulceration after Polya type partial gastrectomy for duodenal ulceration may be as low as the figure of 0.25% quoted by Pulvertaft (1952), reviewing 458 of Visick's cases, but in his operations the level of gastric section was very high. It is probably true to say that the more radical is the gastrectomy, the more rare is recurrent ulceration, but the higher is the incidence of post-operative symptoms. The figure of 5.1% for recurrent ulceration after this operation quoted by Ivy *et al.* (1950) may well be taken as the expected upper limit.

It has been shown that the proved recurrence rate after vagotomy and gastro-jejunostomy in the present series was 3.5% and that there was an additional presumed recurrence rate of 2.1%, making a total of 5.6%. Crile (1952) reported a recurrence rate of 5% following vagotomy and gastro-jejunostomy in 140 cases, and Hoerr (1953) a recurrence rate of 8% in 146 cases. In more recent papers on the results of vagotomy and short-circuit in duodenal ulceration, Bennett-Jones and O'Donnahill (1955) reported 7.4% recurrences out of 95 cases followed from four to six years. Holt and Robinson (1955) gave an incidence of 2.7% in 110 of their patients followed for three years. The much higher figure of 12.4% recurrences has been found by Henson and Rob (1955) in 89 of their patients up to 29 months after operation.

With the exception of this last series, there would therefore appear to be only a slightly higher rate of recurrent ulceration following vagotomy and gastro-jejunostomy, when compared with that which would be accepted with equanimity by some surgeons after Polya partial gastrectomy. However, with regard to the series on which this paper is based, it is possible that there may be a further small incidence of recurrence as the years go by. Therefore it may well be that a ten-year follow-up of these patients may disclose further occasional failures. Nevertheless, this figure is not likely to be large, for, as Guy *et al.* (1953) have shown, the great majority of such unsatisfactory results become apparent within the first two years after operation.

The reports of Wilkins (1953) and Weinberg (1954) do not give sufficient long-term data on recurrence after vagotomy and pyloroplasty for their figures to be comparable. In the present series the recurrence after this operation was 4.5%, and this, as previously stated, is not statistically different from that following vagotomy and short-circuit.

Relief of Symptoms

There are no recent long-term evaluations of the results of the Billroth I operation for duodenal ulceration. This procedure is thought by Moloney (1954) to be better than Polya gastrectomy because the loss of weight is not so marked and symptomatic complaints tend to wear off.

Although it might appear from the findings presented earlier in this paper that cases after vagotomy and gastro-jejunostomy or pyloroplasty show a considerable incidence of minor post-operative symptoms, Ivy *et al.* (1950) found that of the 475 cases after Polya type partial gastrectomy where information was available only 46.3% were symptom-free. There is no significant difference between this figure and that of 53% found symptom-free following vagotomy and short-circuit and of the 47% similarly graded after vagotomy and pyloroplasty in the present series.

If those symptoms associated with gastric retention and recurrent ulceration are excluded, a review of the present series shows that complaints after vagotomy and an adequate gastric drainage operation tend to be relatively minor, and do not approach in severity or disablement the syndromes that sometimes follow partial gastrectomy.

Operative Mortality

The mortality rate following partial gastrectomy performed by experts is now low, for Hosford (1949) reported a death rate of 0.5% in 200 consecutive cases, while Goligher and Riley (1952) thought that a figure of 2% to 3% might be regarded as a fair estimate of the operative risk of death. Johnson and Orr (1953) suggested that up to 4% may generally be accepted as the average mortality rate following this operation.

Crile (1952) has reported 2 (0.4%) operative deaths among 445 patients undergoing vagotomy and gastro-jejunostomy, and Hoerr (1953) 0.5% deaths in patients in whom this procedure was performed, while the figure in the series under review is 1.5%.

It thus appears that there is a lower operative risk for vagotomy and gastro-jejunostomy than for partial gastrectomy.

Conclusions

This review indicates that in a gratifyingly large proportion of cases complete vagotomy combined with an adequate gastric drainage operation is followed by a lasting cure of duodenal ulceration.

The finding of statistically similar figures for recurrent ulceration following vagotomy and gastro-jejunostomy (5.6%) and vagotomy and pyloroplasty (4.5%) suggests that recurrence does not depend upon the type of gastric drainage employed but upon the completeness of vagal section. Support for this contention comes from the insulin-test-meal evidence of incomplete vagotomy found in all those cases of anastomotic or recurrent ulceration where the results of this investigation have been available. Nor has recurrent ulceration been found when vagotomy has been complete. Therefore it can only be presumed that the high recurrence rates reported in some series may be closely related to the incompleteness of vagal section. It is therefore of considerable importance that a surgical technique should be employed which is most likely to ensure complete division of the vagal nerves. The anatomical and operative considerations of Chamberlin and Winship (1947), Dragstedt *et al.* (1947), and Jackson (1949) are particularly valuable in this respect.

An additional incidence of 2.1% of presumed though unproved recurrent ulceration after vagotomy and gastro-jejunostomy raises the recurrent rate for this operation to 5.6% and the total rate in the whole series to 5.1%. This figure is not regarded as being at a prohibitive level, although it is higher than that generally achieved by Polya type subtotal partial gastrectomy. It must be remembered, however, that after vagotomy and a gastric drainage procedure there may also be a further incidence of recurrent ulceration as the years after operation pass by. Elucidation of the final figures for recurrence after these operations must therefore be deferred until at least a 10-year follow-up can be made of patients so treated.

The 6% incidence of gastric retention after vagotomy and pyloroplasty, as opposed to the absence of this complication following vagotomy and gastro-jejunostomy, would indicate that pyloroplasty cannot be relied upon as a gastric drainage procedure. It has also been found that post-operative symptoms after vagotomy and pyloroplasty are relatively more common than after vagotomy and gastro-jejunostomy. For

these reasons vagotomy and pyloroplasty cannot be supported as a procedure for general elective use in duodenal ulceration.

When the post-operative symptoms are considered, the absence of severe postprandial "dumping" phenomena must be emphasized. Moreover, while the incidence of biliary regurgitation (14%), diarrhoea (19%), flatulence (15%), and hypoglycaemic attacks (11%) after vagotomy and gastro-jejunostomy is not small, these symptoms were commonly minor and infrequent. Although direct comparison of symptoms with those occurring after partial gastrectomy is not easy, the figure of 92.4% for clinically satisfactory results after vagotomy and gastro-jejunostomy is similar to that generally quoted for Polya type partial gastric resection. Furthermore, the numbers of patients completely symptom-free after either of these two operations correspond closely.

In some important respects, however, the results of vagotomy combined with a proper gastric drainage operation would appear to be better than those of Polya type partial gastrectomy. Particularly is this so from the viewpoint of post-operative nutrition.

Additionally, the data shown in Table II indicate that the clinical results achieved in the series are as satisfactory in women as they are in men. Finally, the evidence shows that vagotomy combined with gastro-jejunostomy or pyloroplasty has a lower operative mortality rate than Polya partial gastrectomy.

Thus for the present the increased risk of recurrence would seem to preclude the general adoption of vagotomy and gastro-jejunostomy as the elective procedure of choice in chronic duodenal ulceration. The incidence of recurrent ulceration found in the present review is not high enough, however, completely to contraindicate this operation, and there is also evidence to suggest that the late recurrent rate is unlikely to be large.

It is felt, therefore, that the clear advantages that have been described merit its employment in certain selected cases. Thus when elective surgery is necessary in the treatment of duodenal ulceration, vagotomy and gastro-jejunostomy seems to be indicated when it is essential that the post-operative calorie intake be high, as in patients who perform heavy physical work or who have pulmonary tuberculosis. Moreover, the satisfactory results obtained in women would favour its adoption in females in preference to subtotal gastric resection, in view of the disappointing clinical results which this latter operation often gives in this sex. Finally, the lower mortality rate also supports the use of vagotomy and gastro-jejunostomy in old or poor-risk patients.

The final decision whether the better clinical results of vagotomy and gastro-jejunostomy in these cases justify its general use in the surgical management of duodenal ulceration must, however, await the determination of the true recurrence rate of this procedure.

This investigation has been carried out during the tenure of a grant from the Dan Mason Research Foundation, West London Hospital Medical School. It has been made possible by the generous co-operation of Mr. G. F. G. Batchelor, Mr. B. N. Brooke, Mr. H. W. Burge, Mr. W. M. Capper, Mr. G. Y. Feggetter, Mr. J. W. Leslie, Mr. R. Marnham, Mr. T. W. Mimpriss, Professor C. G. Rob, Professor F. A. R. Stammers, and Mr. N. C. Tanner, in allowing me to follow-up their patients. I am also indebted to Dr. C. G. Magee for his assistance, and to Mr. Bonewell, Miss M. Meredith, and Mrs. M. Stewart for their help with the record and secretarial work inseparable from a review of this nature.

SOME NEW ASPECTS OF THE ACTION OF MORPHINE-LIKE ANALGESICS*

BY

O. SCHAUMANN, M.D.

Professor of Pharmacognosy at the University of Innsbruck, Austria

In 1941 Krueger, Eddy, and Sumwalt published a review on the pharmacology of morphine and summarized the world literature on this subject. It was an admirable achievement. They collected the evidence from more than 9,000 publications and condensed it into a volume of 800 pages. Considering that the analgesic action of morphine is by far the most important of its effects, it is surprising that only 9 of these 800 pages were concerned with analgesia and that only 30 of the 9,000 references dealt with its experimental investigation. More than 99% of the work was devoted to the so-called side-effects.

There is a simple explanation for this strange disproportion. Until 1939 morphine and some of its derivatives, such as heroin, "dilaudid" (dihydromorphine hydrochloride), and "eukodal," were our only powerful weapons in the struggle against pain. The clinical experience with these drugs was sufficient to evaluate their analgesic potencies. The mechanism of analgesia was explained by the rather vague assumption of an action on the central nervous system. In their review Krueger *et al.* wrote: "Analgesic action is predominantly central, though recent work advocates a peripheral component. Its site and mechanism have not been determined. Nor has the mechanism of narcotic action been ascertained." This statement was made in 1941.

Measuring Analgesic Potency

After the discovery of synthetic substitutes for morphine much more work was devoted to the study of analgesia. Between 1939 and 1942, after the discovery of pethidine (Eisleb and Schaumann, 1939), innumerable substances have been synthesized in the laboratories of the Höchster Farbwerke by varying the chemical structure of active drugs (Kleiderer, Rice, and Conquest,

*University of London Lecture given at St. Thomas's Hospital Medical School, London.

1945). The pharmacologist was thus faced with the task of looking for analgesic activity in hundreds of compounds and of comparing the potencies of the active derivatives.

This requirement was met by about 50 different methods for measuring analgesia which have been elaborated within the last 10 to 15 years. The purpose of these methods was to provide exact figures for the analgesia produced and to allow a statistical evaluation of the results the accuracy of which could be relied upon.

Nowadays this kind of work is a little overdone, particularly when analgesic potencies are determined up to the second decimal place with well-defined fiducial limits. Often the possibility is overlooked that the values obtained are not the result of analgesia but are due to other factors—for instance, to changes in blood flow. Many workers are not disturbed by the fact that their results are inconsistent with those of other authors, so long as the validity of these results is proved by statistics. In Table I the analgesic potency of pethidine

TABLE I.—Relative Analgesic Potency (Morphine=1)

	Experimental	Clinical
Pethidine		
Author 1	0.135	0.15
" 2	0.45	
" 3	0.94	
Methadone		
Author 4	1.2	1.5
" 5	6.5	

Clinical doses: morphine, 15 mg.; pethidine, 100 mg.; methadone, 10 mg. Relative potency: morphine, 1; pethidine, 0.15; methadone, 1.5.

and of methadone, as tested by different workers, is compared with that of morphine. There is a wide variation in the ratios, and some of the figures are not in agreement with clinical experience. There is no reason to doubt the experimental results or the statistical evaluation of these different results. However, quantitative comparisons in animal experiments are obviously useful only if the results correspond to the experience obtained in man. Therefore, in many cases inadequate methods must have been used, a possibility not always realized.

Nevertheless, we have a number of reliable methods for measuring analgesia. The most subtle methods, however, are not necessarily always the best. As a historical demonstration I would like to tell you which instrument and which method I used in my discovery of the analgesic property of pethidine and in the determination of the analgesic potencies of methadone and of hundreds of other compounds. It was nothing but a forceps with which I pinched the tails of mice. Nevertheless, with this simple method I determined (Schaumann, 1940) the relative potencies of pethidine, methadone, phenadoxone, and ketobemidone, and the results have been confirmed by the majority of later investigators and by clinical experience. The method was actually described as early as 1929 by Haffner.

Criteria of Specificity

With the synthetic analgesics it became possible to separate the specific from the non-specific effects. An effect is specific if it is common to all analgesics whatever their chemical structure, and if the potency in producing the effect runs parallel to their analgesic potency.

Another criterion for the specificity of an action is its great sensitivity against small changes in the chemical constitution. If we exchange the N-methyl group in morphine or in levorphanol against an allyl group, we obtain two

antagonists of morphine. The analgesic effect is also abolished by an exchange of the methyl group in the side-chain of methadone for an ethyl group. From pethidine, an active compound can be derived by substituting a hydroxy-group in meta-position, but inactive products result from substitution in ortho- or para-position.

A particularly striking example of the sensitivity of the analgesic effect to small changes in the chemical structure is the difference between the optical isomers of the same compound. This became clear when the synthetic products became available. The dextro-isomer of levorphanol, for instance, has no analgesic potency, and in methadone the dextro-isomer is 30 times less potent than the laevo-isomer.

This difference between optical isomers allows a clear-cut distinction between the specific analgesic effect of the morphine-like analgesics and general anaesthesia. The potency of general anaesthetics is determined chiefly by their solubility in lipids. Therefore there is no difference between the optical isomers. This has been shown for the optical isomers of the secondary butyl alcohol (Viditz, 1933; Butler and Dickson, 1940) and for some barbiturates (Kleiderer and Shonle, 1943). In local anaesthesia too, there seems to be no significant difference between optical isomers (Gottlieb, 1923; King, 1924).

A further criterion for the specificity of an effect of analgesic is the fact that it is abolished by nalorphine.

Thus there are four criteria which allow us to test whether an effect observed with one of the analgesics is specific or not: (1) the sensitivity to small changes in chemical constitution; (2) the difference in potency between its optical isomers; (3) the antagonistic effect of nalorphine; and (4) the parallelism between the potency in producing the effect and the analgesic potency.

Based on these criteria, there are the following specific effects of morphine-like analgesics: (1) analgesia; (2) the depression of respiration; (3) the effect on intestinal motility; (4) central excitation in cats and mice; (5) the hyperglycaemic effect; (6) the effect on body temperature; and (7) the liability to produce addiction.

It is therefore not correct to say that the depression of respiration and the constipating effect of the analgesics are side-effects. They are inseparable from their analgesic action. This is unfortunately also true for the liability to cause addiction. It will therefore not be possible to find morphine-like analgesics without this undesirable addition, and in fact all efforts in this direction have been unsuccessful.

Analgesics and Constipation

A great deal of work has been wasted on the constipation produced by analgesics. In their review of 1941 Krueger *et al.* devoted 136 pages to this action of morphine and quoted more than 200 references. Nevertheless, in summarizing the results they arrived at the following conclusion: "In spite of the many and extensive studies . . . it is clear that there are many gaps yet to be filled before a clear and complete account can be given of the effect of morphine on the gastro-intestinal tract." The reason for this unsatisfactory result is that the overwhelming majority of authors stuck to the same method (the Thirty-Vella fistula), to the same experimental animal (the dog), and to the same intestinal segment (the small intestine), and were apparently very pleased when they always obtained the same results.

It is not easy to oppose such a bulk of experimental work. I think that the many published tracings which show a rise in tone and an increase in motility of the intestine, however constructive and impressive they may be, only prove that the method is unsuitable to explain the constipating effect in man. The method is open to the following criticisms: first, morphine causes diarrhoea in the dog, therefore the dog is not a suitable animal; second, the Thirty-Vella fistula is not a normal intestine; and third, the small intestine is the least important part of the intestine for the constipating effect.

In my opinion, three factors are predominant in causing constipation after morphine (1) Suppression of the call for defaecation. It is an old observation that a patient under morphine with severe diarrhoea often notices the call for defaecation for the first time only when the fluid has reached the skin. (2) Inhibition of the defaecation reflex. In rabbits (Eddy, 1932; Emerson and Moodey, 1935; Karr, 1947; Scott *et al.*, 1947) and rats (Schaumann, Giovannini, and Jochum, 1952) the number of faecal balls which appear per unit time diminishes, and this diminution runs parallel to the intensity and duration of analgesia (Table II). (3) Inhibition of propulsive motility as by the peristaltic reflex, especially in the large intestine.

TABLE II.—Rat, Number of Scybala

	Dosage (mg./kg.)	No. of Scybala During		
		1-3 hours	4-6 hours	7-9 hours
Control ..	0	4.4	3.2	2.3
L-Methadone ..	0.1	2.9	3.2	3.3
	0.5	1.4	3.0	5.2
	1.0	0	4.0	5.0
D-Methadone ..	1.0	3.5	4.1	3.4
	5.0	1.4	4.0	4.6
	10.0	0.8	3.0	4.3
Morphine ..	0.2	2.5	1.0	2.5
	0.5	1.7	4.2	5.1

Nearly all authors accept the theory of a spastic constipation with increased intestinal motility. In my opinion it is unlikely that this occurs. According to Vaughan Williams and Streeten (1951), morphine spasms in the small intestine of the dog can be overcome by 19 cm. water pressure; the force of the peristaltic wave, however, is at least 15 to 20 times stronger. As everybody knows from his own sad experience, even the anal sphincter is no safe barrier against an oncoming peristaltic wave.

So far I have dealt with the specific effects. The unspecific actions are: their toxicity to animals, spasmolytic effects on smooth muscle, local anaesthesia, and inhibition of certain enzymes. These effects are unspecific because they do not run parallel with the analgesic power of the analgesics, because there is no difference between the optical isomers, because they are not antagonized by nalorphine, and because they occur also with compounds of entirely different chemical structure.

Toxicity

A few more words about toxicity. It can be seen from Table III that there is no constant relation between analgesia and toxicity. Pethidine is about seven times weaker than morphine in producing analgesia, but is twice as toxic for mice. D-methadone is just as toxic as its L-isomer, although its analgesic potency is 30 times weaker. In man the situation is different, because in man toxicity is determined by the depressant effect on respiration. It is therefore not possible to calculate a therapeutic index for use in man from animal experiments. Otherwise the clinical use of pethidine would be criminal, since it has a 15 times lower index than morphine in animal experiments. However, clinical experience has shown that the contrary is true, or pethidine would not have displaced the use of morphine in general anaesthesia to the extent it has.

Paradoxically we might even say: the greater the toxicity of a morphine-like analgesic in mice in comparison to its

TABLE III

	Toxicity (Mice subc. inj.)	Analgesia (Morph = 1)	Analgesia/Toxicity Therapeutic Index (Morph = 1)
	(mg./kg.)	(Morph = 1)	
Morphine ..	400	1	1
Pethidine ..	200	2	1/14
DL-Methadone ..	42	10	1/5
Phenadoxone ..	200	2	1/5
L-Methadone ..	35	11	1/3
D-Methadone ..	50	8	—

analgesic potency, the smaller is the danger of respiratory failure in man. The depression of respiration is antagonized by the central excitatory effect which in mice causes lethal convulsions. Therefore a low therapeutic index in animals means less danger in man. It is also a strange and paradoxical fact that in man the smallest overdoses are the most dangerous in morphine poisoning and that the mortality decreases with increasing doses. Krueger *et al.* have compiled some 200 cases of morphine poisoning from the literature with the following result: with doses from 60 to 600 mg. there was a mortality of 25%; with doses from 700 to 1,200 mg. the death rate went down to 6%; and with enormous doses from 1,500 to 7,200 mg. it reached only 15%. The highest known doses administered—that is, 4.5 g., 4.8 g., and 7.2 g.—were not fatal. Tatum, Seever, and Collins (1929) found the same paradox in monkeys: with 20 to 150 mg./kg. the mortality was 27%, and the fatal effect was due to depression; with doses from 200 to 300 mg./kg. there were no alarming symptoms, and doses of over 500 mg./kg. caused convulsions and death.

The parallelism between the specific actions suggests that a close relation exists also so far as their site and mechanism of action are concerned. This in turn makes it likely that a close relation exists also between the apparently different physiological functions which are affected by the analgesics. In my opinion, this is really the case. All these functions have the common task of warning and protecting the organism against imminent damage; they exert a protective function.

The "Protective System"

There can be no doubt that pain in all its variations—from the subconscious (subcortical) pain reflex to the conscious experience of pain—has such a protective function. The reflex protects against damage of the tissue—just think of the decapitated frog pulling its leg out of an acid solution—and the experience of pain warns against imminent dangers. The morphine-like analgesics inhibit this protective function of pain by suppressing first the conscious experience of pain and in higher doses also the reflex response to painful stimuli.

In analogy, we must recognize a protective function in the regulation of respiration. It protects the body against acidosis. Apart from the subconscious autonomic regulation we have the warning sensation of dyspnoea which corresponds to the experience of pain and which can reach the terrible feeling of suffocation. Here, too, the analgesics block first the conscious sensation of dyspnoea, and finally, in higher doses, the subconscious, automatic regulation of respiration as well.

There is a similar safeguard concerning circulation. We have the regulation of blood pressure and the Bezold reflex. The disagreeable throbbing of the heart and the feeling of anxiety associated with stenocardia warn against imminent collapse by overstrain of the heart and may be compared to the sensations of dyspnoea and of pain. Again the morphine-like analgesics in therapeutic doses abolish the feeling of oppression, and in high doses the blood pressure regulation as well.

The effects on the gastro-intestinal tract and on the temperature regulation can be regarded in the same light. The analgesics first suppress the call to defaecate, then the defaecation reflex, and finally the entire propulsive motility. They first abolish the feeling of cold, then the shivering fit, and finally the whole system of temperature regulation.

These physiological functions can be separated from the rest of the autonomic regulations and from the epicritical system of sensual perception because of their special task and because of their specific sensitivity to the morphine-like analgesics. They can be considered together as forming what I have termed the "protective system" (Schaumann, 1954a, 1954b) (Table IV).

It is characteristic of this protective system that its different functions are brought into action by noxious stimuli and that in man they enter the psychic sphere. All these

TABLE IV.—Some Parts of the Protective System

Individual Function	Noxious Stimulus	Subconscious Regulations	Psychical Equivalent
Protection of tissue Respiration Circulation	Damage to tissue CO ₂ Over-strain	Defence-reflex Hyperpnoea Bezold-Jarisch effect Peristalsis. Defaecation reflex	Sensation of pain Dyspnoea Palpitations. Oppression Call to defaecation Feeling of cold. Shivering fit
Digestive tract	Distension. T.x. stimulus	Temp. reg.	
Constancy of body temp.	Body temp.		

separate functions are inhibited by the morphine-like analgesics in proportion to their analgesic potencies. Analgesia is therefore only one part of a general anti-protective action of the analgesics.

Doses of analgesics which suppress the dysphoric sensations connected with the functions of the protective system do not influence sensory perceptions like touch, taste, vision, and hearing and their mental assimilation. In this respect, analgesics contrast with general anaesthetics. The invaluable relief given by the analgesics rests on their ability to suppress the protective system with its dysphoric sensations and anxiety. When using analgesics we have to keep in mind that they inactivate this protective system, which serves the useful purpose of warning against injury. Therefore the use of analgesics should be permitted, or indeed ordered, only when the warning has been heeded or the functions of the system have lost their meaning.

We have also to remember that liability to produce addiction has its cause in the suppression of these tormenting sensations. The danger of becoming an addict will be particularly great in people who have an abnormally oversensitive protective system and who are troubled with dysphoric sensations by stimuli which are quite normal. These people must be regarded as being ill. Suppression of their over-active protective system at first results in the feeling of relief from their troubles; there is therefore the temptation to continue using analgesics, which in the end results in physical dependence. This is the reaction of the protective system against the depressing effect of the analgesics and becomes apparent in the form of the symptoms of withdrawal. The longer and the more intensive the use of analgesics has been, the stronger will be these symptoms.

Conclusion

When we gained our intellectual powers we lost paradise. We were enabled to enjoy all that is good, beautiful, and true, but we were also condemned to suffer pain, worries, and fear to an extent unknown to animals. But in addition we have been endowed with the mental powers and the free will to obey the warning voice of our protective system, or to stifle it when it becomes a senseless tormentor. If we are forced to stifle these promptings, the morphine-like analgesics are our most efficient weapons for the purpose.

Total	13	12	3	6	6	40

veretum ("omnupon") $\frac{1}{2}$ gr. (22 mg.), six-hourly. Adequate post-operative analgesia to facilitate early leg and breathing exercises has been found to be especially valuable, and rigorous adherence to this regimen has lowered the incidence of fatal pulmonary embolism to one in the last 1,000 major gynaecological operations performed by one of us (E.C.).

During this trial no obvious respiratory depression or change in blood pressure or pulse rate occurred, nor did any patient complain of anorexia or constipation. In the dosage used, dipipanone appeared to have little hypnotic effect. The post-operative patients were awake and completely co-operative as soon as the anaesthetic had worn off; in fact, amylbarbitone sodium, 3 gr. (0.2 g.), had to be given to some of the patients before they were able to go to sleep.

The blood picture of patients whose blood was examined during the trial showed no change attributable to dipipanone. No withdrawal symptoms were noted after up to 80 effective analgesic doses. However, since in the majority of cases pain was short-lived and prolonged analgesia unnecessary, no conclusion can at present be drawn concerning habit formation with this drug.

Morbidity and Mortality

There were no deaths in the series during the period of the trial. One patient, who had a hysterectomy for fibroids, had a small pulmonary embolism on the fourth day. She was given anticoagulant therapy and made a complete recovery.

Summary

The results of the administration of a new analgesic, dipipanone hydrochloride, to two distinct series, each of 100 cases, are presented. All the cases treated suffered from pain severe enough to justify the use of a potent analgesic.

In the dosage employed, dipipanone was an effective analgesic. Adequate pain relief was obtained in the great majority of cases of post-operative pain following major gynaecological surgery and of pain due to a variety of acute and chronic medical conditions. Only 3 out of the 200 cases treated failed to obtain any relief from this drug. The optimal dose was found to be 20 mg. in the medical cases and 25 mg. in the post-operative cases.

The onset of analgesia after subcutaneous injection occurred within 10 minutes and maximal relief was obtained in about 20 minutes in most cases. The effect lasted for approximately five to six hours. There was no obvious depression of respiration or tendency to drowsiness, nor was there any local reaction or pain at the site of injection.

Side-effects were rare, their incidence in relation to the number of doses administered being 4–5%. The only side-effects of any importance were nausea, vomiting, sweating, and giddiness. In only one case were they severe enough to justify transfer to another analgesic.

Our thanks are due to our assistants and to the sisters in charge of the medical and gynaecological wards at Dudley Road Hospital, Birmingham, without whose co-operation this clinical trial could not have been carried out. The material used in the trial was "pipadone" brand injection of dipipanone hydrochloride, kindly supplied by Burroughs Wellcome and Co.

N-ACETYL-PARA-AMINOPHENOL AS AN ANALGESIC

A CONTROLLED CLINICAL TRIAL USING THE METHOD OF SEQUENTIAL ANALYSIS

BY

D. R. L. NEWTON, M.R.C.P., D.Phys.Med.

Assistant, Department of Physical Medicine, St. Thomas's Hospital, London

AND

J. M. TANNER, M.D., Ph.D., D.P.M.

Lecturer, University of London Institute of Child Health, Great Ormond Street, London

Acetanilide and phenacetin have long been used for their analgesic and antipyretic properties. Brodie and Axelrod (1948, 1949) have shown that the metabolism in the human body of acetanilide and of phenacetin closely resemble one another in that the major route in each case involves the production of N-acetyl-*p*-aminophenol (N.A.P.A.P.). In each case a high percentage of the ingested drug is excreted by the kidney as conjugated N-acetyl-*p*-aminophenol:

In addition to the major route shown above there is a minor metabolic route which for acetanilide involves the formation of aniline and for phenacetin the formation of *p*-phenetidin. Although neither of these products has been shown to be directly responsible for methaemoglobin formation it is thought that they are both precursors of the methaemoglobin-forming substance. It seems that N.A.P.A.P. is not responsible for

the formation of methaemoglobin. Neither does it appear to cause the haemolysis occasionally encountered as a toxic manifestation following the administration of acetanilide and phenacetin.

The fact that after ingestion of acetanilide and phenacetin plasma levels of the parent substances remained low whilst the level of N.A.P.A.P. rose rapidly led Brodie and Axelrod to believe that the analgesic and antipyretic properties of both drugs might be due to this derived product. Doses of 1 g. of N.A.P.A.P. given by mouth to human subjects were rapidly absorbed, and peak plasma levels were reached in one to two hours. No methaemoglobin was formed, and it appeared that dose for dose N.A.P.A.P. and acetanilide were equal in analgesic activity.

Using a cutaneous heat-radiation method, Flinn and Brodie (1948) found that the pain threshold of human subjects rose 30 minutes after the ingestion of N.A.P.A.P., reached a peak at two and a half hours, and returned to the baseline at four hours. The maximal rise averaged 30% as against 4% for a placebo.

Boreus and Sandberg (1953) found in rats that the analgesic and antipyretic properties of phenacetin and N.A.P.A.P. were approximately equal, though the latter seemed to be less toxic. In human subjects they found that, following a single 3-g. dose of either drug, methaemoglobin formation was low with phenacetin and negligible with N.A.P.A.P.

Batterman and Grossman (1955) carried out controlled trials, using either N.A.P.A.P. or acetylsalicylic acid as an analgesic, and concluded that, with the exception of exudative forms of arthritis, N.A.P.A.P. was a superior analgesic to acetylsalicylic acid alone for the treatment of musculo-skeletal conditions. Side-effects occurred no more commonly than after the administration of a placebo. A dose of N.A.P.A.P. of 3.6 g. daily for up to 116 weeks failed to produce any blood, kidney, or liver disturbances. No uricosuric effect was noted.

Keele (1953) has mentioned N.A.P.A.P. as an analgesic, but so far as we are aware no controlled clinical trial of this drug has been performed in this country, where it is now marketed under the trade name of "panadol."

Purpose of the Trial

Many patients suffering from musculo-skeletal disorders find that salicylates alone are insufficient to control their symptoms, but a large number gain relief from the use of tab. codein. co. (compound codeine tablets, B.P., containing acetylsalicylic acid 4 gr. (0.26 g.), phenacetin 4 gr. (0.26 g.), codeine $\frac{1}{2}$ gr. (8 mg.)). However, mild side-effects due to one or other of the constituents commonly occur and sometimes are troublesome enough to preclude the routine use of the drug. Thus if N.A.P.A.P. could be shown to be as effective an analgesic as tab. codein. co., and its side-effects significantly less, it might find a useful place in the treatment of rheumatic disorders, and it was for this reason that a controlled trial of N.A.P.A.P. against tab. codein. co. was carried out.

Selection of Patients

The patients who took part in the trial were selected by one of us during the course of routine hospital follow-up attendance. They had to conform to the following criteria, which could be rigidly applied since the number of potentially suitable cases was large: (a) The patient was known to require regularly some form of simple analgesic, usually tab. codein. co., to control symptoms. (b) Either by knowledge of the individual patient or the nature of his or her

disease the observer could be reasonably certain that the same average level of pain could be expected during the whole four weeks of the trial. (Thus all acute and subacute conditions and those commonly showing frequent periods of pain remission were excluded.) (c) No alteration in therapy by drugs, physical methods, or any other means had been made during the period immediately preceding the trial, and sufficient stability of the patient's condition must have been present to obviate the need for any such change during the trial period of four weeks. (Any alteration in condition during the trial period which necessitated a change in treatment automatically excluded that patient from the trial.)

The cases used in the trial were made up as follows:

Rheumatoid arthritis	..	..	..	19
Osteoarthritis	..	..	..	12
"Frozen shoulder" (periarthritis)	..	..	..	6
Ankylosing spondylitis	..	..	..	2
Chronic gout	..	..	..	1
Scleroderma with joint involvement	..	..	..	1
Cervical spondylosis	..	..	..	1
				42

Method of Trial

The two drugs were compared by their action in the same patient, and each comparison was carried out twice on each patient to ensure greater reliability of result. The statistical technique used in the trial was that known as sequential analysis. Sequential methods appear to have been used in medical research on only one or two occasions in this country, but in many forms of clinical trial they offer great possibilities of economy in material, time, and computation. An excellent introduction to the method was given by Bross (1952) and a more complete account has been published by Armitage (1954).

Administration of Drugs

The first requirement of a proper clinical trial is to confuse completely the doctor who gives the patient the drugs, and in this we succeeded admirably. The test period for each patient was four weeks. During the first two weeks each patient received drug A for one week and drug B for one week, and at the end of the fortnight was required to say, at his weekly interview with one of us, which, if either, had been more effective in easing his pain. A similar comparison was carried out during weeks three and four. The order in which the drugs were given was randomized, and the doctor was unaware which he was giving. Indeed, at one time he began to believe, despite knowledge of the statistical design, that he could spot which drug was which from the patients' responses. A record was therefore kept for a few weeks, which when later compared with the identification file showed that he scored no better than chance expectation in his "hunches."

In the first instance each patient was asked to co-operate in the trial of a new analgesic drug: they were never told that they were comparing different drugs, and the few queries which arose were concerned with whether there was a difference in "strength" from one week to the next. At the end of each fortnight the observer questioned the patient concerning his symptoms only: no suggestion was made that different preparations were being compared. The dosage used in the trial was tab. codein. co. 2 three times daily and N.A.P.A.P. 2 tablets (1 g.) thrice daily respectively. Every patient was told to take extra doses of their usual analgesic if required, but it was understood that the trial drug must be the basic medicament.

The randomization was performed as follows: The numbers 1 to 400 were written down in a random order from their appearance in Fisher and Yates tables. Four hundred bottles, stamped 1–400, were then arranged in this order. The first 200 in the row were then filled with drug A, and the last 200 with drug B, the identification file being made at this point. The first two bottles were taken from the A batch and stamped +, and the first two bottles taken from the B batch and stamped -. These four bottles were tied

of the solutions used were, 0.5% solution of bemegride (5 mg. per ml.), and a 1% solution of amiphenazole (10 mg. per ml.), the latter being made up immediately before use.

Postural drainage and breathing exercises were begun and continued daily throughout the patient's stay in hospital. Eleven of the cases regained full consciousness within 12 hours.

Case Reports

Case 1.—A married woman aged 58 was admitted to hospital in coma after taking 15 "carbrital" capsules. On examination she was unresponsive to any stimuli; B.P. 90/0; pulse 80, feeble and regular. Deep reflexes were absent except for plantars, which were flexor. The pupils reacted sluggishly to light and accommodation. She was treated with a total of 3 ml. of amiphenazole and 30 ml. of bemegride and regained full consciousness in 10 hours.

Case 2.—A married woman aged 51 was admitted in coma after taking 15 3-gr. (0.2-g.) tablets of amylobarbitone sodium. On examination she was unresponsive to any stimuli; cyanosed; B.P. 100/40; pulse 110, irregular and of poor volume; systolic murmur at the apex and aortic areas. Deep reflexes were absent except for plantars, which were flexor. The pupils were contracted and responded sluggishly to light and accommodation. She was treated with a total of 8 ml. of amiphenazole and 80 ml. of bemegride and regained full consciousness in nine hours.

Case 3.—A man aged 55 was admitted in coma after taking 15 3-gr. (0.2-g.) tablets of amylobarbitone sodium two and a half hours before admission. On examination he was unresponsive to any stimuli; B.P. 100/50; pulse 84 and regular. Deep reflexes were present but diminished; plantars flexor. The pupils were contracted and reacted sluggishly to light and accommodation. He was treated with a total of 18 ml. of amiphenazole and 180 ml. of bemegride and regained full consciousness in 11 hours.

Case 4.—A man aged 28 was admitted in coma after taking 12 carbrital capsules in mistake for mints in the cinema. On examination he was unconscious but responded to painful stimuli; B.P. 100/60; pulse 70. Deep reflexes were present but diminished; plantars flexor. The pupils were dilated and reacted sluggishly to light and accommodation. He was treated with a total of 4 ml. of amiphenazole and 40 ml. of bemegride and regained full consciousness in nine hours.

Case 5.—A married woman aged 36 was admitted in coma after taking 10 1-gr. (65-mg.) tablets of phenobarbitone one and a half hours before admission. On examination she was unconscious and unresponsive to any stimuli; B.P. 100/60; pulse 88 and regular. Deep reflexes were present but diminished. The pupils were contracted and reacted sluggishly to light and accommodation. She was treated with a total of 3 ml. of amiphenazole and 30 ml. of bemegride, became semi-conscious and muttered unintelligibly, and regained full consciousness in eight and a half hours.

Case 6.—A man aged 45 was admitted in coma after taking 15 tablets of butobarbitone one hour before admission. On examination he was unconscious and unresponsive to any stimuli; B.P. 90/60; pulse 68 and regular. Deep reflexes were present but diminished; plantars flexor. The pupils were dilated and did not react to light and accommodation. He was treated with a total of 4 ml. of amiphenazole and 40 ml. of bemegride and regained full consciousness in seven hours.

Case 7.—A man aged 49 was admitted in coma resulting from 20 1-gr. (65-mg.) tablets of phenobarbitone taken one hour before admission. On examination he was unconscious and unresponsive to any stimuli; B.P. 90/40; pulse 120 and feeble. Deep reflexes were present but diminished; plantars flexor. The pupils were contracted but reacted to light and accommodation. He was treated with a total of 5 ml. of amiphenazole and 50 ml. of bemegride and recovered full consciousness in nine hours.

Case 8.—This patient, the same as in Case 2, now aged 52 was admitted in coma after taking 25 3-gr. (0.2-g.) tablets

of amylobarbitone sodium one and a half hours before admission. On examination she was in coma and unresponsive to any stimuli; B.P. 90/40; pulse 100 and regular. Deep reflexes were absent; plantars flexor. The pupils were dilated and did not react to light and accommodation. She was treated with a total of 10 ml. of amiphenazole and 100 ml. of bemegride, became semi-conscious, and regained full consciousness in six hours.

Case 9.—A married woman aged 29 was admitted in coma after taking 8 3-gr. (0.2-g.) tablets of amylobarbitone sodium three hours before admission. On examination she was unconscious and unresponsive to any stimuli; B.P. 100/50; pulse 80. Deep reflexes were present but diminished. The pupils were dilated and did not react to light and accommodation. She was treated with a total of 9 ml. of amiphenazole and 90 ml. of bemegride and regained full consciousness in eight hours.

Case 10.—A married woman aged 34 was admitted in coma after taking 10 3-gr. (0.2-g.) tablets of amylobarbitone sodium and 20-25 25-mg. tablets of pethidine. On examination she was unconscious and unresponsive to any stimuli; B.P. 100/40; pulse 120 and feeble. Deep reflexes were absent in the lower limbs and diminished in the upper limbs; plantars extensor. The pupils were contracted and did not react to light and accommodation. She was treated with 100 mg. of nalorphine hydrobromide and a total of 4 ml. of amiphenazole and 40 ml. of bemegride, became semi-conscious, and regained full consciousness in three hours.

Case 11.—A single woman aged 25 was admitted in coma after taking 20 carbrital capsules and 20 3-gr. (0.2-g.) tablets of amylobarbitone sodium from seven to eight hours previous to admission. On examination she was unconscious, cyanosed, unresponsive to any stimuli; respirations were slow and stertorous; B.P. zero; pulse 130 and feeble. Deep reflexes were absent except for plantars, which were extensor. The pupils were dilated and did not react to light and accommodation. She was treated with 29 ml. of amiphenazole and 290 ml. of bemegride and became semi-conscious. She relapsed after one hour. A further 15 ml. of amiphenazole and 150 ml. of bemegride were given and full consciousness was regained 17 hours after admission.

Case 12.—A man aged 49 was admitted in coma after taking 30 1-gr. (0.1-g.) tablets of phenobarbitone sodium two hours before admission. On examination he was unconscious and unresponsive to any stimuli; B.P. 100/60; pulse 100 and feeble. Deep reflexes were absent except for plantars, which were extensor. The pupils were contracted and did not react to light and accommodation. He was treated with a total of 22 ml. of amiphenazole and 220 ml. of bemegride and recovered full consciousness in 12 hours.

Comment

It is obviously difficult to compare these cases critically owing to the variety of barbiturates taken, the length of time of coma before the beginning of treatment; and the fact that it was not possible to estimate the blood barbiturate in any of them. However, several salient points do emerge from the small experience gained with this form of treatment: (1) A safe level of consciousness can be attained in a short period of time, which can be maintained and gradually improved to full consciousness in a matter of hours. (2) The incidence of chest infection is minimized. In these cases it was reduced to zero, and all the patients were able to look after themselves within 24 hours. (3) The stay of the patient in hospital was reduced, the time varying from five to nine days—an important factor, bearing in mind the high incidence of barbiturate intoxication and the shortage of beds in a ward for acute medical cases.

Summary

Twelve cases of fairly severe barbiturate poisoning were treated with amiphenazole and bemegride. All the patients regained consciousness within 24 hours, the

majority well within this period. No deaths occurred, and there was no incidence of chest infection in any of these cases. The stay of the patients in hospital was cut down dramatically compared with former methods of treatment. Although the number of cases treated is small, I feel that it is worth while reporting them, in view of the results obtained, which, in my opinion, are a vast improvement on the previous methods at our disposal.

I am indebted to Drs. W. A. Jaques, G. D. Owen, and A. W. B. Edmunds, consultant physicians at this hospital, for permission to publish these cases. In particular I must thank Dr. Edmunds for his advice, encouragement, and criticism, without which I should have been unable to present these cases.

Medical Memoranda

Case of Strychnine Poisoning

Apart from accidental strychnine poisoning, particularly in young children, reports of attempted suicide with strychnine sulphate are uncommon. The toxic dose of strychnine in man appears to vary from about 2 mg., which has resulted in unpleasant symptoms, to about 15 mg., which has caused death. Recovery, however, has taken place after 1 g. or more has been ingested (Thienes and Haley, 1955).

The following case is of an intelligent boy aged 14 who obtained two 4-gr. (50-mg.) capsules of pure strychnine and swallowed them impulsively after a quarrel with his mother.

CASE REPORT

The boy was admitted to hospital about one and a half hours after 1½ gr. (100 mg.) of strychnine had been swallowed. He was fully conscious. Classical intermittent strychnine convulsions, occurring every few minutes, were present. He complained of severe pain, especially in his back, neck, and limbs. His colour was normal, and he looked extremely anxious. A mild stimulus such as holding his wrist produced a generalized contraction. He admitted he had swallowed the capsules of strychnine. No other physical examination was made at this stage because touching him caused convulsions.

He was immediately transferred to the theatre, where he was given atropine sulphate, 1/100 gr. (0.65 mg.) intravenously, followed by thiopentone sodium, 0.5 g., and suxamethonium chloride, 50 mg. A cuffed endotracheal tube, size 7, was passed and controlled respiration begun. The convulsions were then controlled by an intravenous infusion of 1 pint (570 ml.) of normal saline to which 1.5 g. of thiopentone sodium and 200 mg. of suxamethonium chloride had been added. The rate of drip was regulated to 20-30 drops a minute as required to maintain muscular relaxation. His blood pressure was 120/70 and pulse 120.

A wide-bore stomach tube was passed and a few ounces of fluid aspirated. This was followed by several wash-outs. The stomach contents were sent for analysis.

As a cover against respiratory infection penicillin was given intramuscularly and a catheter inserted into the bladder.

Still anaesthetized, the patient was taken to a single room. After six hours the anaesthetic was stopped for approximately two minutes, but tetanic contractions immediately developed. Rigidity of all muscles and marked ankle clonus were present. The thiopentone-suxamethonium drip was therefore continued for another six hours, then stopped again. No signs of contractions occurred, the limbs and

neck muscles remaining quite flaccid. Altogether 1 pint (570 ml.) of normal saline and 1½ pints (850 ml.) of glucose-saline, containing 3.25 g. of thiopentone and 500 mg. of suxamethonium, were given in 12 hours.

On stopping the anaesthetic 3 gr. (100 mg.) of phenobarbitone sodium was injected intramuscularly. The cuffed endotracheal tube was replaced after six hours by an ordinary tube, so as to prevent damage to the trachea by pressure.

The following day the boy merely complained of some back pain and a sore throat, otherwise he was quite well. He was discharged after a week's observation.

A large amount of strychnine was found in the gastric contents and the urine.

COMMENT

As in the treatment of tetanus so in this case of strychnine poisoning, complete control of the convulsions by an anaesthetist using a general anaesthetic plus a muscle relaxant is required.

It was of particular importance to aspirate the stomach after induction of anaesthesia, for a quantity of strychnine was found in the mucous gastric contents, although no food was recovered and ingestion of strychnine had taken place one and a half hours previously. The need for rapid treatment is shown.

It is of interest that in some cases of strychnine poisoning a reappearance of convulsions has been reported more than 48 hours after initial treatment. Strychnine is apparently again released into the blood stream by the liver. In the above case no further symptoms or signs of strychnine poisoning appeared.

Acute Haemolytic Anaemia following Sulphadimidine Therapy

Acute haemolytic anaemia is now a recognized complication of medication with the sulphonamide group of drugs. It was first described by Harvey and Janeway (1937) during sulphanilamide therapy. Since then many further cases have been reported with sulphathiazole (Rothstein and Cohn, 1942), with sulphapyridine (Ravid and Chesner, 1940), and with sulphadiazine (Ross and Paegel, 1946). In addition, comprehensive reviews have been published by Wood (1938) and by Long *et al.* (1940).

No case, however, has yet been recorded of haemolytic anaemia following sulphadimidine ("sulphamezathine") therapy; indeed, toxic effects following the use of this drug are rare and usually limited to mild nausea and vomiting, and it is generally regarded as the "best sulphonamide for routine use" (*National Formulary*, 1955, p. 41).

CASE REPORT

A boy aged 2½ years was admitted to hospital on January 22, 1956. Five days previously he had developed acute otitis media preceded by 24 hours' diarrhoea, for which he had been given 1 g. of sulphadimidine, followed by 0.5 g. six-hourly to a total of 8 g. On January 20 he suddenly began passing dark urine and became progressively jaundiced.

On examination in hospital he was extremely jaundiced and obviously pale and still had diarrhoea, the fluid motions being dark brown in colour with no visible blood or mucus. There was tachycardia, the pulse rate was 160, and the temperature 99.4° F. (37.4° C.). The liver was enlarged to two fingerbreadths, but the spleen could not be felt. A history of measles in August, 1955, was subsequently revealed for which he had then received a short course of sulphadimidine to a total of 3 g.

Laboratory Findings on Admission.—Hb 24% (3.55 g.); W.B.C., 25,000 per c.mm. (segmented polymorphs 63%, metamyelocytes—band forms 3%, lymphocytes 26%, monocytes 8%); the red cells showed anisocytosis and polychromasia and nuclear remnants; 15 normoblasts were counted per 100 W.B.C.s; platelets plentiful; reticulocytes, 11%; Race-Coombs test; both the direct and the indirect were negative. The blood serum was dark brown in colour and showed spectroscopically typical bands of methaemoglobin. Schumm's test was positive. Fragility test of the red cells was normal. The urine was light red in colour and contained free haemoglobin and granular casts, but no red blood cells.

A diagnosis of acute haemolytic anaemia was made and treatment with whole blood transfusion, 2 pints (1,140 ml.), was immediately started together with cortisone, 12.5 mg. six-hourly, by mouth, for six days. Thereafter he made a gradual but uneventful recovery, the haemoglobin level gradually climbed to 95% (14 g.) by February 3, and the only abnormality remaining in the urine on discharge was a slight trace of albumin.

It is interesting to note that the child had received a small amount of sulphadimidine five months before, without any apparent ill effect, and this substantiates the theory of sensitization.

I am grateful to Dr. T. S. Rodgers, consultant paediatrician, and to Dr. K. R. Lown for the opportunity of reporting this case.

Generalized Vaccinia

The following is a report of a fatal case of generalized vaccinia occurring in an infant aged 5 months who had been vaccinated sixteen days before death.

CASE REPORT

The patient was a healthy, well-nourished male infant of 5 months who had been vaccinated on January 17, 1956. The vaccination took normally, but on January 27 (ten days after vaccination) a vesicle appeared on his right leg, and another on his trunk. At this stage fresh vesicles continued to erupt on different parts of his body until the day before admission. On January 29 he vomited, went off his feeds, and passed two or three loose stools.

He was admitted to hospital on February 2 because of his skin rash and a generalized convulsion lasting a few minutes which had occurred about one hour before admission. Following the convulsion he had remained semi-conscious.

On admission the infant was conscious but drowsy. His temperature was 95° F. (35° C.), pulse 168, and respirations 50. He had a generalized vesicular rash distributed over the whole body, including the scalp, both palms, and the sole of the left foot. Some of the vesicles were umbilicated, some haemorrhagic, and some were beginning to crust. Over the left deltoid region the primary vaccination was a raw bleeding area involving the whole skin thickness, 5 cm. in diameter, with undermined, indurated edges. There were no secondary vesicles at this site. Examination was otherwise negative and in particular there were no signs of encephalitis. The infant collapsed and died three hours after admission.

The mother was vaccinated successfully at 7 years and the father in infancy. Neither had been revaccinated. There were no other children.

Post-mortem Findings.—In addition to the skin lesions already described there were numerous petechiae on the

peritoneal surface of the liver, otherwise nothing grossly abnormal was found and there was no evidence of encephalitis. Specimens were taken for virus study and histology.

Histology.—*Skin vesicle:* The vesicle appeared as a circumscribed area of destruction of the epidermis. The appearances suggested autolysis of the epidermal cells *in situ*, leaving clear spaces with the supporting stroma intact and the surface entire. The vesicle contained a few degenerate leucocytes but there was no surrounding or subjacent cellular infiltration. No inclusion bodies were seen by haematoxylin or eosin nor by erythrosin and toluidine blue stains. *Liver:* The petechiae consisted of small zones of necrosis of the liver cells and associated haemorrhage. *Brain:* There was no evidence of encephalitis.

Virology.—Culture, on the chorio-allantoic membranes of developing chick embryos, of the fluid obtained from abdominal vesicles showed the presence of a virus. A further series of chick embryo inoculation tests with diluted virus and virus mixed with antivaccinal serum showed that complete neutralization and inhibition of growth was obtained when antivaccinal serum was added. The virus grew normally without the serum. This result indicated that the virus was vaccinia.

COMMENT

Serious complications of vaccination against smallpox are very rare. According to Jubb (1943) generalized vaccinia occurs in 1 in 100,000 vaccinations. Laurance, Cunliffe, and Dudgeon (1952) give an incidence of 1 in 25,000 for infants vaccinated in the first year of life. Keidan, McCarthy, and Haworth (1953) describe a case of fatal generalized vaccinia and mention that of eight cases known to them seven had been fatal. Including the case reported above the mortality rate of generalized vaccinia in childhood is about 90%.

It is a well-known fact that people with a damaged skin—for example, burns or eczema—are more prone to develop generalized vaccinia than people with a healthy normal skin. Our patient had no evidence of any skin condition. The distribution of the lesions was more in keeping with haematogenous spread rather than auto-inoculation.

Jubb (1943) suggests the following points as being helpful in making the diagnosis of generalized vaccinia: "(1) Auto-inoculation should be excluded. (2) The eruption does not appear earlier than the fourth, and seldom earlier than the ninth, day after vaccination. (3) The eruption must be elsewhere than in the neighbourhood of the vaccination site. (4) There must be a vesicular stage."

We acknowledge the help of Professor A. MacDonald in identifying the virus.

The *Transactions of the Hunterian Society*, vol. 14, records the work of the society for the session 1955-6. It includes Mr. A. DICKSON WRIGHT's presidential address on "How Patients Have Deceived Me," a striking collection of cases of simulated disease and artifacts which serve to show how difficult diagnosis may be sometimes. Also included in the volume is the Hunterian Society's Oration, "Reflections on the Hunterian Method," delivered by the then Sir HENRY COHEN last February, a lecture on "Lung Resection in the Treatment of Pulmonary Tuberculosis" by Professor J. J. NUBUOE; Dr. JOHN FRY's prize essay, "Headache in General Practice," and a useful discussion on sex instruction of the young.

Reviews

VARICOSE VEINS

The Pathology and Surgery of the Veins of the Lower Limb. By Harold Dodd, Ch.M., F.R.C.S., and Frank B. Cockett, M.S., F.R.C.S. Foreword by R. R. Linton, M.D. (Pp. 462 +ix; illustrated. 65s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

"We would say that every 'bad' leg can be materially improved by systematic diagnosis and treatment." This statement, made early in the book, gives a clue to the authors' approach to their subject—an approach which in clarity and detail brings refreshing breath to the study of venous disorders. It is both pleasurable and stimulating to read this admirable monograph, which deals primarily with varicose veins and venous ulcers of the leg. The authors have a very large experience in this field and have gathered besides a great deal of relevant information. They have been assisted by Dr. S. T. Anning and Mr. C. I. Murphie, who contribute valuable chapters on the historical aspects and on the physiology of the leg veins respectively. One learns from Dr. Anning that in 1550 B.C. the author of a papyrus advised against operation for varicose veins—of a remote origin of this branch of surgery. With these two chapters is an excellent one on the surgical anatomy of the leg veins; together they form Part I of the book. Part II is concerned with varicose veins and covers all aspects of their care. Stress is properly laid on exact diagnosis based on a full knowledge of the variable anatomy of the superficial and communicating veins. Part III deals with the investigation and surgery of the deep and communicating veins and of venous ulcers. The importance of incompetent communicating veins at the ankle in the genesis of ulcer, made clear in Mr. Cockett's previous writings, is given due prominence.

The book is generously illustrated by photographs and diagrams of high quality. One joins with Dr. R. R. Linton, of Boston, who writes a foreword, in believing this to be the best book on the subject; moreover, it is likely to be a long time before it is bettered.

C. J. LONGLAND.

GROWING UP

Youth: The Years from Ten to Sixteen. By Arnold Gesell, M.D., Frances L. Ilg, M.D., and Louise Bates Ames, Ph.D. (Pp. 340 + xv. 25s.) London: Hamish Hamilton. 1956.

This is a sequel to a previous book, *The Child from Five to Ten*, and is based mostly on a study of 60 to 88 children at each age from 10 to 16. The majority of the children were of a favourable socio-economic status, representing a high average to superior level of school population. Most of the fathers had professional or skilled occupations. The book attempts to interpret the manifestations of adolescence under the following headings: (1) maturity profiles; (2) maturity traits—"total action system, routines and self care, emotions, the growing self, interpersonal relationships, activities and interests, school life, ethical sense, and philosophical outlook"; and (3) maturity trends—the sequences and gradients of growth. The authors write: "The maturity profiles, maturity traits and the maturity trends are not to be regarded as rigid age norms nor as models. They simply indicate the kinds of behaviour, desirable or otherwise, which tend to occur at certain stages and ages. Every child has an individual pattern of growth unique to him. The profiles, traits, and trends are designed to suggest the various maturity levels at which he is functioning." It is inevitable and natural that the various maturity traits and trends should reflect the American way of life, with particular regard to matters of discipline and attitudes to sex, and this, together with the fact that the children come from a highly selected group, makes the findings less universally applicable than those of earlier books, particularly books dealing with infancy. Yet

all in this country who are concerned with the care of children aged 10 to 16 will find much of interest in this work.

R. S. ILLINGWORTH.

INSECTS OF MEDICAL IMPORTANCE

A Handbook for the Identification of Insects of Medical Importance. By John Smart, M.A., D.Sc., with chapters on Fleas by Dr. Karl Jordan, F.R.S., and on Arachnids by R. J. Whittick, B.Sc. Third edition. (Pp. 303 + xi; 13 plates. 40s.) London: British Museum (Natural History). 1956.

The first edition of this now well-known guide to the identification of insects of medical importance was published in 1943 and reviewed in this *Journal* on January 1, 1944; a second impression, which contained a new index and some minor corrections, appeared later in the same year. The success of the work resulted in the publication of a second edition in 1948, in which knowledge of such medically important insects as fleas and malaria-carrying mosquitoes was brought up to date and many new drawings were added to the sections dealing with the morphology of the Diptera, while the chapter on the distribution and recognition of the different species of tsetse flies was modified in accordance with recently acquired knowledge. The present, third, edition is a photo-litho reprint of the second edition, with, as the foreword explains, such corrections in the text as "have been possible without altering the make-up of the type-face." These changes appear to be few and of little significance, but a further effort has been made to bring the edition up to date by the addition of six pages of addenda and corrigenda, three of them by Mr. P. J. Mattingly, who lists the major revisionary works published since 1947 on the disease-carrying mosquitoes, and three by Dr. Smart, who deals similarly with books and papers on the other arthropods.

There is no doubt that the demand for this book will continue, and it is to be hoped that when the present edition is exhausted the fourth edition will be fully revised, particularly as regards the Arachnida. It is suggested that any economy necessitated by such expansion of the text could be achieved by omitting those sections which are concerned with arthropods of veterinary, as distinct from those of medical, importance.

The present volume maintains the very high standard of its predecessors, and although, alas, its price is £2, as compared with the 15s. charged for the first edition, it is still good value for the money.

R. M. GORDON.

CANCER PAIN

Management of Pain in Cancer. By Eight Contributors. Edited by M. J. Schiffrin, Ph.D. Foreword by Warren H. Cole, M.D. (Pp. 245; illustrated. 33s.) Chicago: Year Book Publishers Inc. London: Interscience Publishers Ltd. 1956.

This book deals with the management of pain in the terminal stages of incurable malignant disease—a formidable problem which confronts the practising doctor almost daily, and yet one which has been somewhat neglected by the medical profession. The aim of the work is to present a simple yet comprehensive description of pain-relieving procedures, together with a discussion of the indications and contraindications for the use of each method. Though the book is written primarily for the family doctor, there are few clinicians who would not profit from its study. In the seven chapters which make up the volume the authors discuss analgesic drugs; nerve blocks; neurosurgical and surgical palliative procedures; chemotherapy, including the use of hormones; radiation; and the psychological management of patients suffering from painful incurable disease. The advice given is clear, concise, and up to date. The drawbacks to the book are its price in Britain, and the somewhat unfamiliar names of a few of the drugs mentioned. To many British doctors it will be unbelievable that Americans can be made at all comfortable on their deathbeds without recourse to heroin.

D. M. DUNLOP.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 10 1956

MORTALITY AND SMOKING

Five years ago Dr. R. Doll and Professor A. Bradford Hill started an investigation into the mortality of British doctors in relation to smoking habits. Their plan was to ascertain the smoking habits of a defined group of men and women, and subsequently to obtain information about the causes of deaths among this group. It was hoped that this method might meet some of the criticisms of the retrospective investigations of the effect of smoking upon the incidence of cancer of the lung which had been conducted by the same investigators¹ and by several other groups²⁻⁵ in various parts of the world, and which had all shown that smoking, especially of cigarettes, greatly increases the risk of developing lung cancer. For this prospective investigation, members of the medical profession of the United Kingdom were asked to reply to a simple questionnaire about their past and present smoking habits. Arrangements were made for the causes of death of all doctors subsequently to be made known to the investigators. The preliminary report on this investigation was published in 1954,⁶ after two and a half years, when the lung cancer deaths among the rather more than 40,000 doctors who had provided adequate replies to the questionnaire amounted to 36. Even at this early stage analysis of the data gave strong confirmation of the earlier retrospective investigations. The second report, published in the opening pages of the *Journal* this week, confirms these preliminary conclusions, refutes criticisms that were levelled against them, and produces some interesting information about the relationship of smoking to other causes of death.

The main part of the analysis concerns male doctors aged 35 and over, among whom there were 1,714 deaths, including 84 from lung cancer. The doctors were classified into non-smokers, who had never consistently smoked as much as 1 g. of tobacco (the

equivalent of one cigarette) a day for as long as a year; light smokers (1-14 g. daily); moderate smokers (15-24 g. daily); and heavy smokers (25 g. and more daily). There was a steady gradient of incidence of death from lung cancer with increasing amount smoked. The standardized rates per thousand were: non-smokers 0.07, light smokers 0.47, moderate smokers 0.86, and heavy smokers 1.66. Although the authors do not comment on this point, it can be seen from one of their tables that the mortality from lung cancer among non-smokers was concentrated in the older age groups, whereas that for heavy smokers was distributed much more widely through the years from early middle age onwards. The mortality from cancer of other sites was almost the same in non-smokers and smokers, the figures being 2.04 and 2.02 per thousand respectively; this observation refutes the suggestion^{7,8} that smoking may simply determine the site of cancer in persons already destined to develop this disease at some site. The total mortality from all causes among smokers was significantly higher than among non-smokers, the rate for non-smokers being 13.25 per thousand and for heavy smokers 18.84. A convincing answer is given to a question of great importance for all smokers: does giving up smoking diminish the risk of developing lung cancer? For smokers who, when the questionnaire was completed, had given up smoking more than 10 years, the mortality rate from lung cancer was 0.35 per thousand; for those who had given up less than 10 years it was 0.59, while for those who were still smoking it was 1.03. The authors point out that the method of investigation is such as to minimize the trends in this, as in other, phases of the investigation; some smokers who were still smoking when the questionnaire was completed may have given up subsequently, and some who had given up at that time may have started again subsequently. In view of this the evidence must be accepted as indicating beyond doubt that giving up smoking does diminish the liability of a smoker to subsequent development of lung cancer. Those who were continuing to smoke 25 or more cigarettes daily at the beginning of the investigation suffered a mortality from lung cancer nearly 40 times that of the non-smokers. The suggestion from earlier investigations that pipe smoking is less dangerous than cigarette smoking is confirmed. Pipe smoking appears to have been about one-third as dangerous as cigarette smoking. The gradient of mortality from lung cancer with increasing consumption of tobacco was found to exist for each year examined separately. It was found that the smoking habits of doctors resident in rural and urban districts were remarkably

similar, so that the results cannot have been affected by varying exposure to atmospheric pollution.

In the same investigation a highly significant trend of increased mortality with increasing consumption of tobacco was found for chronic bronchitis, the death rate ranging smoothly from 0.12 per thousand for non-smokers to 0.72 for heavy smokers. A suggestive gradient was found for coronary thrombosis, and smaller gradients, not statistically significant, for pulmonary tuberculosis and peptic ulcer.

That the danger of smoking is not confined to the increased risk of lung cancer is further demonstrated by another investigation which is reported in the *Journal* this week by Dr. C. R. Lowe (p. 1081). A remarkable feature of the mortality from pulmonary tuberculosis in recent years has been the shift of the peak of mortality in men towards the older age groups. No convincing explanation of this phenomenon has been advanced, though several hypotheses have been considered. There is good evidence that much of the mortality among middle-aged and older men must be attributed to breakdown of inactive disease acquired in earlier life. The question arises whether this reactivation among older men may be due at least in part to the same factor which is known to be responsible for the increasing mortality from lung cancer in the same group—namely, smoking. Dr. Lowe therefore investigated the smoking habits of 1,200 patients with notified respiratory tuberculosis in sanatoria and chest clinics in Birmingham, comparing them with a control population in the same area. This investigation showed that among patients with pulmonary tuberculosis over 30 years of age there was a significant deficiency of non-smokers and light smokers and an excess of moderate and heavy smokers as compared with the controls. These observations suggest that smoking may be an important cause of the breakdown of inactive pulmonary tuberculosis.

The consumption of tobacco in Britain has risen steadily since 1948, and in the first six months of 1956 tobacco consumption was 3% more than for the corresponding time last year.⁹ This increase in tobacco consumption has continued in spite of the fact that the public have had access to the knowledge which has been accumulated about the noxious effects of smoking, since this has been freely discussed in the press, albeit sometimes in a somewhat confusing manner. According to authoritative medical opinion specific steps should be taken to make the facts known in a more effective way. The response of the Minister of Health to advice on these lines from his Standing Medical Advisory Committee¹⁰ was to make a statement in the House of

Commons that the Government would take such steps as were necessary to ensure that the public were kept informed of the relevant information as and when it became available, but that in the present state of knowledge a national publicity campaign would not be appropriate.¹¹ The weight of evidence that smoking has a causal connexion with lung cancer, already sufficient to convince an unbiased observer, has been greatly increased by the latest report from Doll and Bradford Hill. This report also gives statistical evidence of what many had suspected, that smoking is an important factor in determining death from chronic bronchitis; and the evidence produced by Lowe clearly implicates smoking as a factor in the breakdown of pulmonary tuberculosis. The new evidence now published makes it more than ever imperative for all concerned to see that the public is repeatedly informed of the possible dangers to health and life from smoking cigarettes.

REHABILITATION

The development of the modern concept of rehabilitation is due very largely to the pioneer work of Sir Robert Jones and to the consequences of two world wars. It is regrettable that the effect of Sir Robert Jones's teaching and leadership between the wars was greater upon American than upon British medicine, although the B.M.A.'s Committee on Fractures in 1935 did stimulate a restudy of some of the problems of rehabilitation.¹ The social legislation of the late 1940's made no exclusive provision for the disabled, but did include many administrative measures to meet their special needs, so that the numerous Acts did cover most of the field, although it was not always clear which Government department was responsible for a particular service. In retrospect it is perhaps unfortunate that Mr. Ernest Bevin, in his anxiety to maintain full production during the second world war, introduced the Ministry of Labour rather hurriedly into full responsibility for the training and resettlement of disabled persons. The Tomlinson Report² of 1943 which followed, although stating in its first conclusion that "rehabilitation in its widest sense is a continuous process," proceeded, for administrative convenience, to divide rehabilitation into medical and social or industrial aspects, a division never really acceptable to medical opinion. The

changing nature of disability away from traumatic injuries to disorders such as peptic ulcer, chronic bronchitis, osteoarthritis, hypertension, circulatory disorders, and the neuropsychiatric disturbances has placed increasing importance not only upon the social and welfare aspects of rehabilitation but also upon the need to make greater provision for people suffering from partial disability. The prolonged period of full employment, during which the loss of productivity from strikes has been insignificant compared with the loss due to sickness, has also emphasized the magnitude of the problem.

The consequence of these developments and the administrative difficulties encountered by voluntary organizations and the medical profession, as well as the increasing awareness of the importance of rehabilitation by the public, led the Ministers of Labour and National Service and of Health and the Secretary of State for Scotland to set up in 1953 a select committee, under the chairmanship of Lord Piercy, "to review in all its aspects the existing provision for the rehabilitation, training and resettlement of disabled persons, full regard being had to the need for the economy in the Government's contribution and to make recommendations." The committee has received written evidence from over 150 sources, oral evidence from the representatives of nearly 50 organizations, including twice by the British Medical Association, and has visited many centres both voluntary and statutory. The evidence submitted by the Council of the B.M.A., both written and oral, receives a most generous tribute from the committee in its report,³ which was published last week. The committee has exhaustively reviewed and summarized existing provisions as well as frankly discussing many of the problems and criticisms submitted in evidence. It is particularly unfortunate that the terms of reference, "To review in all its aspects the existing provision for the rehabilitation, training and resettlement of disabled persons," suggested that the word rehabilitation did not cover the whole process of restoration of function, in contrast to the view expressed in the British Medical Association's report⁴ of 1946 and reiterated in the written evidence⁵ submitted by the Council to the committee in 1954. Owing to the terms of reference the committee has confined the use of the term rehabilitation "to medical and surgical treatment designed to restore physical and mental functions." This artificial attempt to divide rehabilitation is unfortunate, because throughout the report the concept of rehabilitation as a continuous process including the restoration of the patient to self-supporting work is acknowledged. Just credit is given to the many pioneering experiments which

have been made in this country on behalf of the disabled, and the report stresses that what is most needed is a greater knowledge among the medical profession, industrialists, trades-union leaders, and the public of what could be achieved with a more widespread application of the knowledge available. The recommendation for the publication of special booklets for the medical profession and for social workers and for the public was suggested by the Council of the B.M.A. in its evidence, and it is to be hoped that, although several Ministries collectively are recommended to issue such publications, the responsibility will be accepted without unnecessary interdepartmental delay.

Criticism has been made outside the profession of the importance attached by the Council in its written evidence to the role of the general practitioner, but the frequent references in the report to the important position of the general practitioner in the rehabilitation service are encouraging. Two examples are quoted below:

"The Committee recognizes the many calls on the general practitioners, but it considers (with the British Medical Association) that he can and should undertake fuller responsibility for rehabilitation and resettlement to some of his patients than he normally does now."

"Officers of the local authority, visiting a disabled person at home, should form part of a domiciliary team under the clinical leadership of the general practitioner, with whom all members of the team should be in personal contact in order to bring the maximum benefit to a disabled person living in his own home."

The committee has recommended many of the suggestions made by the Council in its written evidence—the need to obtain reliable information about the real needs of a rehabilitation service; the potentialities of a resettlement clinic; the need for the provision of planned convalescence; the amendment of the regulations for juveniles to cover the period from leaving school until attaining the age of 16; the development of work and welfare schemes for the handicapped both in special centres and in the home.

The committee, while admitting the interest of several Ministries in some aspect of rehabilitation, seems to have been reluctant to suggest administrative reform and is content to leave the co-ordination of facilities to the standing interdepartmental committee. Many experienced in the problems of rehabilitation will regret this decision. The recommendation for the establishment of resettlement clinics—stressed by the B.M.A.—without any recommendation that they should have statutory powers is unlikely to lead to their useful development. Medical interviewing committees were recommended by the Ministry of Health many years ago, and only exceptionally, where there has been someone keenly interested in rehabilitation

(usually a respected and senior member of the hospital staff) has much success been achieved. The loss to industry and in morale arising from the present methods of certification, through not recognizing a state of partial fitness, has been accepted by the committee, but the report fails to recommend even a slight modification of the sickness certificate to include a phrase that in the practitioner's opinion the patient is fit to undertake some work, if not fit for full work, and that he might benefit from a period of rehabilitation. As to the misunderstanding about the degree of fitness necessary for admission to an industrial rehabilitation unit, the report states: "All that is required is that the man should be regarded by the unit doctor as likely to be fit for work at the end of the rehabilitation course. . . . The committee accordingly trusts that removal of any misconception about the eligibility on medical grounds for admission will lead to more industrial workers being sent to these units at an early stage of their recovery." The lack of any definite recommendation, however, is unfortunate, and may lead, with a greater use of the service, to even more friction between the medical profession and the administrative branches of certain departments.

Throughout the report great stress is laid upon the role of three individuals—the medical practitioner whatever his specific standing, the disablement resettlement officer, and the social worker. It is evident that much criticism has been made by those submitting evidence, including the Council of the B.M.A., of the qualifications and training of the disablement resettlement officer; yet the suggestions of the committee for improving the quality, the training, and the conditions of service for such officers are little more than pious hopes—suggestions which include the possibility that the preliminary training be increased to more than three days, some initial supervision on the job, and the selection of individuals from the general staff of the Ministry of Labour for approximately five years for work in this branch.

One important section of the committee's terms of reference related to the need for the utmost economy in the Government's contribution, and on this the report states: "The Committee is satisfied that the existing state of affairs discourages and retards developments which are essential." The specific new proposals are for the granting of approximately £6,000,000 to the local authorities for the development of welfare schemes for the handicapped and a suggestion that the Ministry of Health should deploy "its existing resources in staff and in accommodation both for out-patients and in-patients at the convalescent stage." The Piercy Report, so long awaited, will perhaps disappoint the enlightened, but it does

give a valuable account of work well done, though limited in scope, and which, despite the limitations imposed by the need for economy, has gone far towards laying the foundation of a complete rehabilitation service. The committee acknowledges the British Medical Association's submission that the medical profession has a leading part to play in rehabilitation and that the rate of development and the efficiency of the service will be dependent very largely on the initiative and energy of the profession.

TREATMENT OF BARBITURATE POISONING

There is no agreement yet on the best way to treat patients poisoned by barbiturates. The dangers of too vigorous analeptic therapy are now realized; they include convulsions, vomiting (with aspiration of gastric contents), and cardiac arrhythmias. At the other extreme claims are made that simple management as for the anaesthetized comatose patient is enough. The criteria of severity used in different series vary, and thus comparison of the results of different treatments is hampered. Many cases are mild, and the overall mortality is under 10%. It is the severely poisoned patient in deep coma with low blood pressure, subnormal temperature, and absent tendon reflexes who presents the most difficult problem. J. T. Wright,¹ using ultra-violet spectrophotometric methods, showed a quantitative relationship between barbiturate levels in the blood and the degree of coma. As barbiturates are evenly distributed in the body water, the dose taken can be calculated from the blood level and body weight, but the dose is not a simple measure of severity of poisoning, for other factors such as senility and disease play a part.

It is claimed² that bemegride ("megimide"), 50 mg. intravenously every five minutes in a total dose of up to 1 g. with amiphenazole ("daptazole") 15 mg. by the same route in a total dose of up to 0.3 g., will quickly bring the patient into a "safe state" from which recovery will follow. This week Dr. A. Worlock reports at p. 1099 of the *Journal* a series of 12 cases treated successfully with these drugs in smaller doses than this. Chest infection did not occur, and stay in hospital was short. The successful treatment on these lines of a child as young as 15 months has also been reported.³ However, it has not yet been

⁸ Merivale, W. H. H., and Smith, A. J., *ibid.*, 1955, 2, 1353.

shown conclusively by studies of blood levels that the drug is eliminated faster or that complete recovery is quicker on treatment with bemegride than it would have been with supportive measures and prevention of pneumonia alone. There is thus some doubt about the reputed antagonistic effect. A new method which may rescue the occasional critical case is haemodialysis. It has been shown⁴ that 40% of a dose of phenobarbitone in dogs can be recovered by this method. L. B. Berman and colleagues⁵ successfully treated eight patients by this method and used repeated spectrophotometric determinations of barbiturate in the plasma as a control. Attempts to simplify the method by estimations of barbiturate in the urine are of no value, because secretion of urine is suppressed in barbiturate coma. Exchange transfusion might be a more practicable substitute.

But new methods must not lead to neglect of the basic symptomatic treatment of the poisoned patient. Artificial respiration by the Holger Nielsen method may be imperative and should be continued at hospital by mechanical methods with the help of the anaesthetist. In one case⁶ hypothermia at 84.2° F. (29° C.) from exposure on the sea shore may have helped recovery by cutting down oxygen requirements. Gastric lavage carries the risks of aspiration of gastric contents, of forcing them into the intestine, but if these are avoided by preliminary suction with a Senoran's evacuator, keeping the head lower than the stomach and using less than 1 pint (570 ml.) of fluid at a time, this method of removing the poison is an advantage. Various non-specific measures will prevent the doctor from being robbed of success by some complication such as pneumonia. Penicillin, A.C.T.H., potassium chloride, and maintenance of blood pressure are all important.

A study of the biochemical changes induced by barbiturates was suggested by the observation of R. A. Hunter and H. P. Greenberg⁷ that the symptoms of chronic barbiturate intoxication resembled those of an islet-cell tumour of the pancreas. Hunter and colleagues⁸ found that abnormally high levels of pyruvate and glucose occurred after glucose was given to patients receiving large doses of barbiturates, but not if vitamin-B complex had been given beforehand. The altered electroencephalogram of chronic barbiturate poisoning was also improved. The bearing of these researches on acute barbiturate poisoning remains to be worked out. Two methods of getting rid of the poison at one time advocated may be mentioned only to be condemned. Drainage of cerebrospinal fluid is not effectual, for the levels of barbiturate in the C.S.F. are lower than in the blood. Forced diuresis is of no value, since high rates of

urine flow do not significantly increase the renal clearance of barbiturates.

When confronted with the emergency it should not be forgotten that alcohol, aspirin, and some other common poison may have been taken as well as barbiturates, and the case may well have medico-legal aspects, so that specimens should be kept. The doctor's duty does not extend to informing the police.

LUMBAR SYMPATHECTOMY FOR ARTERIOSCLEROSIS

There is no doubt that lumbar sympathectomy can be of great benefit in the treatment of arteriosclerosis of the lower limbs. Good results follow wise selection of patients for this operation, and in this connexion some interesting points are raised by E. A. Edwards and C. Crane,¹ who have recently published a report on 100 patients followed up for five years after operation. They believe that their group of patients gave a fair sample of the disease; of the 100 patients, whose ages varied from 34 to 82 years, 79 were men and 27 of the total group were diabetic. Thirty-five of their patients died within the five-year period, the majority from coronary heart disease. Diabetes was the only general factor affecting the death rate, and 55.5% of their diabetic patients died as compared with 27% of the non-diabetic group.

The pattern of the local disease before operation bore some relationship to death or survival. A rapid progress of disease before sympathectomy was common in those who died within the five-year period, and established or threatened gangrene was often the presenting symptom in this group. The previous loss of the contralateral limb was associated with a particularly bad prognosis, and five out of nine such patients died within the follow-up period. It was also evident that survival was short in those patients who responded poorly to operation. Fifteen patients had a poor immediate response to sympathectomy, and of these only five survived five years post-operatively. Major amputations proved necessary in ten patients. Seven of these were done soon after operation and the remaining three within a year of operation. The incidence of major amputations was higher in the diabetic group, but a greater proportion of these patients had limbs which were in a desperate condition pre-operatively. Deep necrosis of the foot or leg inevitably led to amputation despite sympathectomy. It was noticeable that most of the serious complications occurred in the early post-operative period, and that once the difficulties of the first few months after sympathectomy were overcome the limb was usually safe. At the end of five years the state of the limb was good in 47 of the 65 surviving patients, fair in thirteen, and poor in five. Claudication was rarely overcome completely but was considerably improved in all patients in the good category. These

¹ Edwards, E. A., and Crane, C., *A.M.A. Arch. Surg.*, 1956, 72, 32.
² Berry, R. E. L., Flotte, C. T., and Collier, F. A., *Surgery*, 1955, 37, 115.
³ Pratt, G. H., *Surg. Gynec. Obstet.*, 1955, 100, 43.
⁴ Troensegaard-Hansen, E., *British Medical Journal*, 1956, 2, 262.

results are somewhat better than those reported in two similar follow-up studies by R. E. L. Berry, C. T. Flotte, and F. A. Collier² and by G. H. Pratt.³ Edwards and Crane feel that this is due to their more discerning choice of patients for operation.

It is clear that the proper selection of patients for lumbar sympathectomy is of great importance. How is this selection to be made? In the past many methods of pre-operative testing, such as response of the skin temperature to spinal analgesia or reflex vasodilatation, have been tried and found wanting, and the decision is best made on clinical grounds alone. In general, lumbar sympathectomy will be followed by a poor result if the pre-operative course of the disease has been rapid, and it is well established that such operative intervention for acute arteriosclerotic ischaemia may precipitate gangrene. Again, sympathectomy will usually fail if gangrene of a major part of a limb threatens, and the operation cannot be expected to save a limb in which the signs of widespread gangrene are unmistakable. Indeed, the correct timing of operation in the course of the disease is most important, and sympathectomy is best employed as a prophylactic treatment in the early stages of nutritional failure rather than as an emergency measure for limbs already in a desperate condition.

A good result can be expected in patients with local superficial necrosis or mild pain at rest without gross loss of tissue, and an excellent outcome will follow sympathectomy if the ischaemia is distal and if one of the pedal pulses remains palpable. If the major symptom is claudication the result of operation will be good so far as preservation of the limb is concerned, but complete relief can be expected only for the patient whose symptoms are mild. In the absence of nutritional change severe claudication is rarely an indication for lumbar sympathectomy. The scope of surgery in arteriosclerosis of the lower limb has widened recently with the introduction of amion implantation.⁴ Further experience of this apparently promising procedure is needed before it can be adequately compared with the alternative methods of treatment.

NOBEL PRIZE FOR CHEMISTRY

Sir Cyril Hinshelwood, P.R.S., shares this year's Nobel Prize for Chemistry with Professor Nikolai Semenov, director of the institute of chemical physics of the Soviet Academy of Sciences. The award is for their work on the kinetics of chemical reactions. Professor Semenov is the first Soviet citizen, though the fourth Russian, to have received a Nobel Prize; the other three were Pavlov (1904) and Metchnikoff (1908), who were awarded the prize for physiology and medicine, and Ivan Bunin (1933), an émigré, who was awarded the prize for literature.

Hinshelwood's researches in chemistry caused him to be elected a Fellow of the Royal Society at the age of 31, and he was appointed Dr. Lee's Professor of Chemistry at Oxford University eight years later in 1937. Now aged 59, he is probably best known to the medical

⁴ *The Chemical Kinetics of the Bacterial Cell*. C. N. Hinshelwood, Oxford, 1946.

profession for the bacteriological investigations he has carried out in the last decade or so. In these he has extended the range of his kinetic studies from molecules to microbes. In a book¹ and in an impressive series of papers with his colleagues he has sought to explain in physico-chemical terms the biological responses of bacteria to changes in their environment. Much of this work has been centred on the undoubted fact that bacteria can be "trained" to become resistant to drugs to which they were originally sensitive. The orthodox view is that permanent drug resistance arises by selection of drug-resistant mutants which were present often in a very small proportion of the cells in a bacterial culture before they had any contact with the drug. Hinshelwood, while not denying that this can occur, claims to have shown that more or less permanent changes in resistance to a drug can be induced in bacterial cells by prolonged exposure to the drug, as a result of a change in the enzyme patterns of the cell impressed upon them by the drug. Some geneticists have thought that this smacks of Lamarckian ideas, but, as Hinshelwood and others have pointed out, the germ-plasm of microbes is not, as in complex animals and plants, screened from the action of the environment. Changes which affect the cytoplasm may more easily affect the nuclear material in bacteria than in more complex animals, and many other workers have shown that such properties as resistance to streptomycin can be conferred on drug-sensitive bacterial cells by means of transforming principles extracted from resistant cells. Such principles are specific deoxyribonucleic acids and are in fact specific mutagenic agents. The idea, therefore, that permanent modifications can be induced in bacterial cells by changes in their environment is by no means as bizarre as it might appear to be at first sight. Hinshelwood with characteristic vigour and determination has marshalled strong arguments in support of his provocative and stimulating ideas on this central problem of microbiology.

SIR WILLIAM GILLIATT MEMORIAL FUND

The death of Sir William Gilliatt a few weeks ago was a great loss to the medical profession in Britain, for he was one of those from whom wise guidance was expected as a matter of course. By his own work and example he contributed much to his chosen specialty, and he would have been the first to approve the objects of those who have decided to raise a Memorial Fund to commemorate his name. The Fund will be held in trust by the Royal College of Obstetricians and Gynaecologists—of which Sir William Gilliatt was a distinguished president—and will be used to foster the aims of the College, especially in encouraging research. Donations may be sent to the Sir William Gilliatt Memorial Fund, The Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, London, W.1.

The next session of the General Medical Council will open on Tuesday, November 27, at 2.15 p.m., when the President, Sir David Campbell, will take the chair and deliver an address.

HEBERDEN SOCIETY

The Heberden Society, with a membership restricted to 100 members and 20 associates, plus a handful of distinguished honorary and corresponding members, exists for the advancement of the study of the rheumatic diseases. It was founded twenty years ago, and ordinarily meets four times a year. A report of a recent clinical meeting is printed below. This year's president is Dr. ERNEST FLETCHER.

Long-term Treatment of Rheumatoid Arthritis

A clinical meeting was held at the Wellcome Foundation in London on October 19. Dr. OSWALD SAVAGE (West London Hospital) opened with a paper on the effect of prolonged adrenal-stimulation therapy upon the course of rheumatoid arthritis. Patients were given long-acting corticotrophin in a daily dose sufficient to produce clinical remission as judged by measurements of the erythrocyte sedimentation rate, tenderness of joints, and strength of grip. The 24-hour urinary output of 17-hydroxycorticosteroids was measured to assess the degree of adrenal stimulation that resulted in each case. The patients fell into three groups, said Dr. Savage: those who responded well but needed continuous adrenal stimulation to maintain their response; those who responded well and continued to respond in spite of an irregular adrenal response, as judged by their output of 17-hydroxycorticosteroids; and those who responded well and continued to respond, in spite of a diminution and finally a cessation of adrenal stimulation.

Dr. Savage stressed the difficulty caused by the variability in potency of different batches of corticotrophin gel, but self-administration of the corticotrophin and the collection of specimens of urine by out-patients for steroid assay had, he said, presented no problems. Some patients had injected themselves for as long as three years without mishap.

Dr. P. S. DAVIS (West London Hospital) had compared the results of the 17-hydroxycorticosteroid assays with the clinical response in the same group of patients. Where there was evidence of adrenal stimulation there was always some clinical response, but the converse did not always hold. In many patients maintained on the same batch of corticotrophin gel the output of 17-hydroxycorticosteroids fell. He thought this was probably due to the development of resistance to the preparation. Some patients on corticotrophin or cortisone therapy had a fluctuating output of 17-hydroxycorticosteroids. Perhaps the explanation of this was that the stress of their disease caused more, or less, utilization, thus affecting the amounts and types of corticosteroid metabolites in the urine. In this connexion Dr. Davis recalled that a large fraction of corticosteroid metabolites was not estimated in the 17-hydroxycorticosteroid assay. However, he did not think that the anomalies he had reported detracted from the value of regular corticosteroid assays in the control of corticotrophin therapy. Dr. A. J. POPERT (West London Hospital) spoke of the adrenal response of patients with rheumatoid arthritis to the stress of operation and severe infection. On several occasions he had not found the expected rise of urinary 17-hydroxycorticosteroids. He too considered that tissue utilization might alter their urinary output. (The work described above is being done with the help of the Dan Mason Foundation, West London Hospital.)

Professor F. T. G. PRUNTY (St. Thomas's Hospital) defined the factors that influence the response of the human adrenal cortex to corticotrophin as follows: (1) The potency of the corticotrophin preparation used, there being a wide divergence between labelled potency and that found on intramuscular injection. (2) The variation from patient to patient in responsiveness of the adrenal cortex to the same dose of the same corticotrophin preparation. (3) The effect of duration of treatment. The response to daily injections

increased to a maximum after a number of days which varied greatly from patient to patient. (4) The response to alterations in dosage, some patients being more sensitive than others to small changes. (5) The decreasing sensitivity to continued administration of corticotrophin seen in some patients. (6) The effect of the patient's endocrine constitution.

In the discussion that followed the need was emphasized for a pure preparation of corticotrophin that would have uniform potency and not be liable to tissue inactivation.

COLLEGE OF PATHOLOGISTS OF
AUSTRALIA

INAUGURAL MEETING

[FROM A CORRESPONDENT IN AUSTRALIA]

Three months ago, at a ceremony in Melbourne, the College of Pathologists of Australia was inaugurated. The college is to combine the function of a learned society with that of a ruling professional body, which makes it unlike any existing body of pathologists in the United Kingdom. It had its origins in the Australian Association of Clinical Pathologists, and the original move towards incorporation into a college came from Brisbane. It is hoped that the new college will encourage original research in pathology and help to raise standards in the specialty by making the approval of its censors the hallmark of a pathologist of truly consultant status. In granting the diploma, full account is to be taken of the special bent of the candidate towards one aspect or another of pathology.

The inaugural meeting on August 20 began with an impressive ceremony in the hall of the Royal Australasian College of Surgeons. After the president of the College of Pathologists, Dr. EDGAR THOMSON, had declared the proceedings open, the Australian Minister of Health, Dr. D. A. CAMERON, performed the official inauguration. In his speech the Minister, himself a medical graduate, stressed the need for the Australian profession, with its small numbers, to maintain a high standard of quality. Dr. Cameron pointed to the importance of pathology in modern medicine, and suggested that three main problems challenged the pathologist: cancer, ageing, and cardiovascular disease. The vice-president, Dr. JOHN PERRY, then gave an address entitled "Pathology's Part in Medicine." He dwelt on Australia's contribution to the specialty, discussing the work of the Bancrofts, Hone, and Swift, passing on to Sir Harry Allan, Martin, and Kellaway, and then to the present day with Burnet, G. R. Cameron, Florey, and Willis. Before the address, honorary membership of the College was granted to Sir Macfarlane Burnet, Sir Peter MacCallum, Professor E. King, and to Drs. Cleland, Duhig, Latham, Kingsbury, Little, O'Brien, Tebbat, Ward, and Webster.

The scientific meeting was marked by a high standard of presentation by those who read papers, despite the informal atmosphere prevailing. It was gratifying to find that some of the ablest pieces of research had been partially conducted while their authors had been in England on travelling fellowships. In this category came Dr. E. S. FINCKH's report on the acute tubular necrosis in rats caused by glycerol, and Dr. V. MCGOVERN's description of the lining cement of blood vessels and its relationship to mast cells. Both these speakers had completed their research at University College Hospital Medical School, London. Professor KING spoke about poliomyelitis virus in monkey tissues, and there followed a vigorous discussion. A reception for members and their wives was held by the committee in the evening, and the next day those attending the meeting dispersed to their homes, in some cases over 2,000 miles away. So great are the distances in Australia that the College would be well worth while if its sole function was to mitigate the professional isolation of these widely scattered pathologists.

Preparations and Appliances

AN EASY LIFTING APPARATUS FOR HELPLESS
AND HEAVY PATIENTS

Dr. A. BRYCE STEWART writes: The apparatus here illustrated has been specially designed to assist nurses in the care of chronic and helpless invalids. During the development of this hoist over the past year several other types of

FIG. 1.—The lifting apparatus with canvas seat and safety strap.

FIG. 2.—Inserting the canvas seat under patient.

ture. The accompanying photographs should give an idea of how this apparatus is used.

The frame is of tubular steel, which, on the removal of five bolts, separates into the upright jib and the horizontal chassis. The winding device is an adaptation of a 14:1 reduction gearbox with a spring release catch in the handle, which automatically locks when not in use, thus preventing movement of the winding-drum. Aircraft steel-wire rope is used, the breaking strain of which is greater than one ton.

The canvas seats—for which a patent has been applied for—are easy and cheap to make, so that several can be used with each machine. Patients are lifted on to a chair and the supporting rubber-covered wires unclipped, leaving the seat in place under the patient, ready for rehoisting on

return to bed. This avoids discomfort to the patient and saves nursing time.

For six months the lifting apparatus has been in use in the geriatric unit of Florence Nightingale Hospital. A trial has also been given at the Robinson Kay Home, where long-stay geriatric cases are accommodated. During these months

FIG. 3.—Ready for clipping the seat to the hoisting apparatus.

several interesting facts emerged: a bed-bath takes two nurses about 20 to 25 minutes and is then not as satisfactory as a proper bath. A technique has been worked out at the hospital whereby the patient is undressed before being hoisted from bed and is wrapped in a blanket. The patient is wheeled in the hoist to the bath, lowered in the canvas seat into the bath, washed, hoisted out of the bath, partially dried, and wheeled back to bed, where drying is completed on a blanket over a rubber sheet. The whole process takes between 10 and 15 minutes.

My thanks are due to Dr. F. R. Glover (Medical Superintendent) for his encouragement, to Dr. R. S. Savidge (Consultant Physician), and to the staff of Florence Nightingale Hospital. Also to Mr. H. Wilkinson (Secretary to the Bury and Rossendale Hospital Management Committee) for suggestions on the necessary safety factors, and to Messrs. Smethurst and Halliwell for technical advice. Sackers Ltd., Manor Street, Bury, are manufacturing this apparatus.

THE CHAILEY HERITAGE COMBINED
NOTE AND X-RAY TROLLEY

Dr. E. P. QUIBELL, medical administrator, Chailey Heritage, writes: The bulk of notes and x-ray films can become a real problem in long-stay children's orthopaedic hospitals: a trolley must be strong enough to carry the weight without becoming damaged and yet easily moved from bed to bed. Often, too, a series of x-ray films need to be examined: when put out on the bed they either get

in the way or are knocked on to the ground; in addition, a surface on which notes can be written offers advantages. There should be room, too, for a diagnostic tray. The trolley illustrated here was designed to meet these various desiderata.

Basically, the construction is tubular steel, with sheet-metal surfaces. The top section for the notes, with two partitions, is offset to the back edge, to allow the maximum free surface, and the three compartments below house the x-ray folders (these compartments could advantageously be increased to four in number). Between the two sections is a shelf which fits flush when closed, but provides a good area when pulled out (see photographs). This shelf runs in concealed "guides" to prevent it jamming, and has two oval hand slots: if kept lightly greased it runs very smoothly.

The 4-in. (10-cm.) diameter castors are spring-loaded to reduce the "sway" effect when the trolley is pushed over the door ridges on to the solarium. This eliminates the damage of repeated end-to-end jarring which loosens the structure of so many trolleys in practice.

A light-coloured stove enamel gives a pleasing finish. Although the trolley is heavy, it moves easily and is not unduly bulky.

The photographs show the general appearance and construction, with the sliding shelf in the two positions; also some detail of the castors can be seen.

Details: Height (from ground to top surface), 2 ft. 6 in. (76 cm.); length, 4 ft. (122 cm.); depth, 1 ft. 8 in. (50 cm.); cost, £34 (approximately). The manufacturers are Brighton Sheet Metal Works, Ltd., 43, Devonshire Place, Brighton, 1.

I am indebted to Mr. A. Hayes, radiographer and clinical photographer at the Heritage, for the photographs, and also to the manufacturers for technical help in evolving the model to my design.

ANTIBIOTICS ON PARADE

In Washington, D.C., last month the fourth annual symposium on antibiotics was held. During the three days of the meeting, October 17, 18, and 19, no fewer than 143 papers on antibiotics were read. Their range and emphasis were well summarized by Dr. HENRY WELCH, who presided at the symposium, in his opening address. Dr. Welch is director of the antibiotics division of the U.S. Food and Drug Administration.

In the United States several hundred tons of antibiotics were used each year, said Dr. Welch. With this enormous use, the pattern of bacterial resistance established first with streptomycin and the tubercle bacillus was gradually emerging with other micro-organisms, and now there was the further problem of the overgrowth of resistant fungi. Not surprisingly, therefore, a large number of the papers at the symposium would deal with the therapy of infections due to resistant organisms.

Combined Therapy

Dr. Welch said that during the conference there would be emphasis on a trend towards a rational combined therapy, particularly with synergistic combinations. Oleandomycin, a new antibiotic, was combined in mixtures with tetracycline, oxytetracycline, and penicillin. In addition, it was compounded with penicillin to make a penicillin salt of oleandomycin. To reduce the numbers of both gram-positive and gram-negative bacteria in the intestinal tract before abdominal surgery, a combination of oleandomycin and neomycin was claimed to be useful. Further evidence on the value of a combination of nystatin and tetracycline would be presented. Combinations of neomycin and novobiocin, novobiocin and nystatin, neomycin and bacitracin, neomycin and chlorquinadol, neomycin and erythromycin, neomycin and oxytetracycline, and neomycin and isothiazylsulphathiazole, would all be discussed with respect to their enhanced value and activity, particularly in preparing patients for abdominal surgery. These preparations and others indicated a distinct trend towards combined therapy—"not," said Dr. Welch, "an old-fashioned shotgun approach, but a calculated rational method of attacking the problem of resistant organisms." It was quite possible that we were now in a third era of antibiotic therapy: the first being the era of the narrow-spectrum antibiotics, penicillin and streptomycin; the second, the era of broad-spectrum therapy; the third an era of combined therapy where combinations of chemotherapeutic agents, particularly synergistic ones, would be customarily used.

Practically an entire day, Dr. Welch continued, would be devoted to a discussion of antibiotics as food preservatives, an important economic problem "of great concern to the public health." There would be papers on the use of antibiotics in maintaining the freshness of poultry, fish, beef, ham, and vegetables. Five new antibiotics were to be described: ristocetin, PA 132, an antibiotic oil isolated from a plant, nucleocidin, and alazopeptin, which was active against mouse sarcoma 180. And more information on the relatively new antibiotics bryamycin, vancomycin, and amphotericin would be given. There would also be new studies on older agents such as erythromycin, nystatin, cycloserine, penicillin V, and synnematin B.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Glycyrrhetic Acid

SIR,—If other clinicians add their experiences with glycyrrhetic acid under controlled conditions to those of Dr. F. Ray Bettley (*Journal*, October 13, p. 882) it should be possible to determine conclusively the value of this substance as a topical agent in the treatment of itchy inflammatory conditions.

I have compared glycyrrhetic acid ointment by alternation with hydrocortisone ointment, each patient serving as his own control. The results obtained were:

	Improved	No Change	Worsened
Hydrocortisone	13	2	0
Glycyrrhetic acid	3	8	4

Two preparations of glycyrrhetic acid were used. The results were:

	Improved	No Change	Worsened
Product A	1	7	0
" B	2	1	4

The response to glycyrrhetic acid was clearly inferior to the response to hydrocortisone. The figures are significant in spite of the smallness of the trial. In fact, $P < 0.002$.

No positive evidence, based on controlled trials, has yet been produced that glycyrrhetic acid has an anti-inflammatory action when applied to the skin comparable to that of hydrocortisone.—I am, etc.,

BRIAN RUSSELL.

London, W.1.

Neostigmine-resistant Curarization

SIR,—It was with great interest that I read Dr. A. R. Hunter's article on prolonged curarization (*Journal*, October 20, p. 919), having had two similar cases this year—described in the following report.

A man, aged 67, suffering from extensive carcinoma of bladder, had an operation for transplantation of the right ureter and had an operation for the left ureter. He had a history of pulmonary tuberculosis, and x-ray examination showed extensive cavitation in both lungs with signs of recent activity in one. Biochemical examination, on the day prior to operation, gave a relatively normal electrolyte content and his blood urea was 42 mg.%. The patient was premedicated with pethidine 100 mg., atropine 0.65 mg., and induced with a small dose of thiopentone, D-tubo-0.65 mg., and maintained with curarine and pethidine. He was intubated and maintained with N₂O-O₂ on a closed circuit. He was obese, and several supplemental doses of D-tubocurarine 5 mg. were required to provide adequate relaxation. He had a total dose of 35 mg. of D-tubocurarine. The blood pressure remained steady at the pre-operative level of 130/80 mm. Hg, but tended to rise towards the end of the operation. The pulse was full at rate of 90-100. When the peritoneum was stitched 1.3 mg. of atropine was given, the patient followed by neostigmine in intermittent doses of 2 mg. The patient's canister was removed from the circuit and the patient was mildly hyperventilated to restore level of alveolar CO₂. I had not realized at this stage the probability of a CO₂ accumulation, and had ventilated carefully to prevent anoxia. When neostigmine 6 mg. had been given with absolutely no effort at spontaneous respiration a large dose of nikethamide was given with no result. For three hours the patient was ventilated with high flow of oxygen and partly open expiratory valve. The pulse was now very full at rate of 90-100, and the blood pressure had risen to 170 mm. Hg. A very belated realization of a CO₂ accumulation caused me to hyperventilate with canisters changed every 15 minutes, and a slight return of spontaneous respiration after 40 minutes confirmed my suspicions. An infusion of Na

lactate was started to aid buffering, and an estimation was done which showed a total CO₂ content of plasma of 28 mm./l. and a free CO₂ content of 5.4 mm./l. When 200 ml. of Na lactate had been given the spontaneous respiration showed marked improvement, and by the time the pint (0.6 l.) had been given followed by 200 ml. Na citrate the tidal exchange was adequate. Three hours after the commencement of the Na lactate drip the patient objected to his endotracheal tube, and on its removal he was speaking and moving. He was returned to his ward eight hours after the end of operation and his condition was satisfactory. The blood pressure had fallen gradually during the Na lactate infusion, and was 110/70 on return to bed. Seven days after operation his general condition began to deteriorate, and he died ten days after operation of cardiac failure.

The second case, a primipara of 38 years, had been in labour for 72 hours. An anaesthetic was given in a nursing-home for forceps delivery. Thiopentone 250 mg. and succinylcholine 50 mg. was adequate until the perineum was being stitched, when a further 100 mg thiopentone was given. Respiration was adequate, but a few minutes after the delivery it became depressed and quickly stopped. The patient was flaccid, and tolerated the introduction of a No. 9 cuffed endotracheal tube—and respiration was controlled for one hour with constantly changing canisters—without any return of spontaneous respiration. The pulse was fast and irregular, and the blood pressure rose from a pre-delivery level of 110 to 170 mm. Hg. An infusion of Na lactate was started, and when 250 ml. had been given the blood pressure had fallen to 130 mm. Hg, and feeble efforts at spontaneous respiration were evident. No bleeding had complicated the third stage of labour, and no trauma except for a slight tear of the perineum. When the pint (0.6 l.) of Na lactate had been run in the blood pressure was 110, and the tidal exchange was adequate. A pint (0.6 l.) of glucose 5% was then started, and very shortly the patient started to move and objected to her tube. On its removal she opened her eyes and spoke. She had been on controlled respiration for three hours and assisted respiration for half an hour. The nurse gave a history of difficulty in making the patient eat or drink during her labour, and of vomiting and much belching and passing of flatus. Two days later her haemoglobin was 64% for which she received iron. A fortnight later a full blood count showed a haemoglobin of 66%, a red cell count of 3,890,000 and a white cell count of 7,500 with a colour index of 0.87. A blood film showed no abnormal forms in either red or white cells. Her puerperium was uneventful and she was discharged on the 12th day.

The man, with a respiratory acidosis due to poor ventilating capacity, reacted to active ventilation with frequent change of canisters, and infusions of Na lactate and Na citrate. The woman, with a metabolic acidosis due to vomiting and poor intake during labour, reacted to Na lactate only. In both cases the return to spontaneous respiration was parallel to the fall in blood pressure, and when the latter reached normal levels the return to consciousness was very rapid.

Such cases stress the need for the ready availability of microvolumetric estimation of plasma CO₂ levels and the quick report on pH reading. With these data a reading from a McClean nomogram would give a picture of the degree of acidemia present. It is an established fact that a lowered pH causes a fall in the plasma thiopentone level, but how does the altered pH cause prolonged apnoea with relaxant drugs? The first patient had D-tubocurarine, a myoneural blocking agent, and the second had succinylcholine, a depolarizing drug. Does the plasma pseudocholinesterase activity vary with altered pH?—I am, etc.,

Dublin.

SHEILA KENNY.

SIR,—I read with considerable interest Dr. A. R. Hunter's article (*Journal*, October 20, p. 919). The following case, I feel, is worth recording.

A white male, aged 71, was admitted to hospital on August 18, suffering from a strangulated inguinal hernia. He was successfully operated upon for the relief of this condition, but during the following week developed a persistent ileus. He was submitted to a further operation a week later because it was felt that he had a further mechanical obstruction of the bowel. In accordance with Dr. Hunter's experience, though ill and elderly, the patient was reasonably fit for anaesthesia. The blood electrolytes were normal and the renal function satisfactory. Blood urea 54 mg.%; haemoglobin 81%. Premedication: atropine

1/100 gr. (0.6 mg.), morphine 1/6 gr. (10 mg.). 5.15 p.m., induction: pethidine 25 mg., thiopentone 150 mg., succinylcholine 50 mg. Easy intubation with No. 10 Magill cuffed oral tube. Maintenance: 20 mg. D-tubocurarine chloride at the beginning of the operation in one dose N_2O/O_2 , closed circuit circle absorber. The operation proceeded smoothly, and on closure of the abdomen there was no reason for particular anxiety about the patient's condition.

At 6.15 p.m. 1/50 gr. (1.2 mg.) atropine, followed after five minutes by 5 mg. neostigmine, were given and spontaneous respiration started which was apparently satisfactory in volume. Over the next three or four minutes, however, it very rapidly failed and the patient became cyanosed. He was re-intubated and given artificial respiration. No response to nikethamide or to a further 2.5 mg. neostigmine was observed. The blood pressure started to fall and reached 60/?. A noradrenaline drip was set up and the blood pressure rose to 100/60. Movements of the accessory muscles became apparent at about 10 p.m., and very shallow respiration, insufficient to maintain life, was observed. The use of small doses of N-allyl-nor morphine (5 mg. $\times$ 3) and alternate periods of hypo- and hyperventilation produced no improvement. At 9.15 a.m. the next morning the blood pressure started to fall and cardiac failure and death occurred despite pressor drugs and intravenous plasma. At operation the patient was found to have a volvulus of the small bowel.

The respiratory weakness appeared to be peripheral—that is, at the myoneural junction—and this may come under the heading of "neostigmine-resistant curarization." It is interesting to note that neostigmine had some effect in reversing curarization, though an extremely transitory one.

An extensive search of the literature reveals an astonishing lack of information on the pharmacology of neostigmine. Its mode of metabolism and excretion by the body is unknown; knowledge of its duration of action is extremely uncertain. There are probably many unknown or ill-understood factors concerned with neuromuscular transmission. Potassium and ionic imbalance figures largely in theory and speculation at the present time. However, it seems that remarkably little is known about neostigmine considering the widespread clinical use of the drug, and that this may be a further line of attack on this problem. To quote Dr. Hunter, "It has become almost an article of faith with those who use agents of this type [competitive myoneural blockers] that it is safe to maintain curarization right up to the time at which the abdomen is closed, in the sanguine expectation that the paralysis will then be undone by neostigmine." If such reliance is to be placed upon a single drug it is surely necessary for its pharmacology to be well understood.—I am, etc.,

Prescot, Lancs.

J. B. MONTGOMERY.

SIR,—With reference to Dr. A. R. Hunter's article on neostigmine-resistant curarization (*Journal*, October 20, p. 919), I would point out the possibility of these cases being hidden myasthenics. I have two cases in mind.

The first was a young woman for pneumonectomy in 1954. I induced her with thiopentone 0.5 g. and "tubarine" (D-tubocurarine) 45 mg., maintenance with N_2O and O_2 . At the end of operation she was apnoeic, so I gave her atropine followed, after a proper interval, by neostigmine 5 mg. She began to breathe, but after a few minutes again became apnoeic. Smaller doses of neostigmine were given with atropine, followed by a favourable response but relapsing into a state of apnoea or near apnoea. This line of treatment was followed until breathing became normal in character and fairly good muscle tone could be felt. Neostigmine 25 mg. had been given at this stage. She was now returned to the ward, the operation having been concluded for two hours. She was given a further 10 mg. neostigmine by intravenous drip. Her convalescence was uneventful.

The second case was a woman in her sixties whom I saw in consultation with another anaesthetist half an hour after operation. She had been induced with thiopentone 0.5 g. and had gallamine 45 mg. Maintenance was with N_2O , O_2 , and pethidine. She had an inoperable carcinoma of the uterus. She had been given atropine followed by neostigmine 5 mg. She gave little response to this, but,

following doses of 2.5 mg. neostigmine, her breathing became adequate and muscle tone returned. In all she had a total of 40 mg. neostigmine. She had an uneventful convalescence except for signs of central overdosage of atropine in the first 24 hours post-operatively.—I am, etc.,

Boosterstown, Co. Dublin.

MICHAEL McGRATH.

SIR,—Dr. A. R. Hunter (*Journal*, October 20, p. 919) described a syndrome which many of us have experienced and regard with dread, in view of its almost certain fatal outcome. There are many facets to the problem of the patient who refuses to respond to neostigmine, but in the interest of brevity might I be allowed to mention a few?

My experience leads me to believe that it is most likely to occur in the patient with chronic widespread pulmonary disease with a poor vital capacity who is given large amounts of a long-acting myoneural blocking drug. We are left at the end of operation with an atonic patient making feeble inspiratory gasps accompanied by chin tugging and forehead twitching. Each gasp moves a volume of air hardly greater than that of the dead space. Drugs and hyperventilation have no effect.

Is it possible that in these "dilapidated" patients, as Dr. Hunter describes them, prolonged positive-pressure ventilation itself contributes to the final cardiac failure? I have had a measure of success by insufflating as low down the trachea as possible a jet of moistened oxygen through a long thin plastic endotracheal tube. Dead space is thus virtually eliminated and gaseous exchange by diffusion much encouraged. The tube may be left *in situ* until muscular tone returns, by which time respiratory activity is adequate. Meanwhile what little reserve of respiratory and cardiac action these patients possess is used to good effect.

Finally, I have never seen the syndrome after one or repeated doses of succinylcholine, and my experience leads me to hold that in such patients the safest method of obtaining good operating conditions is to use this relaxant with a maintenance anaesthetic of light ether and oxygen.—I am, etc.,

Wolverhampton.

J. F. RICKARDS.

B.C.G. and Vole Bacillus Vaccines

SIR,—I am grateful to Dr. P. D'Arcy Hart for his reasonable letter (*Journal*, October 20, p. 938), and I accept his assurance that the cases of tuberculosis which occurred during the Medical Research Council's survey were evenly distributed throughout the various groups of children in the different centres. Nevertheless, my main criticisms of the report still seem to be unshaken.

B.C.G. enthusiasts are always the first victims of their own propaganda, and their belief that B.C.G. is harmless dies hard. It is true, as Dr. Hart points out, that I have drawn attention elsewhere to the dangers of B.C.G. vaccination, but in case I might be thought to be prejudiced I quote from a recent authoritative pronouncement by Wallgren,¹ one of the leading exponents of B.C.G. in the world. He writes: "The knowledge that progressive B.C.G. tuberculosis may occur in human beings must shake our belief in the harmlessness of B.C.G. and should perhaps also lead us to re-examine the case for mass vaccination. It is no longer possible to contend that B.C.G. is harmless." In the same paper Wallgren mentions that, so far, four deaths have occurred from vaccination in Scandinavia alone. I cannot see any more reason, therefore, for ignoring a cold abscess caused by vaccination than for saying that death from B.C.G. tuberculosis is not the same as death from a natural infection. Dr. Hart does not deny that, apart from two cases of erythema nodosum, no record was kept of the lesions which followed B.C.G. in the survey.

I cannot agree that tuberculosis case-finding can be efficiently pursued by correspondence or by home visitation, unless, of course, it is intended to discover only cases of "clinical importance." If this was the purpose of the survey, there was no need to x-ray any of the children until

obvious symptoms aroused suspicion. But the diagnostic value of mass radiography is based on the fact that active pulmonary tuberculosis is often clinically unimportant and cannot be excluded except by radiography. Admittedly the percentage of vaccinated and unvaccinated children who were x-rayed was approximately the same, but percentages are comparable only if the totals to which they refer are comparable, and the vaccinated children exceeded the unvaccinated by 7,500. It follows that nearly twice as many vaccinated children as controls escaped being x-rayed during the survey.

The failure of Calmette and others to demonstrate convincingly a protective effect of B.C.G. vaccination in the early years of its long history was not entirely due to lack of large, well-controlled experiments but rather to attempts to compress the behaviour of tuberculosis into short, convenient periods of observation. The research worker is inclined to forget that tuberculosis is not especially, or even commonly, a disease of infancy, childhood or adolescence, but runs throughout the whole span of human life, and indeed, in this country, is now most lethal in middle-aged and elderly people. If our view of tuberculosis is broad and long, it becomes more than a coincidence that the maximum popularity of B.C.G. began with the discovery of the anti-tuberculosis drugs, the tremendous benefits of which have given B.C.G. a vicarious efficacy. For the same reason nothing has been accomplished in countries where mass vaccination has been practised for many years which has not been equalled or surpassed in countries where B.C.G. has never been used. It is necessary, therefore, to receive with healthy scepticism even such a careful study as the Medical Research Council's report, and the search for a genuine vaccine against tuberculosis must still be continued.—I am, etc.,

Dungannon, Co. Tyrone.

B.C.G. Vaccination after Replacement Blood Transfusion

SIR,—We read with interest the account by Drs. A. S. Hutcheson and P. Macpherson (*Journal*, October 13, p. 863) of a rapid and severe reaction following B.C.G. vaccination of an infant who had received an exchange transfusion.

We think this must have been coincidental, as in our series we have had no similar occurrences. In the years 1952 to 1955 inclusive, 84 babies who have received exchange transfusions in the Royal Maternity Hospital, Belfast, have also received B.C.G. vaccination. Seventy-five of these were examined and tested after vaccination, and no abnormal findings were observed at the vaccination sites or in normal tuberculin reactions. One baby developed the post-vaccinal tuberculin reactions. One baby developed a regional abscess, but this did not appear until more than 12 months after vaccination.

It would be impracticable to check the Mantoux reactions of the donors concerned, but there is evidence that at least 50% of the adult population of Northern Ireland are Mantoux-positive, and the chances are that the great majority of the babies received blood from one or two such positive donors.—We are, etc.,

Belfast.

W. A. B. CAMPBELL.
H. M. PURSER.

Troublesome Staphylococci

SIR,—Staphylococcal resistance is even more difficult to assess after reading the *Journal* of October 13. May we soon have a leading article with more precise appraisal? Dr. Walsh McDermott's article (p. 837) is at strong variance with your leading article (p. 867). The leading article states: "There is a lot to be said for the idea that the use of antibiotics is selecting a tougher race of these organisms." Dr. McDermott says: "... Something we all knew—namely, that a penicillin-susceptible staphylococcal infection in a

patient virtually never becomes drug-resistant during therapy." The belief in acquired resistance during therapy is almost universal. All colleagues questioned, including a bacteriologist, believed in such acquired resistance of staphylococci. It is supported by your leading article (*Journal*, July 28, p. 217): "Our staphylococci are what we make them; the more an antibiotic is given, the more frequent does resistance to it become."

And yet it was "something we all knew"—penicillin-susceptible staphylococci virtually never become resistant during therapy. This deserves more comment than it has yet evoked. On what series is the remark based? To what extent does it apply to antibiotics other than penicillin? Can we imply there is no basis for the cry against indiscriminate use of antibiotics against staphylococci?

Dr. McDermott invalidates most popular experience on account of superadded infection in open lesions. I assume our safest attitude is to persist in the acquired resistance hypothesis unless disproved by a series of needle puncture cultures from closed lesions, which should be presented in the future.—I am, etc.,

London, N.W.2.

P. D. ELDER.

Herpes Zoster

SIR,—I should like to congratulate Dr. L. J. Barford on a most useful factual memorandum on herpes zoster (*Journal*, October 13, p. 864).

It is not clear if these patients were seen in general practice. If so, they probably represent almost the total incidence of zoster in the practice population during the period under review, and the age distribution as given could be much enhanced in value if it were related to the age distribution of the practice. Would it be putting Dr. Barford to too much trouble to ask him to obtain the necessary figures so that the age specific incidence could be calculated? It takes time to collect figures like this, and each contribution adds to the pool of knowledge about the natural history of this interesting disease.

One other statement in the memorandum calls for comment. In discussing the distribution of the rashes in relation to the sensory nerve areas, Dr. Barford writes: "There was some overlapping, as adjacent roots were often affected." If this refers to the spinal nerves it is of great theoretical importance, because the posterior root ganglia are anatomically well separated from one another. Was the decision that adjacent roots were involved dependent on the area of the skin covered by rash? If so, this is a rather misleading criterion, the skin areas supplied by the spinal nerves being widely variable, as Head and Campbell¹ first showed in a paper which is the classic for all time on the subject.—I am, etc.,

Cirencester.

R. E. HOPE SIMPSON.

REFERENCE

¹ Head, H., and Campbell, A. W., *Brain*, 1900, 23, 353.

SIR,—Doctors are usually considered to be bad patients, but they ought to be, as John Hunter and others certainly were, good observers of their illness, so the medical memorandum on herpes zoster by Dr. L. J. Barford (*Journal*, October 13, p. 864) tempts me to describe my own case from notes taken at the time, though it happened several years ago. It started with an uncomfortable and inexplicable feeling of coldness over the abdomen, just as if a cold pack had been laid upon it. I recognized it at once as similar to that described at times by patients for which I had never been able to find a cause. After two days this persistent chilly feeling mercifully passed off, to be replaced by a tender spot, about $\frac{1}{2}$ in. (1.3 cm.) in diameter, some 4 in. (10 cm.) to the right of the umbilicus. This was not hyperaesthetic in the ordinary sense, but it was sufficient to make the pressure of my trousers uncomfortable. It was not painful on pressure or tender on pinching, etc., and did not, so far as I knew, correspond to any special viscus. In spite of this I began to develop a flatulent dyspepsia, which I thought

might be due to a nervous indigestion, work having been very strenuous.

After two days more this spot slowly enlarged and then faded away to give place to a feeling of heaviness and discomfort around the liver. The dyspepsia increased and so did the discomfort, so that I could not sit in a chair with any comfort, and for three successive nights it woke me up at 3 a.m. By that time it had spread round to the kidney area, and it began to dawn on me that I was really developing herpes zoster. And so it was, for nine days after my first sensation of coldness the tell-tale pink papules appeared exactly where my tender spot had been. I got my wife to give me 2 ml. of "dekadexolin" (an intragluteal injection of vitamins A and D), and stayed in bed for two days, by which time the spots had almost faded, and I was well again.

The point of this recital is that so many of the symptoms I felt are so often described by patients whom we tend to describe as neurotic; in fact I wondered whether I was becoming neurotic myself. Though they showed, so far as I could find by careful examination, no physical signs whatever, they were in fact all due to some derangement of the posterior horn cells caused by the herpetic virus. I think that we too readily dismiss symptoms without signs as being psychological and of no importance, when they may have a really physical basis and be extremely uncomfortable into the bargain. I think too that we are often content to note pain, flatulence, etc., without sufficient inquiry as to the exact type. This may be useful for statistical analysis, but it almost certainly hides from us those finer points on which correct clinical diagnosis may well depend.

I mention the treatment with dekadexolin and its effect, because this is almost invariably what has happened in the many cases in which I have used it in the past 25 years. But there is one curious thing about it. Though it will usually cause the rapid disappearance of the eruption it does not, in my fairly large experience over the years, prevent the development of post-herpetic pain, though it reduces the pain at the time. Injections of vitamin B₁₂ in large doses have been recommended for herpes zoster, and I have used them several times. Personally I have not noticed much effect upon the eruption itself, but I think that these injections do tend to limit or prevent the post-herpetic pain. It is most probable that the two sets of vitamins act differently—for I do not think that there is any known connexion between the fat-soluble vitamins and cyanocobalamin—and it is curious that one should affect the eruption and the other the pain. If this observation should prove to be correct it might throw some light on the processes involved in at least one virus disease.—I am, etc.,

Winstord, Cheshire.

W. N. LEAK.

Antidote on the Label

SIR,—Several times a year I receive an urgent and frantic call from a parent whose child has swallowed some disinfectant or other commercial fluid. This usually means a call to the local chemist to find out if the fluid is poisonous and, if so, further inquiries to find out the antidote.

It would be a great help to us if manufacturers of household products labelled "Not for consumption" could print clearly on the label the immediate steps to be taken if the fluid is swallowed accidentally.—I am, etc.,

W. Horsley, Surrey.

DICK GLOVER.

Tranquillizers

SIR,—In view of the popularity of the so-called tranquillizing agents in the U.S.A. and the possibility of the same thing happening here, the experience of a patient of mine might be of interest to the medical profession.

A girl 18 years of age took two of these tablets before going to a dance. After the dance she missed the last bus home and was offered a lift in the car by a complete stranger and accepted it. In the car, she told me, she was assaulted by the driver and she did not resist him at all; after some time they both fell asleep. When they both woke up the driver tried to assault her again, but this time she resisted him strongly and asked him to drive her home. The driver, being a stranger to the district, asked two passers-by, who turned out to be policemen. The girl jumped out of the car and complained to the police about

the assault. Needless to say, the police could not prosecute the driver. The driver told them the girl was the willing party. I may add the girl does not touch alcohol in any form.

I think the reason why the girl did resist on the second occasion was that she must have recovered sufficiently from the effect of the drug to realize what was going on, after her short sleep.—I am, etc.,

Liverpool, 18.

H. J. PRATAP.

Abuse of Antibiotics

SIR,—I was very glad to read in Dr. S. Henry C. Clarke's letter (*Journal*, October 13, p. 883) the reference to moniliasis resulting from the use of antibiotics. It is all too often overlooked that the suppression, not only of pathogenic bacterial flora but also of the normal bacterial saprophytes in the mouth and intestine, encourages the growth of *Candida (Monilia) albicans*.

From the viewpoints of the allergist one often notices nowadays that allergic conditions such as asthma, rhinitis, and in some instances eczema, migraine, or colitis appear for the first time or become more severe after a course of antibiotic therapy. Many such cases will be found to have developed an allergic sensitivity to *Candida albicans* which is detectable by intradermal testing with the appropriate extract to give the immediate (15–20 minutes) raised wheal reaction. Fortunately for these patients, specific desensitization (hyposensitization) is usually very effective treatment to overcome so grave a sequela of antibiotic usage.—I am, etc.,

Pharmaceutical Advertisements

SIR,—Many pharmaceutical firms have tried to meet the problem of usefully presenting literature to the profession by publishing loose-leaf books, card indices, etc., giving essentially practical facts—but, of course, for their own products only. There does not, however, seem to be any standardization between the pharmaceutical firms on the form of presentation. I envisage a committee to be formed of the medical representatives of the firms and representatives of the medical profession which could publish a loose-leaf file to which all firms could subscribe the brief important facts about all the products available on the market (and not, as has been sometimes done, the products issued in the last so many years and in "current use").

I suggest that the details of each product could be printed with a space for notes and headed with its name and a one- or two-word description of its action and the disease(s) in which it is useful. Underneath should be the logical headings with a short bibliography at the bottom. It would be very useful to have a distinctive mark if prescribable on E.C.10. The full details would have to be thought out, but the products of each firm could be easily grouped together and all printed in the particular firm's colour, incorporating a thumb index for each. The firms could be arranged alphabetically. The first part of the file should be a comprehensive therapeutic index (fully cross-referenced) of all products available.

This project would not prevent firms sending out any amount of literature as they do now, but doctors would be able to throw all the advertisements out in the sure knowledge that they all have a complete brief description of each product available. It would be interesting to read views about this idea from various firms and colleagues.—I am, etc.,

London, W.12.

JOHN D. W. WHITNEY.

Medical Education

SIR,—The writers of two letters in the *Journal* of October 20 (p. 940) concern themselves with the question of education within medicine. Recently I was privileged to hear an excellent paper by the headmaster of a well-known grammar school read to a mixed gathering of legal and

medical graduates, the former being our kind and generous hosts. The paper, for the most part, dealt with the preparation and selection of promising youths—which it was meant to do. It was quite splendid within its terms of reference. As at one point some extraneous matter was introduced, or so I thought, by another speaker, I had the temerity to venture a few words on the subject broached by Dr. R. J. Knight and Dr. H. Stewart Moore.

These few words were simply a suggestion that anyone interested in (1) education in medicine, (2) education in general, could do no better than procure copies of the several lectures on the subject given by Sir Francis Walshe, consulting neurologist to University College Hospital and to the National Hospital for Nervous Diseases, Queen's Square. I take the liberty of quoting the titles in my possession, with the names of the publishers: *Humanism, History and Natural Science in Medicine* (Linacre Lecture, 1950, Livingstone, Edinburgh); *The Structure of Medicine and its Place Among the Sciences* (Harveian Oration, 1948, Livingstone, Edinburgh); "Teachers of Medicine" (*Lancet*, 1947, 2, 817); "On Clinical Medicine" (*Lancet*, 1950, 2, 781); "The Arts of Medicine and Their Future" (*Lancet*, 1951, 2, 895); *Thoughts Upon the Equation of Mind with Brain* (Hughlings Jackson Lecture, 1952, Macmillan, London).—I am, etc.,

Cheslyn Hay, Staffs.

L. DILLON MALONE.

Increase in Scabies

SIR,—In recent months there has been a significant increase in the number of cases of scabies attending outpatients. What is disturbing is that in most of these cases the diagnosis was unsuspected by the general practitioner. Ten years of almost complete absence of scabies has tended to make older practitioners forget the diagnosis, while a new generation of doctors have qualified who know not scabies. This diagnosis should always be considered in any patient who itches, particularly if the itching is worse at night. Itching in other members of the family is almost conclusive.

The causes of the epidemic variations of scabies are not really known. Increased incidence has been attributed to war, but though this may accelerate an increase it is not the primary cause, as was shown by the rising figures during the pre-1939 years. Unlike most epidemic diseases, one attack does not confer any real immunity on the individual, though he may possibly show fewer acari in subsequent attacks. Decreased incidence seems to depend on "group immunity," that is to say, on the development of active anti-scabies measures by the community. Among these I would emphasize early diagnosis by the doctor, adequate treatment, and, above all, the synchronous treatment of all members of the household and other possible contacts, whether they are obviously affected or not. It was the institution of scabies clinics to implement these latter that halted the epidemic during the war. Unless the lessons learnt during the war are remembered and we give a "booster dose" to our "group immunity," we shall probably see a steady increase in the incidence of scabies in the near future.—I am, etc.,

Leeds, 2.

F. F. HELLIER.

Sickling in an African Community

SIR,—Arguing from the same facts and assumptions, Drs. H. Lehmann and A. B. Raper and Dr. William A. Wilson arrive at very different conclusions about the possibility that a high sickling rate can be maintained solely through differential mortality from malaria. Thus the former hold (*Journal*, August 11, p. 333): "If selective death of non-sicklers from malaria was responsible for the maintenance of the 39% sickling rate in Bwamba, 10.6–24.2% of all normal homozygotes (or 6.9–15.7% of the whole child population) would have to die from malaria. Reasons are given for supposing that the actual death rate to be observed would approximate to the lower rather than the higher of the two

limits, and that such a death rate from malaria is to be expected in Bwamba." The latter states (*Journal*, August 25, p. 481): "From the available data there is still seen to be a big gap to be closed between the 24% reduction needed by the hypothesis and the 7% or so which malaria can effect." In their reply (*Journal*, October 13, p. 882) Drs. Lehmann and Raper suggest that Dr. Wilson has confused death rates on non-sicklers with rates for the whole population, and conclude, "There is indeed little 'gap' left, barely enough for Dr. Wilson to extract his 'red herring'."

The theory that persons with the sickle-cell gene are protected against death from malaria is attractive and stimulating, and it is important to determine whether the high sickle-cell trait rates found in Africa can be maintained solely by a differential mortality consistent with estimated malarial death rates. It seems worth while, then, to resolve in simple terms a conflict of opinion which is, largely, over the correct application of arithmetic.

Drs. Lehmann and Raper accept the widely held view that the sickle-cell gene is inherited as an allele of the gene for normal blood, the heterozygotes showing the trait and the sickle homozygotes the anaemia. They discuss clearly the basis for their view that virtually all the sickle homozygotes die young. They then make the tentative hypothesis that a negligible proportion of the heterozygotes die from malaria. Given this, the essential feature of their argument is that the number of deaths from malaria necessary to balance the deaths of the sickle-gene homozygotes varies with the distribution of all deaths by age. They show that to maintain a sickle trait rate of 39%, in a population where 35% of the births survive to puberty, 15.7% of the children born must die from malaria in a model where all the malaria deaths occur before the deaths from other causes, but only 6.9% if the malaria deaths take place after the other deaths. They surmise that a considerable proportion of the non-malarial mortality must occur at very early ages and that the percentage mortality from malaria required for maintenance of the sickle gene will therefore be nearer the lower than the upper of the two values.

Up to this point I think the argument is both sound and clear. The mortality of 65% before puberty is rather extreme (with such a rate the average number of children born per woman of completed fertility would have to be about eight to maintain the population size) and not conservative as the authors state, but it is not impossible. I agree that a fair proportion of child deaths would occur before the effect of deaths from malaria became considerable.

It is in the next stage that the calculations become obscure and there is a possibility of confusion. Drs. Lehmann and Raper quote death rates from malaria given by Colbourne and Edington¹ and by Duren² which are reasonably consistent. They then say that these rates imply a loss from malaria deaths of 5% to 19% of all children born. Now the rates quoted are age specific rates—that is, expressed in the form of deaths per thousand living in the population at the appropriate ages. They cannot be translated in terms of a percentage of children born without some assumptions about the age distribution of the population—that is, in reasonably stable conditions—about overall death rates. It is not stated how the percentages 5% to 10% were calculated, and I do not see how they can be derived from the malaria death rates estimated on assumptions consistent with the previous argument. If we continue this argument in a logical way we must apply the age specific malarial death rates to the forms of population implied by the alternative models. In the first model the malaria deaths occur first, so that the population at risk in each year of age does not differ much from the number born. Taking Colbourne and Edington's estimated malaria death rates of 17 per 1,000 in the first year of life and 10 per 1,000 at ages 1–5 years, of 1,000 births approximately 17 will die in the first year and 40 in the next four years, to give a mortality of 5.7% of births as compared with the 15.7% required by the model. The upper limits of Duren's rates would lead to a slightly higher mortality, but even with these, and making allowances for some deaths after the age of 5, not more than half of the necessary deaths from malaria can be accounted for. In the second model, deaths from malaria can be accounted for. In the second model, on which Lehmann and Raper lay most stress, the non-malarial mortality occurs first, and the population has been reduced to 419 in each thousand born before the malaria death rates can be applied. Colbourne and Edington's estimates then give 0.419 × applied. 57 deaths under the age of 5—that is, 2.4% of births. Again, even with ample allowances for higher rates, this does not amount to half the 6.9% required. These models are, of course, both very unrealistic, but it is easy to show that much the same relationship is obtained with intermediate cases.

It seems to me that Drs. Lehmann and Raper have neglected in their argument the fact that, although the number of deaths from malaria required to maintain the sickle gene varies with the distribution of mortality, the number of deaths due to fixed age specific rates varies in much the same way. I may be wrong in this, for the relevant portions of their calculation are not explained, but, if so, I do not see how they can reconcile the quoted malaria death rates with those required by the hypothesis they are considering.

There is a further point which, although of less importance, should not be neglected. The death rates from malaria quoted are for communities where the sickle trait rates are lower than 39% (perhaps 20% is a fair average). On the hypothesis that heterozygotes are not susceptible, 80% of the children are exposed to the risk of death from malaria in these communities but only some 60% of the Baamba. In using the same overall death rates from malaria for the latter it is being tacitly assumed that the death rates of susceptibles among the Baamba are about one-third higher than in the other communities.

On the assumptions made by Drs. Lehmann and Raper, it seems to me that the gap between recorded death rates from malaria and those required to maintain some of the high sickling trait rates found is still substantial. This does not mean that it cannot be closed. I think it is possible with other assumptions which lead to more complex models to do this, and I hope to publish something on the subject shortly with Drs. H. Foy and A. Kondi.—I am, etc.,

W. BRASS,
Department of Statistics,
Marischal College.

Diagnosis of Early Pregnancy

SIR.—In the *Journal* of October 27 (p. 987) there is an annotation on the diagnosis of early pregnancy with particular reference to the production of withdrawal bleeding by the administration of hormones.

I wrote a letter to the *Journal* (August 18, p. 419) expressing misgivings about the safety of such tests to the foetus. I pointed out that the disturbance of the endocrine balance of the mother and foetus early in pregnancy, when the main structures in the foetus are being laid down, might result in the production of foetal abnormalities. In a subsequent issue a case was reported (*Journal*, September 15, p. 600) of the delivery of a malformed foetus after this test had been used, although the writer was of the opinion that the association was coincidental. Your annotator completely ignores this side of the problem, but he does suggest that it is possible that in some cases the treatment may have in actual fact procured an abortion.

It is to be hoped that the widespread use of these tests will not lead to a repetition of the story of x-ray pelvimetry, for a procedure of no therapeutic value.—I am, etc.,

London, N.W.8.

H. G. BRITTON.

SIR.—I found the article by Mr. G. Douglas Matthew (*Journal*, October 27, p. 979) on the use of "orasecron" as a simple clinical test for the diagnosis of early pregnancy most interesting. When "disecron" became available I used it often as a test for early pregnancy, and now I find it simpler to use orasecron. The patients also appreciate not having to be injected and not having to come to the surgery twice for that purpose. I agree with Mr. Matthew that the oral administration of combined progesterone and oestrogen in the dosage prescribed would appear to constitute a reliable clinical method of diagnosing early pregnancy.

Now, Sir, your annotation (p. 987) on the same subject ends: "Finally, there is usually no urgency for a certain diagnosis of early pregnancy, and if the family doctor cannot make a confident diagnosis re-examination of the patient in three or four weeks' time is nearly always conclusive. Pregnancy, like murder, will out." Leaving aside those several cases seen each year in general practice where one must consider advising a therapeutic abortion, the general

practitioner will at any given time in a large practice have anything up to half-a-dozen cases on his hands of patients who are terribly anxious to know early on whether they are pregnant. I have precisely six such cases in my practice at this minute. For example, recently a patient consulted me when one week overdue. She was in a terrible state of anxiety because she has four children. I believe that she is becoming menopausal. With the aid of orasecron I shall be able to advise her one way or the other within seven to fourteen days.

It would appear that your annotator has little knowledge of this problem in general practice. It is a very real one, and orasecron is a very real help. Eight to twelve weeks of anxiety are harder to bear than one to two weeks. The grateful patient will tell you that it is so.—I am, etc.,

Ruislip, Middlesex.

T. DAVID LAMBERT.

Speech Therapy

SIR.—Following the recent correspondence on speech therapy, I should like to add a note, and may I also comment on the answer to the question on stammering ("Any Questions?" June 30, p. 1556)? It contains statements that need exploring and correcting. It is stated that over 80% of stammerers are males; this is said to be seen in no other form of psychoneurosis, and it is implied that therefore stammering is not psychological in origin. However, the majority of enuretics, delinquents, and fetishists are males; kleptomaniacs are almost entirely females, as are also sufferers from anorexia nervosa; and there are many other psychological disturbances preponderant in one sex or the other. It may be that the aggressiveness of the male is one factor in the more frequent occurrence of stammering in the male. The conditions leading to stammering are present in the first two or three years of life.

Stammering may in some cases be "cured" by speech therapy, but stammering is a symptom, and the removal of that symptom will be followed by the development of other symptoms or even by psychosomatic illness unless the whole person is treated. Speech therapy is invaluable in organic speech defects, such as cleft palate, cerebral palsy, after brain injury, etc., but the treatment of stammering is psychotherapy.—I am, etc.,

London, W.1.

BARBARA WOODHEAD.

SIR.—May I briefly express my thanks to Miss Ruth Bennett for her very able supporting letter (*Journal*, October 27, p. 1000)? In answer to her question as to male therapists I would say there is no "rule," but the point should be borne in mind whenever progress is unduly slow and there is likely to be a "transference" situation developing. As to the advice of the family doctor to leave the stammerer alone because the subject will "grow out of it," that is right in a way, since at the commencement of trouble the great thing is to avoid making the child concentrate anxious attention on his speech, since anxiety is always inhibiting. But the fact of a stammer developing is not to be ignored. It must be regarded very seriously as a sign that all is not well with the environment or handling of the child, and the family doctor should be the first in the field to hunt down the causes of stress.—I am, etc.,

Scarborough.

R. MACDONALD LADELL.

Treatment of Iron-deficiency Anaemia

SIR.—The correspondence that has followed the article by Drs. E. Cope and R. O. Gillhespy and Mr. R. W. Richardson (*Journal*, September 15, p. 638) cannot fail to confuse the practitioner who is faced with the common problem of treating iron-deficiency anaemia. It must be conceded that the observations of the three authors were not continued sufficiently long to be really conclusive, but this does not justify all the criticisms of Dr. S. Bradshaw (*Journal*, October 27, p. 996). Thus, although it is true that "as the haemoglobin level rises so does the intestinal mucosal block to iron absorption become more effective,"

it does not follow that "at a haemoglobin level of 100%, iron absorption from any oral preparation is very small—certainly too small to build up the lost iron stores in any reasonable time." If this were true, all the cases treated before the days when parenteral iron became available would have relapsed from time to time; but those of us who were brought up in those benighted times know that this was not so. We did, however, learn, albeit empirically, that, once the haemoglobin level had risen to about 80%, it was necessary to increase the dose of iron. To say that "it is probably the failure of oral iron preparations to do more than merely raise the haemoglobin level that is responsible for those many patients who return to their doctors time and time again with anaemic symptoms" is unfair to these medicaments; if relapse occurs, it is because treatment has not been continued sufficiently long and because adequate doses have not been given in the later stages. The progress that has been made in connexion with oral iron treatment is due to the production of compounds much less likely to upset the digestion than was, for instance, Blaud's pill.

It must be remembered that there is no exact method of determining that the iron stores are filled but not overfilled; that is to say that, with parenteral treatment, there is no safeguard against producing siderosis. Then again, although there are a few cases of iron-deficiency anaemia which will not respond adequately to oral iron, this is no reason for treating every case by the parenteral route, which is by no means devoid of side-effects, even if the possibility of overdosage is left out of account.

Dr. Bradshaw makes the whole subject unduly simple, but Dr. Bertha Klempman (*Journal*, October 27, p. 997) helps us to a balanced view by saying: "The haemoglobin level at which oral iron absorption is severely impaired varies with each individual." In short, the saturation of rather hypothetical iron-receptors in the intestinal mucosa is too facile an explanation, and it is probably true that parenteral iron is the treatment of choice in those rather uncommon people whose intestinal absorption of iron is severely impaired at relatively low haemoglobin levels.

I cannot enter into the question of the relative incidence of digestive upsets with the different preparations of oral iron, but I can state, without fear of contradiction, that the bits of iron from the grinding of axes are neither haemopoietically potent nor likely to clarify our views on the best line of treatment.—I am, etc.,

London, W.1.

A. PINEY.

SIR.—According to the letter from Dr. S. Bradshaw (*Journal*, October 27, p. 996), if any of us are so unfortunate as to be old enough to deplete our iron reserves, it is years before they are made up again, even if oral iron be taken. Should we deplete them again before they are made up, they may well become exhausted. Presumably women between the ages of 14 and 45 have extremely low iron reserves. Frankly, his statements are hardly credible, as 50% or more of the nation would be anaemic, or on the verge of anaemia.

He mentions "patients who return to their doctors time and time again with anaemic symptoms—each time to receive oral iron, to respond, and then to relapse again in a few weeks." The obvious remedy for this is to instruct the patient to have one iron tablet a day, either for the rest of her life or until she ceases to menstruate. She will appreciate this much more than having her hide pricked for an intramuscular or intravenous injection.—I am, etc.,

Colchester.

M. E. LAMPARD.

Future of Diagnostic Procedures

SIR.—Recently a patient of mine aged about 2 years who five days previously had swallowed a halfpenny was refused x-ray check on the progress of the coin because of the possibility of producing leukaemia. Provided the money is eventually returned without any trouble, as is usually the case, one need not be particularly concerned about the effect of such a decision on this little girl. However, this instance does draw attention to the new medical and legal situation

created by the recent work in connexion with the relationship between exposure to x rays and leukaemia. Obviously in some cases an entirely new conception of when x-ray investigation is justified must shortly come about. Also, for the time being at any rate, more reliance is going to be placed again on older methods of diagnosis, such as antenatal abdominal palpation.

If medical science is to be even partially deprived of diagnostic radiography, search will have to be made among more recent discoveries for an alternative. Possibly some elements in the ray spectrum may be found to be relatively harmless, and these might even be simply produced by filtration of existing cathode emanations. In the meantime attention will be drawn to the possibility of using modified echo sounding and radar apparatus, at least for the detection of foreign bodies in the abdomen.

Members of the public in general, as well as of the medical profession, may well wonder how many diagnostic procedures undertaken in the past with impunity will in the future prove to have been not unmixed in their blessing. It seems unlikely that intravenous dyes and the like have been harmful, but, for instance, where do we stand in relation to the use of radioactive isotopes? At what age can a patient now be said to run no risk at all in exposure to diagnostic or therapeutic radiation? What is going to be the medical and legal standard now? For instance, would a court now allow a doctor the right to use his discretion to withhold x-ray investigation where hitherto it would have found him negligent?—I am, etc.,

Eye, Suffolk.

J. SHACKLETON BAILEY.

Sampling from the Electoral Roll

SIR.—I am a little concerned lest anyone should copy the method of sampling used by Dr. I. T. T. Higgins and his colleagues in their investigation of respiratory disability in an industrial town (*Journal*, October 20, p. 904). It is biased. They wanted a sample of men aged 55 to 64 and used the electoral roll in the following way: "The procedure adopted was to sample at random from the serial numbers of individuals, to regard the selected numbers as selecting a house, and to include in the final sample all men in the chosen houses who were of the correct age." They say: "By this method the chance of selecting a house is roughly proportional to the number of its inhabitants, so that, again roughly, each individual has the same chance of being included in the sample."

This last statement is not even roughly correct. First, the chance of selecting a particular house is exactly proportional to the number of electors registered for that address—that is, the number of adults aged 21 and over. Then if all the men aged 55–64 are taken from the house selected the chance of any man found having entered the sample is still proportional to the number of adults aged 21 and over registered for his address (apart from cases where people have moved since the register was compiled this is the number of adults aged 21 and over living with him). Thus the requirements of simple random sampling that each eligible person should have an equal chance of entering the sample are far from met.

To correct for the unequal probability of selection, the results for each individual need to be given a weight inversely proportional to the number of adults registered for that address. This has not been done. The necessity for so doing could have been avoided altogether if more appropriate methods of selecting the sample had been used.

It is quite possible that in this particular case the selection of men with unequal probability has not affected the conclusions reached. We do not know. However, this biased method of sampling could lead to seriously misleading results where the attributes being studied are correlated with the number of adults living with the person selected. I hope the method will not be copied.—I am, etc.,

London, W.C.1.

Obituary

ROBERT B. OSGOOD, M.D., F.A.C.S.
Hon. F.R.C.S.

Dr. Robert Bayley Osgood, emeritus professor of orthopaedic surgery at Harvard, died on October 2, aged 83. He was recognized throughout the world as an orthopaedic surgeon and medical teacher of great distinction.

Robert Bayley Osgood was born at Salem, Mass., on July 6, 1873, and graduated M.D. at the Harvard Medical School in 1899, the year in which he began to practise as an orthopaedic surgeon in Boston. Not long afterwards, in 1903, he published a paper on lesions of the tibial tubercle occurring during adolescence, this being the first description of the disorder which later came to be known as "Osgood-Schlatter disease." During all his professional life he was on the staff of the Massachusetts General and Children's Hospitals, being in charge of the orthopaedic service at both; and at the Harvard Medical School he was appointed John Ball and Buckminster Brown professor of orthopaedic surgery in 1922. Among the books of which he was author or part-author were *Diseases of Bones and Joints* (1909), *The Evolution of Orthopaedic Surgery* (1925), *Fundamentals of Orthopaedic Surgery in General Medicine and Surgery* (1931), and *Medical and Orthopaedic Management of Chronic Arthritis* (1934). His work brought him international renown, and he was an honorary member of numerous foreign orthopaedic associations, including the British and Australian associations. In 1925 he gave the Hugh Owen Thomas Lecture in Liverpool, and in 1943 Major-General W. H. Ogilvie (now Sir Heneage Ogilvie) conferred on him at the British Embassy in Washington the Honorary Fellowship of the Royal College of Surgeons of England. He was also an Honorary Member of the Section of Physical Medicine at the Royal Society of Medicine.

During the first world war Dr. Osgood served with the American Forces overseas, and in 1918 he was appointed a consultant to the office of the Surgeon-General in Washington. In later years he held numerous official appointments, including those of chairman of the advisory board of orthopaedic surgeons to the trustees of the Shriners' Hospitals for Crippled Children, and chairman of the advisory committee for services for crippled children at the Children's Bureau, Department of Labour, Washington. As long ago as 1921 he was president of the American Orthopaedic Association, and a few years later he became president of the New England Surgical Society.

We are indebted to Mr. H. J. SEDDON for the following appreciation:

Perhaps the most outstanding quality of Dr. Robert Osgood's, greater even than his reputation as a surgeon, was his beneficence; it embraced causes and individuals alike. His command of orthopaedics was profound, though he cared little for operative surgery; what mattered far more to him was that orthopaedics in America should be done well.

A few months ago, after I had visited two Shriners' hospitals, both in California, I happened to ask an American friend how it was that all the Shriners' hospitals I had ever visited were staffed by such excellent men. His answer was that from the first the policy had been to appoint only first-class surgeons. "Bob Osgood used to do it, you know"—that was regarded as a sufficient explanation. If we go back nearly 40 years to the minutes of the inaugural

meeting of the British Orthopaedic Association, held on February 2, 1918, we read that "Major Robert B. Osgood, of Boston, U.S.A., who had helped very considerably in the preliminary steps which had led to the formation of the Association, was present as a specially invited guest." Much lay behind this simple statement. There was a clash of powerful personalities: Osgood dealt with it.

He was interested in individuals, too. Twenty-six years ago I paid my first visit to Boston; it was just before Christmas. At the Children's Hospital I met Dr. Osgood, and, having listened to him in the course of a ward round, I realized that here was a great man. But there was nothing Olympian about him. When we had finished he asked me if I could sing. I said I could scrape up a rather cracked tenor that sounded all right in a sufficiently large crowd. He asked me to have dinner with him that evening and then go with him to a carol practice. We went to a large hall where we found Dr. Richard Cabot in his shirt-sleeves fiercely rattling a baton and trying to knock some sort of discipline into a mob of carol singers. Dr. Osgood was a respectable tenor, and I followed him rather than the score. (Dr. Philip Wilson in an adjoining group was, I think, a magnificent *basso profundo*.) On Christmas Eve we were let loose on Beacon Hill, and finished up in the snow-covered courtyard of the Massachusetts General Hospital for our last performance. Then we went back to Beacon Hill, where candles were alight in every window and where every door was open to receive us. In no house was the welcome warmer than in Dr. and Mrs. Osgood's; there was supper for everyone and presents from the Christmas tree. This was the beginning of an enduring friendship, enriched—for me—by a regular correspondence. But I was only one of scores of young men whom Robert Osgood guided with good advice, always given gently and humbly.

This cultivated Bostonian, one of the small band of outstanding men who gave their city its unique place in orthopaedics, differed from many of his contemporaries in having left few memorials of his eminence as a surgeon. A disorder of adolescence bears his name; I know of no operation that does. But all that is best in American orthopaedic surgery owes something to Robert Osgood. His noble influence is remembered too, perhaps even still felt by a few, in our own country, which he loved almost as much as he did his own.

VLADIMIR FILATOV, M.D.

Professor Vladimir Filatov, who died at Odessa on October 31 at the age of 81, was an ophthalmic surgeon of international repute and renowned for his work on corneal transplantation. He was a member of the Academy of Sciences of the U.S.S.R.

Vladimir Petrovich Filatov was born at Saransk, in the Ukraine, on February 15, 1875. He studied medicine in Moscow, graduating as a doctor in 1897. After holding hospital appointments in Moscow he moved to Odessa in 1908, and a few years later was appointed director of the ophthalmological institute there. Although best known for his work on corneal grafting, he was no narrow specialist and had written on such subjects as trachoma, malignant tumours of the eye, and the bacteriology of eye infections. The results of his research were published mainly in Russian journals, but he wrote an account of transplantation of the cornea which appeared in *Archives of Ophthalmology* (N.Y.) in 1935. During the second world war he worked at a hospital in Tashkent, where his experience of tissue grafting was applied to the treatment of war wounds. He continued working at Odessa until the time of his death, directing the Ukrainian Experimental Institute for Eye Diseases and Tissue Therapy. He was also a deputy of the Ukrainian Supreme Soviet.

We are indebted to Sir STEWART DUKE-ELDER for the following appreciation:

Vladimir Filatov was undoubtedly one of the great ophthalmologists of our generation, and many ophthalmologists in this country have regretted the fact that closer contact with him and a more personal appreciation of his ideas have been impossible. His greatest contribution was in the biology of corneal grafts and the perfecting of the surgical techniques of keratoplasty. It will be remembered that von Hippel, of Göttingen, was the pioneer who, towards the end of the last century, made this operation a clinical possibility. Filatov shares with Elschsig, of Prague, the distinction of evolving the techniques which made the operation a practical surgical procedure. As early as 1913 he was experimenting on the feasibility of total corneal grafting, transplanting the entire cornea with a margin of sclera and conjunctiva. This drastic procedure, of course, gives no clinical results of value, but the attempt illustrates his courage as a surgical enthusiast.

There are two major advances with which his name is associated in connexion with corneal grafts. The first of these concerns the use of eyes from cadavers. Some time previously Magitot, of Paris, had shown that a graft could be preserved for a period varying from one to two weeks at a low temperature in haemolysed blood. With this as a basis Filatov went further and popularized the use of a grafts removed from the eyes of cadavers; as early as 1934 he was using such eyes 41 hours after death. This, of course, opened up a vast source of graft material and is universally practised to-day with great benefit.

The second great advance he made was in the employment of lamellar grafts, not for visual purposes but with a view to obtaining a suitable bed for a final graft. In the previous century von Hippel had practised lamellar keratoplasty and Elschsig in the early 1920's had demonstrated that a corneal graft would take only if there were a sufficiency of clear cornea in the eye of the recipient; a graft inserted into a bed of corneal scar tissue invariably turned opaque. In such a cornea Filatov inserted a clear lamellar graft, and at a later stage inserted a penetrating graft for visual purposes. In work such as this he noticed that the implantation of a graft tended to clear corneal opacities which might already be present. Upon this observation he built up a theory of the stimulation of tissues by the release of "biogenic substances," a theory which became a considerable cult in Russian medicine. With this as theoretical basis, he launched a new method of therapy based on the injection, topically or systemically, of a great number of animal and vegetable substances, the products of which were assumed to stimulate the tissues of the host, and for a time this method of "tissue therapy" was widely employed in the treatment of a host of degenerative ocular diseases which responded to no other therapy—myopic chorio-retinal atrophy, primary pigmentary degeneration of the retina, optic atrophy, and so on. The most common material ultimately advocated was derived from the placenta, and the method of use was either to inject placental extract or to insert subconjunctival implants of placental tissue. Most ophthalmologists are agreed that, whatever the theoretical justification for this form of therapy, in practice it brought little or no benefit, and it has generally fallen completely out of use. However this may be, Filatov will always be remembered for his achievements in technical surgery and for the originality of his concepts.

A. FAY MACLURE, M.D., F.R.C.S., F.R.A.C.S.

Mr. A. Fay Maclure, honorary consulting surgeon to the Alfred Hospital, Melbourne, and formerly lecturer in surgery at the medical school, died at Melbourne on October 4, aged 72.

After graduating at Melbourne in 1907, Alfred Fay Maclure came to London to continue his surgical education and took the F.R.C.S. in 1911. He returned to

Melbourne to become a member of the staff of the Alfred Hospital just before the first world war, in which he served as a captain on the staff of the 3rd General Hospital at Lemnos. He was appointed O.B.E. in the 1919 New Year Honours, by which time he had attained the rank of major (temporary lieutenant-colonel). During the years that followed he became one of the best-known and most popular surgeons in Melbourne.

We are indebted to Sir GORDON GORDON-TAYLOR for the following appreciation:

Perhaps a few lines in the columns of the *British Medical Journal* may be vouchsafed to an old friend of Fay Maclure to pay tribute to his memory. Almost half a century has passed since I may have helped in some small fashion to steer him through the examinations which preceded the acquisition of the Fellowship of the Royal College of Surgeons of England which he obtained in 1911. He became a Foundation Fellow of the Royal Australasian College of Surgeons in 1927, having been elected to the surgical staff of the Alfred Hospital, Melbourne, in 1913. No lengthy saga of surgical communications can have made his name familiar to the modern generation of British surgeons, for he was a man of the scalpel rather than the pen, and even to the modern "Alfredian" he has been for a number of years little more than a legendary name, though for a quarter of a century he ranked as the foremost surgical opinion in the State of Victoria.

The hammer-blow of fate has struck hard at "The Alfred" this past year, which has lost by death Sir Alexander Stewart, for many years its president and an old Aberdeen schoolfellow of my own, whose vision and kindness of heart initiated a liaison with my own Middlesex Hospital; Sir Wilberforce Newton; and now Fay Maclure. The surgical tradition of "The Alfred" was founded by Hamilton Russell, Lister's last house-surgeon at King's College Hospital, and, if it be Hamilton Russell who brought Lister's lofty idealism to "The Alfred," it was his devoted acolytes, such as Fay Maclure and Balcombe Quick, happily still full of youthful vigour, who carried the torch that Hamilton Russell lit.

No man more truly symbolized the motto of "The Alfred"—"Service and Care"—than did Fay Maclure, and the address which he gave on the occasion of the unveiling of the honour board in the Alfred Hospital commemorating "Alfredians" who had made the supreme sacrifice in the two great wars incorporated the high traditions of "The Alfred" and was used in fact at his own funeral service, emphasizing his own life of "Service before self," and will be quoted once again by another veteran of the 1914-18 war at the memorial service at the Melbourne Shrine on Armistice Day, for "there could be no finer call to duty." Some prescient fairy may have been at Fay's christening and whispered the name "Alfred," but he was never anything except Fay to everyone, though as Fay Maclure of "The Alfred" he will long be remembered by surgeons of Victoria and throughout Australasia.

J. C. CRUICKSHANK, M.D., D.T.M.

The obituary of Professor J. C. Cruickshank was published in last week's *Journal* (p. 1061). We are indebted to Professor ROBERT KNOX for the following appreciation:

Those who knew Jack Cruickshank well know what a rare personality he had. There can be few men so free as he was from pompousness and self-seeking. Quiet and unassuming in his manner, he was a shrewd judge of men. As a teacher he was outstanding, and many of his former pupils and colleagues all over the world will always remember the energy and care with which every detail of his many teaching activities was planned and carried out. His contributions to research, both fundamental and applied, were of great value—

interestingly and clearly written with characteristic absence of wild and unprofitable speculation. Perhaps one of his best pieces of work was a thorough study of the epidemiology of typhoid fever in Devon over a period of years when he was in charge of the Public Health Laboratory at Exeter, but this is only one example of the consistently high standard of his work. He was a man of very great ability which he never used for selfish ends or personal advancement. His knowledge of his subject was both wide and deep, and both in bacteriological and in other matters too he made it readily available with characteristic generosity. Those who knew him and his family can never forget the warmth of his welcome, his simple humour, the essential sanity and the unfailing depth of his friendship. His family will have the deepest sympathy of all their many friends.

Dr. J. L. FARQUHARSON, whose death occurred at Amersham on August 24, was a much-loved general practitioner in that part of Buckinghamshire, where he had practised since 1937. The son of a well-known Southampton doctor, John Langwell Farquharson was educated at Bedales School and St. Thomas's Hospital, his medical education being interrupted by a period of service in the first world war. He qualified M.R.C.S., L.R.C.P. in 1923, and, after holding house appointments at Bristol General Hospital, spent two years as chief assistant medical officer in the Sarawak Civil Service. Returning to England in 1928, he went into general practice at Weston-super-Mare in partnership with the late Mr. Philip Martin, and, having taken his F.R.C.S.Ed. in 1929, was elected to the staff of the Weston-super-Mare General Hospital as an honorary assistant surgeon. But, although he quickly made himself a most competent general surgeon, his main interest remained in general practice. He always wished to live nearer his friends, who were mostly in the London area, and in 1937 he resigned his surgical appointment at Weston and settled in practice at Amersham, at first in partnership and later on his own. Even there, however, he did not cut himself off entirely from surgery, and up to the advent of the National Health Service still continued to operate at Chesham Cottage Hospital. But his practice was absorbing so much of his time that he reluctantly decided to give up surgery altogether. A man with strong socialist leanings, he welcomed the National Health Service wholeheartedly and gave to it his very best. He continued in active practice until illness obliged him to give up earlier this year. He leaves a widow and three children. Farquharson was not only an able doctor, he was also a great individualist and a very vital person with the most diverse interests, which included the arts, politics, sport, and, above all, his garden. Very few busy doctors can have led such a full life, and he had a wonderful capacity for communicating his enthusiasms. His engaging and dynamic personality will be sadly missed by his many friends and patients, to whom he was so often a robust mental tonic and a constant source of inspiration.—H. G. E.

The death of Dr. ETHILDA B. M. HERFORD on August 26 at the age of 84 removes one of the few remaining members of the British Psycho-Analytical Society who took part in the activities of the small group responsible for establishing a society to study psycho-analysis in England. Born in Surrey on December 6, 1872, the daughter of Mr. Edward E. Meakin, for some years editor of *The Times of Morocco*, Ethilda Budgett Meakin was educated at the North London Collegiate School and at University College, London. As a preparation for a career in medicine she worked for two years with a mission in the slums of Glasgow. She then studied at the Royal Free Hospital School of Medicine for Women and graduated M.B. from London University in 1898, taking the B.S. degree in the following year. After graduation she held appointments as assistant medical

officer at the Camberwell Infirmary and the Grove Hospital until 1902, when she went to India to become acting physician in charge of the Coma Hospital, Bombay. From 1904 to 1907 she was medical superintendent of the Victoria Hospital for Women in Calcutta. Between the years 1902 and 1912 she held postgraduate appointments at various European universities. Up to the time she left India her main interest was in gynaecology, on which she published a number of papers. Her marriage to Oscar Herford, a gifted violinist, took place in 1907 in Calcutta. They had three sons, one of whom is a doctor, and a daughter, who is herself qualified and married to a doctor. The family returned to live in England in 1917 and settled at Reading.

Dr. SYLVIA M. PAYNE writes: Dr. Ethilda Herford's interest in psycho-analysis was aroused by the early publications of Freud and extended through contacts with members of the staff of the Brunswick Square Clinic, founded by the late Dr. Jessie Murray and carried on subsequently by Dr. James Glover, Ella Sharpe, and others. She was present at the International Psycho-Analytical Congress held at The Hague in 1920. There she met Karl Abraham and went to Berlin to work with him for a few months, and subsequently with Ferenczi at Budapest. On her return to Reading she gave her time to the study and treatment of functional nervous disorders by psychotherapy and psycho-analysis in particular. She became a director of the British Hospital for Functional Nervous Disorders in Camden Town. In 1928 she published a paper on the infantile mind and its relations to social problems and mental hygiene. In 1921 she was elected an associate member of the British Psycho-Analytical Society; membership was granted her in 1934; and later she was appointed honorary physician to the Institute for the Scientific Treatment of Delinquency and the London Clinic of Psycho-Analysis. Dr. Herford's life was characterized by an outstanding interest in human nature, and a desire to use every means available to relieve human suffering. A powerful personality and the mind of a pioneer were allied to the spirit of a child moved by a sense of the wonder and beauty of creation and reverence for life. Through all difficulties she looked for what was good. With her husband she became a member of the Society of Friends and took an interest in organizations, local or international, which had the aim of promoting peace. A deep interest in education and the problems of young people led to an association with the late Howard Whitehouse in 1919 as a founder and governor of the very successful school at Bembridge, Isle of Wight. The decision to study medicine was made when this was not yet regarded as a desirable career for women, and she joined the psycho-analytical group without waiting to see if it was accepted by the medical profession as a whole, and made sacrifices to obtain psycho-analytical training with those best equipped to give it. During the years following her admission to the British Psycho-Analytical Society she practised psycho-analysis in Reading, and attended the scientific meetings regularly and was present at almost every congress. Her attitude was always receptive, and she would take from the papers and discussions the material which appealed to her and in which she believed. Towards the end of her life she did not spare herself the fatigue of travelling from Reading to attend scientific meetings in London, and she retained her keen interest in the practice of psycho-analysis to the last. Her absence will be felt by all who knew her. Her recreations were determined by her love of a simple outdoor life and lack of interest in personal possessions. She went camping with her family to the end of her life, and died in her sleep when on holiday in a caravan by the sea which had always been for her a particular joy.

Dr. S. R. ARMSTRONG, of Belfast, died on October 15 at the age of 69. Samuel Richard Armstrong was born at Manorhamilton, Co. Leitrim, on May 29, 1887, and studied medicine at Queen's University, Belfast, where he graduated M.B., B.Ch. in 1913. He then held house appointments at the Belfast Infirmary and the Belfast Maternity Hospital. During the first world war he served in France in command

of No. 10 Casualty Clearing Station and as physician-specialist with No. 8 Casualty Clearing Station. He made a special study of chest wounds, carrying out some original investigations, and for his services he was appointed O.B.E. in the 1919 Birthday Honours, having been previously mentioned in dispatches on two occasions. After the war he settled in practice at Belfast, and from 1919 to 1952 was a part-time visiting medical officer to the Belfast Union Hospital (now the City Hospital) under the old Belfast Board of Guardians. He also gave his services as honorary physician to the Ulster Society for Educating the Deaf, Dumb, and Blind. He is survived by a widow, a son, Dr. Neville Armstrong, and two daughters.

A colleague writes: I had the privilege of assisting Dr. S. R. Armstrong in general practice for two years and of knowing the warm friendship of his family circle. It has been gratefully said of him that he cared responsibly for every patient; he had a great interest in the homes and families, relatives and relationships, the occupations and welfare of each one. He gave to me and others affectionate and careful instruction. He served with distinction in the first world war, and reported the first case of encephalitis lethargica occurring in military personnel. At this time he made a lasting friendship with the late Sir William Thomson, professor of medicine in Queen's University. He was appointed to the visiting staff of the Belfast Union Hospital and continued to visit the children's medical wards there until he reached retiring age. He suffered a severe myocardial infarction at the early age of 43, and it was an index of his morale and force of character that he again took up his practice single-handed and continued, in spite of later episodes, as an essentially private family doctor, vigorously eschewing the National Health Service. He had an immense fund of experience and wisdom and set a very high standard of practice. The hallmarks of his work were painstaking attention to detail combined with a precise knowledge of the latest publications on research; he expected these qualities of those who worked with him, were they consultants or assistants. It was while holding a surgery that he suddenly died. He leaves a widow, two daughters, and a son, who qualified recently, to whom many will extend their gratitude for a life energetically poured out and their immediate sympathy in the bereavement.

D. L. W. C. writes: Dr. S. R. Armstrong was a remarkable man. His health was not good, and what would have defeated a lesser man only acted as a stimulus to him in pursuit of his work and ideals. He was largely instrumental in modernizing and transforming the old Poor Law hospital at Belfast into an up-to-date unit. He specialized in the diseases of children and organized his department most efficiently. He also planned and carried through a surgical extension to his medical wards, no mean feat under difficult and changing conditions and controls. Dr. Armstrong was a rugged individualist who was sure of what he wanted and how to get it. He did not suffer fools gladly, but was a generous colleague who did not bear malice or spite and had a saving sense of humour. The Belfast City Hospital owes much to his efforts, and the Dufferin and Ava Children's Hospital is his enduring memorial.

Mr. ARTHUR BURTON, honorary consulting surgeon to Cromer Hospital, died at Cromer on October 23 at the age of 86. Arthur Burton was born in London on March 24, 1870, and was educated at Marlborough College and at King's College, Cambridge, where he obtained a second-class in the Natural Sciences Tripos in 1891. He went on to St. George's Hospital to receive his clinical training, being awarded a prize for proficiency in his third year, and qualified by taking the London Conjoint diploma in 1894. In the following year he obtained the degrees of M.B., B.Chir. and four years later proceeded to the M.D. He was elected F.R.C.S.Ed. in 1912. After qualification he held the appointment of junior house-physician at the old North-Eastern Hospital for Children, now the Queen's Hospital for Children, and then became house-physician at Adden-

brooke's Hospital, Cambridge, a post he held for two years. He was also house-physician and physician to out-patients at the General Lying-in Hospital, York Road, and clinical assistant at the old London Throat Hospital, in Golden Square, and at the Westminster Ophthalmic Hospital. Going to South Africa as a civil surgeon attached to the Army Medical Department, he later became a surgeon-captain in the South African Constabulary and medical superintendent of Grey's Hospital, Pietermaritzburg. On his return from war service he settled in general practice at Cromer in partnership with the late Dr. H. C. Dent. Soon afterwards he was appointed honorary surgeon to the Fletcher Convalescent Home at Cromer, and subsequently became honorary surgeon (later consulting surgeon) to the Cromer Cottage Hospital and honorary consulting surgeon to Kelling Sanatorium. During the first world war he served as a captain in the R.A.M.C. For many years he was divisional surgeon in the St. John Ambulance Brigade, and in 1941 was appointed an officer of the Venerable Order of St. John of Jerusalem. He and Mrs. Burton helped to found the Cromer orchestra in 1908. He is survived by a son and a daughter.

Dr. MALCOLM McLELLAN, who practised at Friockheim, Angus, died suddenly on October 25, aged 47. By his death the community has lost a very good family physician and a charming personality. Malcolm McLellan studied medicine at Glasgow, graduating M.B., Ch.B. in 1933. After holding the posts of house-physician at the Royal Infirmary and house-surgeon at the Royal Samaritan Hospital for Women, Glasgow, he went into practice at Airdrie. During the war he served in the R.A.F., attaining the rank of squadron-leader. Further promotion was in his reach, but he preferred to remain in a clinical rather than an administrative capacity. Coming to Friockheim after the war, he developed this rural practice by his keen interest in the community and his good service, both in his professional and in his social capacities. He was chairman of the Angus Division of the B.M.A. and joint secretary of the local medical committee. In country dancing he achieved worldwide renown, especially in the music of this art. A team trained by him has been asked to go to Moscow and may yet accept this invitation. He was interested in sport and also was an elder of the Church. As a family doctor his interest in his patients was both real and personal, and by them his death will be felt as that of a friend.—D. M.

Dr. G. E. FRIEND, who was medical officer of Christ's Hospital, Horsham, for over thirty years, died at Reading on October 26, at the age of 81. Gerald Edward Friend was born at Reading on May 19, 1875, the son of the Rev. Martin T. Friend, and was educated at Bradfield College and at Keble College, Oxford. He received his clinical training at St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1905. After qualification he held appointments at the Victoria Hospital for Children, the Chelsea Hospital for Women, and Brompton Hospital, before becoming medical superintendent of St. George's Hospital in 1908. He was editor of *St. George's Hospital Gazette* from 1904 to 1908. He left St. George's in 1913 to take up the appointment of school medical officer at Christ's Hospital, holding the post until 1946, when he retired. In the Medical Officers of Schools Association he served on the council and on the editorial committee, and held in turn the offices of honorary secretary, treasurer, and president, and on retiring from Christ's Hospital was elected an honorary life member. His keen interest is shown in the association's records, which contain the papers he read and his many contributions to discussions. A firm believer in the improvement of health by dietary measures, he was a member of the B.M.A.'s Nutrition Committee from 1932 to 1938, and during the second world war he acted as honorary general secretary of the Food Education Society.

Dr. T. L. SCOTT writes: In 1913 Gerald Friend went to Christ's Hospital as resident medical officer from St. George's

Hospital, where he was medical superintendent. He remained at Christ's Hospital until his retirement in 1946. He is remembered by all who knew him as a fatherly man, with a gruff voice and rough exterior covering a firm but very kindly disposition—a man who showed a real interest in the medical welfare of his patients, sparing no effort when they were ill, but showing clearly his disapproval of the shirker or slacker. His keen interest in feeding and his regular weighing and measuring of the boys provided the material for his well-known book, *The Schoolboy—A Study of His Nutrition, Physical Development and Health*. He believed that regular weighing was of supreme importance and expected boys and staff to share that belief. He is reputed to have said of a boy who had misbehaved, "Well, then, I shan't weigh him," as though this were the severest punishment he could receive. To his successor he left an organization and administration easy to follow, one which had stood the test of time and needed little change to meet modern requirements. The staff of Christ's Hospital remember him as a family man, the father of four sons who filled the house with young life and activity in which father took a lively part. His house was an important focus of Christ's Hospital society. His enthusiasm for his garden and his skill at croquet provided, at his home, his relaxation from medical duties. A keen interest in the theatre dating from the Oxford University Dramatic Society was kept alive by the frequent demands that he should practise his skill in the art of make-up for school and house plays. Those who knew him speak of him with respect, and relate that he liked to think for himself and would express himself vigorously when roused. To all who knew him he will ever be remembered as a kindly man, a painstaking doctor, and above all as a real friend.

Medical Notes in Parliament

Prescription Charges

Dame IRENE WARD (Tynemouth, Con.) asked the Chancellor of the Exchequer on November 1 if he would state the basis and machinery on which the new charges for prescriptions would be reimbursed to those who could not meet the charges without hardship, and who, though outside the National Assistance scales, had a personal budget which on a small fixed income could not meet further charges without hardship. Mr. R. H. TURTON, Minister of Health, who replied, said that repayment would be made on the same basis as at present to any person who could show that his resources were insufficient by National Assistance standards to meet the charge. The machinery for claiming, and making, repayment would be on similar lines to that which was already well established and had proved satisfactory, but he was reviewing it in consultation with the National Assistance Board and other bodies concerned in order to see if it could be improved at any point. Mr. Turton added, in reply to further questions, that there would be two categories of patients, as now: those who were already on National Assistance, and those for whom hardship was created which brought them on to the National Assistance standard. Last year there were nine million applications in respect of prescription charges. Of these, 30,000 were from persons not in receipt of National Assistance, and in 95% of these the claim was upheld.

Mr. G. RIPPON (Norwich, South, Con.) asked the Minister of Health whether he would provide for those on National Assistance, and others for whom payment for drugs and appliances would constitute hardship, to have their prescriptions written on a special coloured form which would exempt them from payment and thus would enable them to avoid the inconvenient process of seeking reimbursement. Mr. TURTON said the suggestion would be administratively impracticable. Moreover, it would mean asking doctors and chemists to exercise a test of means, which they could not possibly carry out.

Miss M. HERBISON (North Lanarkshire, Lab.) asked the Secretary of State for Scotland on October 30 what were the regulations with regard to the number of items which could be put upon one prescription form. Mr. J. STUART stated that there were no regulations on the subject. Doctors had been asked, and it was their normal practice, not to write more than two prescriptions on one form.

Mr. S. SWINGLER (Newcastle-under-Lyme, Lab.) asked the Minister if he would exempt diabetic persons from the proposed increase in charges for prescriptions. Miss PAT HORNSBY-SMITH said no, but any person who, on application to the National Assistance Board, showed that he would suffer financial hardship in accordance with the board's standards would be able to obtain a refund. Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked for a statement from the Minister that would relieve the anxiety of these and other chronic patients. Miss HORNSBY-SMITH said she could not give an undertaking, but would pass on the suggestion to the Minister.

Replying to Mr. HENRY PRICE (Lewisham West, Con.), she said the length of a prescription for diabetics and chronic cases was entirely a matter for the doctor. The Ministry was advised that there would be no practical obstacle in the way of supplying it up to three months when treatment was stabilized.

Cost of Drugs

Major TUFTON BEAMISH (Lewes, Con.) asked the Minister of Health for a table consolidating the conclusions reached in the two official investigations into the comparative costs of national formulary and proprietary preparations ordered on Health Service prescriptions, simply showing the total number of proprietary preparations costed, and what total percentages of these were cheaper than their standard equivalents, had the same cost, or had no equivalents. Mr. TURTON provided the following table and footnotes to it:

Date of Statement	No. of Proprietary Preparations Costed	Cheaper than Standard Equivalent ¹	Same Cost as Standard Equivalent	No Equivalent ²
May, 1955	312	22%	24%	47%
April, 1956	326	20%	2%	51%

¹ In the great majority of these cases the ingredient cost of the proprietary preparation is higher than that of the standard preparation. The lower total cost is due to the basis on which chemists' dispensing fees are distributed.

² A few of these preparations have been classified by an independent advisory committee as of proved therapeutic value, but not yet standard, and a few have not yet been considered. The majority have been classified as not therapeutically superior to standard preparations.

Atmospheric Pollution

Mr. N. DODDS (Erith and Crayford, Lab.) on October 30 put several questions to the Minister of Housing and Local Government on progress made in protecting the people against the harmful effects of smog this winter. Mr. DUNCAN SANDYS stated that the only sure protection against the ill effects of smog was prevention of air pollution. This could not be accomplished all at once, but would require a sustained effort by all sections of the community over a number of years. Since last winter progress had been marked by the passing of the Clean Air Act, which provided the legislative framework for an intensive attack on pollution by smoke, grit, and dust from all sources. Government Departments and other bodies concerned, including the Medical Research Council, the Department of Scientific and Industrial Research, and the fuel industries, were actively co-operating. An Order under the Act would shortly be laid before Parliament specifying the appointed day for those provisions which related to smoke control areas, new furnaces, the height of chimneys, the appointment of Clean Air Councils, and certain other matters. It was intended that the remaining provisions of the Act, which dealt with emissions of dark smoke, grit, and dust from industrial premises, railway engines, and vessels, should be brought into force in the early part of 1958. Meanwhile, arrangements had again been made for warnings to be broadcast by the B.B.C. this winter, if and when persistent fog was

forecast, with advice to the public about the steps they should take. Householders and industry would be asked to take special care to minimize smoke during periods of fog.

Industrial Health Service

Mr. FREDERICK LEE (Newton, Lab.) asked the Minister of Labour on October 30 what progress had taken place in the arrangements for an Industrial Health Service. Mr. R. CARR, the Parliamentary Secretary, stated that since November, 1955, continued progress had been made. The report of the pilot industrial health survey of the town of Halifax had been completed and the Industrial Health Advisory Committee was considering that report. The pilot survey of the pottery industry was in progress in Stoke-on-Trent. Arrangements had been made to co-ordinate the work of the various departments concerned with occupational health research problems. The strength of the medical branch of the Factory Department had been increased and the other parts of the inspectorate were also to be increased.

Vaccination Certificate

Mr. S. VIANI (Willesden, West, Lab.) asked the Minister of Health on November 1 how the United Kingdom representative voted on the decision of the Ninth World Health Assembly to recommend a change in the form of the international certificate of vaccination or revaccination against smallpox; and whether it was now his policy to accede to the proposed change. Mr. TURTON told him that the decision was adopted *nemine dissidente*, but after further consideration the Government decided to reject the amended certificate on the ground that it no longer provided space for recording repeated attempts at primary vaccination.

Hong Kong Medical Staffs

Mr. JOHN RANKIN (Glasgow, Govan, Lab.) asked the Secretary of State for the Colonies why he had ruled that Hong Kong should not receive assistance from the World Health Organization for the training of urgently needed medical personnel, and whether he was aware of the difficulty that had resulted from the cancellation of fellowships that had been arranged two years ago. Mr. A. LENNOX-BOYD stated on October 31 that the governing principle was that assistance from United Nations Specialized Agencies was designed to meet technical needs which could not be met from local (or, in the case of dependent territories, metropolitan) resources. It was not intended as an alternative source of financial aid. In all the cases quoted the training could be supplied in the United Kingdom. The inclusion of these or any other fellowships in World Health Organization budgets did not imply a commitment by Her Majesty's Government to take them up.

Mr. RANKIN said it was proposed to proceed with the building of a hospital in Hong Kong with 1,300 beds, and there were 33 medical students in training this year. If the Secretary of State was going to cut off this source of financial assistance for staffing, what alternative did he intend to put in its place to make sure there were sufficient medical personnel? Mr. LENNOX-BOYD said they had to look to priorities, and the local Government knew quite well that the necessary training could be given in the United Kingdom.

Malta Commission

Mr. W. TEELING (Brighton, Pavilion, Con.) asked the Secretary of State for the Colonies for a statement on the present position of the medical profession in Malta, and why the commission from this country on medical matters had not yet left England.

Mr. LENNOX-BOYD said the subject matter of this question was one for Maltese Ministers and the Maltese Medical Officers' Union, and his concern in the matter had been confined to recommending an independent chairman, which he had done.

Food-poisoning from Frozen Eggs

Mr. A. HURD (Newbury, Con.) on October 29 asked the Minister of Health to what extent frozen eggs sampled at the ports had been found to be infected with germs likely to cause food-poisoning; from which countries the infected consignments came; whether frozen eggs in shell were suspect; and what action was being taken to safeguard consumers here more thoroughly. Mr. TURTON said that shipments of imported frozen egg were being sampled, and only batches with negative samples had been released without conditions. During the last twelve months infected samples had been found in some of the shipments from China, Australia, South Africa, and New Zealand. The degree of infection had varied widely from 1 to 30% of the samples. The sampling was continuing. The department was in close touch with the importers, and communicated with the authorities in the exporting countries as necessary. They were all concerned to maintain a high bacteriological standard. He had no knowledge of any import of frozen eggs in shell.

He stated in answer to Mr. B. JANNER (Leicester, North-west, Lab.) on October 29 that during the twelve months to the end of September 563 samples were reported by the Public Health Laboratory Service to be infected.

Doctors' Pay Increase

Lieutenant-Colonel M. LIPTON (Brixton, Lab.) asked the Minister of Health on November 5 what action he was taking on the £20m. pay increase claimed by the medical profession. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, said it had already been made known that the Government would not feel justified in considering any claim for a general increase in medical remuneration in present circumstances. As to the profession's assertion that there was a contractual obligation involved, the Minister was taking legal advice on this. Lieutenant-Colonel LIPTON said that it was some time since the Minister decided to take legal advice. Could they be told what was the effect of it, and whether the Government was under a contractual obligation to concede this pay increase? Miss HORNSBY-SMITH said she could not give a reply at the moment.

Medico-Legal

COLLABORATION IN AUTHORSHIP

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Mr. R. A. R. Taylor's book entitled *Poliomyelitis and Polioencephalitis* was the subject of an action tried before Mr. Justice Glyn-Jones in the Queen's Bench Division recently.¹ Mr. Taylor claimed a declaration that the copyright in the book was his. He also asked for an injunction to restrain Miss Lorna Prior from claiming that she owned the copyright in the book or in any part of it or had any legal interest in it, and damages. Miss Prior counter-claimed against Mr. Taylor and the publishers and printers that a substantial part of the book was taken by Mr. Taylor without her consent from her unpublished thesis entitled "Clinical Observations on the Treatment of Poliomyelitis." Miss Prior's thesis had been put forward by her in connexion with her fellowship of the Chartered Society of Physiotherapists.

In 1946 Mr. Taylor, who was then Hunterian Professor of the Royal College of Surgeons, had been appointed medical superintendent of Pinderfields Hospital, Wakefield, of which Miss Prior was the superintendent physiotherapist. During the 1947 poliomyelitis epidemic Pinderfields, under Mr. Taylor, was one of the principal treatment centres, and as a result of experience during the epidemic Mr. Taylor in 1948 started to make notes for a book and Miss Prior started to make notes for her thesis.

¹ *Yorkshire Post*, October 25, 26, 27, 30.

In his judgment Mr. Justice Glyn-Jones said that, while the two works were being written, Miss Prior and Mr. Taylor were on terms of close affection and that in February, 1953, when she sent him a copy of her thesis before submitting it for the fellowship nothing had happened to disturb either that affection or the long history of collaboration between them. There were substantial passages in the book parallel to passages in the thesis, but he was confident that a very large proportion of them were written by Miss Prior for Mr. Taylor to incorporate in his book.

In the circumstances he could not hold that Mr. Taylor was not free to make use of material which Miss Prior had put at his disposal or that she had not been free to make use of any material supplied by him. In substance her thesis was her own work and she was entitled to the credit for it, but there was no breach of her copyright by Mr. Taylor or his publishers or printers. He thought that Mr. Taylor's was a work in which they both collaborated, and he did not find it possible to divide the book into parts which he wrote or she wrote.

After counsel for both parties had seen the Judge in his private room it was announced that Mr. Taylor's claim for damages and Miss Prior's counter-claim for infringement would both be dropped, and an order was made that Miss Prior should pay the costs of the action, estimated at £1,500.

Law of Copyright

Now that the multiplication of specialties in medicine has made collaboration in the authorship of books and papers increasingly common, it is as well that the broad implications of the law of copyright should be generally appreciated among aspiring authors. The Judge observed that the only result of the unhappy dispute between Miss Prior and Mr. Taylor was, he feared, that neither her thesis nor his book could profitably be published, and much was lost which might have been saved.

The common-law conception of copyright, that a man has a right of property in his artistic creation, arose out of the need to prevent the unauthorized copying of books. It is this basic right, to prevent other people from copying an author's original work, which is recognized by the existing copyright legislation. Protection is not confined to England but is extended by means of the Berne Convention to members of the Berne Union. This protection does not apply to the United States, which is not a member of the Berne Union, but Canada and most of the European nations are members.

The first owner of the copyright in a work is normally the author, and any subsequent owner must derive his title from the first owner. The copyright is a right of property which can be sold, exploited under licence, or disposed of by will and so on, like any other right of property. If prospective authors intend to collaborate it is important that they should decide and agree between themselves before creating their work what the basis of their collaboration is to be with regard to what may be a right of great value if their creation is a success. Is it to be a truly joint work, so that they are to own the copyright jointly, or is one to do the lion's share and be sole author, merely helped by collaborators whom he may pay and to whom he will no doubt make handsome acknowledgments in his preface?

The main exception to the principle that the author is first owner of the copyright is where an employee under a "contract of service" creates a work in the course of his employment. The problems involved in distinguishing between "contract of service" and "contract for services" are familiar in the field of the responsibility of hospital managements for negligence. Where there is a contract of service, as for example in the case of the editor of a periodical, it is his employer who is first owner of the copyright in the editor's leading article. "Our medico-legal correspondent's" masterpieces on the other hand are probably written under a "contract for services," so that the copyright is probably his own. But he is by no means sure.

FALSE MATERNITY CLAIM

A woman who claimed that she had given birth to twins was paid £24 in benefits by the Ministry of Pensions and National Insurance in 1955. In June this year she again said she was going to have twins and claimed similar benefits—which made a Ministry inspector suspicious, Darlington (Co. Durham) magistrates were told when she appeared before them on October 30. The woman, Mrs. Violet Laing, of Darlington, pleaded guilty to two charges of attempted false pretences and was found guilty on two further charges of false pretences. She was sent to prison for a year.

Mr. M. O'Connor, for the Ministry, said that last year Mrs. Laing submitted a claim for maternity benefit. She also got a doctor to sign and say that a child was going to be born to her. In July, 1955, she filled in a form to the effect that she had had twins, and Dr. D. W. Dawson, of Darlington, certified that she had had the twins, but he had not attended the confinement.

When interviewed, said Mr. O'Connor, Mrs. Laing told an inspector she had had a miscarriage in 1955, so did not claim any benefits. As to the 1956 claim, Mrs. Laing had said she told the inspector that she had given birth to twins but they were stillborn. She said that Dr. V. G. Crowley (a partner of Dr. Dawson's) had attended her confinement. If it had been known that she had had a miscarriage in 1955, Mrs. Laing would never have been paid £10 maternity benefit for each child, or £4 benefit for a home confinement, said Mr. O'Connor.

In evidence, Dr. Dawson said he did not attend Mrs. Laing's confinement in 1955. He probably signed the form for her, thinking that one of his partners had attended her.

Dr. Crowley said that, although he signed a certificate to the effect that he had examined Mrs. Laing, he could not say for certain whether he had done. He did not attend her when she gave birth to stillborn twins, as she had alleged. Mrs. Laing went to his surgery one night and said that she had forgotten to ask the district nurse to sign a form about her confinement. "I thought one of my partners had delivered them and I signed the form in good faith." The doctor added that Mrs. Laing had had numerous miscarriages.

Dr. F. Klauber, the third partner, said he had signed a form for welfare foods for Mrs. Laing, but he had not examined her completely. He did not attend any miscarriage or her confinement in June, 1955. She had told him that one of the twins was in Chester-le-Street and the other had died. Later he saw her with a child, which she told him was one of the twins.

Mrs. Laing said in evidence she had had a miscarriage in 1955, and she did not fill in any forms for benefits and she received no money at all. "I never got a warrant from the Ministry and I never got any money at all. I applied for a maternity grant and nothing else."

She agreed with Mr. O'Connor that she had "induced" doctors to sign forms for her by claiming she had had twins. Mrs. Laing said she had never had twins in her life, and the child that she showed Dr. Klauber was not hers.

Mrs. Laing was stated to have previous convictions. At the end of the case she intimated that she would consider an appeal.

STRESS AND CORONARY THROMBOSIS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On November 1 Mrs. Celia Allfrey, widow of Captain Jack Allfrey, R.N., appealed to the High Court¹ from a refusal by the Pensions Appeal Tribunal to grant her a pension. Her husband had died of coronary thrombosis on July 4, 1954, at the age of 51, after 36 years' service in the Navy.

Mrs. Allfrey's case was that the condition of Captain Allfrey's coronary artery was aggravated by the stress of his job as personal secretary to Admiral of the Fleet Lord Fraser of the North Cape from 1938 to 1951. A naval officer who had been personal secretary to Admiral of the Fleet Sir Dudley Pound when he had been First Sea Lord had also died of coronary thrombosis, and so had another naval officer who had undergone great stress in an executive

¹ The Times, November 2, 1956.

position. In each case the widow had been given a pension. In addition to medical evidence in support of her case, a United States Naval Headquarters directive was produced showing that U.S. naval medical opinion regarded stress as a factor causing coronary disease in serving officers.

The case for the Minister of Pensions, supported by much medical evidence and articles on the subject by leading medical authorities on the condition, was that stress is not a factor which causes coronary thrombosis or the physical conditions which lead to it.

Mr. Justice Ormerod, in his judgment, said that before the tribunal the Medical Services Commission had reported fully to the effect that stress had no effect on the development of coronary thrombosis. He could not say that there was not ample evidence before the tribunal to justify them in deciding as they did. The appeal had therefore to be dismissed.

Vital Statistics

Week Ending October 27

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 578, whooping-cough 1,552, diphtheria 9, measles 3,009, acute pneumonia 316, acute poliomyelitis 114, dysentery 568, paratyphoid fever 14, and typhoid fever 2.

Infectious Diseases

The incidence of infectious diseases increased in England and Wales during the week ending October 20. The largest rises in the numbers of notifications were 644 for measles, from 2,146 to 2,790, 112 for dysentery, from 524 to 636, 76 for whooping-cough, from 1,393 to 1,469, and 68 for scarlet fever, from 532 to 600.

The largest rises in the incidence of measles were 279 in Lancashire, from 500 to 779, 75 in Cheshire, from 83 to 158, 63 in Cornwall, from 77 to 140, and 53 in Yorkshire West Riding, from 158 to 211; the only large fall was 73 in Middlesex, from 113 to 40. Only small fluctuations were recorded in the local trends of scarlet fever. The largest rise in the notifications of whooping-cough was 49 in Lancashire, from 178 to 227. 6 cases of diphtheria were notified, being 4 fewer than in the preceding week; 2 cases were notified in London.

The notifications of acute poliomyelitis numbered 140; there were 13 more for paralytic and 23 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 22 (Manchester C.B. 12, Liverpool C.B. 3, Ashton-under-Lyne M.B. 2), London 13 (Fulham 3), Middlesex 13 (Ealing M.B. 8, Harrow M.B. 2), Cheshire 12 (Stockport C.B. 5, Bucklow R.D. 3, Bebington M.B. 2, Hazel Grove and Bramshall U.D. 2); Kent 11 (Tonbridge R.D. 8).

The largest centres of dysentery were Yorkshire West Riding 147 (Rotherham R.D. 31, Leeds C.B. 21, Huddersfield C.B. 20, Tadcaster R.D. 14, Sheffield C.B. 13), Lancashire 130 (Rawtenstall M.B. 57, Liverpool C.B. 25), Yorkshire West Riding 50 (Haltemprice U.D. 45); London 46 (Wandsworth 13), Essex 38 (Ilford M.B. 23, West Ham C.B. 11), Durham 32 (South Shields 21), Leicester 31 (Leicester C.B. 31), Warwickshire 30 (Coventry C.B. 26), Staffordshire 23 (West Bromwich C.B. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus ————, the figures for 1956 thus ————. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 20 (No. 42) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Retirement of Lord Malvern.—On October 31 Lord MALVERN resigned from the high office of Prime Minister of the Federation of Rhodesia and Nyasaland. Lord Malvern, perhaps better known to medical men as Sir Godfrey Huggins, statesman and surgeon, had held unbroken office as a Prime Minister for 23 years, a record never equalled in the British Commonwealth.

Wellcome Trust.—The Wellcome Trustees announce a grant of 69,000 dollars (about £25,000) to the Pennsylvania University School of Medicine, Philadelphia, to support for five years a Wellcome associate research professorship in the department of anaesthesiology under Dr. ROBERT D. DRIPPS. An American anaesthetist, Dr. HENRY L. PRICE, has been appointed to the post. This is the second research professorship in anaesthesia to be endowed in the North American continent by the Wellcome Trust. In May this year Dr. J. G. ROBSON, from King's College Medical School, Durham University, took up a five-year appointment at McGill University as Wellcome research professor of anaesthesia. The Wellcome Trustees also announce that on November 12 the office of their chairman, Sir HENRY DALE, O.M., F.R.S., and of their scientific secretary, Dr. F. H. K. GREEN, will be transferred from 24, Harley Street, to 52, Queen Anne Street, London, W.1 (telephone: WELbeck 5721/2).

Proctor Medal for British Pathologist.—Dr. NORMAN ASHTON, director of pathology at the Institute of Ophthalmology, London University, has been awarded the highest American honour in ophthalmic research—the Proctor medal. This is the first time the medal has been awarded outside America. The Proctor medal, endowed as a memorial to her husband by the widow of a Boston ophthalmologist, is presented each year by the Association for Research in Ophthalmology (of the United States) to an investigator who has made notable basic contributions to the science of ophthalmology. The presentation will take place at a banquet in New York next June, following a scientific meeting at which Dr. Ashton will address the Association for Research in Ophthalmology. Dr. Ashton's researches include studies on the pathology of retrolental fibroplasia.

Research at Harwell Gains Leukaemia Award.—Four workers from the Medical Research Council's radiobiological research unit at Harwell have jointly been awarded one of two thousand-dollar Robert Roesler de Villiers awards by the Leukemia Society Inc., of New York. The award is for research by Dr. C. E. FORD, Ph.D., Mr. J. L. HAMERTON, Dr. D. W. H. BARNES, and Dr. J. F. LOUIT, director of the unit, which was reported in a paper to *Nature* (1956, 177, 452). The citation states the award is in recognition of the "elegant and conclusive demonstration that general hematologic recovery after total body irradiation is enhanced by bone marrow cell colonization, even from a different species—a discovery of potentially great significance in the therapy of human leukemia." The demonstration depended on the use of "marked" cells from a strain of mouse with a microscopically recognizable peculiarity of its chromosomes. On his colleagues' behalf, Dr. Loutit went to New York this week to receive the award on November 7. A paper reporting an extension of the work for which the award was made was published in the September 15 issue of the *British Medical Journal* at page 626.

Antimicrobial Agents in Food.—Those wishing to submit evidence to the preservatives subcommittee of the Food Standards Committee on the use of antimicrobial agents in food must do so by December 31. The subcommittee is engaged in a review of the Public Health (Preservatives, etc., in Food) Regulations, 1925-53. Evidence should be sent to the subcommittee's joint secretary at the Ministry of Agriculture, Fisheries, and Food, Great Westminster House, Horseferry Road, London, S.W.1.

Nov. 10, 1956

MEDICAL NEWS

BRITISH
MEDICAL JOURNAL 1129

St. John Ambulance Brigade.—At the dinner during the annual surgeons' conference on November 3 and 4 at B.M.A. House,

[Photo Studios, London, W.]

Major A. C. WHITE KNOX, surgeon-in-chief and principal medical officer of the St. John Ambulance Association, was presented with his portrait to celebrate his 50 years' service with the Brigade. The portrait, here illustrated, was painted by Miss ANNA ZINKEISEN, whose wartime drawings for surgeons of clinical and pathological subjects are well known, and was the gift of 500 surgeons of the St. John Ambulance Brigade in token of their great affection and esteem for their surgeon-in-chief. Besides being a busy general practitioner, Major White Knox is an assistant commandant in the City of London's special constabulary, a low-handicap golfer, a crack shot, and an able negotiator on Government committees. He taught the Royal Family first aid during the last world war.

Royal Society of Health.—Dr. J. A. SCOTT, medical officer of health to the London County Council, has been elected chairman of the Royal Society of Health's congress, meetings, and publications committee for the ensuing year. The 1957 Congress is being held at Folkestone from April 30 to May 3, and among those who have been appointed presidents of sections or conferences at the congress are the following: *Sections.*—LORD INMAN OF KNARESBOROUGH, chairman of Charing Cross Hospital (Hospitals); Dr. J. R. REES (Mental Health); Dr. R. S. F. SCHILLING (Occupational Health); Sir WILFRED FISH (Preventive Medicine); Professor P. C. C. GARNHAM (Tropical Hygiene). *Conferences.*—Dr. J. D. KERSHAW (Medical Officers of Health).

Jenner Medal.—The Royal Society of Medicine's Jenner medal for distinguished work in epidemiological research will be presented to Dr. PERCY STOCKS, formerly chief medical statistician at the General Register Office, at a meeting of the Section of Epidemiology and Preventive Medicine on November 16. Sir CLEMENT PRICE THOMAS, the society's president, will make the presentation.

Leeds University.—Among the grants announced at the meeting of the University council last month was one of £9,000 from the Nuffield Foundation for research on the intensification of x-ray screening images in radiological diagnosis. Emeritus titles were conferred on Professor F. S. FOWWEATHER and Professor H. W. SYMONS on their retirement from the chairs of chemical pathology and clinical surgery respectively. It was reported that Professor A. M. CLAYE, professor of obstetrics and gynaecology, had received the honorary M.D. of Melbourne University while in Australia.

British Surgeons in Russia.—A party of four British surgeons, two from Scotland and two from England, are due back from a fortnight's visit to Russia on November 11. They are Sir WALTER MERCER and Professor JOHN BRUCE, respectively President and a Vice-President of the Royal College of Surgeons of Edinburgh; Mr. VICTOR RIDDELL, London director of surgical studies at St. George's Hospital, and Mr. GEORGE ARMITAGE, lecturer in clinical surgery at Leeds. Their hosts were the Academy of Medical Sciences and the Ministry of Public Health of the U.S.S.R. The visit was arranged by the British Council.

Artificial Kidney.—There have been several modifications of the "artificial kidney" devised by W. J. Kolff, of Kampen, Holland, in 1944, notably that of J. B. Merrill, of Boston. Recently French workers in the department of J. Hamburger in the Necker Hospital, Paris, have carried out further improvements, and one of these artificial kidneys is now ready for use in the Postgraduate Medical School at Hammersmith. The machine works by dialysing venous blood, which is then returned to a vein. The indications for the use of an artificial kidney are limited, but include high blood urea, high blood potassium, severe acidosis, and certain forms of poisoning.

Crash Helmets.—The British Standards Institution has published a revised British Standard (B.S. 2001:1956) for motor-cyclists' protective helmets. The tests for resistance to impact, penetration, and the effects of weather, and for the flexibility of the peak, have been made considerably more searching. Copies of the standard, price 3s., may be obtained from the British Standards Institution, 2, Park Street, London, W.1.

Sir John Stopford, F.R.S., who recently retired from the vice-chancellorship of Manchester University (see *British Medical Journal*, July 28, p. 252), was made a Freeman of the City of Manchester at a ceremony on October 16.

Surgeon Rear-Admiral S. G. Weldon has been appointed an honorary physician to the Queen.

Dr. W. S. C. Copeman has been invited by Lisbon University to deliver three lectures in the faculty of medicine this month, to mark the inauguration of an institute of rheumatology associated with the new teaching hospital of Santa Maria.

Mr. F. W. Law, senior ophthalmic surgeon at Guy's Hospital, has been re-elected Master of the Spectacle Makers' Company.

Dr. R. W. Allison, medical officer to the Australian National Antarctic Research Expedition to Mawson, 1955-6, has been awarded a Polar medal by the Queen.

COMING EVENTS

Royal Medico-Psychological Association.—As this year's Maudsley bequest a three-day refresher course in psychiatry will be held at the Royal Society of Medicine on November 12, 13, and 14, starting at 10 a.m. each day. The course will comprise 12 lectures by leading authorities, followed by questions. Open to all doctors and psychologists (tickets £2 for the course, or 15s. for a single day). Details from the Royal Medico-Psychological Association, 11, Chandos Street, London, W.1.

London Medical Exhibition.—In the New Hall, Royal Horticultural Society, Greycoat Street, London, S.W.1, November 12-16. The exhibition is open from 11 a.m. to 6.30 p.m., and on November 15 from 11 a.m. to 7.30 p.m. Professor IAN AIRD will open the exhibition at 11.30 a.m. on the first day.

Radio.—The B.B.C. presents in its series "Our Day and Age" a dramatized account of the work of the Emergency Call Service. Light Programme, November 12 at 8.30 p.m.

Marie Curie Memorial Foundation.—Annual meeting at 64, Rutland Gate, London, S.W.7, on November 14 at 4 p.m. Miss P. HORNSBY-SMITH, M.P., will address the meeting.

Faculty of Radiologists.—Sir JOHN CHARLES will deliver the Crookshank lecture at the Royal College of Surgeons on November 16 at 5 p.m. His subject will be "The Contribution of Radiology in Preventive Medicine."

James Mackenzie Lecture.—Dr. I. D. GRANT will deliver the College of General Practitioners' third James Mackenzie lecture in the Great Hall, B.M.A. House, on November 17 at 11.30 a.m. His subject will be "Family Doctors, Their Heritage and Their Future." Visitors welcome.

Institute for the Study and Treatment of Delinquency.—Annual meeting on November 19 at 5.30 p.m. at 11, Chandos Street, Cavendish Square, London, W.1. Details from the Institute, 8, Bourdon Street, Davies Street, London, W.1.

NEW ISSUES

British Heart Journal.—The new issue (Vol. 18, No. 4) is now available. The contents include:

CRIGHTON BRAMWELL. Maurice Campbell.
A CLINICO-PATHOLOGICAL STUDY OF CORONARY DISEASE. P. J. D. SNOW.
A. Morkan Jones, and K. S. Daber.
THE EFFECTS OF ADRENERGIC-BLOCKING AGENTS ON THE PULMONARY CIRCULATION IN MAN. J. Mackinnon, C. F. H. Vickers, and E. G. Wade.
MITRAL STENOSIS WITH VERY HIGH PULMONARY VASCULAR RESISTANCE AND ATYPICAL FEATURES. J. Mackinnon, E. G. Wade, and C. F. H. Vickers.
THE NATURE OF THE INCREASED PULMONARY VASCULAR RESISTANCE IN MITRAL STENOSIS. E. G. Wade, J. Mackinnon, and C. F. H. Vickers.
A CLINICAL METHOD OF STUDYING THE ELASTICITY OF LARGE ARTERIES. James Conway and K. Shirley Smith.
THE COURSE AND PROGNOSIS OF COARCTATION OF THE AORTA. Maurice Campbell and J. H. Baylis.
THE NAIL FOLD CAPILLARIES IN COARCTATION OF THE AORTA. S. Spence Meighan.
TRICUSPID ATRESIA. James W. Brown, Donald Heath, Thomas L. Morris, and William Whitaker.
CONGENITAL HEART DEFECTS FOLLOWING MATERNAL RUBELLA DURING PREGNANCY. Douglas Stuckey.
THE EFFECTS OF RESERPINE ON HYPERTENSIVE PATIENTS OVER A PERIOD OF TWO YEARS. Robert Hodgkinson.
CARDIAC AMYLOIDOSIS. Robert Benson and J. F. Smith.
ACQUIRED HEART DISEASE WITH ARGENTAFIN CARCINOMA. A. J. Goble, D. R. Hay, Reginald Hudson, and M. Sandler.
CASE REPORTS
TRUNCUS ARTERIOSUS AND A SINGLE VENTRICLE. Ian C. Cree.
THE EFFECTS OF DIGITALIS ON NODAL RHYTHM WITH RECIPROCAL BEATS. Evan Fletcher and Maude Stevenson.
BICUSPID PULMONARY VALVE IN ASSOCIATION WITH CALCIFIC AORTIC STENOSIS. J. B. Enticknap.
HOPE GOSSE. Sir Zachary Cope and Sir John Parkinson.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 12

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Professor H. C. McLaren: Pelvic Tumours Complicating Pregnancy.
UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, 5.30 p.m., Professor H. Grüneberg, F.R.S.: Genes in Mammalian Development.

Tuesday, November 13

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Dr. Macdonald Critchley and Dr. J. L. Bionstein: Medical Aspects of Boxing.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Anatomy and Function of Epidermis.
MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Small Theatre, Clinical Sciences Building, York Place, Manchester, 8 p.m., Mr. G. O. Jelly and Mr. R. T. Grime: Influence of Wilson Hey on Prostatectomy.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Brigadier J. S. K. Boyd: Some Observations on Bacterial Viruses.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Professor Dugald Baird: Influence of Social Environment on Childbearing.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. A. D. Gordon: demonstration of neuroradiology.

Wednesday, November 14

EUGENICS SOCIETY.—At Royal Society, Burlington House, W., 5.30 p.m., Dr. J. A. H. Lee: Some Problems Raised by the Regional Variations in Intellectual Ability in Britain.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Aetiology of Ringworm Infections.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. C. Oswald: Pulmonary Changes in the Reticuloses.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. D. I. Williams: Retention of Urine in Childhood.
LONDON UNIVERSITY.—At School of Pharmacy, 5.30 p.m., special university lecture in pharmacy by Brigadier-General Sir Harold Hartley, F.R.S.: Contributions of Pharmacy and Chemical Engineering to World Needs.
MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Large Anatomy Theatre, Medical School, Manchester University, 4.30 p.m., Professor A. A. Moncrieff: Marasmus.
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor E. P. Sharpey-Schafer: Circulatory Reflexes in Man.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor C. E. Dent: Cystinuria.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Lock Lecture by Dr. M. G. P. Stoker: Latent Infections with Viruses and Rickettsiae.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. N. M. Goodman: Story of International Health.
ROYAL MEDICAL SOCIETY, EDINBURGH.—2.30 p.m., Industrial Visit to Chancellor Flour Mills, Edinburgh.
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Dr. L. H. Murray: Present State of Knowledge with Regard to Vaccination Against Poliomyelitis; 6.15 p.m., Dr. W. H. Kelleher: Prevention, Early Diagnosis, and Management of Poliomyelitis.

Thursday, November 15

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. R. C. Tudway: Reliability of the Radioactive Phosphorus Test for Intraocular Malignancy; Mr. H. F. Freundlich: Some Physical Aspects of the Radioactive Phosphorus Test for Intraocular Malignancy.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Sir Russell Brock: Relation Between the Embryology and Morphology of the Heart and Cardiac Surgery.
EDINBURGH CLINICAL CLUB.—At Royal College of Physicians of Edinburgh, 8 p.m., Mr. F. J. Gillingham: Spontaneous Intracranial Haemorrhage.
HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Dr. A. G. Davies: Planning a Clinic for Hypnototherapy.
INSTITUTE OF CARDIOLOGY.—9.30 a.m., Sir John Parkinson: Auricular Fibrillation and Flutter.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Mr. C. R. Helsby: Renal Calculous Disease.
LONDON UNIVERSITY.—(1) At King's College, 5 p.m., Dr. Grey Walter: Electrical Activity of the Brain. (2) At School of Pharmacy, 5.30 p.m., special university lecture in pharmacy by Brigadier-General Sir Harold Hartley, F.R.S.: Contributions of Pharmacy and Chemical Engineering to World Needs.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Aspects of Refraction Work—(6) Hypermetropic Patients and Presbyopes.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At Liverpool School of Tropical Medicine, 7.30 p.m., laboratory meeting.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Queen's College, Dundee, 5 p.m., Dr. N. H. Ashton: Oxygen as a Cause of Blindness in Premature Babies.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: neurology demonstration.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 5 p.m., Dr. Dorothy Needham, F.R.S.: Biochemistry of Muscular Action.

Friday, November 16

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Crookshank Lecture by Sir John Charles: The Contribution of Radiology in Preventive Medicine.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. V. B. Green-Armlytage: Dyspareunia.
●LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 6.30 p.m., Sir Charles Dodds, F.R.S.: Pharmaceutical Applications of Modern Biochemistry.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. D. H. Patey: Importance of Anatomy in the Surgery of the Salivary Glands; 4 p.m., Professor A. W. Woodruff: Human Filarial Infections.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—At Barnes Hall, Royal Society of Medicine, 2.15 p.m., 31st Maudsley Lecture by Dr. J. R. Rees: Psychiatry and Public Health.

Saturday, November 17

BIOCHEMICAL SOCIETY.—At Institute of Psychiatry, 2 p.m., 356th meeting. Scientific papers.
COLLEGE OF GENERAL PRACTITIONERS.—At Great Hall, B.M.A. House, W.C., 11.30 a.m., third James Mackenzie Lecture by Dr. I. D. Grant: Family Doctors. Their Heritage and Their Future.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bisset.—On October 28, 1956, to Dr. Sheona Lamont, wife of Dr. H. W. Bisset, of West Hartlepool, Co. Durham—a son.
Lambley.—On October 28, 1956, at The Barratt Maternity Home, Northampton, to Joan, wife of Derek G. Lambley, F.R.C.S., of "Penshurst," Church Brampton, Northants, a brother for Richard, Julian, and Angela—Derek William Gordon.
Mansel-Jones.—On October 19, 1956, to Mair, wife of Dr. David Mansel-Jones, of "The Watersplash House," Brockenhurst, Hants, a son—Paul Adrian.
Reichenfeld.—On October 27, 1956, at Birmingham Maternity Hospital, to Ragnheidur, wife of Hans F. Reichenfeld, M.B., M.R.C.S., D.R.C.O.G., a brother for Halla and Kristin—Robert Ernst.
Sender.—On October 27, 1956, at the Canadian Red Cross Memorial Hospital, Taplow, Bucks, to Valerie (formerly Coster), wife of Dr. Neville Sender, a son—Jonathan Jerome.

DEATHS

Armstrong.—On October 15, 1956, Samuel Richard Armstrong, O.B.E., M.B., B.Ch., of 19, Malone Road, Belfast.
Barton.—On October 23, 1956, at Cromer, Norfolk, Arthur Burton, M.D., F.R.C.S.Ed., aged 86.
Cuthbert.—On October 23, 1956, at Edinburgh, Mary Isabella Shaw Cuthbert, M.B., Ch.B., D.P.H., of 16, Nethergate, Crail, Fife, and Kalimpong, Bengal, India.
Findlay.—On October 26, 1956, at Hammersmith Hospital, London, W., Louis Findlay, M.B., Ch.B., of W.H.O. and U.N.R.W.A.
Garry.—On October 27, 1956, at Ridgemoor, Englefield Green, Surrey, Thomas Gerald Garry, M.B.E., M.D., M.Ch., late of Cairo, Egypt.
Herbertson.—On October 14, 1956, at Newcastle-upon-Tyne, William Herbertson, M.D., husband of Phyllis Herbertson, M.B., B.S., J.P., and father of Basil Marriott Herbertson, M.D.
McGeagh.—On October 20, 1956, at Mona Lodge, Ramsey, Isle of Man, George Robert Denison McGeagh, M.C., M.R.C.S., L.R.C.P.
McLellan.—On October 25, 1956, Malcolm McLellan, M.B., Ch.B., of Eastgate House, Frickheim, Angus.
MacLeod.—On October 21, 1956, at Milford Lodge, Shrewsbury, Harold Hay Brodie MacLeod, M.B.E., F.R.C.S.Ed., aged 91.
Robinson.—On October 23, 1956, Bruce Ross Robinson, M.R.C.S., L.R.C.P.
Robinson.—On October 23, 1956, Jean Mary Robinson, M.B., B.S.
Todesco.—On October 24, 1956, James Massimo Todesco, M.D., D.P.H., late of Croydon, Surrey.
Tomlin.—On October 25, 1956, at Guy's Hospital, London, S.E., Edgar Ernest Dexter Tomlin, M.B., B.S., of Winchester, Hants, aged 44.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Spontaneous Cure in Diabetes

Q.—Is spontaneous cure or very great amelioration known to occur in diabetes mellitus, particularly after insulin therapy?

A.—Spontaneous cure is very rare in true diabetes mellitus; it may happen, however, when the diabetes is associated with a pituitary tumour in which destructive changes occur. Surgical removal of medullary and cortical adrenal tumours may also cure diabetes due to overproduction of adrenal hormones.

Insulin therapy may produce a considerable increase in carbohydrate tolerance and, in newly treated cases, especially children, this improvement may for a while simulate cure. These cases, however, almost invariably relapse within a few weeks or months. There are also other possibilities of error. The presence of a reducing substance in the urine may be due to renal glycosuria, some medicine such as aspirin, or a rare condition such as familial pentosuria. Error in diagnosis will be avoided if no patient is regarded as having, or is treated for, diabetes until there has been at least one definitely abnormal blood sugar. Infections and other illnesses may greatly aggravate a mild diabetes and increase the insulin requirement many times; infective hepatitis and coronary thrombosis are notable in this connexion. More rarely a previously high insulin dosage will, for no apparent reason, fall greatly; this is sometimes seen in diabetic girls after puberty. The importance of diet, weight, exercise, and possibly mental stress cannot be over-emphasized in relation to fluctuations in insulin requirement. Conditions such as Simmonds's disease and Addison's disease will greatly increase insulin sensitivity and therefore reduce insulin requirement. Lastly, some mild overweight patients are relatively insensitive to insulin and tolerate large doses; in such cases withdrawal of insulin may make very little difference to the control of their diabetes.

Nocturnal Frequency in Elderly Men

Q.—Why do ageing men have to rise once, twice, or more often in the night to micturate? Why are women not so affected?

A.—The difference in the incidence of gradually increasing nocturnal frequency of micturition in the two sexes is due to the great frequency with which pathological changes occur in the prostate gland.

Men in the age groups over 60 very often develop prostatic enlargement or fibrosis. Prostatic enlargement may give rise to frequency of micturition by virtue of the prostate's size and its tendency to project upwards into the bladder, thus rendering the bladder more irritable. Frequency also results from the presence of increasing amounts of residual urine which compels the patient to pass urine more often. The small fibrous prostate also results in gradually increasing frequency by causing obstruction and residual urine. Four-fifths of enlarged prostates are adenomatous or fibro-adenomatous, but one-fifth are malignant, and the percentage incidence of malignancy increases with age.

Prostatitis has an incidence in the older age groups as well as in young and middle-aged men. During the acute phase great frequency, discomfort or pain on micturition, low backache, hypogastric discomfort, and perineal pain, and

sometimes a raised temperature in the early stages, are the symptoms; even when the acute phase has passed, frequency may persist for weeks or months until the gland returns to its normal size.

These various abnormalities of the prostate are therefore responsible for most cases of nocturnal frequency in the male. Very old men with cerebrovascular disorders and those who are simply senile sometimes develop increasing nocturnal frequency of micturition in the absence of obvious clinical evidence of prostatic enlargement or obstruction such as difficulty in urination and residual urine. In such cases it is believed that the spinal centres concerned with the activity of the bladder no longer exercise their normal control over the contractions of the detrusor muscle, so that the bladder contracts and empties itself more frequently than normal both by day and by night. In such cases removal or resection of the prostate would not assist the patient.

Tuberculosis of the kidney, with which vesical tuberculosis is commonly associated, has a definite but infrequent incidence in the older age groups in the male (more than in the female), and diurnal and nocturnal frequency are the earliest symptoms of the condition; many of these cases are often wrongly diagnosed as cases of enlargement of the prostate gland.

Most of the other causes of frequent micturition at night (as well as by day), such as malignant bladder tumours, apply to both sexes, and their existence is usually revealed by symptoms other than frequency alone—for example, haematuria. Recurrent cystitis is much commoner in women than in men, but the symptoms of this condition are usually intermittent rather than continuous, except where the rare contracted bladder results as a late sequel; in the latter cases intolerable diurnal and nocturnal frequency may be present.

Aspiration of Interlobar Empyema

Q.—What is the best route for aspirating an interlobar empyema?

A.—Interlobar empyema is a collection of pus which has become lodged between the fissures of the lung. The line of the greater fissure extends from the back roughly at the level of the angle of the scapula and presents anteriorly close to the mediastinum and on the diaphragm. Pus may be shut off anywhere in the fissure, but commonly presents as a rounded swelling against the back of the chest wall; anteriorly it forms a fusiform swelling with the apex at the hilum and a broader base on the diaphragm in front. An empyema in the lesser fissure is rare.

The effusion can only be located satisfactorily by radiographs in the antero-posterior and lateral planes. Associated pleural effusion or thickening may obscure the interlobar shadow, but it can usually be determined whether the empyema is in front or behind. The site for aspiration posteriorly is about a hand's breadth from the spine in the sixth or seventh space. The fourth or fifth space in about the nipple line would be suitable for most collections anteriorly placed.

Cheeses for Reducing Diets

Q.—What types of cheese are most suitable for those on a reducing diet?

A.—If we could assume that the subject would eat equal amounts of various kinds of cheese their suitability for inclusion in a reducing diet would be inversely related to their calorie equivalents, which would in turn depend mainly on their fat contents. Thus cottage cheese, made from skimmed milk and providing only about 200 calories per 100 g., would be most suitable. Next would come Dutch and Camembert, each providing slightly under 300 calories. Cheddar and Gorgonzola, made from full-cream milk, would follow with about 400 calories. Stilton, made from

milk with extra cream, would provide about 470 calories, and cream cheese, which contains very little protein, about 800 calories. These simple conclusions, however, must be modified according to how much of the cheese is eaten, and what is eaten with it. The insipid cottage cheese will be excellent for a reducing diet if it is eaten with lettuce or watercress, but not if it is taken on bread with thickly spread butter. Possibly the subject will prefer a small portion of highly tasting cheese, such as Gorgonzola or Camembert, to a large helping of milder cheese. Camembert seems an attractive proposition in combining a strong taste with a low calorie value. A small portion of Gorgonzola may be eked out with celery or watercress. In the same way pickled onions may serve to make a slender portion of Cheddar appear more adequate.

Heredity in Pernicious Anaemia and Addison's Disease

Q.—Is there evidence of a hereditary factor in non-tuberculous Addison's disease or pernicious anaemia? In one family these diseases have occurred in siblings on two occasions each.

A.—In non-tuberculous Addison's disease a few familial cases are known, but no adequate genetic study is available. With pernicious anaemia there is undoubtedly a raised incidence of the conditions among the relatives, but no simple genetic determination, and no figures for risks to relatives, have been established. It has been claimed that unaffected relatives unduly often show achlorhydria, and it has been suggested that it is this which is genetically determined and predisposes to pernicious anaemia. Recently¹ it has been shown that pernicious anaemia is commoner among persons of blood group A.

Flat Feet in Children

Q.—At what age is *pes planus* of significance in a child, and what treatment is recommended?

A.—A child's foot looks flat until the age of 2 because the arch is filled with a fatty pad which disappears after walking is learnt. A boy of 2 who appears to have flat feet when standing has therefore probably only a persisting pad of fat. If in a year or two he still appears to have a flat foot when standing, the diagnosis of flat foot would be confirmed. However, treatment is unnecessary unless the parents find that the uppers bulge inwards at the heel, in which case a wedge, about one-eighth of an inch (3.2 mm.) thick at its broad end, on the inner side of the heel may help. There is likely to be spontaneous improvement before the age of 10, and in any case such flat feet seldom cause symptoms.

Galactorrhoea

Q.—A patient weaned her second child at 6 months of age, but six months later her milk still flows slowly all day to such an extent that unless she wears pads of cotton-wool inside her brassière her clothes are soaked. I have tried really tight support to the breasts, restricted fluid intake, long and short courses of stilboestrol and even of testosterone, all without effect. The same trouble followed the birth of her first child, and was not helped by stilboestrol then. After 18 months' continued failure to check the flow of milk, my predecessor suggested a further pregnancy as a cure, and the patient took his advice. But now she does not want any more children. What investigations and treatment are advised?

A.—It is common for milk to continue to be present in the breasts after weaning, and many multiparae can express a little for some years after their last pregnancy. When the amount of milk continues so great as to soil the patient's clothes, as in this case, it may be because the woman is

unduly anxious that her breasts should dry up and manipulates them to see whether the milk has yet gone. If therefore she can be brought to ignore the problem and to avoid handling the breasts, the copious flow may abate. However, both breasts should be carefully examined for any inflammation. DeLee described the case of a woman whose breasts secreted copiously for over four years (except during two intervening pregnancies) until a small abscess in one breast was found and treated. Galactorrhoea may also occur as a feature of a pituitary tumour, usually in association with amenorrhoea (as in the Chiari-Frommel syndrome), and it would be wise to radiograph the pituitary fossa. Nevertheless it is well known for galactorrhoea to occur, albeit rarely, for no apparent reason at all, and, while its spontaneous cure may attend the resumption of menstruation, the condition may prove intractable.

Evidence to Establish Parthenogenesis in Man

Q.—In connexion with the recent claim about virgin birth, is there any test that conclusively establishes that a particular child could not possibly have been fathered, or is such a claim bound to be based on circumstantial evidence or evidence of a negative character?

A.—With one possible exception the claim of virgin birth can be based only on evidence of a negative character. For example, virgin birth is practically excluded where the child has a blood-group antigen not present in the mother. But the converse, even for all the blood types, does not prove virgin birth, since the father might have transmitted antigens similar to those present in the mother. The one possible exception is the test of skin grafting from daughter to mother. It is argued that the capacity for a skin graft to take seems to depend on so many genes that a successful graft provides convincing evidence of virgin birth. Even here, however, a remarkable coincidence of the relevant genes transmitted by the father with those present in the mother cannot completely be excluded. In the recent claim a skin graft did not take.

NOTES AND COMMENTS

Chronic Haemospermia.—Mr. C. H. CORBETT, F.R.C.S.Ed. (Pickering, N. Yorks.), writes: In your "Any Questions?" columns the question of chronic haemospermia was raised (October 20, p. 951). I had a case of interest some years ago of a police sergeant, and I was searching for literature upon the subject. A friend of mine lent me two French works upon urology and there I found what I required. Trauma was one of the causes—chronic, of course—and this heavy policeman of 40 to 50 summers rode a bicycle upon his rounds. He arranged to stop this cycle-riding and his chronic haemospermia disappeared.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

HYPERPARATHYROIDISM AND STEATORRHOEA

BY

D. R. DAVIES, F.R.C.S., C. E. DENT, M.D., F.R.C.P., and A. WILLCOX, M.D., F.R.C.P.

University College Hospital and Middlesex Hospital, London

[WITH SPECIAL PLATE]

The association of bone disease with steatorrhoea has been well known since the classic descriptions of rickets in coeliac disease (Parsons, 1927) and of osteomalacia in idiopathic steatorrhoea (Bennett *et al.*, 1932). All the descriptions, however, whether based on clinical signs, biochemical studies, or radiology or histology of bones, state that the bone disease is identical with that of classical rickets or of osteomalacia, which of the two depending on the age of the patient. The possibility, however, that parathyroid overaction may also occur in this condition has been strongly stated by Albright and Reifenstein (1948). They suggest that the changes in plasma levels of calcium and phosphorus are closely related to overaction of the parathyroid glands. Those cases of steatorrhoea which tend to have a low calcium and normal phosphorus level correspond to cases in which calcium deficiency (due to the steatorrhoea) has occurred without secondary parathyroid hyperplasia. Cases in which the plasma calcium remains at nearly normal levels but the phosphorus level is low represent the result of the same calcium deficiency, but with sufficient parathyroid hyperplasia to maintain a nearly normal calcium level. This hyperplasia then causes a fall in phosphorus level owing to increased renal excretion of phosphorus by the action of the parathyroid hormone. This interpretation has many supporters, but is disputed also by other workers, including ourselves, on the grounds that other signs of parathyroid overaction are usually absent—for instance, the bone histology, the urine calcium output, and the size and histology of the parathyroid glands when obtained *post mortem*. An alternative hypothesis, which we ourselves favour and which can equally well explain the altered levels of calcium and phosphorus and many of the other findings in steatorrhoea, assumes that, for obscure metabolic reasons, the condition mimics a deficiency of vitamin D. This then leads to increased phosphate excretion by the kidney by a direct renal action. This hypothesis does not involve the parathyroid hormone in the explanation of the lowered plasma phosphorus level.

Arguments of this kind become exceedingly involved, and in the absence of parathyroid hormone assay they are impossible to settle either way. It is the purpose of this paper to describe two cases in which we think that unambiguous radiological signs of hyperparathyroidism

have occurred in the presence of steatorrhoea, and also to suggest that steatorrhoea may sometimes be the cause of apparent cases of "primary" hyperparathyroidism.

Case 1

A midwife aged 37 was seen by one of us (A.W.) on August 6, 1952, at the request of Dr. Oswald Savage. She lived in the Channel Islands and had remained there throughout the German occupation in the war. It was during this period, in 1942, that diarrhoea started. This was intermittent, with up to seven actions of the bowel in a day, but there were long spells of freedom, and in 1945 the diarrhoea ceased. In 1950 she developed abdominal distension and was admitted to a hospital for investigation. Sprue was diagnosed, and treatment with folic acid and "anahaemin" was followed by improvement in her condition. However, she abandoned the treatment after three months. In April, 1951, acute appendicitis developed, and following appendicectomy she noticed the gradual onset of stiffness, particularly of the back and hips, and a waddling gait. She had also lost about a stone (6.4 kg.) in weight in spite of a normal appetite, and had become easily fatigued and dyspnoeic on slight effort. Menstruation was normal, bowels regular without diarrhoea, and micturition normal. There was nothing relevant in the past or family history, except that she had had "consumption of the bowels" at the age of 9 months.

She was of spare build and weighed 8 st. 10 lb. (55.3 kg.). The waddling gait was striking, as though she had bilateral osteoarthritis of the hip-joint. She was obviously anaemic, but without glossitis or stomatitis. There was, however, scaling of the skin of the hands and feet, with brown pigmentation on the neck. The abdomen was moderately distended. Blood pressure 110/60 mm. Hg. Chvostek's sign negative. Urine normal. Blood investigation a week previously showed: haemoglobin 48% (Haldane); red cells 3,200,000 per c.mm.; colour index 0.75; leucocytes 5,200 per c.mm. Radiological examination of the hands, lumbar spine, and pelvis showed decalcification. It was thought that the symptoms were due to multiple deficiencies secondary to idiopathic steatorrhoea, and, as she refused to stay in London, she was advised to return to the care of her physician in the Channel Islands.

Nothing more was heard of the patient until August, 1953, when the following letter was received from her doctor: "She has had amenorrhoea for four months, and I think she is pregnant. She is no longer anaemic, but her waddling gait is worse and she complains of excruciating pain in the sacro-iliac region which compels her sometimes to go on all fours." In view of this arrangements were made to

5002

Will Doctors ever rule the Earth?

Does that seem so very illogical? Is it not possible or indeed probable that in the distant future such a thing could well come about? When nation has ceased to fight nation may not a greater war begin? An all-out war on man's natural enemies. A war in which man is united against those things that mar his health and curtail his very existence? Led by the future's finest medical minds and with every resource, both physical and financial, this humane army could so speed the march of medical progress, could wield such power for good, that all other human activities would be put secondary. Sooner or later will not future man subscribe wholeheartedly to the science of life? Will he not extol those dedicated to his well-being and survival? And will they not become exalted throughout the Earth? But pause awhile and consider. What will be their weapons in this fight of fights? Surely they won't still be the stethoscope or the scalpel. Neither will they be the antibiotics of this present age. Or will they? Perhaps such "wonder drugs" as Terramycin will still be the medical man's most powerful weapon. Perhaps broad-spectrums will even then play a leading role in conquering man's afflictions. But who is so bold as to predict the future? One can only use today's foremost weapons to the extent of today's foremost knowledge to probe the future and treat the present. Medical men of another age will stand on our shoulders and see further. Will it be they who rule the Earth?

Terramycin is the Trade Mark of Chas. Pfizer & Co. Inc., for their brand of Oxytetracycline

admit her to the Middlesex Hospital, where she arrived on October 3, 1953, the delay being due to her reluctance to enter hospital. She said that since August, 1952, she had taken folic acid, iron, and "multivite" tablets with improvement. The last menstrual period was in March, 1953, and with the pregnancy she had felt well but the stiffness and back pain had increased. However, she had been resting during the last two months with considerable relief of the pain. She had no further diarrhoea, but had nocturnal frequency of micturition (about four times a night).

On examination the mucosae were found to be normal; the fundus of the uterus lay half-way between the symphysis pubis and the umbilicus, and there was slight pitting oedema over the sacrum. The signs otherwise were unchanged. B.P. 120/60 mm. Hg. Chvostek's sign negative. Urine normal.

She was seen by Mr. Ian Jackson, who confirmed pregnancy. Pelvimetry showed the true conjugate measurement to be 3.7 in. (9.4 cm.) and the shape of the brim markedly android, while the subpubic angle was very narrow. The bones of the pelvis were porotic, and there was a fracture of the superior ramus of the pubis on both sides. Mr. Jackson advised caesarean section just before term, and Mr. P. H. Newman considered that weight-bearing should be avoided because of the risk of fracture of the femoral neck.

Investigations and Treatment

Owing to the pregnancy and the inability to stand, investigations were somewhat restricted. On October 6, 1953, the blood picture was as follows: Hb 9 g. per 100 ml., red cells 3,900,000 per c.mm., P.C.V. 34%, M.C.V. 87 μ , M.C.H.C. 26.5%, white cells 5,900 per c.mm.; plasma

GRAPH 1.—Case 1: Calcium and phosphorus levels.

57%; fat-balance determination showed 77% absorption. She was treated as follows: folic acid, 20 mg. daily; "cervon," 1 fl. dr. (3,552 ml.) thrice daily; one multivite tablet thrice daily; calciferol, starting with 50,000 units daily, increased to 100,000 units daily on October 15, 200,000 units daily on October 26, and finally 250,000 units daily on November 11, which was continued; calcium phosphate, 60 gr. (4 g.) thrice daily.

Progress

She was delivered of a normal boy, weighing 5 lb. 4 oz. (2.38 kg.), by caesarean section on December 8, 1953. The post-operative progress was uneventful. On December 16 she was allowed to start walking, as x-ray examination suggested that calcification had taken place in the pelvis. She left hospital on December 30. No further news of her was received till December, 1955, when she wrote to say that she continues in excellent health, without pain or stiffness, and is well able to do all her housework without getting tired. Her son is growing satisfactorily and enjoys perfect health.

Radiological Assessment

Radiographs are available of most of the skeleton dating from the first time she was seen in July, 1952, and during

her subsequent admission to the Middlesex Hospital from October to December, 1953.

In July, 1952, there were signs of osteomalacia of comparatively acute onset, for early Looser zones were present in both pubic rami and ischia, without much deformity, the bones as a whole otherwise appearing well calcified and of normal structure (Special Plate, Fig. 1a). The lumbar vertebrae were slightly biconcave and showed increased density of their upper and lower regions to give the appearance of horizontal stripes ("rugger-jersey sign"). In the hands there were very early subperiosteal erosions of the middle phalanges with erosions of the tufts of the terminal phalanges (Plate, Fig. 2a). These latter changes are diagnostic of hyperparathyroidism of either primary or secondary origin.

When examined again in early October, 1953, the skeleton revealed evidence of simultaneous progression of all the radiological signs of the disease. The pelvic fractures now showed bony displacement; the vertebral biconcavity was perhaps more marked in the lumbar region, but, more convincing, it now affected the thoracic vertebrae as well, which also showed a "rugger-jersey sign." The hyperparathyroid changes in the fingers were also more extensive (Plate, Fig. 2b).

By the end of December, 1953, after the birth of the baby and after the patient had received large doses of calciferol, many of the radiological signs had regressed. The pelvic fractures were showing a callus reaction (Plate, Fig. 1b) and the hyperparathyroid lesions in the hands were healing (Plate, Fig. 2c). The biconcavity and "rugger-jersey sign" of the lumbar vertebrae were still unchanged (Plate, Fig. 3).

Case 2*

A married woman aged 41, employed as a coil winder, was referred to one of us (C. E. D.) by Dr. M. E. Morgans on account of bone pains and associated abnormal radiological findings. When admitted to University College Hospital on January 1, 1955, she complained of pains in both thighs intermittently for ten years and a loss of height of about 4 in. (10 cm.). Over the previous five years she had lost 2½ stones (15.9 kg.) in weight, and in the last three months had developed breathlessness on walking and additionally more severe pains had appeared in the arms, ribs, and back. She had been well until 1944, when the pains in the thighs began. These were first interpreted as due to rheumatism, but as they got worse and prevented her from walking she was admitted to another hospital, where tuberculosis of the hip was diagnosed and she was put to bed with traction on the right leg. (The radiographs taken at that time are unfortunately not obtainable.) After two months she was allowed up but found she was no better, and at the end of a further three months the pains gradually lessened and she was able to return to work. However, in 1945 there was an exacerbation, this time with pain in the chest and arms as well as both buttocks, and she was readmitted to the hospital. Radiographs then showed gross decalcification; the serum calcium was 12 mg. per 100 ml., alkaline phosphatase 28 K.-A. units, and urinary calcium 200 mg. in 24 hours. She had iron-deficiency anaemia, which was satisfactorily treated with oral iron. A diagnosis of hyperparathyroidism was then considered. Of a further short admission later that year the notes state that she had a waddling gait and pain in the buttocks; serum calcium 11.5 mg. per 100 ml., phosphatase 46 K.-A. units.

She was able to return to work soon afterwards and remained well until about two years ago, when the pains reappeared in the thighs, and more recently in the other parts of the body. She was able to work until admission, but was by that time in very great pain and could not have continued much longer. On further questioning she admitted to having occasional swelling of the ankles in the summer

*This case was described and discussed at a meeting of the Section of Endocrinology of the Royal Society of Medicine on May 23, 1956.

months. She said she was always constipated, having a bowel motion once every three or four days. Her periods were normal, and her general health was good apart from the pains.

Clinical Examination

Examination showed a short, pale woman of unusual body configuration, as can be seen from the accompanying photographs.

Case 2, showing body configuration suggesting coeliac dwarfism with additional more recent decrease in trunk length.

There was tenderness over the ribs and lower back; joint movements were full.

Laboratory Investigations

Haematological investigation showed haemoglobin 14 g. per 100 ml., red cells 4,160,000 per c.mm., colour index 1.14, M.C.D. 7.9 μ , M.C.V. 102 μ , white cells 6,000 per c.mm. (differential normal). In the bone marrow there were no definite megaloblasts, but some of the intermediate normoblasts had nuclei deficient in chromatin, suggestive of vitamin deficiency (Dr. E. Graves). Glucose-tolerance curve was flat, beginning at 96 mg. per 100 ml. and rising to a maximum of 123 mg. at 30 minutes. Plasma levels were: Ca 11.4 and P 2.0 mg. per 100 ml.; alkaline phosphatase 69 K.-A. units; Na 143, K 5.2, HCO₃ 19.2 and Cl 109 mEq per litre; albumin 4.9 and globulin 1.8 g. per 100 ml.; urea 24 mg. per 100 ml.; urea clearance 116% and 112%; maximum urea concentration 2.7 g. per 100 ml. Urine concentration and dilution test, S.G. 1020-1006 with greatly delayed excretion of water load. The urine was otherwise normal except for a very low concentration of calcium. Fat-balance studies (59 g. of fat daily) showed absorption values of 87.5% and 87.1% in two consecutive six-day collection periods.

Radiological Findings

Radiographs showed the thoracic cage to be very small (Special Plate, Fig. 4). The pelvis was trefoil in shape (Plate, Fig. 5), and the lumbar vertebrae had marked biconcavity as well as showing the "rugger-jersey sign." The bones throughout had a thin cortex and prominent fuzzy trabeculae. The suspicion of hyperparathyroidism thus aroused was fully confirmed by the typical subcortical erosions of the middle phalanges and phalangeal tufts (Plate,

Fig. 6a) and the fuzzy appearance of the skull (Plate, Fig. 7). These findings were held to indicate the presence of both long-standing chronic osteomalacia and more acute severe hyperparathyroidism with osteosclerosis. The small chest and dwarfism appeared to be consistent with a diagnosis of coeliac disease continuing in mild form into adult life. There were no deformities suggesting rickets in childhood.

Course and Treatment

Our first diagnosis, based on the patient's body build and the biochemical findings, was that she had lifelong steatorrhoea. Our subsequent finding of a macrocytic anaemia in the peripheral blood and of abnormal red cells in the bone marrow, as well as of a low urine calcium output and flat glucose-tolerance curve, seemed to confirm this, as also

GRAPH 2.—Case 2: Calcium balance data before and after very large doses of pure dihydrotachysterol. Note negative balance before treatment, with high faecal excretion and low urinary output. A typical vitamin-D response obtained after giving the dihydrotachysterol. The response is, however, slow and small considering the large dose.

doses of dihydrotachysterol (given as pure compound) showed the changes expected of a case of steatorrhoea—namely, a very high faecal calcium level which the dihydrotachysterol treatment only slowly lowered (Graph 2). Her symptoms were partially relieved during this treatment, but there was no change in the radiological signs of hyperparathyroidism. We assumed that we were improving the osteomalacia somewhat, but that the hyperparathyroidism was not controllable by this means. While this investigation was proceeding she was given 10 mg. of folic acid twice daily, which rapidly reduced the size of the red cells.

As she was still incapacitated by pain, it was decided that surgical exploration of the neck should be undertaken for a parathyroid adenoma. The dihydrotachysterol was therefore discontinued and the neck explored on March 11, 1955, by Mr. D. R. Davies. Two of the parathyroid glands were normal; a third was large and was removed. It weighed 150 mg. and was identified as a chief-cell adenoma. The fourth parathyroid gland could not be found, so the wound was closed and the patient returned to the ward. She did well during the next few days, but subsequently developed fever with pain and swelling in the neck which proved to be due to a wound abscess. This was incised on March 25, when a great deal of pus came away. Coincident with the development of the abscess her plasma calcium level slowly fell and her aches and pains disappeared. A radiograph at this time showed definite improvement in the subperiosteal erosions in the hands.

She was sent home almost symptom-free on April 8, with only 10 mg. of folic acid twice a day as treatment. The significant biochemical findings throughout her stay in hospital and subsequently are shown in Graph 3. It may be seen that the calcium content had returned to normal, with the phosphorus still remaining at a low level. The

phosphatase level had also fallen. It was thought that the hyperparathyroidism was relieved but that more vitamin D would be needed later for the osteomalacia. It was interesting that while the plasma calcium level was falling she began to pass loose, pale stools, typical in appearance of those of steatorrhoea.

GRAPH 3.—Case 2: Main details of treatment and more important plasma changes. Note the slow fall to normal levels of plasma calcium after the first parathyroid tumour had been removed on March 11, 1955, followed by its return to abnormally high levels, and then finally the precipitous fall to tetany levels when the second parathyroid adenoma was removed on November 9, 1955. After the second (not the first) operation there was also a large rise in phosphorus level.

Out-patient Follow-up

When seen on May 2, 1955, she was well in herself but some pain had returned in the thighs. Radiographs on this date suggested some regression of the subperiosteal erosions and there was a rise in the plasma calcium level (Graph 3). In the following week her clinical condition was similar: the plasma calcium was still raised and she was definite that she had become constipated again. From then until September it seemed clear that her condition was deteriorating, the pains getting worse, and the constipation persisting. In case this was due to an increase in the osteomalacia, however, she was given five capsules a day (about 3 mg.) of "A.T.10." This had no appreciable effect on her clinical condition, and in a month or two it was obvious that the x-ray signs of hyperparathyroidism were much worse and that the phosphatase level had ceased to fall. It was therefore decided to readmit her, since the most likely explanation was that she had another adenoma in the fourth parathyroid gland, not identified at the previous operation, and that her improvement after that operation was probably due to its having been temporarily damaged at that time. This line of reasoning also suggested that if there was another adenoma it would probably be found in the neck, not in the mediastinum.

Second Admission

She was readmitted to University College Hospital on October 10, 1955. Her clinical condition was very similar to that on her first admission, and so were the biochemical findings (Graph 3). The A.T.10 treatment was stopped to see if the plasma calcium level would become normal, but it did not fall more than about 0.5 mg. per 100 ml. She was then given a ten-day course of cortisone, 150 mg. a day, to make sure that the raised plasma calcium level was not due to an overdose of A.T.10. When the calcium level is raised owing to an overdose of or sensitivity to a vitamin-D

preparation administration of cortisone in this dosage would cause it to fall, whereas this does not occur if the rise is due to a parathyroid tumour (Dent *et al.*, unpublished observations; see also Dent, 1956). As the cortisone had no effect in this case it was decided to re-explore the neck, and this was done on November 9. The two normal parathyroid glands on the right side were again identified. Thorough exploration of the left side revealed a large lump weighing 1 g. behind the clavicle near scarring due to the wound sepsis in the first operation. This was identified as a chief-cell adenoma of the parathyroid gland and was removed. The post-operative course was satisfactory, the wound healing well. However, two days after the operation she developed tetany, which continued for some time in spite of the administration of large doses of A.T.10 and of intravenous calcium gluconate. Her bone pains completely disappeared in a few days and the looseness of the bowels returned.

The biochemical changes and major treatments are shown in Graph 3. It is to be noted that after some time on A.T.10 alone she was given a short course of cortisone. This was in the hope of improving her steatorrhoea and thus perhaps her response to the vitamin D. However, her symptoms and blood chemistry remained unaffected, therefore it was discontinued. Then 15 mg. of vitamin D₃ daily was added, and for a short time a very large dose in tablet form of calcium ascorbate ("calci-C," Physiological Chemicals Co. Inc.), as this compound is alleged to be especially well absorbed from the gut. However, no significant changes in plasma level occurred during this time, suggesting that the compound was not absorbed. After two weeks on both A.T.10 and vitamin D₃ the former was stopped altogether, but there was a slight fall in the plasma calcium level, presumably because the action of the A.T.10 was dwindling faster than the vitamin D₃ action was beginning. Calcium-balance determinations during this period showed that she was retaining about 1 g. a day. The dose of vitamin D₃ was then increased to 30 mg. a day, and on this enormous dose the plasma calcium level began to rise steadily.

During her last two months in hospital the anaemia worsened. This was shown to be of iron-deficiency type with a serum iron level of only 56 µg. per 100 ml. It was treated with intramuscular injections of iron with good results.

A curious and unexpected feature of the post-operative recovery phase was the rise in plasma phosphorus level; this attained 3.3 mg. per 100 ml. a few days after the operation, then rose to about 4 mg. for a few days during the treatment with A.T.10 alone, to reach a peak of 7 mg. while the large dosage of vitamin D₃ was being given. It has fallen from these high levels since the plasma calcium has become almost normal. Her urine was occasionally analysed during this period and found to contain the usual quantities of phosphorus (400–700 mg. a day). There therefore appeared to be a definite change of kidney threshold, which would be consistent with some degree of hypoparathyroidism. We can only suggest that the function of the two remaining glands was subnormal because their blood supply had been disturbed or perhaps because our therapy was affecting them.

She was discharged symptom-free on February 6, 1956. Since then she has maintained excellent general health, and x-ray examination of her bones shows spectacular improvement (Special Plate, Fig. 6b). Final dosage and plasma levels are shown in Graph 3.

Discussion

We have described two cases of steatorrhoea in which radiological signs thought to be specific for hyperparathyroidism (Pugh, 1951; Dent and Hodson, 1954) have been found. We are not aware that this has been previously described. Biochemical reasons for supposing that there is

some degree of hyperparathyroidism in many cases of steatorrhoea have, however, been put forward many times (Albright and Reifenstein, 1948), while Salvesen and Bøe (1953) have carried the argument still further with their unusual suggestion that the hyperparathyroidism they assume to be present in steatorrhoea is the cause of the osteomalacia. We do not wish to argue whether this purely biochemical evidence is valid, or even whether it is supported by our more unambiguous findings in these two cases. It can well be argued the other way round, that, because such radiological signs are exceedingly rare in steatorrhoea, therefore the frequent occurrence of hyperparathyroidism is unlikely. We are still left with the problem of whether one is or is not convinced by the biochemical arguments as against radiological ones. It is of interest that Bennett *et al.* (1932) made no specific mention of hyperparathyroid changes in the bones in any of their 15 cases of steatorrhoea. Professor Turnbull's report of the bone histology of their Case 12 does, however, strongly suggest this, since it states that "osteoclasts are present in considerable number . . . in this portion of bone active resorption by osteoclasts is undoubtedly greater than normal."

Our first patient had a remission of the radiological hyperparathyroid changes which coincided in time with the end of her pregnancy and with the administration of large doses of calciferol. It is possible that either or both of these factors may have been responsible for the remission, but we prefer to think it was due only to the calciferol, because of data which we have on other cases but which are not complete enough to present here in detail. It is interesting that our first patient also had marked signs of osteomalacia of the more acute type (Dent and Hodson, 1954) associated with Looser zones and without gross deformities of the long bones. Her spine, however (Special Plate, Fig. 3), showed clear signs of osteosclerosis in that the upper and lower borders of each vertebra were more dense than normal to give the appearance of horizontal bands previously described as the "rugger-jersey sign" (Dent, 1955). This triple combination of hyperparathyroidism, osteomalacia, and osteosclerosis has been previously described only, so far as we know, in chronic renal failure (Crawford *et al.*, 1954). This observation is most intriguing, for the usual explanations given for the pathogenesis of renal osteodystrophy can hardly have been applicable to this patient, whose renal function as ordinarily measured was normal and whose plasma levels of calcium and phosphorus were unlike those occurring in renal failure.

The second patient we think was probably an adult survivor of coeliac disease, since she was very small in stature and of a bodily configuration similar to that found in other patients we have seen in whom coeliac disease in childhood had been adequately diagnosed. It seems clear, however, that something else happened to this patient during the last ten or more years, because her symptoms of bone pains and loss of height date from this time. It is possible that she reached adult life with some degree of dwarfism due to coeliac disease and then developed more severe osteomalacia and hyperparathyroidism. Presumably at first the latter was due to parathyroid hyperplasia, as in our first case, but after some time two of her glands became adenomatous, and from then on behaved in an uncontrollable fashion. This would lead to the rise in serum calcium level and produce the constipation which was such a paradoxical finding in a patient in whom steatorrhoea had been diagnosed on the other clinical evidence. It is interesting that in this case we have twice witnessed the disappearance of symptoms, a lowering of the plasma calcium level, and a loosening of the bowels. The first occasion was after the initial parathyroid exploration when the first adenoma was removed; the second after the removal of the second and last adenoma, which was much larger. The first operation was followed by wound sepsis, which we think must have interfered temporarily with the function of the other parathyroid adenoma, which had not then been discovered and removed.

If our interpretation is correct, hyperparathyroidism may sometimes occur in steatorrhoea. It can at first be reversed by giving vitamin D (Case 1). It may, however, become uncontrollable in this way, and then it produces a clinical picture easily confused with that of primary hyperparathyroidism (Case 2). When this happens the bone changes of hyperparathyroidism are found combined with those of osteomalacia, and the urine calcium level is low (not high, as in primary hyperparathyroidism). We strongly suspect now that one of our own cases treated for primary hyperparathyroidism in University College Hospital some years ago was indeed such a case of steatorrhoea, but we have unfortunately been unable to carry out a reinvestigation. We also have records of another case with mild steatorrhoea following partial gastrectomy, in which "primary" hyperparathyroidism is very strongly suspected on biochemical and radiological grounds. Unfortunately surgical intervention, and hence confirmation of our diagnosis, is contraindicated on other grounds. It is of interest that a case of parathyroid adenoma associated with pancreatic steatorrhoea has recently been reported (Page, 1954). It is a plausible speculation that hyperparathyroidism as described here in steatorrhoea may also occur as an occasional complication of rickets or osteomalacia due to causes other than steatorrhoea.

Summary

Two cases of steatorrhoea are described in which radiological evidence of hyperparathyroidism as well as of osteomalacia was obtained.

In one case the serum calcium level was always 9–10 mg. per 100 ml. Treatment with vitamin D led to a remission of the bone pains and of the radiological signs of osteomalacia and hyperparathyroidism.

In the second case the plasma calcium level was 11–12 mg. per 100 ml. Some relief of bone pains followed treatment with vitamin D, and the calcium balance responded in the expected way. There was, however, no change in the radiological signs of hyperparathyroidism. Symptoms were relieved and plasma calcium level and radiological signs returned towards normal temporarily after one, and permanently after a second, parathyroid adenoma had been removed.

It is concluded that in some cases of steatorrhoea a parathyroid hyperplasia occurs which is reversible with vitamin-D treatment. In other cases, however, presumably of longer duration, one or more adenomata will develop. Treatment by operation will then be required, as in primary hyperparathyroidism.

It appears that radiological signs of both osteomalacia (or rickets) and hyperparathyroidism can occur in steatorrhoea as well as in renal osteodystrophy. Both of our cases also demonstrated osteosclerosis of the vertebral bodies, as may sometimes be found in renal disease.

We wish to thank Sir Harold Graham Hodgson and Dr. Campbell Golding for help in the radiology, and Sir Charles Dadds for the biochemistry, in Case 1; also Dr. J. Hodson for help in the radiology, and Professor M. Maizels and his Department and Mr. G. Philpot for help with the biochemistry, in Case 2.

VALUE OF RADICAL THYROIDECTOMY IN THE TREATMENT OF THYROID CANCER

BY

MARCEL DARGENT, M.D.

From the Professor Léon Bérard Centre, Lyons

[WITH SPECIAL PLATE]

In 1939, in collaboration with Marcel Bérard, an attempt was made to remove in one block the cancerous thyroid lobe together with the muscles, the lymphatics and the veins of the neck on the same side. It was felt that such a one-stage block-dissection was justified by four indisputable pathologico-anatomical facts: (1) the high incidence of unilateral tumours of the thyroid parenchyma without involvement of the opposite lobe ; (2) the possibility of spread of the growth along the cervical aponeuroses and, more particularly, the sheaths of the infrahyoid muscles ; (3) the frequent invasion of the lymphatics and the risk of development of malignant cervical lymphadenopathy ; and (4) the frequent invasion of the venous drainage of the gland, and even of the internal jugular vein.

These, therefore, were the principles of the operation. In practice it was not often indicated. Out of 208 cases of thyroid cancer operated upon at the Lyons Centre from 1940 to 1955 block removal was performed in only 50. These 208 cases form part of a series of 237 cases of thyroid lesions operated upon during this same period. Altogether the block operation was carried out in 57 of the 237 cases, so that in 7 of them there had been a diagnostic error.

The material available in a cancer centre is not suitable for comparisons to be made with other operations. Most cases of thyroid cancer are not referred to us at the beginning, such cases being nearly always subjected to subtotal thyroidectomy or even total unilateral thyroid lobectomy in a general surgical ward in the course of treatment of nodular goitre. Quite often, also, advanced cases of generalized cancer are referred to us when they are already beyond the stage when surgery can be contemplated. We are therefore left with lesions whose malignant nature can be determined on clinical grounds—obvious characteristics of the tumour or the recurrence, the existence of cervical lymphadenopathy, and the presence of one or more metastases. Such cases, representing 24% of those seen, have been treated by radical thyroidectomy.

Comparison of our results with those reported by other workers is difficult, since the indications for this radical operation as described by Crile, Wilson, Frazell, Hayes Martin, and others are seldom stated. We can therefore only give an account of our own experience in endeavouring to determine the place of this operation in the treatment of thyroid cancer.

Extent of Operation

It is not necessary to describe anew the technique, already defined (Dargent and Bérard, 1940); extirpation of the lobe, the surrounding muscles, and all planes of the neck on the corresponding side, the internal jugular vein included, constitutes the standard operation. Ligation of the jugular veins, and, more particularly, of the internal jugular, must be done at the outside, if the risk of neoplastic embolism is to be avoided. Since 1946 we have applied the

principle of the conservation of the external branch of the spinal accessory nerve, tracing it from the upper part of the neck, and following it from top to bottom in the sternomastoid muscle, immediately after ligation of the jugulars below the clavicle. Conservation of this nerve is possible only if there are no adherent lymph nodes at the upper part of the carotid sheath.

Contrary to some workers (Hayes Martin, for example), we do not include the submaxillary region in this dissection of the neck. We have never found any lymphadenopathy or seen any recurrences in that area.

In a few cases the operation was extended to other structures. (1) In four cases both thyroid lobes were removed, in two of them leaving only a thin slice of thyroid parenchyma on one side. Total thyroidectomy was considered justifiable because of the existence of bilateral lesions in the glandular parenchyma in one of these cases, and in the parenchyma and cervical lymph nodes in the other. In this latter case bilateral radical thyroidectomy was carried out in two stages with an eight-day interval. In the other two cases there was only a unilateral lesion, but the whole gland was extirpated because there were bone metastases; these were to be treated later with radioactive iodine. (2) In one case the operation was extended to the mediastinum, in which a primary cancer had developed, whereas the affected lymph nodes were situated at the level of the neck. The tumour, which was adherent to the superior vena cava, was approached through a sternotomy. (3) In three cases the common carotid artery was resected as well. In one of these cases it was already evident that a bilateral tumour existed. (4) In one case partial and in another total resection of the trachea was performed. In one of these some of the normal tissue left was used to form a temporary tracheotomy; in the other case total laryngectomy was also necessary. (5) Twice a piece of the oesophageal wall had to be resected, continuity being immediately restored by suture. (6) In 13 cases the dissection involved the recurrent laryngeal nerve and sometimes the vagus nerve itself, owing to their invasion by tumour growth. (7) In one case the operation included the internal third of the clavicle, which was invaded by a metastasis or, more likely, by direct extension of the tumour in the muscle sheaths.

General Indications

Total radical thyroidectomy was performed in 57 cases: in 50 for cancer and in 7 for non-neoplastic lesions. In 31 of the 57 cases there was a definite thyroid tumour with one or more indications of localized malignancy without remote metastases; in 10 of the cases there was unilateral recurrent-nerve paralysis. Among these 31 cases were 7 in which an erroneous diagnosis had been made as follows. (1) Two cases of thyroid tuberculosis with homolateral cervical lymphadenopathy. (2) Three cases of pharyngolaryngeal cancer of spino-cellular type, with cervical lymphadenopathy and recently developing goitre due to a haematocoele or to ordinary congestion, in one of them accompanied by paralysis of the recurrent laryngeal nerve. In these three cases the cancers could not be seen endoscopically, but their presence was revealed by the lymphadenopathy. In one case cure was obtained after eight years, radiotherapy being given in addition to surgical treatment. (3) A case of breast cancer in which there were apparently primary supraclavicular and carotid lymphadenopathy and a very limited primary lesion with co-existing unilateral goitrous enlargement. (4) A case of achromic naevocarcinoma of the abdominal wall, with recent goitrous development, unilateral haematocoele, and paralysis of the recurrent laryngeal nerve mistakenly connected with the thyroid lesion, whereas it was an early manifestation of a metastasis at the base of the skull. The possibility of these sudden goitrous enlargements, when they coincide with a cancer arising from another site and are accompanied by cervical lymphadenopathy or paralysis of the recurrent laryngeal nerve, being mistaken for thyroid cancer cannot be too strongly stressed.

There remain in this group, then, only 24 cases of actual thyroid cancer, clinically typical, and eight of which also had paralysis of the recurrent laryngeal nerve. Of the 24 cases, 23 had a strictly unilateral tumour and lymphadenopathy.

In six cases the lesion was a recurrence of a thyroid cancer incompletely operated upon from three weeks to 45 years previously; five times out of six the recurrence was situated on the same side as the original lesion.

In 12 cases of thyroid tumour the malignant nature of the growth was signified by the existence of remote metastases. In eight cases there were bone metastases, in one of them situated in the fourth dorsal vertebra and giving rise to paraplegia, in one in the second lumbar vertebra with signs of increased density of bone, and in three in the sterno-clavicular area; in two cases there were pulmonary metastases, in one case ocular metastases, and in one diffuse lymph-node metastases. Surgical intervention was decided upon in 10 of the cases following the teaching of Léon Bérard that the presence of distant lesions does not necessarily contraindicate a radical operation on the thyroid itself. The other two cases were subjected to total thyroidectomy. The opposite lobe, even if healthy or merely adenomatous, was always removed, so that fixation of radioactive iodine by the metastases could be attempted.

In four cases what appeared to be a primary tumour of the neck was present; in three of these an attempt at concentration of radioactive iodine by the growth was unsuccessful. In three of the cases an exploratory incision showed that in each case the lesion was a lymphadenopathy secondary to a small cancer of the thyroid lobe in the early stages and of papillary type. The fourth case was even more unusual, the lesion consisting of a large neoplastic mass developing in the internal jugular vein following the irruption of a tumour in the median thyroid vein; the lobar lesion was detected only during the operation.

In one case there was a tumour of the mediastinum, which was detected only after the appearance of a left cervical lymphadenopathy and which had proved resistant to radiotherapy. This case necessitated a sternotomy in order to remove the primary lesion, and wide dissection of the neck.

In one case a large infected ulcerated tumour of the neck, including the vessels, had completely replaced the right thyroid lobe.

In one case there was an apparently idiopathic paralysis of the recurrent laryngeal nerve. After numerous clinical examinations a small, deep-seated, hardly perceptible papillary cancer was found situated close to the left side of the trachea (Special Plate, Fig. 1).

Finally, in one case there was a suspicious-looking goitre with cervical lymphadenopathy coexisting with a breast cancer. The latter had been surgically removed and histologically confirmed. Biopsy of a cervical lymph node and exploratory dissection of the neck led to the detection of a papillary cancer of the thyroid.

Types of Lesion

Histologically, there is a substantial number of papillary and of orthoplastic pleomorphic epitheliomata, as is shown in Table I. There are a few rare types of sarcoma, as a plasmocytoma and an osteosarcoma (Table I).

It may be of interest to note the number of cases in which the surgical specimen showed invasion of the venous lumina—that is, in which this was not merely apparent histologically. It has already been shown that in one case the first pathological finding was a tumour in the internal jugular vein, which proved to be an orthoplastic pleomorphic cancer. In another case the endojugular tumour contained partly calcified arteries opening into the venous circulation. This was a cancer with clear Hürthle cells (Special Plate, Fig. 2).

Lymph-node invasion is very common; it is a constant finding in case of papillary and of anaplastic cancer (Plate, Fig. 3). As has already been pointed out, this was the most

TABLE I.—*Pathological Findings in 50 Cases of Thyroid Cancer Treated with Radical Thyroidectomy*

Histological Types	No. of Cases	With Venous Invasion	With Lymph node Invasion
Orthoplastic epitheliomata	32	8	25
Vesicular	1	0	1
Trabecular	6	1	4
Papillary	10	2	9
Hürthle-cell	2	2	2
Pleomorphic (trabecular, vesicular, papillary)	13	3	9
Anaplastic epitheliomata	9	1	9
Malpighian epithelioma ..	1	0	1
Sarcomata	8	3	5

Osteosarcoma	1	0	1
Lymphosarcoma	1	1	1
Plasmocytoma	1	1	1
Total	50	12	40

frequent indication for the radical operation. The figures cited in no way prejudice those for actual invasion by thyroid cancer, since the cases dealt with here are selected ones. A curious finding in a case of orthoplastic pleomorphic epithelioma was the existence of an apparent lymph-node enlargement which was in reality a fibrocytoma of the neck.

Finally, although histological invasion of the sterno-thyroid musculature is common, we saw in one case a nodule of growth in the posterior belly of the digastric muscle (Plate, Fig. 4).

The incidence of involvement of the recurrent laryngeal nerve has not yet been determined—the frequent finding of a recurrence at the site of previous trauma having clouded our judgment in this respect. On at least three occasions involvement of the nerve at its point of entry into the larynx instead of where it crosses the inferior thyroid artery was unexpectedly encountered.

Results

On the whole results (Table II) are encouraging: 16 out of 34 patients were alive after three years, 11 out of 29 after five years, and 4 out of 18 after 10 years. More detailed

TABLE II.—End-results at 3, 5, and 10 Years After Operation

Histological Types	Total Cases	At 3 Years		At 5 Years		At 10 Years	
		No. of Cases	Alive	No. of Cases	Alive	No. of Cases	Alive
Orthoplastic epitheliomata	32	21	16	18	11	10	4
Vesicular	1	1	2	1	0	1	0
Trabecular	6	3	2	3	1	1	0
Papillary	10	6	4	4	3	3	1

Sarcomata	8	6	0	5	0	4	0
Total	50	34	16	29	11	18	4

analysis shows that the results are disastrous as regards anaplastic cancer or sarcoma, and that only in cases of orthoplastic papillary or pleomorphic cancer, with relatively slow spontaneous enlargement, is there a possibility of long-term survival.

Out of the 12 cases in which there was invasion of the venous channels, seven patients were followed up for five years or more, and only three survived. This fact is extremely important, because, although two of these surviving patients were not free from eventual metastases or recurrences, one survived for eight and a half years before dying from intercurrent disease (cardiopathy).

Among the 12 patients operated upon in spite of metastases, there was one survival of four and a half years—a case of trabecular cancer with paraplegia due to metastasis

in the fourth dorsal vertebra. Radiotherapy following thyroidectomy enabled the patient to walk for two years. Another patient is alive after three years, and two others have survived two years. There is one recent cure (six months). In two cases subjected to total thyroidectomy in order to assist concentration of radioactive iodine the metastases continued inactive, though in the more favourable case of the two the patient did not survive beyond 18 months.

The failures are represented by the following.

(a) *Post-operative Deaths*.—There were three post-operative deaths: one from acute pulmonary complications on the fourth day; one from acute mediastinitis; and one after a sudden rise in temperature on the fifteenth day, probably due to a serious hormonal disturbance, since a similar episode on the eighth day had responded strikingly to A.C.T.H. therapy.

(b) *Recurrences and Early or Late Metastases*.—All patients with sarcoma had an early recurrence and died within a year. In the case of malignant plasmocytoma there was an unmistakable diffuse recurrence of the tumour on the upper lip; in that of osteosarcoma the recurrence was mainly confined to the oesophagus.

In the two cases of haemangio-endotheliosarcoma death was due to intracranial metastases. In one case these occurred at the level of the sclerotic before the operation, and continued with meningeal localization. In the second case they were also meningeal. At the fifth month the patient sought advice for a so-called "wen" of the scalp, corresponding to a loss of tissue from the vault of the skull. This was noted clinically but not controlled radiographically. The tumour consisted of blood-clot containing red cells. A few days later death occurred from meningeal haemorrhage. One of the characteristics of this type of lesion is that it gives rise to haemorrhagic metastases.

The three cases of histiocyte-sarcoma terminated in rapid death within two to three months, from cerebral metastases with acute intracranial hypertension in one case, and from mediastinal recurrence in the others. The outcome was similar in the case of lymphosarcoma.

The only case of Malpighian epithelioma also suffered local recurrences, which appeared very early in the trachea and oesophagus. This introduces the highly controversial question of the origin of these lesions; thus the growths in the trachea and oesophagus may themselves have been primary lesions. As early as 1913 Herrenschiidt referred to forms with tracheo-oesophageal invasion.

All the cases of anaplastic epithelioma had recurrences or rapid metastatic spread. In actual fact two cases out of six which had been followed up for more than three years already had metastases at the time of operation. In one recent case, in which death occurred within six months, there was an extremely painful calcifying metastasis in the second lumbar vertebrae. A radical thyroid operation, perhaps owing to the effect on the parathyroid glands, completely relieved the pain.

In cases of orthoplastic epithelioma the frequency of recurrence and of metastasis was much more varied, and long periods of survival have been, and still are being, noted.

In the one case of vesicular cancer in this series the radical operation did not prevent serious recurrences four years later. This does not indicate the real period of survival, as in this case the first operation for goitre was performed 45 years earlier, and two recurrences had already been operated upon.

Among the three cases of trabecular cancer, the patient with paraplegia due to metastasis in the fourth dorsal vertebra survived 4½ years after radical thyroidectomy. In the case of endothoracic tumour, stripping the growth from the vena cava was most difficult. In spite of favourable radiographs,

investigation of the mediastinum with radioactive iodine showed that active foci persisted. Death occurred after 2½ years, post-mortem examination revealing a malignant bud in the vena cava (see Figs. A and B; also Special Plate, Fig. 5).

In the six cases of papillary cancer the results were good. Nevertheless there were two deaths in the first three years due to pulmonary metastases. One of these two cases is interesting in that both lobes of the thyroid were involved from the outset. It was felt that the total thyroidectomy carried out in two stages accelerated the development of diffuse pulmonary metastases. In a further case there was a delayed recurrence; the patient had already been operated upon for a recurrence after partial thyroidectomy nine years previously. Another recurrence took place more than five years after the radical thyroidectomy, and since the patient was elderly and the lesion, which was adherent to the clavicle and to the veins at the base of the neck, appeared inoperable, it was decided to tie the arteries supplying the opposite lobe and give radioactive-iodine treatment. This was found to be impossible, however, as the suppression of thyroid function resulted in a severe reactivation of the local recurrences, which had remained dormant for 14 years.

In the two cases of Hürthle-cell tumour, in both of which venous invasion had been found, there was one failure due to the occurrence of pulmonary metastases at the sixth month.

Among the nine cases of pleomorphic cancer, in which it was impossible to decide whether the growth was predominantly vesicular rather than trabecular or papillary, there were few failures. Only one patient died of cancer; he had bone metastases at the time of operation, and concentration of radioactive iodine was unobtainable in spite of total thyroidectomy. This case may be added to the other, more recent, case not included in these follow-up results and already referred to.

There was one case of recurrence five years after radical thyroidectomy and ending fatally 6½ years later from mediastinal pulmonary metastasis. This, again, is a case in which operation for a recurrence was needed 16 years after an initial partial thyroidectomy and five years after reoperation for a first recurrence. As with the papillary form of cancer, local recurrence after radical thyroidectomy has always occurred on the side operated upon, in the scar, and never on the opposite side.

Finally, one patient died after ten years from diffuse bone metastases which for four years were successfully treated with radioactive iodine. He had had a left radical thyroidectomy and complementary radiotherapy. In this case there had never been a local recurrence, but six years later a functionally active right acromioclavicular metastasis developed which concentrated the isotope spontaneously. This phenomenon was utilized several times in order to treat the bone lesion.

These, then, are the actual results of radical thyroidectomy. There was never any question of complementary

FIG. A.—Radiograph showing mediastinal thyroid tumour.

FIG. B.—Same case as Fig. A, one year later.

FIG. 1.—Case 1: Radiographs of pelvis—(a) July 31, 1952; (b) December 17, 1953. Early signs of Looser's zones present in (a). These have progressed, leading to deformity, in (b), where some callus reaction due to recent treatment is visible.

FIG. 2.—Case 1: Radiographs of terminal phalanx of right middle finger—(a) July 31, 1952; (b) October 20, 1953; (c) December 25, 1953. Note erosion of terminal tufts so highly characteristic of hyperparathyroidism. This gets much worse from (a) to (b) while disease was spontaneously progressing. In (c) tuft has re-formed to show sharp outline, corresponding to short period of calciferol treatment.

FIG. 3.—Case 1: Radiograph of lumbar vertebrae on December 17, 1953, showing marked biconcavity due to osteomalacia and increased density of upper and lower margin of each vertebral body, giving appearance of horizontal stripes—"rugger-jersey sign."

FIG. 4.—Case 2: Radiograph of chest on January 3, 1955. Note small thoracic calcifications, drooping clavicles, winged scapulae. Appearance very similar to case of proved lifelong steatorrhea shown as Fig. 5 in paper of Dent and Hodson (1954).

FIG. 5.—Case 2: Radiograph of pelvis on January 2, 1956. Note deformities of osteomalacia of fairly long standing. Looser's zones, present in pubic rami in January, 1955, now rapidly healing.

Figs. 6 and 7 overleaf

FIG. 6.—Case 2: Radiographs of index finger of right hand—(a) January 3, 1955, typical of its appearance throughout time hyperparathyroidism was operative; (b) February 3, 1956, two months after removal of parathyroid tumour. Note marked refilling of subperiosteal erosions and beginning re-formation of tuft of terminal phalanges. Improvement still continuing. FIG. 7.—Case 2: Radiograph of skull on January 3, 1955. Note typical fuzzy appearance of hyperparathyroidism. This was maintained till the second operation, two months after which it started to regress.

M. DARGENT: RADICAL THYROIDECTOMY FOR CANCER OF THYROID

FIG. 1.—Specimen removed at radical thyroidectomy for small deep-seated cancer adherent to trachea with apparently idiopathic paralysis of recurrent laryngeal nerve. (Three-quarters size.) FIG. 2.—Low-power view of section of internal jugular vein filled with a tumour bud with calcified arteries. (Patient cured eight years.) FIG. 3.—Predominantly papillary micronodular cancer; cervical lymphadenopathy; venous invasion. a, lymphadenopathy; b, endojugular bud; c, tumour nodule. (Half size.)

FIG. 4.—Specimen removed at radical thyroidectomy with total laryngectomy for cancer, showing infiltration of muscles. a, left lobe; b, passive congestion; c, laryngeal mucosa; d, tumour nodule in omohyoid. (Half size.) FIG. 5.—Operative specimen from same patient as Figs. 4 and 5 in text. a, cervical lymphadenopathy; b, mediastinal tumour. (Half size.)

radiotherapy, but it was applied as a routine to the scar whenever there was lymph-node invasion. In the unfavourable cases it did not, however, prevent local recurrence.

Conclusions

Radical thyroidectomy has limited indications. Its elective indication is papillary or pleomorphic orthoplastic cancer of slow evolution and with cervical lymphadenopathy. In such cases it is the operation of choice and gives the possibility of a ten-year cure without recurrence. Where recurrence follows a partial thyroidectomy the radical operation should still be attempted even if it is necessary to sacrifice the carotid artery or a nerve, as has sometimes happened in cases of recurrence of papillary cancer. It should be noted that, as in the case of other relatively slow-growing cancers, there may be a fresh local recurrence in the scar.

The indication for bilateral radical thyroidectomy seems to be a particularly clear one. The sudden suppression of thyroid function, in spite of compensatory medication, does not prevent metastasis or local recurrence. Where the operation has been aimed at inactivation of the metastases it has not been successful.

It is precisely to those forms of cancer which are already metastasizing but are still limited and growing slowly that this operation can be applied, leaving intact the healthy thyroid lobe, with complementary radiotherapy and with irradiation of any metastasis or, where possible, its removal. The results of such treatment are more encouraging than those of total thyroidectomy. *A posteriori*, it is true that with some anaplastic cancers or sarcomata it has proved useless. Punch biopsy of the thyroid gland is too risky, though it may be carried out tangentially where the tumour is large, but then only rarely. Where there is a definite sarcoma it is better to abstain from surgery altogether or to limit it to a partial operation in order to free the trachea or oesophagus. But since in such cases radiotherapy is disappointing. But in other cases, even if radical thyroidectomy only serves as a palliative operation to free the respiratory and digestive tracts, it would still be worth while.

Only one point remains to be discussed: Should the operation be proposed as a matter of principle? *A priori*, the answer is No, since it would be necessary to confirm that every simple nodular goitre was malignant before dissection of the neck could be performed systematically. But when after a partial thyroidectomy for goitre it is learned that a cancer has been removed, early reoperation on the carotid sheath should be considered. Such an attitude does not often appear to be tenable, although the operation would certainly be of great value in such forms as papillary cancer. Even if it is carried out without delay after strumectomy it would still lose its character of an operation *en bloc*.

The psychological state of the patient must also be taken into account. A patient with cancer of the buccal cavity will more readily accept removal of affected lymph nodes as a matter of course, after radium treatment, than will a patient who has just been operated upon for what he had thought to be an ordinary goitre and who, a fortnight later, is asked to submit to another operation. That is why, on the whole, an expectant policy is more often adopted after subtotal thyroidectomy for early thyroid cancer. If during the operation examination by frozen section shows the existence of a

malignant lesion, a total extracapsular thyroidectomy with dissection of the recurrent laryngeal nerve should be carried out, but to subject a patient without warning to the mutilation following a block dissection of the neck is not to be advised. Here again it may be better to adopt a policy of "wait and see," particularly if probing of the carotid sheath with the finger reveals a suspicious nodule. But for the other varieties—lesions in the earliest stage, of the nodular type, operated upon for a simple goitre—this extensive prophylactic operation is not to be recommended.

DISSECTION OF AORTA AS A COMPLICATION OF TRANSLUMBAR AORTOGRAPHY

BY

H. GAYLIS, Ch.M., F.R.C.S.

AND

J. W. LAWS, M.B., F.F.R., M.R.C.P.

From the Departments of Surgery and Radiodiagnosis, the Hammersmith Hospital and Postgraduate Medical School of London

Percutaneous lumbar aortography introduced by dos Santos, Lamas, and Pereira Caldas in 1929 has become established as a procedure of proved value, particularly in the investigation of vascular and renal conditions. Complications, some fatal, were soon reported, and were partly responsible for the delayed acceptance of aortography in Great Britain and the United States of America. Although the nature of the contrast medium (100% sodium iodide) was responsible for some of the complications in the early cases, it was soon found that complications occurred even when less toxic substances were used.

Complications usually resulted from the injection of the whole or greater part of the contrast medium into a visceral branch of the aorta, resulting in damage to the organ supplied by the vessel, occasionally associated with thrombosis of the vessel itself. The more serious complications include gangrene of gut from superior or inferior mesenteric arterial thrombosis (Wagner and Price, 1950; dos Santos, 1955), anuria and renal necrosis from injection into renal arteries (dos Santos, 1955), hypertension with retinopathy (Miller, Wylie, and Hinman, 1954), acute pancreatitis from injection into the coeliac axis (Robinson, 1956), paraplegia (Boyarsky, 1954), rupture of the aortic wall (dos Santos, 1955), and chylothorax due to damage to the thoracic duct (Maluf and McCoy, 1955).

We wish to describe a complication—aortic dissection—in which a part or the whole of the contrast medium is injected into the media of the aorta causing a dissection (of the aorta) analogous to a spontaneous dissecting aneurysm and giving rise to a characteristic

radiographic picture. This complication is important for three reasons. It may give rise to misinterpretation in diagnosis if its true significance is not appreciated; there may be serious sequelae; and it may occur in spite of the most scrupulous technique. Furthermore, we believe that this event is not uncommon and that it offers an explanation for some of the complications of aortography usually ascribed to arterial thrombosis or to the direct toxic effect of the contrast medium.

Technique of Aortography

The technique of aortography, as used in the following cases, is described here, as it is relevant to the discussion.

Endotracheal general anaesthesia is used and the patient is placed prone on a simple cassette tunnel. A metal marker is placed on the skin over what is judged to be the spine of L1, and this is checked by a control radiograph. The aortography needle used is 16 s.w.g., 18 cm. long, and has a short bevel. A two-way tap, one opening of which is connected to a syringe containing heparin saline, and the other by means of "polythene" tubing to the syringe containing the contrast medium, is attached to the hilt of the needle. At a point about an inch (2.5 cm.) below the twelfth rib a nick is made in the skin to facilitate the introduction of the aortography needle. The needle is then inserted and directed upwards and medially towards the twelfth dorsal vertebra. After striking the vertebral body the needle is redirected in a more anterior plane until the aorta is encountered. The needle is then slowly advanced until a free reflux of blood enters the syringe containing heparin saline. No contrast injection is made unless this free reflux of blood continues after a trial injection of saline. The two-way tap is then turned so that the needle is connected to the contrast medium, when blood is seen to pulsate freely back along the transparent polythene tube. If this free reflux of blood continues it is assumed that the bevel of the needle is within the lumen, respirations are arrested by the anaesthetist, and the contrast medium is injected. In an adult approximately 30-40 ml. of 70% diodone is injected in three to four seconds by a manually operated pressure pump. The first radiograph is exposed when two-thirds of the contrast medium has been injected, and four further films are taken in the subsequent 10 to 12 seconds by means of a simple hand-change cassette tunnel.

Case 1

A 58-year-old man was admitted to hospital complaining of pain in the right calf precipitated by walking a distance of half a mile and relieved by rest. The patient occasionally experienced coldness and tingling in the toes of the right foot. The symptoms had been present for a year and had become progressively worse. The past history was non-contributory.

Examination of Lower Extremities.—There were no obvious nutritional skin changes in the foot and no appreciable diminution of skin temperature. A systolic bruit was audible over the right external iliac artery immediately above the inguinal ligament.

Pulses	Right	Left
Femoral	Present but diminished	Present
Popliteal	Doubtful	Present
Posterior tibial ..	Absent	Present
Dorsalis pedis ..	Absent	Present

A clinical diagnosis of partial occlusion of the right iliac artery secondary to atherosclerosis was made.

A percutaneous lumbar aortogram showed a picture superficially resembling thrombosis of both common iliac arteries (Fig. 1). This was clearly incompatible with the clinical condition, since both femoral pulses were palpable, although the right was slightly diminished. In addition, it was noted that the radiographs showed no evidence of any significant collateral vessels—a feature so striking in a

complete thrombosis of the aorta (Fig. 2). We were forced to the conclusion that an intramural injection of contrast medium had given rise to this unusual radiographic picture.

FIG. 1.—Case 1. Aortogram showing complete arrest of the contrast medium at the bifurcation resembling bilateral common iliac thrombosis. Note the absence of collateral vessels. Compare with Fig. 2.

FIG. 2.—Case 1. Aortogram of a complete aortic thrombosis showing numerous collaterals. For comparison with Fig. 1.

Apart from severe backache which lasted for 24 hours there were no sequelae. There was no alteration in the peripheral pulses.

Case 2

A 62-year-old man was admitted to hospital complaining of severe pain in the right calf and thigh after walking a distance of 30 yards, which was relieved by rest. A year previously tenotomy of the right tendo Achillis had been performed with only temporary relief of pain. There were no obvious nutritional skin changes or muscle wasting in either limb. Systolic bruits were audible over both femoral and external iliac arteries, but were more pronounced on the right side.

Pulses	Right	Left
Femoral	Present	Present
Popliteal	Present	Present
Posterior tibial ..	Present	Present
Dorsalis pedis ..	Present	Present

A diagnosis of occlusive vascular disease of the iliac arteries was made.

The aortogram, which was performed without difficulty, appeared to show a complete thrombosis of the left common iliac artery with diffuse atherosclerotic changes involving the right common iliac artery (Fig. 3). Once again, however, this diagnosis was incompatible with the clinical features, since both femoral pulses were readily palpable both before and after aortography. There were no sequelae.

It seemed likely that, as in Case 1, the unusual appearances had been produced by some form of "extravasation," probably an intramural injection. This impression was strengthened as a result of examining a number of fresh human aortas, in which it was found that the wall of the aorta could be easily separated into two layers by gentle blunt dissection or intramural injection of saline. The plane of cleavage appeared to be adjacent to the intima.

FIG. 3.—Case 2. Aortogram showing non-filling of the left common iliac artery simulating thrombosis. Note the oblique translucent line across the contrast column near the tip of the needle and the "double density" near the origin of the right common iliac artery.

Experiment

In order to investigate the effects of intramural injection in more detail an experiment was designed to reproduce the conditions obtaining at aortography.

An abdominal aorta, including its bifurcation, was removed from a fresh cadaver and all its branches were ligated. This aorta was then incorporated into the circuit

FIG. 4.—Experimental aortogram (and diagram) showing the appearances following intramural injection. Note the non-filling of the left common iliac artery, simulating occlusion of the vessel, and the jet of contrast medium entering the right common iliac artery.

of the Melrose heart-lung machine (Melrose, 1953) and blood pumped through at the same rate and pressure as occurs in the normal abdominal aorta (approximately 3,000 ml. a minute, at a pressure of 100 mm. Hg). The aortography needle was introduced into the aorta, so that the bevel of the needle lay partly within the lumen and partly within the opposite wall of the aorta. At this stage blood returned freely from the hilt of the needle. Then 30 ml. of 70% diodone was injected rapidly in three seconds by means of the pressure injection apparatus, and serial films of the "aortogram" were taken by means of a simple hand-change cassette tunnel. The experiment was repeated on a number of aortas and radiographic appearance of various degrees of intramural dissection was demonstrated. The most interesting of these experiments demonstrated the passage of the contrast medium within the wall of the aorta from the point of the needle down to the bifurcation, giving an appearance of occlusion of the left common iliac artery (Fig. 4).

This simulates exactly the appearance shown in the aortogram demonstrated in Fig. 3. A jet can be seen indicating where the contrast medium

FIG. 5.—Experimental aortogram taken 12 seconds after the injection, showing that most of the intramural contrast medium has been expelled into the lumen of the aorta. A little remains in the wall (→). The irregular calcification is due to atheromatous plaques.

has re-entered the true lumen of the right common iliac artery. A film taken 12 seconds after the injection showed that only a trace of contrast medium remained in the aortic wall, the rest having been squeezed out into the main lumen by the pulsatile flow of blood inside the aorta (Fig. 5).

FIG. 6.—Transverse section of aorta at point A on Fig. 4. Note a dissection in the media (→) extending for two-thirds of the circumference. Atheromatous plaque (→).

The aorta was then removed from the apparatus and fixed in formol-saline. Microscopy revealed that the dissection had taken place in the media, at the junction of the outer third and inner two-thirds (Fig. 6), extending two-thirds of the way round the circumference. The tear in the intima where the contrast medium had ruptured back into the main lumen of the right common iliac artery was clearly delineated (Fig. 7). These experiments reproduced and explained the unusual appearances shown in Figs. 1

and 3, and provided histological proof of the layer in which aortic dissection takes place. Furthermore, aortic dissection affords a probable explanation of a number of complications of aortography for which no very satisfactory explanation was previously available.

Discussion

Mechanism and Possible Effects of Aortic Dissection

Ideally, during percutaneous translumbar aortography the bevel of the aortography needle should lie completely within the lumen of the aorta prior to the injection of the contrast medium. If the bevel lies partly in the wall and partly in the lumen, injection of the contrast medium will cause aortic dissection. This undesirable position of the needle cannot readily be appreciated, because blood will still flow freely from the hilt of the needle in a pulsatile stream (Fig. 8 A). Occasionally only a little of the contrast medium enters the aortic wall (Fig. 8 B) and produces an appearance as in Fig. 9. Should larger quantities be injected intramurally a progressive dissection results and the origin of small blood vessels

may be torn (Figs. 8 C and 8 D). If these small arteries are lumbar or intercostal vessels ischaemia of the cord and paraplegia may result, in the same way as has been described by Weisman and Adams (1944) in spontaneous dissecting aneurysm of the abdominal aorta. Furthermore, if the bulk of the contrast medium is injected intramurally the aortic lumen may be temporarily occluded (Fig. 8 D) and give rise to an appearance simulating thrombosis (Figs. 1 and 3).

Another way in which a major branch of the aorta may be occluded is by an extension of the dissection into the vessel itself (Figs. 8 E, F, G). An example of dissection extending from the aorta into the renal artery is illustrated in Figs. 10 and 11. This aortogram was performed for the

FIG. 8.—Diagram to illustrate how faulty positioning of the aortography needle (A) may result in an intramural injection and dissection of the aorta (B). A progression of this dissection may result in the tearing of the origin of small branches (C) or the occlusion of the main aortic lumen (D). Occasionally the dissection may extend into and occlude a large branch of the aorta—e.g., a renal artery (F and G). N.B.: the bevel of the aortography needle has been deliberately exaggerated for clarity.

investigation of hypertension in a patient with a non-functioning left kidney on excretion pyelogram. There was a history of severe trauma to the left loin, with haematuria several years previously, followed by recurrent attacks of left loin pain. The non-filling of the left renal artery on the aortogram was explained when left nephrectomy revealed a hydronephrotic kidney with negligible renal substance and a small atrophic renal artery.

In the past, cases of gangrene of the bowel and renal necrosis have been ascribed to the local toxic effect of the contrast medium following the injection of the bulk of the

FIG. 9.—Aortogram showing minimal aortic dissection. A small quantity of contrast medium remains in the aortic wall at the tip of the aortography needle after the bulk has passed along the aorta and iliac arteries.

contrast medium into the vessel supplying the organ. This explanation is not an entirely satisfactory one, because there are numerous cases reported in the literature in which all the contrast medium has been injected into a single major branch of the aorta, such as coeliac, superior mesenteric, inferior mesenteric, or renal arteries, without any ill effects. It is more probable that in those cases in which complications have occurred part of the contrast medium

FIG. 10.—Aortogram showing dissection extending from the aorta along the right renal artery.

FIG. 11.—Aortogram taken five seconds after Fig. 10, showing retention of contrast medium in the dissection and persistent nephrogram probably due to stasis following partial occlusion of renal artery.

has entered the artery but simultaneous dissection has caused occlusion of the artery and stasis, thus allowing time for the concentrated contrast medium to exert its toxic effects on the organ.

Although we have been fortunate in that in our cases of aortic dissection there have been no serious sequelae, review of the literature reveals several reported cases in which it seems likely that dissection of the aorta has contributed towards serious complications.

Boyarsky (1954) described a case of complete motor and sensory loss below D 8 segment, occurring after aortography for demonstration of a possible aortic aneurysm. The aortogram was unsatisfactory, in that there was "uneven filling of the renal vessels, the aorta was not filled close to the point of insertion of the needle, but was outlined lower down, where it deviated to the left of the midline. The right iliac artery was filled, but the left was not," even though at clinical examination "there were no obliterative changes in the extremities." These clinical features closely resemble those described in Case 2. Boyarsky considered that the probable cause was thrombosis of the anterior spinal artery or direct toxic action of sodium acetrizate on the cord. From the description of the aortogram, however, it seems probable that aortic dissection occurred similar in type and degree to our Case 2. Some small intercostal and lumbar arteries may well have been torn and the neighbouring spinal cord damaged by interference with its blood supply, in the same way as in a spontaneous dissecting aneurysm.

Antoni and Lindgren (1949) described a case of paraplegia and paresis of the bladder and rectum following aortography. This patient later developed gangrene of the right leg, and died three months after the aortogram. The aortogram was unsatisfactory, since "contrast injection showed that only a part of the aorta down to the superior border of L 2 and vessels in the upper abdomen, became contrast-filled. The point of the needle was at the height of the inferior border of L 1. A part of the contrast medium also proved to lie perivascularly." The following morning there was complete paralysis and anaesthesia from and including the dermatomes T 12 and L 1. At necropsy three months later, the cord was completely necrotic from and including the first lumbar segment, and there were both old and fresh thrombi in the right common iliac artery. The lower intercostal arteries were dissected and examined, but it was "impossible to observe any noteworthy alterations." The cord lesions were attributed to prolonged pressure on the abdominal aorta, due to the patient lying prone with an air pillow under the abdomen—supporting Steno's experiment (Niels Stenson, 1638–86), in which compression of the abdominal aorta at the level of the renal arteries in rabbits produced motor sensory paralysis of the lower part of the body. In view of the technically unsatisfactory aortogram with some contrast medium lying perivascularly, it seems more likely that damage to the cord resulted from aortic dissection and consequent interference with the blood supply of the spinal cord. Unfortunately there was no record of the microscopical appearance of the aorta or its branches.

Dos Santos (1955) quotes a case in which intra-adventitial injection of the whole dose of 100% sodium iodide (100 g. salt in 100 ml. of solution) was followed a week later by death due to rupture of the aortic wall. The radiograph showed an extravasation which outlined the contour of the aorta up to the thorax. By description this rupture may well have resulted from intramural injection causing medial dissection and a local necrosis of the aortic wall. Unfortunately microscopical confirmation is not available.

Smith, Rush, and Evans (1951) described a case in which contrast medium was injected into the wall of the aorta and the patient died 24 days later, owing to "cardiac failure from arteriosclerotic hypertensive disease." The published radiograph shows dissection extending along one renal artery into the base of the other. They state that at necropsy "the aortic wall and peri-aortic area were without abnormality," but it should be remembered that the necropsy

was carried out at least 24 days after the injection, and unfortunately there is no report of microscopical examination.

Miller, Wylie, and Hinman (1954) described a case in which aortography was followed by severe hypertension (B.P. 230/120) with retinopathy. Aortography revealed "peri-aortic extravasation" and direct injection into the right renal artery. An examination of their published radiograph, however, shows strong evidence of aortic dissection which extends into the left renal artery. The right renal artery is unfortunately obscured by the peri-aortic extravasation of contrast medium. Excretion urography showed a non-functioning right kidney, but six weeks later both kidneys gave normal urograms and the blood pressure had returned to the former normal level (140/90). The sudden development of hypertension in this case was presumably due to renal ischaemia, the result of dissection along a renal artery producing a Goldblatt type of renal lesion.

The difficulties of ensuring that the whole of the contrast medium is injected into the lumen has been commented on by many authors, some of whom have adopted other techniques. Fariñas (1941) exposed the femoral artery and passed a catheter up into the aorta. Peirce (1951) and Lindgren (1953) introduced a technique involving percutaneous puncture of the femoral artery with a trocar and cannula, through which a polythene catheter was passed. Seldinger (1953) devised the technique of catheter replacement of a trocar.

Concerning percutaneous translumbar aortography, Lindgren (1953) has pointed out that even if a trial injection of a small quantity of contrast medium shows it all in the lumen of the vessel, some may nevertheless be injected paravascularly during the main injection. Several factors may be involved. If the injection is made with great force, purely mechanical displacement of the needle in relation to the aortic wall may occur, or the rapid injection of a very hypertonic solution may stimulate and cause contraction of the vessel, with the result that the needle tip, if close to the wall, may be displaced into its substance. Aortic pulsation and uncontrolled respiratory movement are further possible causes for displacement of the needle-tip during aortography.

Although a trial injection of a small quantity of contrast medium appears to be an additional safeguard, it should not be forgotten that there is an inevitable delay of three to five minutes for the development of the radiograph. During this time respirations must be resumed and displacement of the needle-tip may occur.

Another device which has been used to avoid intramural injection is a needle with a sealed end and two lateral openings. It is conceivable, however, that when such a needle is inserted obliquely into the aorta, while one orifice may be well in the lumen of the aorta and allow free reflux of blood, the other may lie within the wall so that subsequent injection may cause some dissection, though it is likely to be less than with an orthodox needle.

Conclusion

Fatal complications following percutaneous lumbar aortography are still being reported, in spite of refinements of technique and the exercise of great care. From our experiments it seems likely that aortic dissection could account for a number of these fatal complications. From examination of published radiographs we are convinced that minor degrees of aortic dissection are quite common, although not commented on by the authors, perhaps because the significance is not appreciated.

Summary

A complication of aortography—aortic dissection—is described in which a part or the whole of the contrast medium is injected into the media of the aorta.

Experimental evidence is produced which explains the mechanism of this aortic dissection and demonstrates that this complication is analogous to a spontaneous dissecting aortic aneurysm.

This complication is important for three reasons. It may give rise to misinterpretation if its true significance is not appreciated, since it may closely simulate arterial thrombosis. There may be serious sequelae. It may occur in spite of the most scrupulous technique.

COMPARISON OF TETRACYCLINE WITH CHLORTETRACYCLINE IN TREATMENT OF PNEUMONIA

REPORT FROM THE CITY GENERAL
HOSPITAL, SHEFFIELD*

The effectiveness of chlortetracycline ("aureomycin") is well established in the treatment of pneumonia. The Medical Research Council report (1951) indicated, however, that a proportion of patients treated with the antibiotic develop unpleasant side-effects, particularly affecting the gastro-intestinal tract. Further experience showed that satisfactory blood levels could be obtained with a dosage lower than that used in the original trials, and Finland, Grigsby, and Haight (1954) found that the incidence of toxic effects was thereby reduced, although not eliminated.

Reports from America by Finland, Purcell, *et al.* (1954) and Wood *et al.* (1954) suggested that tetracycline, closely related in its chemical structure to chlortetracycline and oxytetracycline ("terramycin"), might have certain advantages over them in that it was claimed to possess greater chemical stability and lower toxicity in a dosage producing effective blood levels. This has been confirmed by McCorry and Weaver (1955) in this country.

An opportunity arose to study the behaviour of two of the tetracycline group of drugs, tetracycline and chlortetracycline, in cases of clinical pneumonia, and the purpose of this paper is to record the response obtained in a controlled trial, with special reference to drug toxicity.

Methods

The procedure followed that outlined in the M.R.C. report (1951), in which this hospital also participated.

Type of Case.—All patients admitted with clinical pneumonia to the adult medical wards of the City General Hospital, Sheffield, were included in the series, with the exception of (1) those aged 70 years or more, (2) those already convalescent, (3) those in whom the pneumonia was associated with heart failure, and (4) those who had received treatment with an antibiotic or a sulphonamide for longer than the 24 hours preceding admission. To confirm the diagnosis a chest radiograph was taken as soon as possible after admission. In a number of cases this showed the initial clinical diagnosis to be incorrect, and these cases

*Those taking part in the study were:—*Clinicians*: Drs. C. S. Darke, F. J. Flint, R. W. Meikle, and J. E. Middleton; *Bacteriologists*: Drs. E. H. Gillespie, M. Pownall, and J. E. M. Whitehead; *Haematologist*: Dr. S. Varadi; *Pathologists*: Drs. G. D. Powell and A. J. N. Warrack; *Radiologists*: Drs. E. K. Abbott and A. B. Black.

were subsequently excluded. Those patients who were judged to be so ill that they were not expected to survive for 24 hours were designated "desperately ill."

Dosage.—Two groups were established. (1) Tetracycline: Each patient received orally 0.5 g. in capsule form every six hours for three days, and subsequently 0.25 g. every six hours until it was considered safe to stop treatment. Intravenous administration was restricted to patients who were desperately ill, except for a few others in whom an initial high blood level seemed desirable. The dose in either instance was 0.5 g. (2) Chlortetracycline: Dosage as for tetracycline. The physician was at liberty to alter the treatment at any time if it was felt that this would be in the patient's interest.

Allotment to Treatment Groups.—One series of cards were prepared, half of which bore the word "tetracycline" and the other "chlortetracycline," and these were placed in and numbered envelopes in random order. When it was decided on admission that a patient had pneumonia the next envelope in the series was opened and the patient allocated to the treatment group indicated on the card.

Investigations.—On admission and before starting treatment a specimen of sputum or, failing sputum, a nasopharyngeal swab was obtained for full bacteriological examination. This included injection intraperitoneally into a mouse for the isolation of pneumococci. A blood culture was also taken before starting treatment. All pneumococci isolated were typed with antisera. Paired sera were taken, one on admission and a second about ten days later. These specimens were tested for cold agglutinins and for antibodies to the viruses of influenza A and B, and of the psittacosis/lymphogranuloma venereum group, to *Rickettsia burnetii* (Q fever), and to *Streptococcus MG*. Some of these sera were also examined for antibodies to influenza C virus and to the adeno-viruses. In addition a white blood cell count was done as soon as possible.

A radiograph of the chest was taken soon after admission and repeated weekly until either it was clear or no further improvement was expected. If the radiograph was not clear when the patient was discharged from hospital, further radiographs were taken at fortnightly intervals.

Criteria for Aetiological Diagnosis.—These followed the standard procedure, which has been adequately outlined elsewhere (M.R.C. report, 1951). As the investigations were comprehensive the aetiology was seldom in doubt; otherwise it was resolved by full clinical appraisal.

Clinical Trial

Seventy-five patients were admitted to the trial, but 19 were later rejected—6 from the tetracycline group and 13 from the chlortetracycline group. Thus 56 were suitable for analysis, 32 and 24 in each group respectively.

The average total dose of tetracycline was 14 g. in 11 days (limits: 9–21 g. in 6–18 days). The average total dose of chlortetracycline was 12.25 g. in 10 days (limits: 4.5–23.75 g. in 4–17 days). One desperately ill patient received four intravenous injections of tetracycline (0.5 g. each) at six-hourly intervals at the beginning of treatment. Two seriously ill patients received a single initial intravenous injection of 0.5 g. of tetracycline and chlortetracycline respectively.

Comparability of Treatment Groups

Table I shows that the two treatment groups were comparable with regard to sex, day of illness on admission, and temperature on admission. There was, however, a higher proportion of patients aged 60 years or more in the tetracycline group. About half of the patients in each group had significant chronic chest disease. In the chlortetracycline group there was a strikingly lower proportion of patients with lobar consolidation compared with segmental involvement, as judged radiographically, than in the tetracycline group.

The commonest pathogenic organism encountered in both groups was the pneumococcus (Table II). In the chlortetracycline group the incidence of bacteraemia was lower and

the pneumococci isolated were type IX or higher in a greater proportion of cases than in the tetracycline group. In no case was a positive blood culture obtained when the causal pneumococcus was of a higher type than type VIII. Most cases labelled "probably bacterial" were thought to be pneumococcal in that they conformed clinically to the pneumococcal pattern, but, bacteriological examination being incomplete, the aetiological agent was not identified.

It will be seen that the two treatment groups are reasonably comparable with regard to aetiology, but that the tetracycline group consisted of patients who, on the average, were slightly older, had more extensive consolidation, and were more seriously ill as judged by demonstrable bacteraemia. In addition, this group contained the two patients who were desperately ill on admission.

Results of Treatment

Table III sets out the results of treatment in the two groups. The criteria for recording a normal temperature were that it should have remained at or under 99° F. (37.2° C.) for 24 hours. Clinically the lungs were regarded as clear, either when no abnormal physical signs could be elicited or when it was thought that any residual signs were the result of associated chronic chest disease or of pleural thickening. In the same way the chest radiograph was regarded as clear either when it had returned to normal or when any abnormality was considered to represent past disease or pleural thickening.

The number of deaths and of patients who required a change of treatment were similar in the two groups. The patients who received tetracycline fared as well as those who received chlortetracycline, despite the fact that the tetracycline group contained a greater proportion of patients who were older and more seriously ill (Table III). It may be concluded that tetracycline is at least as effective as chlortetracycline in the treatment of bacterial pneumonia.

The complications of pneumonia were few in each group but affected a higher proportion of patients in the tetracycline group (Table IV). Secondary fungal infection of the lung occurred in two patients, both of whom were in the tetracycline group.

Deaths.—There were three deaths in the tetracycline group and two in the chlortetracycline group. Four of the patients had chronic bronchitis and emphysema; four were over 60, and the fifth was 59 years old; four were male and one was female. No death occurred within 24 hours of admission. One of the patients who died while receiving tetracycline had a pneumococcal bronchopneumonia complicated by pulmonary aspergillosis. Further reference is made to this case. Pneumococcal bronchopneumonia was also present in the second, but necropsy showed in addition evidence of old and recent tuberculous infection of the upper lobes. The last patient had a pneumococcal pneumonia complicated by a severe dry pleurisy and pericarditis. She was desperately ill on admission and also had Huntington's chorea, an iron-deficiency anaemia, and chronic hypertensive and ischaemic heart disease. A single intramuscular injection of penicillin was administered to her before death. In the chlortetracycline group the pneumonia was due to pneumococci in one patient and to Friedländer's bacilli in the other. The latter was given a single intramuscular injection of streptomycin shortly before death. Both cases were complicated by terminal peripheral circulatory failure, in addition to chronic chest disease.

Desperately Ill Patients.—There were two such patients; both had pneumococcal lobar pneumonia and both received tetracycline. One made a satisfactory recovery, and the other, mentioned above, died after an initial response to the antibiotic.

TABLE III.—Results of Treatment

Change of Treatment

Apart from those patients who received treatment for fungal infections of the lungs and those who received a single dose of another antibiotic before death, two others required a change of treatment. One patient with pneumococcal pneumonia developed a lung abscess with empyema while receiving tetracycline. Open drainage was performed, but the infection was not controlled until the antibiotic had been changed to intramuscular penicillin. The other patient with bronchopneumonia due to *H. influenzae* showed no response after seven days' treatment with chlortetracycline, but made a prompt and uninterrupted recovery when intramuscular streptomycin was substituted.

All the pathogenic bacteria isolated from the patients in the trial were sensitive *in vitro* to the antibiotics used. The Friedländer's bacillus isolated from the lung at necropsy, however, had become resistant to chlortetracycline but was sensitive to streptomycin.

Toxic Effects and Other Complications of Antibiotic Therapy

The incidence of toxic effects from the antibiotic was similar in the two groups. Table V shows that they were experienced by 9 of the 32 patients who received tetracycline and by 8 of the 24 patients who received chlortetracycline. Three patients became seriously ill—one from

* Days in brackets—day 1 being day of admission.

staphylococcal enteritis, two from fungal infection of the lung; each received tetracycline. In the other cases the toxic effects were mild and treatment was not altered.

In 13 patients the effects occurred singly, in 4 they were multiple, there being no significant difference between the groups. Upper gastro-intestinal symptoms caused little discomfort. Two patients who received tetracycline had mild nausea without vomiting on days 5 and 6-8 respectively; one also had slight diarrhoea. Vomiting occurred in one patient in the tetracycline group on day 11, and in two patients in the chlortetracycline group on days 3 and 1-3 respectively. In the last case it was thought to be partly caused by coughing, as it had been present before the start of treatment.

Mild diarrhoea occurred in three patients who received tetracycline and two who received chlortetracycline. Neither staphylococci nor yeasts were isolated from their stools. The two patients with severe diarrhoea were both in the tetracycline group. In the first it occurred only on day 3 and responded to symptomatic measures; coagulase-negative staphylococci and *E. coli* were cultured from the stools. The second developed a severe enteritis with 20 loose watery stools daily on the nineteenth day after admission. He was then convalescent from pneumonia, for which he had received 15 g. of tetracycline in the first 11 days. *Staphylo-*

coccus aureus (coagulase-positive) and yeasts were present in the stools. He became seriously ill, but the condition was controlled with morphine and kaolin and a course of phthalylsulphathiazole; his diarrhoea subsided by the thirty-first day.

The three patients who developed a drug rash received chlortetracycline. In two instances it consisted of a generalized erythema, and in the third a mild angioneurotic oedema and urticaria developed; one of these patients had a moderate fever for seven days. Four patients were observed to have a red and sore tongue, and two patients complained of slight sore throat, but pharyngeal injection and tonsillar exudate was present in only one and no significant organisms were isolated from either. Another patient showed angular stomatitis.

No patient developed black tongue, scrotal irritation, vaginitis, or fungal infection of a muco-cutaneous surface. Any mental symptoms which occurred were considered to be the result of initial or terminal anoxia or toxæmia in elderly patients. No local or other adverse effects followed intravenous administration of the antibiotics.

Fungal Infection of the Lungs

Two male patients who had chronic chest disease developed fungal lung infections. Both received tetracycline and one died.

The first patient was aged 64 years. He had chronic bronchitis and emphysema and was admitted seriously ill with consolidation of the posterior segment of the left upper lobe and the basal segments of the left lower lobe. Pneumococci type III were isolated from the sputum, but blood culture was sterile. His temperature fell slowly over the first week but rose again on the eleventh day; two days later a heavy growth of *Candida albicans* was obtained from the sputum. Tetracycline was stopped and potassium iodide was administered in increasing doses. Serial radiography showed partial collapse of the left lung, but bronchoscopy revealed only excessive bronchial secretions from which *C. albicans* was grown. Potassium iodide was continued for five weeks and the disease gradually resolved, leaving residual fibrosis in the left upper lobe.

The second patient was aged 63 and had suffered from chronic bronchitis and emphysema for a number of years. He had been ill for 18 days before admission and had received sulphonamides for the first seven days, but the received improvement had not been maintained. A chest radiograph on admission showed patchy bronchopneumonia of the right upper and lower lobes. Pneumococci type XXVII were isolated from his sputum by mouse inoculation, but were isolated from his sputum by mouse inoculation, but without obvious clinical response to oral tetracycline, and serial radiographs showed progressive consolidation in the right lung and later a spread to the left lung. Chloramphenicol was substituted on the seventeenth day, and at this time his sputum was brown, later changing to black frothy mucus. Aspergillosis was suspected. His condition deteriorated despite treatment with oral potassium iodide and intramuscular pentamidine, and he died on the nineteenth day. *Aspergillus fumigatus* was isolated from the sputum two days before death, and necropsy revealed diffuse bronchopneumonic areas in both lungs with multiple small abscesses. The latter areas were shown to be lined by the fungus, which was also isolated from the spleen.

It was concluded in each instance that the fungal infection was the result of antibiotic therapy.

A further analysis of the total dose of antibiotic received by the patients who developed toxic effects showed that their average total dose was the same as the average total dose for all patients in the two groups. On the other hand, the patients who developed late toxic effects—namely, severe diarrhoea, sore tongue, and fungal lung infections—received at least the average dose and in some instances 1 to 3 g. more. Six other patients, however, received a total dose of 17 g. or more of tetracycline without ill effect.

Discussion

The treatment of pneumococcal pneumonia with tetracycline was reviewed by Dowling (1955). The response of the 132 cases reported in the literature in 1954 was generally good; deaths occurred only in the older age groups, and usually serious complicating diseases were present. The death rate of 4.7% was similar to that experienced with penicillin, chlortetracycline, and oxytetracycline. Further reports by Frei *et al.* (1955), Gruner (1955), January *et al.* (1954-5), McCorry and Weaver (1955), and Wilson (1955) confirmed these results, but in bronchopneumonia with chronic chest disease the outcome was not so uniformly satisfactory. The present trial shows that tetracycline possesses similar antibacterial activity to chlortetracycline, in the same dosage. A number of seriously ill elderly patients who also had chronic chest disease were successfully treated; deaths were confined to this group.

Putnam *et al.* (1953) found that effective blood levels of tetracycline were slow to develop in the first 12 hours of oral treatment with 0.25 g. six-hourly, whereas with 0.5 g. six-hourly they were achieved after the second dose. McCorry and Weaver (1955) showed that an early and sustained therapeutic blood level of the antibiotic could be obtained when an oral loading dose of 1 g. was followed by 0.25 g. six-hourly. In the present trial the dosage used was 0.5 g. six-hourly for the first three days of treatment, followed by 0.25 g. six-hourly, as it was thought that the poor-risk cases treated in hospital would benefit from the slightly higher blood levels thereby attained. The analysis of the results shows that this was achieved.

With this dosage the toxic effects of tetracycline and chlortetracycline were similar and occurred in a third of the patients in each group; they were severe in only three cases. It may be argued that the dosage of antibiotic was excessive for the average uncomplicated case of pneumonia, and that this accounts for the relatively high incidence of side-effects. McCorry and Weaver (1955) remarked that a variation of 3-30% in the incidence of side-effects had been noted in reports of treatment with the tetracycline analogues. They suggested that one discrepancy might be in the definition of diarrhoea. In the present trial, however, all diarrhoea consisted of frequent watery stools, and neither loose but infrequent nor bulky stools were observed. Perhaps a further source of error has been the difficulty in deciding whether to attribute the effects to the toxic action of the antibiotic or to the disease and its complications. In a number of cases they may not be disturbing enough to warrant attention, but in this report, even the most trivial of the recognized side-effects of antibiotic therapy have been recorded.

Perhaps by coincidence the one case of staphylococcal enteritis and the two cases of fungal lung infection followed tetracycline therapy. Both the latter had severe complicating chronic chest disease.

In conclusion it would seem that tetracycline is at least as effective as chlortetracycline in antibacterial activity, but it is no less likely to produce toxic effects.

Summary

Thirty-two patients were treated with tetracycline and 24 with chlortetracycline ("aureomycin") in a controlled trial of the two antibiotics in clinical pneumonia. The dosage was 0.5 g. orally six-hourly for three days, followed by 0.25 g. six-hourly in either case. Desperately ill patients received initial intravenous administration of the drugs.

The patients who were given tetracycline were slightly older and more of them had lobar consolidation and a positive blood culture than those who received chlortetracycline, but otherwise the two groups were comparable. In most cases the pneumonia was pneumococcal and about half of the patients in each group had chronic chest disease.

The results show that tetracycline is as effective as chlortetracycline in the treatment of bacterial pneumonia. Deaths were few and were confined to elderly patients with serious complicating diseases.

The incidence of side-effects amounted to about 30% with each antibiotic, although most of these effects were mild. This does not confirm the reported lower toxicity of tetracycline.

The only serious complications followed tetracycline therapy, that is, one case each of staphylococcal enteritis, pulmonary moniliasis, and aspergillosis; in the last case the patient died.

Tetracycline suffers from the same disadvantages as other broad-spectrum antibiotics and should be used only with appropriate care and consideration.

The tetracycline ("achromycin") and the chlortetracycline used in this study were supplied by Dr. A. T. Mennie, of Lederle Laboratories. Our thanks are also due to Dr. K. J. G. Milne, under whose care a number of patients were treated, and to the house-physicians and members of the nursing and technical staff of the hospital for their help.

MANAGEMENT OF ACUTE RESPIRATORY OBSTRUCTION

WITH REPORT OF A CASE

BY

A. E. W. GREGSON, M.B., Ch.B., D.L.O.
Registrar, E.N.T. Department, United Leeds Hospitals

AND

A. J. GUNNING, F.R.C.S., D.L.O.
First Assistant, Nuffield Department of Surgery, Oxford

Acute respiratory obstruction is one of the few remaining otolaryngological emergencies with a high risk of catastrophe, and when it occurs in a small child who has previously been well the failure of treatment is tragic. The case discussed here showed certain unusual features and problems of management.

Case History

A boy aged 3 years and 5 months was admitted to hospital on September 15, 1955. He had been well until five months previously, when, following a short illness manifest by pyrexia and dyspnoea, he had shown undue dyspnoea on exercise. Several (presumptive) upper respiratory infections had occurred in the interim, and whooping-cough had been diagnosed some seven weeks before admission. He had been immunized against diphtheria about 18 months previously.

On the day of admission he had appeared quite well on rising. About 10.30 a.m. he complained of difficulty in breathing, and during a short walk severe dyspnoea developed. At mid-day his parents noticed that his colour had a "blue tint" [*sic*] and this was followed by two bouts

of convulsions. About 3.45 p.m. he would not answer his name and appeared to be unrousable. All through this period his breathing had become increasingly rapid and more laboured. There was no history of hoarseness or of a foreign body being either inhaled or swallowed.

He arrived in hospital at 4.40 p.m. He was sitting hunched forward in bed, with eyes staring and pupils fixed, and the facies anxious. He did not react to his name being spoken. Expiratory and inspiratory stridor was pronounced; dusky cyanosis was present; and there was extreme activity of the accessory respiratory muscles, with inspiratory indrawing of the supraclavicular fossae, the intercostal spaces, and the upper abdomen. The respiratory rate was 60 a minute, temperature 99° F. (37.2° C.), and pulse 160. On auscultation no inspiratory or expiratory air movements could be heard in either lung.

A tentative diagnosis of tracheobronchitis was made, but the possibility of an unsuspected foreign body with super-added infection was considered. The obstruction was thought to be low in the trachea, so that, whatever its cause, laryngoscopy and bronchoscopy were indicated in preference to a primary tracheostomy, for the latter could be performed afterwards if necessary. The child being comatose, no anaesthetic was necessary.

Operation

The fauces were normal. The larynx and the immediate subglottic area were healthy and free from obstruction. The cords moved freely. A Negus child's size bronchoscope, 5 mm. diameter, was then passed through the glottis and the laryngoscope removed. The upper trachea was normal. The lower third was pinker than usual. At the level of the carina a whitish gelatinous mass was seen, completely obstructing the right main bronchus, "riding" the carina, and all but completely obstructing the left main bronchus.

During this procedure, which was carried out rapidly, oxygen was given through the suction attachment to the bronchoscope and, intermittently, by pressure through the bronchoscope itself. One of us kept a constant watch on the radial and carotid pulses.

Cupped biopsy forceps were passed in an attempt to grasp and remove the obstructing mass. This resulted only in the removal of a small piece of very tenacious material, with no relief of the obstruction. Repeated attempts gave the same result, even with a change of forceps. The size of the bronchoscope severely limited the type of forceps used. By now the pulse was irregular and just perceptible in the carotid artery.

As the use of forceps was a failure, the largest aspirating sucker was passed, and an attempt was made to suck the mass free. This succeeded in moving it a little from the left main bronchus, but the suction was just not sufficient to lift it into the trachea and bronchoscope. At this stage, approximately five minutes after the beginning of the operation, the carotid pulse could no longer be felt. The second surgeon therefore started cardiac massage through an upper abdominal incision. He found that cardiac arrest had occurred. While the massage continued, positive-pressure insufflation of oxygen was performed through the bronchoscope, which had been pushed into the left main bronchus past the obstruction. Regular spontaneous cardiac movements began again after one minute. Inflation was continued for a further minute and then another attempt at removing the obstruction by forceps and suction was made.

With oxygenation of the left lung the child's general condition improved, and it was at this stage that he himself did most to relieve the obstruction. While suction was being applied he gave a violent cough, the force of which shot the obstructing mass into the bronchoscope, completely blocking it. The bronchoscope, with the plug, was rapidly removed and oxygen under pressure was administered through a face-mask. There was an immediate further improvement in the child's general condition. After the lungs had been

inflated for a further four to five minutes the bronchoscope, from which the fleshy mass had been removed, was again passed. The mucous membrane of the main bronchi and the carina was covered with exudate and grossly inflamed, while on the right side tenacious pieces of fibrinous exudate were adherent to the walls as low as the secondary bronchi. The exudate was removed so far as was possible, and this did not cause bleeding. The changes on the left side were similar, but not so extensive.

By now spontaneous respiration had started and both sides of the chest were moving well. The pulse was regular and of good volume and force. With the bronchoscope still in place, a tracheostomy was done through the third tracheal ring, a No. 18 Jackson tracheostomy tube being inserted. The abdominal incision was closed.

Tracheostomy was considered advisable, (1) because the bronchi still contained much exudate which had to be liquefied and aspirated, and (2) because the prolonged instrumentation added the risk of subsequent glottic oedema.

Post-operative Progress

The child was conscious on return to the ward, and it was noted that the pupillary reaction to light had returned. He was nursed sitting upright in a steam-tent. The trachea and main bronchi were aspirated through the tracheostomy tube every 15 minutes for the first 24 hours, and thereafter every half-hour. "Alevaire" inhalations through the tracheostomy tube proved very effective in liquefying tenacious bronchial secretion. Streptomycin, $\frac{1}{2}$ gr. (32 mg.), twice daily, and crystalline penicillin, 500,000 units every six hours, were given by intramuscular injection. As soon as the child was able to swallow he was allowed $\frac{1}{2}$ oz. (14 ml.) of water by mouth every half-hour, and by the end of the third day he was given a semi-solid diet.

Although dyspnoea was relieved by the operative treatment, cyanosis and tachypnoea persisted, and radiography on the second day revealed a complete left pneumothorax. This was relieved by the insertion of a No. 9 Jaques catheter through the second intercostal space anteriorly. The cyanosis and tachypnoea subsided within 24 hours, complete re-expansion of the affected lung being obtained.

Post-operative progress thereafter was uneventful. Laryngoscopy on the eighth day showed no abnormality. The tracheostomy was retained, since difficulty in clearing the bronchial secretion persisted, but antibiotic therapy was stopped. The tracheostomy tube was removed on the twenty-second day without incident, and the stoma was allowed to close by granulation.

The child was able to return home on the thirtieth day after operation. When reviewed two months later the tracheal stoma had closed and there was no evidence of respiratory distress when he undertook physical activity with other children of his age.

Histology.—"The section showed much degenerate fibrinoid material in which there were bluish staining areas of bacteria. There was much infiltration by acute inflammatory granulation tissue, in which a few multinucleate cells were seen. No evidence of neoplasm was seen."

Discussion

The site of the lesion in this case coincides with that found by Briggs and Heseltine (1952). We cannot entirely agree with their view that "removal of this (tracheal) obstruction can readily be achieved by adequate and, if necessary, repeated suction." It was both frustrating and frightening to grasp the mass "firmly," only to find small pieces coming away, the larger part remaining adherent to the bronchial wall and the obstruction unrelieved. Suction did move it a little, but the progress was too slow and uncertain, and had the patient not coughed when he did the result may well have been fatal. In these severe cases of respiratory obstruction we feel it is of the utmost importance that the cough reflex should in no way be depressed

by general anaesthesia or sprays of local analgesic. The children are easy to hold, often comatose, and, while it may seem a cruel procedure at the time, it may well be life-saving. All who have passed a bronchoscope will be acquainted with the tussic force transmitted through the instrument in expelling pus, secretion, or blood clot. P. R. Allison (personal communication) has stated that, in the complete absence of a history of aspiration, a foreign body may remain in one place in the bronchial tree for months, and not give rise to cough. If, however, the foreign body is even slightly moved with a bronchoscope or forceps it will immediately give rise to a marked paroxysm of coughing.

In every instance of acute respiratory obstruction diphtheria must of necessity be excluded. Unfortunately in the above case no bacteriological examinations were made on the secretion of the "fleshy" exudate removed. Such a diagnosis is most unlikely in view of the length of history, the report of recent immunization, the clean fauces and larynx, and the absence of bleeding beneath the exudate. However, while it is true that epidemic diphtheria in this country has not been seen for some years, there is a suggestion that the immunization rate of the population is falling (See Table). Should the trend continue, the problem of a

Immunization in the City of Leeds (From Annual Report of M.O.H. for Leeds, 1954)

Year	Population	Births	No. of Persons Receiving Immunization Against Diphtheria	Relation of Number Receiving Immunization Against Number of Live Births, as a Percentage
1948	501,900	9,234	10,338	111.95
1949	504,900	8,447	8,665	102.56
1950	509,700	8,113	7,464	92.00
1951	503,030	8,044	8,154	101.24
1952	504,800	7,740	7,456	96.30
1953	505,500	7,932	6,510	82.09
1954	507,200	7,584	6,857	90.49

series of respiratory emergencies from diphtheria may occur again; in this connexion the observation of Murray (1935), that respiratory obstruction is the only complication to be feared in *Corynebacterium diphtheriae* mitis infections, is worthy of note.

In the case described an added difficulty in diagnosis was the duration of symptoms for five months. It would seem that the original illness, some five months before admission, was an acute respiratory infection, either viral or bacterial in nature. This resulted in a tracheobronchitis, with desquamation of the mucosal epithelium which, with the inspissated secretion, was never effectively expectorated. This caused segmental and even lobar collapse, as evidenced by the continued dyspnoea and intermittent pyrexia which, with a cough, led to the diagnosis of whooping-cough. A further reinfection of the bronchial tree prior to admission led to increased secretion, loss of ciliary action, and consequent swelling of the bronchial plug(s).

In the management of acute and severe respiratory obstruction the primary aim is restoration of the airway. Diagnosis of the cause of the obstruction is of secondary concern, but a knowledge of the aetiology and site of the obstruction, often only revealed by the endoscopy, is essential for further definitive treatment. If a foreign body is found it must be removed, the lung aspirated, and any associated infection treated. If bacterial or viral infection is the cause the measures mentioned above must be employed, antibiotics and any appropriate antisera given, and the patient isolated.

The use of endoscopy prior to tracheostomy in this case, regardless of the site of obstruction, emphasizes once again the long-ennunciated view of Jackson, reiterated by Morgan and Wishart (1947). Laryngoscopy and bronchoscopy should be done first; the purpose of the succeeding tracheostomy is to facilitate the aspiration of secretions from the

bronchial tree when these cannot be effectively moved by ciliary action. The unhurried tracheostomy, with a clear airway maintained by the bronchoscope, contrasts sharply in ease of performance with the difficulty found in the congested neck of a semi-asphyxiated patient.

In any case of respiratory obstruction cardiac arrest may occur. When possible, we feel that such emergencies should be managed by "two-surgeon" teams as described above. One operator watches the carotid pulse and is prepared to undertake cardiac massage at any time, while the other concentrates on the bronchoscopic work and the continuous supply of oxygen through the bronchoscope. Oxygen under pressure should also be administered at regular intervals, using the bronchoscope as an endotracheal tube. This is of the utmost importance, and should not be forgotten by the operator who is engrossed in attempting to clear the airway.

It is stressed that time should not be wasted trying to ascertain the presence of the heart beat, either by palpation at the apex or by auscultation. The time available once arrest has occurred is very limited. Greenfield (1938), quotes Gildea and Cobb in their conclusion that cortical neurones may suffer irreparable damage from five minutes of circulatory arrest. When arrest occurs in the presence of anoxia, a much shorter period would suffice. Therefore, once the carotid pulse is no longer palpable, the chest or abdomen should be opened immediately and rhythmic cardiac massage started. In the above case a trans-abdominal approach was used, as this was the route most familiar to the surgeon concerned. It is only fair to state, however, that cardiac massage through an anterior incision in the fourth left intercostal space is no more difficult or time-consuming to perform. It is easily learnt and should be within the scope of all surgeons regardless of their specialty. The thoracic approach has the added advantage of more effective "massage," since the pericardium can be incised to get more effective compression. This also allows the surgeon to observe whether the ventricles are inert or fibrillating, for, if the latter is found, an electric defibrillator as described by McMillan *et al.* (1952) should be used.

Pneumothorax as a complication of tracheostomy and neck incisions has been well described by several authors (Macklin, 1937, 1939; Neffson, 1942; Morgan and Wishart, 1947; Reading, 1949; Michels, 1951). In the present case there were three possible causes: (1) rupture of an emphysematous bulla on the left lung when this lung was inflated during the cardiac arrest; (2) injury to the bronchial wall during removal of the secretions; and (3) mediastinal emphysema with rupture into the pleural cavity, or an extrapleural spread causing an extrapleural pneumothorax secondary to suction of air through the tracheostomy wound. This last cause is the most likely, for even with the bronchoscope in position there was a degree of obstruction still remaining in the smaller bronchi due to the exudate. At no time during the post-operative period had the tracheostomy tube slipped out of the tracheal opening—the usual cause of air being sucked into the mediastinum.

The use of alevaire almost continually for the first three post-operative days was of great help in liquefying the secretions and rendering them more easily aspirated.

Summary

A case of acute and severe respiratory obstruction and its management is described.

The cause was thought to be acute tracheobronchitis added to an already present partial obstruction, this obstruction being caused by a previous respiratory infection.

Immediate treatment by bronchoscopic aspiration and tracheostomy was given. Cardiac arrest, which occurred during this treatment, was dealt with satisfactorily by cardiac massage.

The possibility of cardiac arrest occurring in these cases is stressed and its treatment discussed. This part of the management is greatly facilitated by a second surgeon being available.

Pneumothorax as a post-operative complication is discussed.

The value of alevaire in the immediate post-operative period is mentioned.

We are indebted to Dr. E. C. Allibone, under whose care the patient was admitted, for permission to publish this report. We thank Professor P. R. Allison, Dr. G. A. W. Neill, and Mr. G. S. Seed for their encouragement and their many helpful criticisms.

A COLORIMETRIC METHOD FOR THE DIAGNOSIS OF PHAECHROMOCYTOMA

BY

GEORGE P. BURN, B.M., B.Ch.

AND

E. O. FIELD, D.M.

Department of Biochemistry (Radcliffe Infirmary),
University of Oxford

It is well known that a patient suffering from phaeochromocytoma excretes a large amount of noradrenaline in the urine. Such urine, or an extract made from it, produces a rise in blood pressure when injected into a cat (von Euler and Hellner, 1951; Burn, 1953); in our opinion this biological method is reliable for quantitative assay (Burn, 1954). However, it is expensive, and recently there has been a dearth of suitable cats. Accordingly we have developed a chemical method of estimating noradrenaline in urine with which we have been able to diagnose two cases of phaeochromocytoma.

Method

At pH 6.5 noradrenaline can be adsorbed from urine on the cation-exchange resin "amberlite IRC-50" (Bergström and Hansson, 1951), and can be eluted with excess of hydrogen ions. This stage gives a relatively large volume of solution free from the urinary pigments. Concentration of the extract is effected by adsorption on aluminium hydroxide, followed by solution in a small volume of acid and precipitation of the aluminium.

The colour reaction employed is the condensation of noradrenaline with ethylene diamine (Natelson, Lugovoy, and Pincus, 1949); the reaction produces a yellow colour with an absorption maximum of 405 m μ and a millimolar extinction coefficient of 10.

Preparation of Urine.—Urine was collected for 24 hours into a Winchester bottle containing 5 ml. of conc. HCl. An aliquot of 100 ml. was adjusted to pH 6.5 with N NaOH, using a glass electrode.

Construction of Amberlite Column.—The amberlite column was set up as shown in the Diagram. The glass tube containing the amberlite was of 18-mm. bore and about

14 cm. long. It had a constriction at the lower end, which was plugged with either glass or cotton-wool and which was connected to an S-shaped piece of glass tubing having a capillary bore. This tubing was arranged so that its outlet corresponded approximately with the level of the amberlite. The filter funnel set up above the tube could accommodate about 200 ml. To fill the column the filter funnel was removed and the apparatus was filled with water. Then 6 g. of dry amberlite IRC-50 was poured into the tube and stirred to dislodge air bubbles. The filter funnel was then replaced.

Construction of amberlite column.

Preparation of Amberlite Column.—The column was washed with successive 25-ml. portions of 2N H₂SO₄, demineralized water, N NaOH, water, 0.5 M phosphate buffer pH 6.5, water, in that order, each fluid being allowed to run through the column before the addition of the next one. The flow rate was about 2 ml. per minute. The column was used repeatedly, the washing being sufficient to clean and regenerate it.

Adsorption and Elution of Noradrenaline.—After the column had been prepared 100 ml. of urine adjusted to pH 6.5 was passed through it followed by 25 ml. water. The filtrates were discarded. The noradrenaline was eluted with 30 ml. of 2 N H₂SO₄.

Purification with Aluminium Hydroxide.—To the eluate there was added 1 ml. of 20% Al₂(SO₄)₃·18H₂O and the solution adjusted to pH 8 by the use of a glass electrode. 5 N NaOH was added until aluminium hydroxide began to precipitate and then N NaOH was added until pH 8 was reached. The precipitate was centrifuged down and the supernatant discarded. The precipitate was partly dissolved and partly suspended in 1 ml. of M H₃PO₄ by stirring with a glass rod. The mixture was transferred to a 15-ml. centrifuge tube. A further 1-ml. portion of M H₃PO₄ was used to dissolve up the remaining precipitate adhering to the large tube, and this was also transferred to the 15-ml. centrifuge tube. Complete solution of the precipitate was achieved by shaking this tube. The aluminium was precipitated as the phosphate by the addition of 1 ml. of M sodium acetate, giving a final pH of 4.5 to 5.5. The precipitate was separated by centrifugation. The supernatant was transferred to another tube calibrated at 10 ml. The aluminium phosphate precipitate was washed with 1 ml. of water by stirring with a glass rod and again centrifuged. The second supernatant was also transferred to the calibrated tube.

Colour Reaction.—To the solution in the calibrated tube there was added 0.5 ml. of ethylene diamine (redistilled under reduced pressure). The solution was adjusted to pH 11, using alizarin yellow G as an external indicator (no adjustment was usually necessary), and made up to 10 ml. with water. The precipitate of hydroxides that formed on the addition of ethylene diamine did not interfere with the colour reaction. Gaseous oxygen was bubbled through the solution for about three minutes. The solution was heated on a waterbath at 50° C. for one and a half hours and centrifuged. The extinction was determined on a "unicam" spectrophotometer at 405 m μ in a 1-cm. glass cell.

Alternative Colour Reaction.—An alternative colour reaction involves the formation of a purple complex between reduced noradrenaline (or adrenaline), ferric ion, and ethylene diamine in alkaline solution. The colour forms at

a reaction above pH 7.5. At this pH it is stable for at least one hour, but its stability diminishes with increasing pH.

To the solution obtained after precipitation of aluminium phosphate (and including the washings) was added 1 ml. of saturated potassium oxalate. The precipitate (of calcium oxalate) was centrifuged off and the supernatant was transferred to a calibrated tube. Now 0.1 ml. of conc. H₂SO₄ followed by 0.1 ml. of 5 mM ferric alum were added and mixed; 0.5 ml. of ethylene diamine was added and mixed, and the optical density was read at 550 m μ after 10 minutes. The millimolar extinction coefficient of the purple complex was 2.

Results

Recovery of Noradrenaline Added to Normal Urine.—To 100 ml. of normal urine was added 100 μ g. of noradrenaline. The urine was adjusted to pH 6.5 and subjected to the extraction procedure. A second aliquot of the normal urine to which no noradrenaline had been added was extracted as a control. A third aliquot was also extracted and 100 μ g. of noradrenaline added to the final extract; this solution served as the standard. The mean recovery in 14 experiments was 58% (S.D. 9.7%).

Normal Subjects.—Extracts of 100-ml. samples of urine from normal subjects gave extinctions of up to 0.15. If a recovery of 58% is assumed, an extinction of 0.15 corresponds to about 50 μ g. of noradrenaline. Assay of such an extract on a spinal cat showed no pressor effect (less than 5 μ g. of noradrenaline).

Diagnosis of Phaeochromocytoma.—We have examined 100-ml. samples from the 24-hour collections of 29 patients who were suspected of suffering from phaeochromocytoma. In 26 cases the extinction was less than 0.15; the mean extinction was 0.086 (S.D. 0.020). In three cases the extinction was greater than 0.15.

Case 1 gave an extinction of 0.29; a duplicate estimation gave 0.33. A duplicate extract was assayed on a spinal cat, but the extract had no pressor effect (less than 5 μ g. of noradrenaline).

Case 2 gave an extinction of 0.47. Biological assay showed that the extract contained 50 μ g. of noradrenaline. Taking account of the recovery, and of the volume of the urine, we found the excretion was 2,000 μ g. of noradrenaline per 24 hours. At operation a right adrenal tumour was removed, but the patient did not obtain a remission of his symptoms. A further sample of urine (after operation) gave an extinction of 0.65; biological assay showed the presence of 70 μ g. of noradrenaline. Subsequently a left adrenal tumour was removed.

Case 3 gave an extinction of 1.35. Biological assay showed 150 μ g. of noradrenaline; this corresponded to an excretion of 4,000 μ g. of noradrenaline per 24 hours. A phaeochromocytoma was found at operation.

The alternative colour reaction was also performed on Cases 2 and 3. The extinctions were 0.07 and 0.19 respectively (corrected for reagent blank), corresponding to 125 μ g. and 350 μ g. of noradrenaline per 100 ml. urine.

The results are shown in the Table.

Results in Three Cases

Method of Estimation of Extract	Recovery of 100 μ g. Noradrenaline from 100 ml. Normal Urine	Abnormal Urine. μ g. Noradrenaline per 100 ml. Urine		
		Case 1	Case 2	Case 3
Biological assay	50%	Nil	100	140
Colour reaction				300
405 m μ	58%	43	100	160
Alternative colour reaction 550 m μ	55%	—	125	—
				350

Discussion

Recovery.—Examination of the stages of the extraction procedure indicated that about 15% of added noradrenaline was lost on the amberlite column, that there was no appreciable loss as a result of the use of aluminium hydroxide,

and that there was a loss of 20 to 30% on the precipitation of aluminium phosphate. Both these losses can be reduced: in the first case by increasing the volume of sulphuric acid used to elute from the amberlite resin; and in the second case by repeated washing of the aluminium phosphate precipitate with sodium acetate buffer of pH 5. However, these procedures result in dilution of the extract.

Specificity.—The extraction procedure favours cations, whereas the colour reactions take place with catechols. Catecholamines possess both of these properties. Consequently the reaction is also given by "corbasil," isoprenaline, and "epinine," substances which are used medicinally and excreted in the urine in sufficient quantity unchanged. The false-positive result obtained in Case 1 was due to the administration of "neo-epinine."

Normal Values.—The values given by normal urine are thought to be due to the presence of biologically inactive catecholamines (von Euler *et al.*, 1955). Accordingly we prefer to express our results in terms of the extinction itself rather than by conversion into a quantity of noradrenaline which would give the same extinction. We have taken the value of 0.15 as the upper limit of normal.

Alternative Colour Reaction.—The alternative colour reaction with ferric ion has two advantages; it is less sensitive to pH and the colour develops rapidly at room temperature. However, the extinction coefficient is only one-fifth of that obtained by the first method. We have occasionally observed the formation of a precipitate on adding the ethylene diamine, which did not dissolve in excess of the reagent and which depressed the development of the purple colour.

Summary and Conclusion

A colorimetric method is described for the diagnosis of phaeochromocytoma.

Two cases of phaeochromocytoma have been diagnosed by this method, and the results were confirmed by biological assay.

In our opinion the chemical method can be relied upon to exclude the diagnosis of phaeochromocytoma. On the other hand, when a positive result is obtained we think it should be confirmed by biological assay.

We wish to acknowledge the help and encouragement given by Mr. J. R. P. O'Brien; we are indebted to Mr. H. W. Ling, of the department of pharmacology, for the biological assays.

The committee for Commonwealth University Interchange has published a report on its work over the last eight years. Its object has been to facilitate the movement of university teachers and graduates within the Commonwealth. Eighty-five universities and university institutions in the United Kingdom, Canada, Australia, New Zealand, South Africa, India, Pakistan, Malta, Ceylon, Hong Kong, Malaya, Singapore, the Gold Coast, Nigeria, East Africa, and the West Indies participated in the scheme, and a total of 389 visits were arranged. The members of the university staffs whose visits have been assisted have ranged from vice-chancellors and scholars of international repute to young postgraduate workers at the outset of their academic career. About 6% of the visitors were medical or working in allied fields of science. The scheme is administered in co-operation with the British Council and financed by grants from the Commonwealth Relations Office, the Colonial Office, and the committee of Australian Vice-Chancellors. The chairman of the committee is Sir CHARLES MORRIS, Vice-Chancellor of the University of Leeds. The report may be obtained from the British Council, 65, Davies Street, London, W.1.

INTRACRANIAL HAEMATOMA CONCEALED BY LEAKAGE OF CEREBROSPINAL FLUID*

BY

CAMPBELL CONNOLLY, F.R.C.S.

Neurosurgeon, Midland Centre for Neurosurgery; Honorary
Neurosurgeon, United Birmingham Hospitals

Persistent leakage of cerebrospinal fluid from the nose or ears, resulting from fractures involving the nasal air sinuses or middle ear, may greatly alter the classical clinical picture of acute intracranial haematoma and may confuse the diagnosis. The usual clinical picture of acute intracranial haematoma consists essentially of a head injury, in most cases associated with immediate loss of consciousness and followed by a lucid interval or lightening of consciousness. Later, deterioration of the state of consciousness occurs, and this is often accompanied by dilatation and inactivity of the pupil on the side of the clot and weakness of the limbs on the opposite side. In such cases it is unusual for the lucid interval to last for more than a few hours, although cases have been described in which this interval has been prolonged.

King and Chambers (1952) recorded eight cases of extradural haematoma in which operation was not required until 24 hours to 11 days after the injury. They thought that the bleeding was probably venous in origin in four cases. All their patients recovered, and they made the point that the prognosis was better when pressure symptoms were slow in developing, as compression of the brain was less rapid. None of their cases had any associated leakage of cerebrospinal fluid from the nose or the ears. Jackson and Speakman (1950) described a case of extradural haematoma which came to operation on the thirty-sixth day after the injury. In the meantime, before the case reached them and before the presence of the haematoma was determined, there had been intermittent severe headache, which had been relieved by repeated lumbar puncture and drainage of cerebrospinal fluid. They did not, of course, advocate such a dangerous procedure.

Persistent leakage of cerebrospinal fluid from the nose or ears will tend to lower intracranial tension so that the formation of intracranial blood clots may be facilitated. A large haematoma may form in this way, but while the leakage of cerebrospinal fluid continues the intracranial tension may remain within normal limits. The brain, although displaced, may not be compressed, so that its function may remain unimpaired. A large intracranial blood clot may thereby show no evidence of its presence on clinical examination. Johnson and Dutt (1947), in a paper discussing treatment of wounds involving the dura overlying the air sinuses, mention the case of a Gurkha soldier who sustained a gun-shot wound involving the right mastoid temporal region and who, when operated upon five days after the injury for dural repair to stop the leakage of cerebrospinal fluid, was discovered to have a large intracerebral haematoma which had apparently been unsuspected.

*Based upon a paper read at a combined meeting of the Association of British Neurologists and the Society of British Neurological Surgeons, 1953.

Schneider and Tytus (1955) recorded two cases with post-traumatic cerebrospinal fluid otorrhoea. The first case was that of a woman who after a fall survived for seven days with profuse drainage of blood and cerebrospinal fluid from the ear. At post-mortem examination an undiagnosed massive fronto-temporal parietal extradural haematoma and a small intracerebral haematoma were found. The second case was that of a man who after a blow on the head drained copious amounts of cerebrospinal fluid from the right ear and gradually developed signs of a haematoma in the posterior fossa without marked deterioration of consciousness. Recovery was uneventful after the evacuation of the blood clot 48 hours after the injury. They felt that in both these cases leakage of cerebrospinal fluid allowed the patients to decompress themselves and permitted expansion of the extradural haematomas without evidence of increased intracranial pressure.

Profuse leakage of cerebrospinal fluid from the nose sometimes shows little tendency to cease spontaneously, so that it is stopped only by operation to repair the dural defect as advocated by Cairns (1937). Accordingly, large intracranial blood clots are sometimes discovered only as chance findings at this type of operation: this is illustrated in Cases 1 and 2. Should spontaneous diminution or cessation of leakage of cerebrospinal fluid occur when a sizable intracranial clot is present, the patient may show evidence of a rapidly expanding intracranial lesion. This is illustrated by the two cases of traumatic cerebrospinal fluid otorrhoea (Cases 3 and 4).

Case 1

A boy aged 17 fell 30 ft. (9 m.) over an embankment while riding a motor-cycle. He was said to have been unconscious after the accident, but on admission to hospital he was able to reply to questions. There was profuse leakage of blood-stained cerebrospinal fluid from the left nostril, but no abnormal neurological signs were found. X-ray examination of the skull showed a comminuted fracture of both frontal sinuses. The profuse leakage of cerebrospinal fluid persisted, but he remained otherwise well and alert. An operation for dural repair was performed on the twenty-first day after the accident; a bifrontal bone flap was reflected, and in the left fronto-temporal region a large extradural haematoma, consisting of approximately 70 ml. of partially liquefied old black blood clot, was discovered as a surprise finding. The patient made an uninterrupted recovery.

Case 2

A man aged 27 was involved in a motor-cycle accident. On admission to hospital he answered questions quickly and rationally. There was a profuse discharge of blood and cerebrospinal fluid from both nostrils, but apart from anosmia there were no abnormal neurological signs. X-ray examination of the skull showed a wide fissure fracture of the right frontal bone involving the right frontal sinus. The patient's state of consciousness and neurological signs remained unchanged. The bleeding from the nose ceased, but he continued to leak cerebrospinal fluid from the right nostril. Lumbar puncture was performed on the thirteenth day after the accident and the pressure was only 30 mm. of water. On the fifteenth day an operation for dural repair was carried out. When a bifrontal bone flap had been reflected a large extradural haematoma, consisting of approximately 75 ml. of old black blood clot, was seen lying in the right frontal region. When this had been evacuated a further 25 ml. of old blood clot was discovered beneath this, in the subdural space. The dural defect was repaired, and after the operation the patient made an uneventful recovery.

Case 3

A man aged 49 was involved in a road accident. On admission to hospital he was drowsy but could be roused to answer questions. There was a profuse discharge of blood-stained cerebrospinal fluid from the left ear. Apart from deafness in this ear no abnormal neurological signs were discovered. X-ray examination of the skull showed multiple fissure fractures in the left temporal plate running down towards the left petrous bone. On the day after the injury his state of consciousness had returned to normal and there were still no abnormal neurological signs. He remained quite well, although the leakage of cerebrospinal fluid persisted.

On the morning of the seventh day it was noticed that the leakage of fluid from the left ear had diminished. It continued to diminish during the day, and in the afternoon it was noticed that he was becoming drowsy. On the following morning (the eighth day) the leakage of cerebrospinal fluid from the left ear had almost ceased. The patient, however, was found to be in coma, the right pupil had become widely dilated and fixed, and a left-sided hemiparesis had developed. Operation was performed under local analgesia and the right temporal region was exposed. There was a large subdural haematoma, approximately 2 cm. thick, consisting of old black blood clot with green discoloration at the edges. When this had been evacuated a laceration of the underlying temporal lobe was revealed, and further clot was evacuated from within the substance of the brain. The vessels in relation to the cortical laceration were thrombosed and there was no evidence of recent bleeding, the haemorrhage almost certainly having occurred shortly after the accident, as the result of a contra-coup lesion. Post-operatively the patient made a slow but steady recovery.

Case 4

A boy aged 19 fell approximately 40 ft. (12 m.). On admission to hospital he was drowsy but responded briskly to painful stimuli. There was a profuse blood-stained discharge from the left ear, but no abnormal neurological signs were discovered. X-ray films of the skull showed a wide fissure fracture running vertically in the left squamous temporal region towards the petrous bone. During the first two days his state of consciousness improved so that he was able to answer questions, though he remained somewhat irrational. The leakage of fluid from the left ear persisted until the third day, when it began to diminish.

On the morning of the fourth day the leakage of fluid from the left ear had ceased. His state of consciousness was approximately the same and there were no abnormal neurological signs. However, in the latter part of the day it was noticed that he was becoming increasingly drowsy, and for the first time he was discovered to have developed a well-marked right-sided hemiparesis without pupillary abnormality. A burr-hole was made in the line of the fracture in the left temporal plate and an extradural haematoma, consisting of approximately 75 ml. of solid black blood clot, was evacuated. There was no bleeding from the dural vessels underlying this, and it was thought that all bleeding had ceased some time previously. After operation, he made a good recovery.

Discussion

There can be little doubt that had there been no leakage of cerebrospinal fluid in Cases 1 and 2 both patients shortly after the accident would have required urgent operation for the evacuation of the large intracranial clots. The persistent leakage of cerebrospinal fluid through the nose, however, provided them with a decompression, so that the clots gave rise to no symptoms or signs. The possible presence of an intracranial haematoma when operations are performed for dural repair in persistent cerebrospinal fluid rhinorrhoea will be an additional reason for reflecting bifrontal bone flaps

and for carrying out an intradural repair as recommended by Cairns (1942). By this means the whole of the anterior fossa and anterior temporal regions on both sides can be inspected without difficulty.

In both the cases of cerebrospinal fluid otorrhoea (Cases 3 and 4) the operative findings showed that all the intracranial bleeding had ceased some time before operation, almost certainly soon after the injury—that is, eight days previously in Case 3 and four days previously in Case 4—yet in both, while the leakage of cerebrospinal fluid persisted, the state of consciousness remained satisfactory or improved. At that stage perhaps the only indication of the presence of a clot, short of air studies or angiography, might have been shift of the pineal body had it been calcified and visible on plain x-ray films of the skull. When the leakage of cerebrospinal fluid diminished, both patients quickly became comatose and developed severe hemiparesis with, in one case, evidence of a third-nerve lesion. Thus it seems that the intracranial blood clots, subdural and intracerebral in one case and extradural in the other, began to compress the brain only when the intracranial pressure rose as a result of the cessation of leakage of cerebrospinal fluid. Such cases, therefore, call for special observation when the leakage of cerebrospinal fluid is diminishing.

In the presence of leakage of cerebrospinal fluid, other causes of deterioration of consciousness and of the neurological state of the patient are spread of infection intracranially and epilepsy. Meningitis usually produces fever and neck stiffness before clouding of consciousness and can be diagnosed with certainty by lumbar puncture. Intracranial abscesses may produce a very similar picture to intracranial haematoma, but it is unlikely that the onset of symptoms will coincide with the cessation of leakage of cerebrospinal fluid. Epilepsy, when a fit has passed unobserved, would be suspected when the loss of consciousness had been very sudden, and, in the absence of further fits, would be followed by rapid spontaneous improvement. Treatment of the intracranial haematoma consists essentially in its evacuation. Fortunately, this is more easily performed than in the case of an acute haematoma requiring operation soon after injury, as bleeding from the vessel responsible for the formation of the clot will have ceased some time previously.

Summary

Profuse cerebrospinal fluid rhinorrhoea or otorrhoea resulting from head injury, by lowering intracranial pressure, may facilitate the formation of large intracranial haematomas.

While the leakage of cerebrospinal fluid persists there may be no deterioration of consciousness and no abnormal neurological signs to suggest the presence of a haematoma.

When the leakage of fluid diminishes there is a need for special observation, as a haematoma, if present, may begin to compress the brain and require urgent evacuation.

Four illustrative cases are described.

MASS THERAPY WITH PIPERAZINE ADIPATE IN THE CONTROL OF THREADWORM INFESTATIONS

BY

R. D. HILL, M.B., Ch.B.

Shetland Isles

Many attempts have been made to evaluate the success of vermicides against threadworms (*Enterobius vermicularis*), notably that by Standen (1953). In recent years attention has been focused on piperazine, following the studies by Mouriquand *et al.* (1951) and Turpin *et al.* (1952). White and Standen (1953) regarded piperazine hydrate as the drug of choice for the treatment of threadworms in children. However, it seems that all these trials were made on selected populations—namely, children admitted to hospital for medical or surgical treatment. Furthermore, in each trial only individuals or, at most, families, were treated, and the tests ended at the cure of the patient. No follow-up was made to discover how soon reinfestation occurred. For these reasons the following account of an attempt at mass therapy, with a six-months follow-up of the results, may be of interest.

I am the sole medical practitioner on an island in the Shetland Isles with a total population of 866. Of these, 194 are children aged 1 to 14 years. I noticed that a number of children (18 in three months) were brought to me by their mothers suffering from the effects of "worms." In each case a threadworm infestation was found. It soon became apparent that treatment of the children individually did not eliminate the condition, owing to the rapid reinfestation which occurred. I therefore decided to undertake a form of mass therapy. This has previously been shown to be most effective in other helminthic infestations—for example, hookworm. Expense ruled out the treatment of every person on the island, so I decided to treat all the children aged 1 to 14 years. Piperazine adipate was used. A form requesting permission to do this was sent to their parents, who without exception gave their consent.

Incidence of Infestation and Symptoms

In order to estimate the frequency of infestation, 50 children living within easy access of the surgery were swabbed with adhesive "cellophane" tape swabs, and the specimens examined microscopically. A child was adjudged infested if two or more ova were found on the slide, and no child was regarded as free until five specimens had been examined. The main difference between this sample of children and the total child population of the island of the same age consisted in rather better than average housing conditions in the sample group and a higher proportion of children under 8 years of age—62% (31 out of the 50) compared with 41% for the whole island.

The age distribution of the sample group of children is shown in Fig. 1, and of those found to be infested with threadworms in Fig. 2. Thirty-two (64%) of the sample group were infested. There was a high infestation rate in those aged 2 to 11 years, while those under or above these ages were less often infested. In Fig. 3 the number of specimens necessary to obtain a positive result is given: 27 (84%) of the 32 positive results were obtained after examining three specimens. Fig. 4 shows how the percentage of infested children in a family rose with the number of children in the family. The apparently anomalous finding for families with three children is accounted for by the fact that three of the four families investigated go around persistently as a tight knot of little girls, hand in

hand, leading their younger siblings and forming a constant group comparable to a family association of nine children.

The clinical histories of the children in the sample were obtained from their mothers, who were asked: Has your child had anything wrong with him during the last two months? Has he suffered from itching or scratching of his bottom, bed-wetting, nightmares, or teeth-grinding? Have you yourself suffered lately from worms? The answers to these questions are summarized in the Table. The clinical histories were then correlated with the results of the swab examinations. Of the 34 children with no symptoms, 17 had positive swabs and 17 negative. Of the 16 children with symptoms, 15 had positive swabs and one was negative.

Details of Sample Group

	No.	Microscopical Examination	
		No. Positive	No. Negative
No. without symptoms	34	17	17
" with	16	15	1
Pruritus	6	5	1
Enuresis	6	6	0
Nightmares	1	1	0
Teeth-grinding	4	4	0

FIG. 1.—Age distribution of whole group (194 children) and of sample group (50 children).

FIG. 2.—Age distribution of the 32 infested children in the sample group.

When individual symptoms were considered, it was found that five of the six children with pruritus had positive swabs and one was negative; all the six children with enuresis were positive; the one child with nightmares was positive; and all the four children exhibiting teeth-grinding were positive. (One child suffered from both pruritus and enuresis.)

Method of Mass Treatment

On the day after the last swabs had been taken every child on the island aged 1 to 14 years began a course of piperazine adipate at a daily dose of 300 mg. per year of age up to a maximum of 1.8 g. a day. The piperazine, which was in tablets containing 300 mg. of the adipate, was given for seven days, stopped for seven days, and then given for a further seven days.

Through the courtesy of the headmasters of the two schools on the island it was arranged that the school-age group should receive their vermicide at school so far as was possible. They were dosed by their individual teachers on arrival at school again at midday, and for a third time just before leaving in the afternoon. Since the courses lasted seven days, each child on leaving school on Friday was given enough tablets for Saturday and Sunday. Thus it was certain that these children (151) took their tablets for at least five out of the seven days. Since piperazine acts with maximum effect after three days' treatment (Turpin *et al.*, 1952), even five days' treatment should be effective. The piperazine for the children below school age (43) was distributed by the district nurse and myself, and the importance of its regular administration was emphasized. Mothers were instructed to pulverize the tablets if any difficulty was experienced in giving them whole. Each parent was given a form setting out basic rules of hygiene—for example, cutting the nails short, washing hands before meals, etc.—and a request to report any illness, however slight, in any child during the campaign.

Since the islanders are, in general, people of integrity, I feel sure that nearly all the children did get the treatment recommended. Only two of the sample (4%) failed to do so, and this figure is probably also representative of the island as a whole.

FIG. 4.—Percentage of children infested related to number of children in family.

Results of Treatment

Fourteen days after the completion of treatment the 32 children in the sample group who had been previously found to be positive were swabbed on six successive

mornings. Only two of these children, a boy aged 3 years 11 months and a girl aged 2 years 3 months, both from the same large family, were found to be still positive. On inquiry the mother confessed that, in spite of every effort, she had been unable to induce these children to take the tablets. After a further course of treatment, with the tablets made into a mixture, both children became negative.

Six months later the whole sample group was swabbed again. Twenty children were infested—that is, 40% of the group compared with the 64% who were found to be infested before treatment began. The age distribution of these 20 children was much the same as those originally infested (Fig. 5). Of the 32 originally positive, 18 had

FIG. 5.—Age distribution of the 20 infested children in the sample group six months later. (See Fig. 2.)

become reinfested, and two who were originally negative had become positive. One of the latter, a boy, was originally the only one negative in a family of five children; six months after treatment all of this family were reinfested. The other, a girl, came from a family of four children, two of whom were positive originally, and two of whom had become reinfested after six months.

Originally, 12 of the 14 families in the sample were infested. Six months after treatment only six families were infested. Twenty out of the 24 children (83%) in these six families were infested on both occasions, whereas in the other eight families only 12 of the 26 children in them (46%) were infested originally and none six months later. The mothers in the six families found to be infested on both occasions were all themselves infested; five of the fathers were absent from home for at least 90% of the time, and the remaining father was not swabbed.

FIG. 6.—Number of specimens needed before positive result obtained in the 20 cases.

At the follow-up, positive swabs were obtained more readily than before treatment, 65% of the positives being found at the first swab and 90% by the third (Fig. 6). But it was my impression that the ova on each positive slide were much fewer than at the original swabbing. However, as counts were not done, this cannot be stated with certainty.

The original questionnaire about symptoms was repeated to each parent in the sample group six

months after treatment was completed, care being taken, so far as was possible, not to influence the replies. Of the 16 children who originally had symptoms, eight were now free of them, and one was free of one of his symptoms. Three children were relieved of pruritus, four of teeth-grinding, and one each of the nightmares and enuresis. The child who had had both pruritus and enuresis was cured of both for a time, but later the enuresis recommenced. Of the nine* children relieved of symptoms, three (one pruritus, one enuresis, and one teeth-grinding) had become reinfested. Of the eight children who were not relieved of their symptoms, five had enuresis and three pruritus. Six of these children had become reinfested; the two who were not reinfested suffered from enuresis. One of these was a boy of 2 years 7 months, the other a girl of 10 years whose father had been absent for seven years undergoing treatment for tuberculosis.

All the children in the sample who were still positive after six months were then given a further course of piperazine adipate. One month after the completion of this course they were all negative. At this date all symptoms had disappeared, except that the five children with enuresis were still as badly affected as ever.

Side-Effects

Few side-effects were experienced by the 194 children who were treated. On the first day of treatment, three girls (aged 7 years 3 months, 5 years 8 months, and 3 years 6 months) were reported to have vomited after their evening meal. The eldest of these was found to have enlarged and inflamed tonsils and a temperature of 101° F. (38.3° C.), and the piperazine was stopped. The other two were feeling quite well when seen, and, as no abnormality could be discovered on examination, their treatment was continued without further ill effects.

On the fourth day of treatment a boy aged 4 years 1 month vomited but was quite well when seen. He completed his course without further ill-effects. On the sixth and seventh days three boys in the same family (aged 11 years 2 months, 7 years 11 months, and 5 years 6 months) developed slight diarrhoea. Two other boys in the family were unaffected. The upset was so slight that I was not told about it until treatment had been completed. During the second course no side-effects were reported.

Conclusions

Piperazine adipate is an effective and safe vermicide. Of the 30 infested children in the sample who completed treatment, all were free of ova two weeks later; and, although seven cases of vomiting or diarrhoea among the 194 children treated were reported, one of these was undoubtedly caused by a concurrent infection and the remainder were of so slight a nature that the children concerned missed no time at school and when examined no abnormality could be found. No child missed a dose of vermicide because of side-effects. With piperazine adipate it is possible to disinfect a community of children by mass therapy, but unless the parents (especially the mothers) are treated at the same time reinfestation soon follows.

Although a large number of children were positive six months after treatment, their infection did not appear to be so heavy as originally. In addition, I have had only one complaint of infestation since the mass treatment, as opposed to 18 in three months before it was done.

There appears to be some relationship between the symptoms of pruritus, teeth-grinding, and nightmares and infestation with threadworms. Ten children with these symptoms were cured of them when freed from threadworms. Of six children with enuresis, however (12% of the sample), only one was cured when treated for threadworms, but she was infested at the second examination. Her cure would appear to be coincidental. In the other five the enuresis was unaffected by treatment.

*This figure includes the child in whom one of his two symptoms had been relieved.

Summary

The mass treatment with piperazine adipate of all the children aged 1 to 14 years on one of the Shetland Isles is described. The object was to rid them of threadworms. A total of 194 children were treated.

A sample group of 50 children were examined by anal swabs, and their mothers questioned about their symptoms, before and after treatment. Before treatment 32 were found to be infested with threadworms. Two weeks after treatment all 30 who completed the course were free of infestation. Six months later 20 had become reinfested, but one month after a second course of treatment all were again free. There was also amelioration in symptoms, generally ascribed to threadworm infestation, with the notable exception of enuresis.

Side-effects of treatment were few and unimportant.

It is concluded that mass treatment with piperazine adipate is effective in eradicating threadworm infestation in a community of children, but to prevent relapse parents, especially the mothers, must be treated at the same time.

My thanks are due to Dr. S. A. B. Black, medical officer of Health for Zetland, for his advice and encouragement; to Nurse Cowie, who helped to distribute the piperazine adipate; to the headmasters of Livister Primary School and Brough Secondary School for their willing co-operation; and to British Drug Houses Ltd., who generously supplied, free, the large amount of piperazine adipate required in the form of "entacyl" tablets. My thanks are also due to the mothers and children of the sample group who conducted, and submitted to, the numerous tedious and embarrassing swabbings which were necessary.

WHIPWORM INFESTATIONS TRIAL OF FOUR PIPERAZINE COMPOUNDS

BY

A. G. HUCKER, B.Sc., L.M.S.S.A., D.P.M.
Psychiatrist and Deputy Physician-Superintendent

AND

F. D. SCHOFIELD, M.B., M.R.C.P., D.T.M.&H.
Department of Clinical Tropical Medicine, London
School of Hygiene and Tropical Medicine

A simple satisfactory treatment for *Trichuris trichiura* (whipworm) infections in man has yet to be found. Some success in apparently light infections has been obtained with hexylresorcinol enema and papain (Jung, 1954; MacCarthy, 1954). The worm is seldom said to give rise to severe symptoms, but if a safe and easily administered drug is found to be effective against some intestinal helminths it should be tried against *T. trichiura* also. It was noted that the ova of this worm appeared irregularly in the stools in light infections, so a comparison of a quantitative nature in groups of patients was thought more likely to give a reliable indication of the efficacy of a drug than qualitative comparisons in individual patients.

The piperazine compounds are very safe and effective against roundworms and threadworms. A trial of piperazine hydrate and adipate against *T. trichiura* infections in children has been reported from Australia by

Dunn (1955), who found that the hydrate, in a dosage of 75 mg. per kg. of body weight daily for three days, cleared only 4 out of 22 (18%) children of ova; but he found the adipate cleared 28 out of 31 (90%) children of ova in dosage of 300 mg. per year of age, to a maximum of 1,800 mg. daily for three days. An opportunity to study the adipate again, and also to try other piperazine compounds, occurred in the autumn of 1955, when news was received of heavy *T. trichiura* infections among patients at a hospital for mental deficiency. An account of the clinical aspects of these is under preparation by one of us (A.G.H.). The therapeutic trial of four piperazine compounds is reported here—the phosphate, citrate, sebacate, and adipate.

Details of Trial

The patients were divided into four groups, each of 20 individuals, and all members of each group were given one of the drugs. Most of the patients were boys aged 7 and upwards, but four were adults. The stools of all the patients in each group were collected just before treatment and the number of eggs per gramme was estimated by a modification (Caldwell and Caldwell, 1926) of the Stoll method using sugar solution. We are indebted to Mr. F. R. N. Pester, of the Helminthology Department, London School of Hygiene and Tropical Medicine, and Mr. K. A. Fuller, of the Wellcome Laboratories of Tropical Medicine, for undertaking the egg counts. For the phosphate, citrate, and sebacate the dosage given was equivalent to 500 mg. of piperazine hexahydrate three times daily for seven days in all cases. The dosage of the adipate was 600 mg. (equivalent to 502 mg. of hexahydrate) three times daily for seven days. No other measures, such as starvation or purgatives, were employed. No side-effects of the drugs were noted. Two weeks after the completion of the course of treatment the stools were again collected and examined by the same observer as had examined them previously. The observers were kept in ignorance of the nature of the preparation administered to each group.

In the stools of three patients there were ova after, but not before, treatment; and in the stools of one patient there were ova before, but not after, treatment. High egg counts, up to 75,000 per gramme of faeces, were found in some cases. The difference between the number of eggs per gramme of faeces before and after treatment was calculated for each patient. In some, especially those with comparatively light infections, large differences were noted, but these tended to cancel each other out when the mean difference for each group was calculated.

Details of Four Groups

Group	Compound of Piperazine	No. of Infected Patients	Mean Egg Count per g. Faeces before Treatment	Mean Difference in Egg Count after Treatment	Standard Error of Difference	t	P
I	Phosphate	17	4,400	+1,315	±686	+1.92	0.1-0.05
II	Sebacate	17	6,600	-2,176	±2,593	-0.84	0.4
III	Adipate	18	3,900	-367	±478	-0.77	0.4-0.5
IV	Citrate	18	10,400	+456	±602	+0.76	0.4-0.5

The mean difference for each group and its standard error are shown in the Table. The application of "Student's" t test to these figures shows that none of the means was significantly different from zero. None of the compounds of piperazine, tested in doses which are effective against *Ascaris lumbricoides* and *Enterobius vermicularis*, had any action on *T. trichiura*.

Summary

A trial of the therapeutic effects of four piperazine compounds—the phosphate, sebacate, adipate, and

citrate—administered by mouth was carried out among patients heavily infected with *T. trichiura*. No therapeutic effect was observed.

We wish to thank Dr. H. E. Beasley, physician-superintendent, for his encouragement and permission to undertake the investigation, and the nursing staff of the hospital concerned for their co-operation. Brigadier J. S. K. Boyd, of the Wellcome Laboratories of Tropical Medicine, kindly supplied the drugs used, and Mr. O. D. Standen and Dr. L. G. Goodwin, of the same laboratories, have been very helpful in the preparation of the paper.

Medical Memoranda

Torsion of the Gall-bladder

About a hundred cases of acute torsion of the gall-bladder have been reported in the literature since Wendel's case (1898). From the Scandinavian countries single cases have been reported by Hansen (1920), Arnesen (1929), Koch (1943), Ekdahl (1951), and Berg (1955). It is rare for one surgeon to see more than one of these cases during his lifetime; yet four surgeons have seen two cases and one surgeon has seen three. The latter is of the opinion that a correct pre-operative diagnosis is possible. To make the gall-bladder capable of undergoing torsion it must either have a complete mesentery or its body be free, the mesentery only fixing its neck. This state of affairs is brought about either as a congenital anomaly or as an acquired relaxation, atrophy of the connective tissue permitting increased ptosis of the gall-bladder (Maingot, 1948).

Detailed reviews of published cases have been made by Short and Paul (1934) and Bean and Symond (1953). A further case is here presented.

CASE REPORT

A 70-year-old woman was admitted to Surgical Department A of Frederiksberg Hospital at 9.30 p.m. on July 4, 1953, with a twelve-hours history of acute diffuse pain in the abdomen, later localized to the right iliac fossa. The pain was of a constant character with colicky exacerbations, and she vomited several times. There had been a normal motion twelve hours before, but no flatus had been passed since.

On examination she was noted to be a rather fat ill-looking old lady obviously in pain. Her tongue was dry, temperature 99.6° F. (37.5° C.), pulse 100, and regular. The abdomen was large with a slightly prominent right side; there was no abdominal distension, but a tender mass was felt in the right iliac fossa in the area between the iliac crest and a scar from a right pararectal incision (appendicectomy). Pelvic and rectal examination gave no information. With a provisional diagnosis of intestinal obstruction, possibly caused by a caecal tumour or a caecal torsion, a straight x-ray film of the abdomen was taken, followed by a radiograph of the colon after a barium enema. No signs of obstruction were found, but it was noted that the hepatic flexure of the colon was placed lower than usual. With the application of local heat, and fasting, the patient was observed for some hours. The temperature rose to 101.2° F. (38.4° C.), and the abdomen became slightly distended. It was noted that the tender mass in the right iliac fossa shifted somewhat in position and size. A renewed straight x-ray film of the abdomen showed some air in the small bowel but no fluid levels. At this juncture the possibility of an acute obstructive cholecystitis was discussed, but as no definite diagnosis had been reached it was decided to operate.

A laparotomy was performed through a right transrectal incision medial to the old scar. On opening the peritoneum

a moderate amount of fluid was noted, and some adhesions had to be cut. A heavy, reddish-black gangrenous gall-bladder 20 cm. long presented itself in the wound, being suspended from the liver by a small partial mesentery. It had undergone a 360-degrees anticlockwise torsion. After untwisting and isolation and ligation of the cystic duct and artery, the gall-bladder was easily removed. The wound was closed in layers with a drainage tube to the gall-bladder bed. The patient made an uneventful recovery.

The removed gall-bladder contained numerous small gall-stones, and microscopical examination showed a haemorrhagic necrosis of its wall.

COMMENT

If an old woman is seized by a sudden colicky pain of persisting character in the middle of the abdomen, right hypochondrium, or right iliac fossa, a diagnosis of gall-bladder torsion may be considered. In some cases there is a distinct zone of maximal tenderness over a small area, as pointed out by Case (1951) and Bell (1955). Furthermore, if a tender rounded tumour is found, varying in size during observation, it should be possible to arrive at the correct pre-operative diagnosis—namely, torsion of the gall-bladder. The treatment is early cholecystectomy.

Combined Congenital Malformations of Oesophagus and Heart

It is well known that more than one congenital malformation may occur in the same patient, and that certain malformations are commonly associated together. A better knowledge of such definite combinations might help both in diagnosis and in the understanding of the causative factors. The following case had congenital malformations affecting both the oesophagus and the heart.

CASE REPORT

A 19-year-old primipara, with a normal history of pregnancy when seen at the antenatal clinic, was delivered of a severely anoxic male infant on December 21, 1954. Labour was normal, but hydramnios was present. The infant weighed 5 lb. 6 oz. (2,450 g.). In spite of repeated careful aspiration there was a continuous and copious discharge of mucus from the mouth and nose. At six hours, examination showed a deeply cyanosed infant with rattling respiration, from whose nose and mouth clear mucus was still discharging. Loud rhonchi were heard over the chest, and a loud systolic murmur maximal at the apex of the heart. An unsuccessful attempt was made to pass a tube into the stomach, and the infant died, anoxic and very deeply cyanosed, 63 hours after birth. A post-mortem radiograph showed that the upper oesophageal segment ended as a blind pouch, while the lower oesophageal segment communicated at its upper end with the bifurcation of the trachea.

Extract from Necropsy Report.—The oesophagus ended in a blind sac-like enlargement 3 cm. from its proximal end. At the point of its bifurcation the trachea communicated with the distal portion of the oesophagus, which had a diameter of 6 mm. and ended normally in the stomach. The heart was enlarged, the right ventricle being dilated and hypertrophied. The left ventricle was smaller, with thinner walls than usual. The aorta and pulmonary artery

sprang from a common trunk arising from the right ventricle, with four valves at its cardiac orifice, some of which were thicker and harder than normal. At 1.5 cm. from the cardiac origin of the trunk the right and left pulmonary arteries arose, while the aorta continued to form the arch from which rose the great arteries and also the ductus arteriosus linking the aorta with the right pulmonary artery. There was an opening, 8 mm. in diameter, in the membranous upper portion of the interventricular septum with a thickened whitish margin. The left atrioventricular ostium and bicuspid valve were corresponding. The other internal organs showed no congenital malformations. Histologically, there was perivascular fibrosis of the myocardial vessels and coronary atheroma. There was also fibrosis of the valves of the common arterial trunk.

COMMENT

Until recently there was no way of saving the lives of infants with congenital oesophageal atresia. But now a considerable number of successful operations on such cases have been reported. This has led to considerable optimism. However, the prognosis remains hopeless when there is an associated grave abnormality of the heart.

Clinical Trial of Glycyrrhetic Acid Ointment

Glycyrrhetic acid is obtained from liquorice. There is a structural similarity between glycyrrhetic acid and cortisone, and it has been shown that liquorice extracts contain substances with deoxycortone-like activity (Molhuysen *et al.*, 1950).

Adamson and Tillman (1955) used 2% glycyrrhetic acid ointment in a variety of skin conditions, mostly eczematous, in which good results had previously been claimed for hydrocortisone. They suggested that their results were encouraging enough to indicate that glycyrrhetic acid ointment should be given a further trial.

We have carried out such a trial as follows.

METHOD

2% glycyrrhetic acid ointment and a control containing only the ointment base were used. The preparations were supplied in tubes labelled ointment A and ointment B, and it was not known until the conclusion of the trial which preparation contained the active ingredient. Two groups of patients with lesions, the majority eczematous, which might be expected to respond to local hydrocortisone were treated.

Ointment A		Ointment B	
Glycyrrhetic acid	2%	Wool fat	20%
Wool fat	20%	Liquid paraffin	25%
Liquid paraffin	25%	White soft	ad 100%
White soft	ad 100%		

Paired Comparison Group.—Twenty patients with symmetrical lesions were treated with ointment A on one side, ointment B on the other, the majority as in-patients. Precautions were taken to ensure that neither patient nor observer knew which preparation was applied to which side. The ointment was rubbed in night and morning, and the affected areas were protected with dressings. Treatment was continued for an average of seven days, and the results were assessed on the basis of objective changes in the lesions, as unchanged, improved, or deteriorated (Table I). With one exception, symmetrical lesions in individual patients behaved identically with both preparations.

TABLE I.—Paired Comparison Group (20 Cases)

Ointment	Unchanged	Improved	Deteriorated
A	7	7	6
B	8	6	6

Alternate Case Group.—Ointment A and ointment B were supplied alternately to 30 patients, who were instructed to rub in the ointment gently night and morning. After the results of this initial treatment had been assessed at the end of seven days or earlier, treatment was to be continued with the other preparation for a similar period, so that the effects of both ointments could be observed in the same individual. As the trial proceeded it was found that no fewer than 12 patients had become unsuitable for treatment with the second preparation because of deterioration in the lesions contraindicating further greasy applications, because the lesions had healed completely, or because they were unable to remain under observation. Of the 18 patients given the second treatment 3 did not report for final assessment. Thus results of treatment with both ointments are available in 15 patients (Table II) and with one ointment only in a further 15 patients (Table II). There appears to be no significant difference between the effects of ointment A and ointment B.

TABLE II.—Alternate Case Group

Ointment	Unchanged	Improved	Deteriorated
Results with both A and B (15 Cases)			
A	4	10	1
B	3	9	3
Results with either A or B (15 Cases)			
A	3	2	3
B	2	1	4

COMMENT

In neither group was any significant difference apparent between the effect of 2% glycyrrhetic acid ointment and the control base. To maintain uniformity with trials proceeding elsewhere, a greasy ointment base was used which we consider generally unsuitable for the treatment of eczematous conditions.

A substantial proportion of the lesions were intolerant of the treatment applied. This is not surprising, as the application of greasy remedies to eczematous lesions in an acute or subacute phase is usually contraindicated. Hydrocortisone is a striking exception, in that even acute weeping lesions are often improved by this remedy when applied in a greasy base. In no instance was such improvement produced by the glycyrrhetic acid preparation, which further suggests that in its present crude form this substance has little or no hydrocortisone-like effect.

These findings are at variance with the impression of Adamson and Tillman (1955) that glycyrrhetic acid preparations have a hydrocortisone-like effect. It may be that these conflicting results depend on some active constituent of liquorice which is present in varying amounts in different samples of glycyrrhetic acid as at present commercially obtainable.

Further work is necessary to elucidate the nature and therapeutic effect of the fractions of crude liquorice extracts and commercial glycyrrhetic acid. Meanwhile it appears to us premature to suggest that glycyrrhetic acid ointment is a satisfactory substitute for hydrocortisone.

We are indebted to Dr. E. V. B. Morton, of Boots Pure Drug Co. Ltd., for much helpful advice and for arranging supplies of the preparations used, and to Dr. Pamela Horne and the nursing staff for their help in carrying out the trial.

Reviews

NEW TEXTBOOK OF ANATOMY

Textbook of Human Anatomy. By J. D. Boyd, M.A., M.Sc., M.D., Sir Wilfrid E. Le Gros Clark, M.A., M.D., D.Sc., LL.D., F.R.C.S., F.R.S., W. J. Hamilton, D.Sc., M.D., F.R.S.Ed., J. M. Yoffey, D.Sc., M.D., F.R.C.S., Sir Solly Zuckerman, C.B., M.A., M.D., D.Sc., F.R.S., and the late A. B. Appleton, M.A., M.D. Edited by W. J. Hamilton. (Pp. 1,022+xii; illustrated. £5.) London: Macmillan and Co. Ltd. 1956.

This new textbook of human anatomy is bound to arouse considerable discussion among anatomists, surgeons, and all who are concerned with the contributions which anatomy must make to the medical curriculum. It is designed primarily for the medical student in his preclinical years of study, and is a serious attempt to remove many of those difficulties of which both students and teachers have complained in the past. To correlate structure with function, to eliminate unnecessary topographical detail in descriptions of the various body systems, and to form a link with previous studies in biological subjects have been the aims of the contributors. How far have they succeeded in their purpose?

Surgeons and experts in other specialties will not like this book, because they will not find in it the detail of topographical anatomy to which they are accustomed to refer their clinical and postgraduate students, but it is only right to indicate that it does not seek to supplant the reference book as such; the latter will still be necessary for the postgraduate specialist. On the other hand, many anatomists in Great Britain, of whom the reviewer is one, will welcome this attempt to produce something worth while which can be recommended to our students.

There will be complaints that the sections appear uneven in their presentation of the subject. This is because each contributor is not only a distinguished anatomist but also a research worker of repute in his own particular field. Each is bound, therefore, to treat with his individual emphasis the topics which he has to cover. This is all to the good, and the editorial co-ordination has been done effectively but discreetly so that individuality of presentation has not been completely suppressed.

Some minor criticisms must be made, and doubtless the following points will be considered when future editions are planned. It is unfortunate that the metric and English systems of measures are used indiscriminately, even in the same chapter. The illustrations, many of them in colour—and from the competent pens of A. K. Maxwell and F. B. Price—are of a high standard in most cases. Some, however, are too complicated (e.g., Fig. 303); in some, colour has not been wisely used (e.g., Fig. 326), and the occasional error in labelling a drawing has been overlooked (e.g., Fig. 163). The publishers have produced this book to their usual high standard and are to be congratulated upon it. One can recommend it to medical students. Students of what may be called medical auxiliary subjects will find it useful, and all teachers of anatomy should possess it.

J. S. BAXTER.

BODY FLUIDS

The Body Fluids: Basic Physiology and Practical Therapeutics. By J. Russell Elkinton, M.D., and T. S. Danowski, M.D. (Pp. 626+xxii; illustrated. 80s.) London: Baillière, Tindall and Cox. 1955.

Dr. Elkinton and Dr. Danowski are well known for their pioneer work while they were together at Yale, and they are, of course, still actively engaged now, one in Philadelphia and the other in Pittsburgh. Distance has not prevented their fruitful collaboration in this book, the most ambitious of a number which have been appearing on the problems of the body fluids and their electrolytes. There are two sections—on principles, and on their application to clinical problems. The first makes heavy going at times. With some of the

material this is inevitable; the authors do not hesitate, for instance, in the opening pages, to approach the problems of the thermodynamics of the steady state, showing the trend of modern thought and also where to seek for more information. The second section provides a ready source of reference on almost any clinical question concerning the regulation of water and electrolytes in the body; a lengthy table of contents and a good index make it easy to find one's way about the voluminous text, though the style and the numerous diagrams may not appeal to some. Many chapters bring together for the first time much useful information, as on artificial dialysis and on the technique of balance studies.

The exponential growth of scientific literature makes monographs indispensable, and a major function of such works should be to provide a guide to the literature. The authors are to be congratulated on making easily available an immense amount of bibliographical material, conveniently arranged by chapters and with the titles of articles included. Even so the bibliography is not exhaustive; thus Duckworth's notable works on magnesium have been neglected. One must grant that in so large an undertaking errors inevitably creep in, and some references have in fact been inaccurately cited. Another edition will undoubtedly eliminate misprints. A by no means extensive sampling revealed them by chance in Pace's formula for the fat content of the body (p. 95) and in a table (p. 494) where the magnesium content of the body appears to have been calculated in millimols and not in milliequivalents. The book is well produced and at a reasonable price.

PAUL FOURMAN.

FLUOROSCOPY

Fluoroscopy in Diagnostic Roentgenology. By Otto Deutschberger, M.D. Introduction by Frank J. Borrelli, M.D., F.A.C.R. (Pp. 771+xvii; illustrated. £7 14s.) Philadelphia and London: W. B. Saunders Company. 1955.

This is a well-produced and beautifully illustrated radiological textbook, with a commendably systematic and scientific outlook on its subject. The first part deals with the technical and physiological aspects of fluoroscopy, and does so admirably; it is well worth the attention of any clinician who needs to use a fluoroscope, and it will serve as a splendid introduction for the radiological student embarking on his physics course. The major part of the book is devoted to the clinical applications of fluoroscopy, and also affords a great deal to praise. The section on gastroenterology is extremely well and clearly set out, and is supported by some admirable diagrams and reproductions of radiographs. The cardiological section is also well done, although the classification of congenital heart disease, which is based on anatomical and embryological considerations, would have been more useful had it followed the modern trend of classification according to the presence or absence of cyanosis and the degree of vasculature of the lung fields; and no mention seems to be made of endocardial fibro-elastosis or anomalous pulmonary venous drainage. The section on diseases of the chest suffers from the fact that the author's systematic approach has led him to devote a great deal of space to lesions in the diagnosis of which fluoroscopy plays little or no part, and little guidance is given on the indications for, or the real value of, fluoroscopy of the chest. To quote only a few examples, ten pages are devoted to the discussion and description of pulmonary tuberculosis; there are discussions on the differential diagnosis of miliary and submiliary shadows; and fluoroscopy is hardly the routine method of assessing the response of tumours to x-ray therapy. In a similar fashion, 15 pages devoted to the normal and abnormal encephalogram appear a little excessive, and the value of the book would be greatly enhanced by a more ruthless pruning and selection of material.

These criticisms apart, this book should be of great value to the clinician who has to practise fluoroscopy and to the radiological student, but it is unlikely to be of great value to the practising radiologist.

CONWAY DON.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 17 1956

ERADICATION OF CONGENITAL SYPHILIS

The marked decline in the incidence of early infectious syphilis since the war has been accompanied by a fall in the numbers of cases of congenital syphilis. In 1954, only 48 new cases of infantile syphilis were seen at venereal disease clinics in England and Wales. While the smallness of this number is a matter for congratulation, it should be noted that in the same year the clinics were also treating 638 older children and adults with congenital syphilis.¹ These patients represent the known failures of prevention, and there must be many more who are at present unrecognized. Besides the risk of physical disabilities such as interstitial keratitis and nerve deafness, the congenital syphilitic may be handicapped in other ways. A medico-social survey of 200 families of congenital syphilitics carried out on Tyneside by W. V. Macfarlane and his colleagues² has shown that illegitimacy was twice as common among these children as in their uninfected siblings and that they more often followed less skilled employment.

The greatest hope for the eradication of congenital syphilis lies in the extension of routine antenatal testing of maternal serum. In 1952 the estimated number of births in the Tyneside area was 31,705, and W. V. Macfarlane found that, out of 15,812 antenatal Wassermann tests (50%), only 491 (3%) came from general practitioners who were remunerated for the care of 15,178 pregnancies.³ If these figures are applicable to the country as a whole (and experience in at least one London laboratory undertaking routine antenatal tests suggests that they may be), this method of preventing the disease is not being used as widely as it should be. While general practitioners are understandably reluctant to risk upsetting their patients, the taking of a blood specimen for

grouping and Rhesus-testing affords a means whereby serum tests for syphilis can also be carried out without disturbing the patient, except when a positive result shows the need for further investigation. The importance of the antenatal test is emphasized by S. M. Laird's experience in the Manchester area⁴: in 139 cases of congenital syphilis attending V.D. clinics no antenatal test had been carried out in 75, and in a further 19 it was performed so late in pregnancy that effective treatment could not be given before the birth of the child. Laird also illustrates by case histories the need for repeating the test in each pregnancy.

Only a very small proportion of blood samples from pregnant women give positive results to tests for syphilis. In 1954 the figure for seven blood transfusion centres doing this work was 0.25% among primiparae and 0.32% among multiparae.¹ At one London hospital only a minority of the women whose blood gave positive results when tested antenatally were unknown cases of syphilis; the majority were known syphilitic patients who had received adequate treatment in the past. Unfortunately pregnancy may be associated with non-specific serum reactions, and the application of the treponemal immobilization test to pregnancy sera has suggested that an appreciable proportion of positive results (perhaps one-fifth) are due to such reactions, especially when the serum tests are only weakly positive or give discordant results among themselves.⁵ The doubtful test should not, however, be lightly regarded, since it may indicate infection, as in the case described by F. J. G. Jefferiss.⁶ Because of this uncertainty it is very desirable that, when an antenatal test is found positive in the absence of any corroborative evidence of syphilis, a further specimen should be submitted to full serological investigation before any action is taken. The urgency of the decision about whether to give treatment or not often renders this a counsel of perfection, but if treatment is given before the diagnosis is established both mother and child should receive the same surveillance as is given to proved cases.

Infection of the foetus is thought not to occur before the formation of the placenta, and treatment is aimed either at preventing the penetration of the placental barrier, or, if given later in pregnancy, of "curing" the infected foetus *in utero*. The use of penicillin has transformed the outlook, and if effective treatment is given early in pregnancy the birth of a non-syphilitic child is almost a certainty. The need for retreatment of the mother during subsequent pregnancies is doubtful, but many physicians feel that she should be given an "insurance" course of

¹ Report of the Ministry of Health for the year ended 31st December, 1954. Part II. *On the State of the Public Health, 1955*, H.M.S.O., London.

⁶ Jefferiss, F. J. G., *British Medical Journal*, 1954, 2, 1200.

treatment. When the mother is seropositive, her reagin may pass through the placenta into the child's circulation and it may be found seropositive at birth, although showing no clinical or radiological evidence of syphilis. In these circumstances the infant should not be immediately stigmatized as syphilitic, but repeated quantitative serum tests should be carried out. If the positive reaction is due to a "carry over" of maternal reagin, the child's tests become negative within a few weeks; whereas if it has been infected the titre tends to rise rapidly.

Although antenatal testing gives the best means of detecting and preventing the potential case of congenital syphilis, the routine examination of school-children affords another opportunity of bringing cases to light. Although Macfarlane and his colleagues² found 29.1% of dental abnormalities among their 172 patients, they noted that none of these had been referred to the clinic by dental surgeons. The recognition of a congenital infection is also important as a focus from which contact tracing can begin: in the Tyneside survey Macfarlane and his colleagues were able to examine 534 out of a possible 1,031 family contacts, and 254 of these were found to be infected.

Congenital syphilis is a preventable disease which, with the facilities already existing, could be greatly reduced below the present small incidence, if not completely eradicated. The occurrence of a case should be regarded as a reproach to those to whom the mother has entrusted the supervision of her pregnancy.

RESPONSIBILITY FOR HOMICIDE

The text of the Government's Homicide Bill, put forward in supersession of Mr. S. Silverman's Bill to abolish the death penalty for murder, contains sweeping provisions for the reform of the law of murder while retaining the death penalty for murders falling within certain categories. One of its provisions, if it becomes law, will reduce the importance of the M'Naughton Rules in murder trials in England. The effect of Section 2 of the Bill is to introduce into English law the Scottish doctrine of "diminished responsibility," which was recommended by the B.M.A. as an alternative to the plea of insanity in its evidence before the Royal Commission on Capital Punishment in 1950.¹ Lord Justice Clerk Cooper's definition of that doctrine is: "Even if a man charged with murder is not insane, still our law [Scottish] does recognize—although it is only latterly that it has done so—that, if he was suffering from

some infirmity or aberration of mind or impairment of intellect to such an extent as not to be fully accountable for his actions, the result is to reduce the quality of his offence in a case like this from murder to culpable homicide." The Association recommended that in such a case the jury should be able to find some such special verdict as "Guilty, with diminished responsibility." This section of the Bill provides that:

"Where a person kills or is party to a killing of another, he shall not be convicted of murder if he was suffering from such abnormality of mind (whether arising from a condition of arrested or retarded development of mind or any inherent causes or induced by disease or injury) as substantially impaired his mental responsibility for his acts and omissions in doing or being a party to the killing."

The onus of establishing this defence is laid, as it is in a plea of insanity, on the defence, but, if it is established, instead of a conviction of murder there must be a conviction of manslaughter. The part of the Bill in which this section is included does not apply to Scotland and does not affect the present Scottish law. The provisions of s. 2 are clearly far wider than the M'Naughton formula, but there will no doubt be many occasions when defence counsel will find difficulty in deciding whether it will be best for his client to plead insanity, with Broadmoor as the result if the plea succeeds, or to plead diminished responsibility under s. 2 and take a chance on the sentence for manslaughter which the court may think appropriate, knowing that after conviction there is still the opportunity while in prison for his client to be certified.

In many cases diminished responsibility under s. 2 will apply although the M'Naughton Rules will not. The medical evidence will then have to establish three points to the satisfaction of the jury: first, that the accused was suffering from abnormality of the mind; secondly, that the abnormality arose from a condition of arrested or retarded development of mind or from any inherent causes or was induced by disease or injury (it would be difficult to phrase the requirement more widely); and, thirdly, that because of the abnormality his mental responsibility for his acts or omissions in relation to the killing was substantially impaired. The last point may well give rise to the same sort of difficulty as that which the application of the M'Naughton Rules has made familiar. To argue about the impairment of mental responsibility by an abnormality is to speak in terms of philosophy rather than of medical science. No doubt this is deliberate, so that the ultimate decision is left to the jury, who will have to make what they can of the medical evidence called before them.

PROFESSIONAL COHESION

The Council of the Association, whose proceedings are published in this week's *Supplement*, spent much of its one day's meeting on November 7 in discussing the profession's claim for increased remuneration. Various speakers feared that members generally might believe the Council was being inactive: members were saying that "the Government would get away with it" and would succeed in dividing the profession. There was a call for "leadership," for the holding of special meetings in the Divisions. The debate showed that members of Council, and the Council as a whole, were anxious about the present delay and determined that our negotiators should be in no doubt of the Association's support in obtaining a speedy resolution of the matter. The long delay has made medical men look beyond the present dispute to the cause of it—namely, the National Health Service. One speaker confirmed the view previously expressed in the *Journal* that criticism had extended to the Service itself and was widespread. One remarkable example of this was the recent meeting of general practitioners called by the Edinburgh Local Medical Committee¹: "Those present were firmly of the opinion that the present structure of the National Health Service was fair neither to the patient nor to the doctor." It is evident that the dissatisfaction of recent correspondents is not just the grouching of a handful of malcontents.

The pettifogging arguments about whether a food is a drug, the form-filling, the regulations, earnest discussions on whether a week's leave not taken one year can be carried on to the next, the ever-increasing intrusion of the administrator both centrally and locally—all this and much more is turning medicine into an administrator's maze where the unfortunate doctor soon loses his sense of direction and will end up by losing his sense of profession. Small wonder, then, that increasing numbers of medical men and women feel frustrated and discontented, and look hopefully at the medical services in Australia and New Zealand to see if some of the lessons learned there could be applied here at home. No one suggests that perfection has been reached in these great Dominions. But the medical profession there, not to mention Canada, seems by and large to be contented, and the public to be satisfied with the medical care it receives. The existing widespread dissatisfaction in Britain with so many aspects of the N.H.S. is something more than an expression of the prevailing discontents in the professional classes. There is a feeling that the obstacles in the way of practising "good medicine"

¹ *Supplement to the British Medical Journal*, 1956, November 10, p. 181.

increase rather than diminish; that quantity counts more than quality; that in some unexplained way virtue has gone out of the profession: and on top of this there is the ubiquitous politician.

The politician all too plainly sees the Health Service as a principal piece on his political chess-board. A Minister of Health, with his present enormous powers, may by a rare coincidence be genuinely interested in the medical services and all that these entail. More likely than not he regards his post as one of the halting points in his career. All this degrades medicine, and the clamour grows for medicine to be taken out of politics. The National Health Service is not in a healthy state. We need to close our ranks, and examine and diagnose the causes of the malaise that besets the profession. We need to concentrate effort when it comes to negotiating with the Government on the outward and visible sign of our discontent: inadequate pay for work done, and, more important, breach of contract. There are growing stresses within the profession, and this is in itself still another, and serious, manifestation of the sickness of the N.H.S. It is no service to the profession to disguise these things, or to withhold critical and honest comment on the contemporary medical scene. There are signs now that what has been called the "conspiracy of silence" is being broken down, and men are becoming outspoken in their comments on the politicians' pipe-dream, the National Health Service. The probing, it is hoped, will continue. In the meanwhile we must unite and concentrate our forces to compel the Government to keep to its promised word, and give our negotiators all the support they need for persistent, courageous, and urgent action. If the outcome is successful they will have gained something more valuable than money: they will have realized the force of professional cohesion.

CARDIAC ARREST

During surgical operations the heart may stop beating from a variety of causes. They fall into three main groups: anaesthetic factors, the surgical procedure, and cardiovascular disease in the patient. All have been the subject of detailed review.¹ B. B. Milstein's Hunterian lecture, recently published,² is an authoritative account of incidence, aetiology, and methods of resuscitation.

Cardiac arrest secondary to asphyxia is perhaps the commonest and the most readily preventable. Electrocardiographic studies³ suggest that autonomic overactivity—either sympathetic or parasympathetic—can lead respectively to ventricular fibrillation or vagal inhibition. Cardiac disorders of this kind are more likely to occur in the presence of anoxia and hypercapnia.

The danger of ventricular fibrillation is greatest with anaesthetics which sensitize the heart to adrenaline (whether of endogenous origin or injected); such agents are chloroform, cyclopropane, and trichlorethylene. Ventricular fibrillation has been encountered during hypothermia; the exact cause in this instance is a matter of conjecture. Ventricular fibrillation may also be caused by electrolyte changes, in particular a rise in serum potassium, which can result from hypercapnia. Vagal inhibition can occur reflexly from the inhalation of irritant vapours or following surgical manipulation of branches of the vagus. Atropine will prevent this effect. Cardiac arrest during hypotensive anaesthesia is perhaps surprisingly rare; a very sudden induction of hypotension, leading to an acute fall in filling pressure and in coronary perfusion, may lead to cardiac arrest. During hypotensive anaesthesia asphyxial incidents are not tolerated and may lead rapidly to total circulatory failure. Among the surgical causes, cardiac arrest may follow gross haemorrhage or shock, air or fat embolism, and, more directly, surgery on the heart. In the last instance the problems of diagnosis and access for resuscitation are notably simplified. It is not surprising that the incidence of cardiac arrest is highest in the elderly, in poor-risk patients, and in patients with cardiovascular disease.⁴ In many cases of cardiac arrest during operations acute myocardial infarction has been found at necropsy.

Some authorities⁵ maintain that accurate determination of the aetiology of cardiovascular collapse or arrest is impossible in the absence of electrocardiography. Certainly electrocardiographic tracings may show a characteristic sequence of changes, which may be a guide to the resuscitative measures most likely to succeed. In the vast majority, however, an electrocardiograph will not be running and the diagnosis of cardiac arrest must rest on simpler and more immediate evidence: absence of carotid pulse, cessation of peripheral circulation, extreme pupillary dilatation, and absence of palpable or auscultatory heart beat. Once cardiac arrest is diagnosed there must be no delay in efforts to restore a circulation by cardiac massage, for absence of circulation for longer than five minutes (at normal body temperature) will be followed by irremediable neuronal damage. The heart may be approached from the upper abdomen through the diaphragm, but more effective massage is possible via a left thoracotomy incision. Subdiaphragmatic massage does not produce an effective circulation and so cannot be recommended. Artificial respiration with oxygen is maintained throughout resuscitation. Once some circulation is restored by effective cardiac massage attention can be directed to restoration of a normal heart beat. It has recently been observed that cardiac massage can very easily maintain cerebral cortical activity (and presumably viability), as

indicated by electroencephalography during periods of cardiac arrest. Electrical defibrillation may be indicated, or, if the heart is atonic despite massage and oxygenation, then intracardiac adrenaline in moderate doses may be of benefit. In some centres an artificial pacemaker is available and may help. Measures designed to promote an effective coronary flow are probably of the greatest value in restoring the heart beat, and to this end compression of the aorta during cardiac massage has been advised. The remarkable experiments of W. B. Kountz,⁵ who was able to revive cadaveric hearts by coronary perfusion, are encouraging evidence in this connexion.

It has recently been demonstrated that with suitably raised voltage both the electrical defibrillator and artificial pacemaker can be effective by means of external electrodes applied to the unopened chest, and these methods applied in sequence have thus been used successfully for cardiac resuscitation^{6,7}; such a course of action is attractive in that it can be applied when it is not feasible to open the chest. On the other hand, electrical defibrillation may not succeed on a dilated, anoxic heart until tone has been restored by massage. With a closed chest diagnosis of the state of the heart, even with the electrocardiograph, may be uncertain, and therefore such external attempts at resuscitation must not excuse a fatal delay in performing thoracotomy.

The chances of successful cardiac resuscitation vary according to the cause of the arrest and are lessened by pre-existing cardiac disease. A recent report⁴ records a recovery rate of 50% in cases treated for cardiac arrest. Successful resuscitation occasionally follows very long periods of cardiac massage, and the question therefore arises of when to abandon resuscitative measures⁸ in a case of cardiac arrest. There is no point in continuing massage when the heart ceases to fill in diastole: under these conditions massage will no longer produce a palpable pulse or other signs of effective circulation. When the duration of total circulatory arrest is such that extensive and irreversible neuronal damage is certain—a period slightly over five minutes at normal temperatures—then there is no chance of a successful outcome.

COMPRESSION OF CAUDA EQUINA

Lesions of the intervertebral disks cause much suffering among adults of all ages. The lesions may be the result of acute or chronic trauma or they may arise in its apparent absence. The amount of damage caused to the nervous system depends on the situation of the lesion—in relation to its level and to the nature of the herniation. In the cervical region compression of roots or spinal cord may give rise to symptoms varying from local paraesthesiae to complete tetraplegia. In the thoracic region, though herniation of intervertebral disks is much less common, compression of the spinal cord can readily occur, causing exceedingly severe symptoms and signs. These compression lesions have been well reviewed by J. E. A. O'Connell¹ and were discussed in these columns last year.² Reports of the clinical aspects of compression

of the cauda equina by prolapsed intervertebral disks have appeared from B. Fairburn and J. M. Stewart,³ and recently from W. B. Jennett,⁴ whose material consisted of 25 cases treated at Oxford with the addition of another 34 reported in the literature.

Most cases of sciatica are due to more or less severe lesions of the cauda equina, but Jennett concerns himself with those in which there are signs of profound bilateral sensory or motor loss. Sacral sensory loss and loss of control of the sphincters were almost invariable, and severe motor paralysis was present in nearly half the cases. The presence of signs of severe compression does not necessarily mean that there is massive protrusion of a disk, for other cases in which paralysis was just as sudden and complete were found to have relatively small herniations. These were associated with dense adhesive arachnoiditis. Little is known about this aspect of disk pathology or the extent to which it contributes not only to pre-operative symptoms and signs but also to post-operative sequelae. The condition may be found in patients operated on for a second time in whom myelography has previously shown free passage of the contrast medium. In just under half the cases in the Oxford series, which is the largest single group so far reported, paralysis came with the first attack of pain, and in a similar number it followed within a few days of the sudden onset of pain. The chief pointers to the diagnosis are a history of bilateral symptoms, sphincter disturbance coupled with sacral sensory loss, and weakness or paralysis of muscles in the lower limbs. The importance of careful sensory testing in the perineum is sometimes overlooked. On spinal manometry all these cases were found to have partial or complete block.

The sensory fibres of the cauda equina are preganglionic and therefore do not regenerate if destroyed. Motor recovery after acute compression is slow and often incomplete. Indeed, the results of the treatment of spinal-cord compression are often better than those of compression of the cauda equina, though complete paraplegia is very unusual after injury to the cauda equina and adequate walking ability is generally attained. The more sudden and severe the compression and the longer the duration before it is relieved, the worse are the prospects of recovery. Of 14 patients described by Jennett who had total loss of bowel and bladder control, only two regained full function, though most of the others could manage with occasional incontinence. It might be expected that these severer symptoms would be found more commonly in the upper lumbar regions, but the three lower lumbar disks accounted for all but eight of the 59 cases he reviewed. These lesions may give rise to fatal complications by virtue of their far-reaching effects, and two patients in the combined group died as a result of their prolapsed disk. A third died from an unrelated disease, but death was precipitated by the condition. This work again draws attention to the risks of manipulation, particularly under anaesthesia, for sudden movements were frequently the precipitating factors in

the cases reported. Emphasis must therefore be laid on the need for early recognition of the condition in order that patients may be saved from a life of crippledness and incontinence, possibly terminated by resulting complications, for, when treated in time, there is a fair probability of recovery.

HEPARIN-LIKE ACTION OF DEXTRAN SULPHATE

Complex polysaccharides or dextrans can be produced by microbiological activity, and during recent years there has been much study of dextrans produced from sucrose by *Leuconostoc mesenteroides*. During its growth this micro-organism produces an enzyme which polymerizes the glucose portion of sucrose to form dextran. The molecular size of natural dextrans is enormous and partial hydrolysis effects a reduction. Thereafter special techniques of fractionation allow graduation of molecular sizes and make possible the selection of a dextran with the desired distribution of molecular size.^{1,2}

When dextran is sulphated it has a heparin-like action: this is a property held in common with other polysaccharide sulphuric esters. K. W. Walton³ showed that the toxicity of these substances was related to their molecular weight and that the sulphuric ester of dextrans below a certain molecular weight was non-toxic. On these principles C. R. Ricketts and K. W. Walton⁴ prepared a dextran sulphate which had anticoagulant properties but was not toxic: this material has been given a clinical trial and favourably reported on in 1953.⁵ Comparison of the effects of single intravenous doses of heparin and dextran sulphate showed that the latter had a slightly longer duration of effect. When dextran sulphate was introduced, clinicians using anticoagulant therapy had become accustomed to and experienced in the use of heparin. Because dextran sulphate, though less expensive, was thought to have a similar action to heparin it has not been widely used as a routine anticoagulant. The studies reported a fortnight ago in this *Journal* by S. M. Jeavons, K. W. Walton, and C. R. Ricketts⁶ and H. Cohen and G. R. Tudhope⁷ should revive interest in the use of dextran sulphate in anticoagulant therapy. When this substance was given by intermittent intravenous injection it was found to have a marked cumulative effect if treatment was prolonged beyond three to five days. Thereafter a single daily intravenous injection of dextran sulphate was enough to produce a therapeutically effective prolongation of the clotting time. Although this method of treatment requires a daily venepuncture, so also does the use of coumarin drugs, necessitating the estimation of the one-stage prothrombin time, especially in the earlier weeks of treatment. The reasons for this cumu-

lative effect of dextran sulphate, as compared with heparin, have been investigated. The difference could not be ascribed to varying urinary excretion. It may be that the dextran has a slower rate of metabolic breakdown in the body, permitting accumulation, possibly in extravascular fluid. Cohen and Tudhope also report that treatment with dextran sulphate caused an initial fall in serum total cholesterol. When the dose was reduced to 5,000 units daily as a consequence of the cumulative effect, the lower cholesterol level was generally not maintained: the reduction only persisted while the dosage was 10,000–15,000 units daily. An occasional complication, which has also been reported with heparin, was alopecia coming on after two or three weeks of continuous treatment. Cohen and Tudhope also reported the occurrence of diarrhoea with blood in the stools in two patients, and it is clear, therefore, that dextran sulphate must be used with care.

VAGINAL EXAMINATION IN LABOUR

The relative importance of the various causes of maternal morbidity and mortality has changed over the years, as was remarked on recently in these columns.¹ That infection has receded in importance in the last quarter-century is shown by statistics as well as by the diminishing space devoted in successive editions of obstetric textbooks to puerperal sepsis. Various factors have contributed to this favourable development, notably better antenatal care, advances in techniques of asepsis and antisepsis, and the advent of chemotherapy and antibiotics. When, however, the dangers of exogenous infection were first appreciated, vaginal examination in labour began to be regarded as dangerous, and the practice of checking the progress of labour by palpation per rectum was taught to medical students and pupil midwives. It is likely that the pendulum swung too far and that the dangers of vaginal examination in labour, with adequate precautions against introducing infection, were overemphasized. Many textbooks still assert that the vast majority of labours can be conducted safely without a single examination by the vaginal route, but recent years may have seen more liberal views appear. But few obstetricians would give unqualified support to the opinion, recently aired,² that, in hospital practice, repeated clean (but non-sterile) vaginal examinations can be made to follow the progress of labour without added risk to the parturient. Childbed fever is no longer the scourge of midwifery, but deaths from infection still occur.

Rectal examination in labour is not devoid of drawbacks. Most women find it more unpleasant, if not more painful, than when the vaginal route is employed. During the performance the posterior vaginal wall, which is not surgically clean, is rubbed against the cervical os when the degree of dilatation is being assessed. And the findings per rectum are sometimes uncertain or unreliable. This is especially true with regard to dilatation of the os in prolonged labour, particularly when

associated with incoordinate uterine action. In such cases the cervix often has a thin zone immediately surrounding the external os and a thicker zone peripherally, and the junction of the two may be mistaken by the finger in the rectum for the ring of the os.

What then are the indications for performing a vaginal examination in labour? The answer is—when ever an exact assessment is required and rectal examination either is unlikely to suffice or has proved insufficient for this purpose. This is most likely to occur when there is delay in labour; but, whenever the attendant is in doubt about the position of the baby, the degree of dilatation, or the progress of a trial labour, vaginal examination should be carried out without hesitation. Due precautions must be taken against introducing infection, and if there is vaginal bleeding the operating theatre is the best place for performing the examination in case placenta praevia is encountered. The onset of foetal distress is also an indication for using the vaginal route, both to exclude compression of the umbilical cord and to ascertain whether the baby can be quickly and safely delivered from below or whether caesarean section is necessary to save it. Indeed, in many training centres pupil midwives are taught to perform vaginal examination, with the full ritual of precautions, in every labour at the time of rupture of the bag of membranes. This is a suitable time to exclude prolapse of the cord and for a thorough assessment of the progress of the labour. It is true that, if the head is deeply engaged and the labour clinically normal, vaginal examination at this time is not strictly necessary; but those who practise midwifery must obtain considerable and continuing experience of the normal "touch-picture" if they are to appreciate the uncommon abnormal.

GOWERS MEMORIAL LECTURE

Earlier this week, on November 15 at the Royal Society of Medicine, Sir Francis Walshe, F.R.S., delivered the first Gowers Memorial Lecture, choosing as his subject "The Nature and Dimensions of Nosography in Modern Medicine." The funds endowing the lecture are part of a sum left by the two daughters of Sir William Gowers to commemorate their father's name. Part of the bequest has been used to establish a library of general books for the use of both patients and staff at the National Hospital, Queen Square, the hospital with which the name of Sir William Gowers will always be associated. As Sir Gordon Holmes¹ wrote at the time the library was opened: "To him (Sir William Gowers) the National Hospital is largely indebted for the high level of its clinical practice; few have added so much to its reputation as a centre of scientific medicine or contributed more to its policy as a teaching school." It is fitting that the first Gowers lecturer and recipient of the Gowers Memorial Medal (see p. 1185) should be Sir Francis Walshe, who has himself so notably carried on both at the National Hospital and at University College Hospital the clinical traditions established by Sir William Gowers and the other eminent founders of modern neurology.

¹ Holmes, G., *British Medical Journal*, 1951, 2, 1397.

THE EMPLOYMENT OF THE RHEUMATOID ARTHRITIC*

BY

F. S. COOKSEY, O.B.E., M.D., F.R.C.P.

AND

D. A. BREWERTON, M.D., B.Sc., M.R.C.P.

From the Department of Physical Medicine, King's College Hospital, London

The rheumatoid type of arthritis is one of the most variable disorders encountered in medical practice. Unfortunately those cases which run a long, painful, and crippling course have so influenced doctors, social workers, employers, and the public that many of them tend to take an unduly pessimistic view of the employment prospects in this disease. It is forgotten that many rheumatoid arthritis often causes little disability. Many patients continue to work throughout their illness; others return to their own or more suitable jobs after a few weeks or months; and only a minority are unable to work for a prolonged period.

Course of Rheumatoid Arthritis

The disease cannot be divided into clear-cut stages, but it is helpful if early and late cases are considered separately. The early stages are characterized by active inflammation, but this is often mild, and many patients continue at work, while some even fail to consult their doctor. When the activity is more severe work may be impossible, but this depends as much on the nature of the job as on the severity of the disease. Unexpected exacerbations and remissions are common and make prognosis extremely difficult.

After a variable period of months or years the inflammation usually subsides and function improves as a result. Although there may be some superadded fluctuation in joint activity from time to time, the arthritis is now more stable and predictable. The permanent deformities and degenerative changes usually increase slowly, but their extent is very variable. Often they are not severe. Kellgren, Lawrence, and Aitken-Swan (1953), in a field survey, found that half of the rheumatoid arthritics in a population sample had lost no working time for five years.

Medical Responsibility for Employment Problems

Rheumatoid arthritis is an unstable disorder in sharp contrast to stable disabilities such as the loss of a limb, blindness, or residual paralysis after poliomyelitis. In the stable disabilities it is usually possible to conclude treatment and medical rehabilitation. Then welfare and employment officers can take the responsibility for resettlement into suitable living and working conditions with only limited medical guidance.

In rheumatoid arthritis finality is seldom reached in the treatment, rehabilitation, or resettlement of a difficult case. Furthermore, assessment for work is largely a medical matter requiring clinical examination and an understanding of the potential function and prognosis in each patient. With difficult employment problems it is never enough to fill in a reference form and leave the rest to lay personnel. The physician must take an active interest himself and co-operate with employers, personnel managers, and employment officials at all stages to ensure that his patient is guided into suitable work.

Resettlement Conferences

At King's College Hospital resettlement conferences have been held regularly for several years. These are designed to assist the resettlement of patients with disabilities of many

*Read in the Section of Physical Medicine at the Annual Meeting of the British Medical Association, Brighton, 1956.

kinds and have proved particularly helpful for rheumatoid arthritics. They are attended by the physician, the disablement resettlement officer (D.R.O.) from the local employment exchange, the almoner, the occupational therapist, the physiotherapist, and the patients. These conferences have been an education to all concerned and have created a very helpful liaison with the D.R.O. He is essential, for he knows what work is available, what it involves, and whether the patient's training and ability are adequate.

Results are not as good when patients come from other districts where direct liaison with the D.R.O. is lacking. This is not the fault of the D.R.O., for he cannot be expected to appreciate all the medical aspects of an individual case, and the standard form is no substitute for direct discussion. Under such circumstances better results are sometimes obtained if the almoner makes direct contact with employers who are known to be co-operative.

Management of Rheumatoid Arthritis in the Early Stage

From the start patients must be helped to understand their disease and how to live with it. In particular it is important to allay the great fear so often experienced, but not always expressed, of being crippled and unable to work or to undertake household duties. It is also necessary to make clear to patients the limitations imposed by their disease. All too often they persist in an unjustified belief that they will eventually return to their original work. This may keep them unemployed long after they are capable of doing more sedentary work without difficulty. Indeed, it is too much to expect that they will make the decision to change their work without a full understanding of their disease and its implications. For instance, to obtain employment a disabled farm-worker may need to take his family to a neighbouring town where light engineering work is available. Without a full explanation from the doctor he may stay on in the country indefinitely, hoping for an impossible measure of recovery.

It is also wise to consider a patient's employment at the earliest opportunity. This should not be left until the active phase has subsided. Apart from saving time, the doctor's interest in return to work is good for morale.

The patient's customary work must be taken into account from the outset, and it is a fortunate circumstance when it is of a sedentary nature. If the work involves heavy manual labour or much walking or climbing, the patient will have to change to more suitable work sooner or later. Unless there is early recovery he should be advised to accept the necessity to change his work, and plans should be made for resettlement as soon as possible. Labourers in heavy industry and the building trades are a particular problem, for usually they have attained only a low educational standard. When their disability enforces a change of occupation it is always difficult to find alternative jobs, as most of them are suitable only for unskilled manual work.

The change from moderate activity to still lighter work may be necessary, but this is never an easy decision to take. Two factors need to be considered. Reduced physical activity usually favours the joints. On the other hand, change of employment often involves less skilled work and lower wages, except for young patients who are able to undertake a full course of vocational training. Sometimes it is best to temporize and advise sedentary employment well within the patient's physical capacity until the joint activity has subsided. This is certainly better than no employment at all and does not prevent the patient from obtaining more suitable and highly paid work when his condition improves.

A period of rest from work is sometimes advisable. Whether to insist on rest or to allow patients to continue at work is a difficult decision which may have to be taken several times in the course of the disease. General rest and local rest for the affected joints are probably the most effective forms of therapy at any stage. On the other hand, patients who are busily occupied in work within their physical capacity are often less conscious of pain and less apprehensive about their disability than those who are off work and have little to do beyond attending hospitals for

¹ *British Medical Journal*, 1956, 2, 932.

² Fara, F. J., Steward, M., and Standard, J., *Amer. J. Obstet. Gynec.*, 1956, 72, 1.

The purpose of this letter is to call attention to the importance of species diagnosis. It seems not to be generally realized that, at least in tropical Africa, *P. falciparum* (malignant tertian) is the dominant species of malaria.

somewhere in the region of 90% of all species. Yet laboratory returns show that about 50% of positive blood films are diagnosed as *P. vivax*. Our records show that over 10% of films diagnosed as *P. vivax* were, on re-examination, found to be *P. falciparum*, all from tropical Africa. The principal reason for this margin of error is probably due to the fallacy that if the parasites seen are a little larger than the very small ring stage then the species cannot be *P. falciparum*. This is not so, especially in patients who have had several days of fever in the primary attack before reporting sick. In these patients the parasites may be a mixture of minute ring forms, growing trophozoites, and even pre-segmenting forms. The presence of *P. falciparum* parasites in the peripheral blood beyond the young ring form is usually an indication of a severe infection and calls for immediate and drastic treatment, unlike all other species of human malaria.¹

It is not difficult to diagnose correctly *P. falciparum* parasites if it is remembered that in this species: (1) There is no enlargement of the host cell. (2) Ten to twenty per cent. of the host cells may harbour two or more ring forms. (3) Ten per cent. or more of the ring forms may show a double dot of chromatin. (4) In the trophozoite and later stages the pigment is one or two solid lumps, as against 50 or more grains in all other species (this is of the greatest significance). (5) Numerous ring forms are on the periphery of the host cells—marginal or *accolé* forms.² (6) Stippling (Maurer's dots) consists of about ten grains and is a mixture of dots, streaks, and loops, as against uncountable numbers of stippling dots of equal size in all other species, and distributed evenly over the cytoplasm of the parasite.—I am, etc.,

Cholesterol and Vascular Disease

SIR,—I was very interested to read Dr. J. G. M. Hamilton's account of the recent B.M.A. visit to the U.S.S.R., and especially to see the photograph of Professor Pickering in conversation with Professor Anitchkov (*Journal*, November 3, p. 1049).

Anitchkov and I were together in Aschoff's laboratory in Freiburg im Breisgau in 1911–12, and I knew him very well. I heard all about his work (with Chalator) on the experimental production of atherosclerosis in rabbits by feeding them through a stomach-tube with cholesterol dissolved in sunflower oil, and on my return to Glasgow repeated these experiments in Sir Robert's Muir's department. The results were the same as those described by Anitchkov—extensive changes in the walls of the aorta and large arteries and even development of aneurysms. I reported these results at a meeting of the Association of Physicians in, I think, 1913,¹ where they attracted considerable interest, especially from the late Sir Clifford Allbutt. I next tried the same experiments in cats, but they were totally unsuccessful. So far as I know, no one has produced results in carnivorous or mixed-feeding animals, which seemed to me to rob the work of much of its importance in its possible bearing on human disease. I have been told that, in experiments done abroad, hanging up rabbits by the hind legs for periods every day will eventually bring about similar effects. My results were never published in any journal, for the 1914 war and its new problems enveloped me soon afterwards. They would have added little to Anitchkov's work.

In view of the present interest in cholesterol in relation to human vascular disease, I think it is worth repeating that the experiments were only successful in herbivorous animals—rabbits.—I am, etc.,

Winchester.

Delayed Emptying of Gastric Stump after
Gastrectomy

SIR,—The problem of the gastric stump which fails to empty after gastrectomy is fortunately rare, but it may occasionally be serious or even fatal. It has often been discussed in the American and Continental literature, but has hardly been mentioned by British authors. The problem is this. After gastrectomy the patient recovers in the usual way, bowel sounds return in two to three days, wind is passed per rectum, and the abdomen remains soft and flat. The gastric aspirations, however, remain large for many days and far more fluid is withdrawn than the patient drinks. Bile is usually absent, but there may be traces of it occasionally. If the gastric tube is withdrawn the patient vomits and barium meal remains in the stomach until it is vomited or aspirated. If the abdomen is re-explored a wide, healthy-looking stoma is found and the surgeon is at a loss to account for its failure to transmit fluid.

Many causes and remedies have been suggested, of which the following are a few: (1) inflammatory oedema (treat with antibiotics or intra-gastric adrenaline); (2) gastric atony (treat with cholinergic drugs); (3) neuro-muscular imbalance (treat with intra-gastric local anaesthetics or left-sided paravertebral block); (4) hypoproteinaemic oedema (correct fluid and electrolyte balance). My experience has been that gastric emptying is more often delayed after a gastro-duodenal than after a gastro-jejunal anastomosis, and that vagotomy performed at the same time as gastrectomy causes no more trouble than gastrectomy alone. There has been no evidence that hypoproteinaemia or hypokalaemia was responsible. Gastric aspiration and maintenance of the fluid and electrolyte balance have always been successful, and on two occasions they have been continued for two weeks. Recently, however, I encountered a patient whose stomach did not start to empty until 24 days after operation and in whom more active measures were taken.

She was a spinster aged 41 with a posterior simple gastric ulcer, 5 cm. in diameter, and adherent to the pancreas. It had been present for eight years, had perforated seven years previously, and had caused repeated small haematemeses. Anaemia was corrected with blood transfusion and iron intramuscularly, and on August 8, 1956, she underwent gastrectomy. The operation was difficult, but the stomach was divided above the ulcer and a gastro-duodenal anastomosis was performed. The stoma was not as wide as it might have been, but it admitted a finger. An incisional hernia was repaired at the same time. Post-operatively everything went well except that for 12 days the gastric aspirations remained two or three times greater than the oral intake, which was 30 ml. of water hourly. The serum potassium fell to 2.5 mEq per litre for two days, but its correction had no effect on the stomach. A barium meal remained in the stomach for at least six hours. Because the stoma might have been too small, the abdomen was reopened on August 21. The stoma appeared quite adequate and uninfamed. However, it was undone and a gastro-jejunal anastomosis, which admitted two fingers with ease, was performed. A Ryle's tube was passed through the stoma to allow jejunal feeding. The stomach was not aspirated until two days later, when a small quantity of foul-smelling fluid was vomited. The Ryle's tube was then pulled back into the stomach and 100 ml. of thin pus was aspirated. Thereafter water was given by mouth, the stomach was aspirated as before, and the fluid became clear within a day or two. A polythene tube was inserted via the long saphenous vein into the inferior vena cava and was used for giving concentrated glucose as well as water and electrolytes. There was still no improvement, however. The aspirations remained large and were unaffected by adrenaline (20 ml. of 1 : 1,000 via the gastric tube), lignocaine ("xylocaine viscous") (20 ml. by the same route) or "mecothane" (5 mg. by subcutaneous injection). By August 30 there were signs of severe infection, uncontrolled by penicillin, streptomycin, and tetracycline. The temperature rose to 103.6° F. (39.8° C.) and the pulse rate increased. The abdomen remained soft and flat and bowel sounds were present. Radiography and a leucocyte count showed no sign of a subphrenic abscess. The most likely sources of infection were the indwelling gastric and intravenous tubes, and a feeding jejunostomy was performed so that the intravenous catheter could be removed and the patient fed adequately.

Erythromycin (500 mg. followed by 250 mg. six-hourly) was introduced through the jejunostomy, but no feeds were given at first. Two days later (September 1) the blood pressure fell to 80/50 mm. Hg, and the serum sodium concentration was being maintained with difficulty. These findings suggested the possibility of adrenal exhaustion following the period of starvation, and hydrocortisone (300 mg. in 24 hours) was given intravenously. At the same time feeds (which included the gastric aspirations) were started through the jejunostomy and the patient was given chlorpromazine (25 mg. three times a day via the jejunostomy) to relieve her mental anxiety. The next day (24 days after the original gastrectomy) the temperature was normal, the blood pressure was rising, the patient felt much better, and the gastric aspirations fell to less than the oral intake. The Ryle's tube was removed, oral feeding was started, and recovery thenceforth was rapid.

There are several points of interest. First, why did the stoma start to work after 24 days? Did it do so "spontaneously," or because of erythromycin, hydrocortisone, or chlorpromazine? We shall certainly try these remedies next time we meet the same problem. Secondly, a feeding tube for the jejunostomy is much better than an intravenous tube for the prolonged administration of food. The jejunostomy should probably have been made the first time the abdomen was re-opened, once it was seen that there was no organic obstruction. Thirdly, the simplest solution to the problem might be to pass a double tube at the time of gastrectomy. One lumen would drain the stomach in the ordinary way and the other would go through the stoma and could be used for feeding if the stomach failed to empty. Perhaps others with more experience of this problem will tell us where the fault lies and how the condition can be treated or prevented.—I am, etc.,

Belfast.

RICHARD B. WELBOURN.

Medical Relief Appeal

SIR,—The Medical Association for the Prevention of War, in common with all members of the medical profession, has been deeply concerned at the events of the last two weeks. The tragic abandonment of the rule of law, and the renewal of violence in the Middle East and in Eastern Europe, have done much to destroy the gains which had been won for a saner attitude in world affairs.

Our association was formed, as its name implies, in the cause of preventing war. In view of what has occurred, we wish also to take some steps to minimize its effects. We are therefore appealing as a matter of urgency to our colleagues in the profession for contributions towards the purchase of medical supplies, which will be made available in kind to the International Red Cross for use in whichever theatre of war they are then most urgently needed in. We also urge our colleagues to support us in pressing upon all the Governments concerned a return to the attitudes of humanity and responsible conduct which seemed lately to be gaining acceptance among them.

Contributions should be sent to the treasurer of the association, Dr. A. F. Mohun, 168a, Finchley Road, London, N.W.3, and not to any individual officers of the association.—We are, etc.,

ALEX. COMFORT.
RICHARD H. DOBBS.
PHYLLIS DOBBS.

Tests for Drunkenness

SIR,—The letter by Mr. G. F. Rowbotham (*Journal*, October 20, p. 941) has just been brought to my attention. Police have the heavy responsibility of arresting an individual when apparently under the influence of drink or drug so as to be incapable of having proper control of a motor vehicle. Surely, therefore, the primary object of calling a doctor is to make sure that the apparent condition causing the arrest is not due to illness or other cause giving the same symptoms as "drunk in charge." For similar reasons the prisoner is given an opportunity of calling his own

doctor (particularly helpful knowing the individual and his medical history) or, as an alternative, any other doctor.

The general police practice is to take all persons arrested to the nearest police station, where a senior officer has the responsibility of accepting or refusing the charge. Persons injured or seriously ill would of course be taken direct to a hospital. It follows, or so I suggest, that police are not bound to accept medical evidence, and cases have occurred where, for example, an accused has sobered up very quickly on arrival at a police station, and a conviction has been obtained despite medical evidence being in favour of the accused. In general, however, police would never go against medical evidence where illness was masked by drink.

It is suggested that, with the law and police procedure as it is—with the onus of proof on the prosecution—there is really little defective with the system of examination at police stations. A much more serious practical difficulty would be the question of obtaining three doctors quickly with the necessary experience and qualifications in all but the large centres of population, bearing in mind the vital importance of quick examination.—I am, etc.,

W. J. KELLY,
Superintendent,
Leicestershire and Rutland Constabulary.

Anaesthesia and Apnoea Neonatorum after
Caesarean Section

SIR,—In the *Journal* of July 28 (p. 241) Dr. Joseph Taylor, of Tanganyika, refers to the use of spinal anaesthesia in preventing apnoea neonatorum after caesarean section. There is no doubt of the value to the baby of this technique, but with regard to the mother I would like to strike a note of warning—especially since Dr. Taylor has to act as surgeon as well as anaesthetist. Under these circumstances one hears of the sudden collapse of the patient "even before the operation could be started." This collapse may be due either to hypotension or to respiratory embarrassment. In the series of over two hundred caesarean sections performed under spinal analgesia at the Christian Medical Hospital during the last three years¹ there were four cases of intercostal paralysis that needed artificial respiration for some time.

I consider spinal block to be a safe, and under certain circumstances desirable, method of anaesthesia for caesarean section provided (1) there is someone trained to care for the patient while the surgeon operates, and (2) that means for artificial respiration—e.g., the Oxford inflating bellows—are available.—I am, etc.,

Anaesthetic Deaths

SIR,—A large number of hospitals in Britain have inadequate and sometimes quite primitive operation theatres. This accommodation creates a serious bottleneck in the hospital service and is an important cause of that tendency for our hospitals to become "surgical sausage machines," as Dr. John E. Elam writes in his letter (*Journal*, October 27, p. 995).

The miserably inadequate theatre accommodation in many of our hospitals compels the use of those theatres for a major part of the day and night. Even planned operations must often be fitted into an overburdened surgical programme, and many an emergency is unduly delayed before operation. Most surgical teams are unable to use two theatres for a list and therefore work unnecessarily long hours. Patients sometimes wait all day for operation, or even suffer the extreme upset and inconvenience of being put off until the following day. Unconscious patients frequently return from the theatre in the late afternoon or evening and are still in need of careful observation when only a sparse night staff is available. In these circumstances it is a cause for wonder that more disasters do not occur.

A number of the misadventures to which your leading article refers (*Journal*, October 13, p. 868) would be avoided if hospitals were provided with generous theatre suites and ample recovery rooms. It is no exaggeration to say that in many places the theatre accommodation needs to be doubled, and the profession would be well advised to press vigorously for the necessary reforms. Not only would this ensure that patients are dealt with more safely and expeditiously, but it would also greatly relieve the strain on the surgical and nursing staff, to which Dr. Elam has also referred.—I am, etc.,

Radlett, Herts.

R. S. MURLEY.

Case of Fetishism Treated by Aversion Therapy

SIR,—In a recent report of the treatment of a case of fetishism by aversion therapy (*Journal*, October 13, p. 854) it was suggested by Dr. M. J. Raymond that the predisposition to fetishism "may lie in an unusual capacity to form conditioned responses, and that this capacity may be used as an asset in treatment." If, with Pavlov, we accept that the ability to condition is a general property of the nervous system, then an objective and quantitative method of assessing conditionability before the onset of treatment would be of prognostic value. As part of a series of investigations being carried out in the psychology department of the Institute of Psychiatry (Maudsley Hospital) such a technique has been developed.

Furthermore, it has been demonstrated experimentally that certain normal personality types (introverts) form conditioned responses very readily, whereas others (extraverts) form conditioned responses much less readily; also certain types of neurotics (anxiety states, obsessive-compulsives, reactive depressives) form conditioned responses readily and others (hysterics, psychopaths) form conditioned responses only with difficulty.¹ It may be that much of both normal and abnormal behaviour is explicable in terms of the ability to form conditioned responses. For example, it has been suggested² that certain aspects of delinquent behaviour may be expressed in terms of a capacity or lack of capacity to form conditioned responses. In the specific cases cited by Dr. Raymond we would expect to find that the patient formed conditioned responses with ease and had a particular kind of personality.

It should be possible to use these techniques both as an aid to diagnosis and as a prognostic predictor of success in treating the patient by any form of therapy based directly upon conditioned responses and learning theory.³ In this latter respect it should be observed that drugs may be used in two distinct ways. They may be used in the manner reported by Dr. Raymond, in which the aim is to produce a conditioned aversion in which the effects of the drug are evoked by a stimulus which originally produced a quite different response. Drugs may also be used as stimulants or depressants directly to facilitate or hinder the formation of any new conditioned response or the expression of an existing one.⁴ Both uses have their place in any form of therapy based upon conditioning or learning theory.—I am, etc.,

Neostigmine-resistant Curarization

SIR,—We were most interested to read of Dr. A. R. Hunter's experiences with cases of neostigmine-resistant curarization (*Journal*, October 20, p. 919). During the past twelve months we have seen three of these cases in this hospital and one of us has previously seen two such cases in another hospital. All of these cases were in poor general condition, exhibiting various degrees of dehydration and electrolyte upset. Notwithstanding, as in the case of the patients described by Dr. Hunter, they had all been accepted in the circumstances as fit for general anaesthesia and opera-

tion. The most recent one is perhaps of greatest interest, not least because it is the only case we know of where recovery has taken place.

This was a small wizened lady of 67, weighing 6½ st., who had previously had an operation at this hospital for relief of intestinal obstruction. On that occasion her electrolytes were estimated as follows: Na 121 mEq per litre; K 5 mEq per litre; NaCl 71 mEq per litre; CO₂CP 32 mEq per litre; blood urea 204 mg.%. At operation a band obstruction of ileum was relieved and the anaesthesia was uneventful. On her second admission to hospital one month later she again presented as an intestinal obstruction. Her electrolytes were: Na 112 mEq per litre; K 3 mEq per litre; NaCl 65 mEq per litre; CO₂CP 38 mEq per litre; blood urea 72 mg.%. Anaesthesia was induced with thiopentone 150 mg. and gallamine 80 mg. All spontaneous respiration ceased and a cuffed No. 9 oral tube was easily passed. Anaesthesia was maintained by controlled respiration with nitrous oxide/oxygen for the duration of the operation—one hour—during which an obstruction of the small bowel due to adhesions was relieved. At the end of the operation there was still complete apnoea and no reaction to tracheo-bronchial irritation, and this state was apparently unaffected by the administration of 5 mg. of neostigmine and atropine 1/50 gr. (1.3 mg.) in divided doses. The patient was attached to a Blease pulmoflator and respiration was thus artificially maintained for five hours, during which numerous attempts were made to restart normal breathing by the periodic introduction of CO₂ into the gas mixture, switching off the machine for a period, and giving intravenous nikethamide and bemegride. At the end of this time, very slight spontaneous respiration of the heavily curarized type commenced. This was insufficient to maintain colour and circulation, but slowly increased in volume during the periods when the pulmoflator was switched off. At the end of a further hour, atropine 1/100 gr. (0.65 mg.) and neostigmine 1 mg. were given. This was followed by marked improvement in respiration and a further 4 mg. of neostigmine and 1/100 gr. (0.65 mg.) of atropine were given. Tidal volume improved greatly and respirations became normal in character. The tube was removed in a further five minutes, the laryngeal reflexes now being in evidence, and the patient made an uneventful recovery, although hypotension required a noradrenaline drip for some hours.

All the other cases which we have seen have been of the same type—that is, a history of vomiting usually prolonged and fairly severe causing upset in electrolytes and hydration. Unlike Dr. Hunter's patients, ours have all had a frank obstruction rather than a primary peritonitis and ileus. In the case described, the lowered serum potassium might seem to indicate the cause of the condition as suggested by Dr. Hunter, but in one of our other cases the potassium was estimated as 5 mEq per litre.

These cases undoubtedly present a serious problem to the anaesthetist and Dr. Hunter has done a service in drawing attention to their existence. We do not, however, feel too happy about his suggestion regarding the use of a suxamethonium drip, as it is in this type of patient that one might expect to find a lowered pseudocholinesterase level. Regional analgesia would seem to be the answer for the moment, although the great problem is to diagnose the existence of the condition beforehand.—We are, etc.,

Belfast.

W. E. B. SCOTT.
J. C. CLARKE.

SIR,—I have read with interest Dr. A. R. Hunter's article on neostigmine-resistant curarization (*Journal*, October 20, p. 919). I first met this problem two years ago. I was summoned on two occasions by a resident anaesthetist because the patient would not breathe adequately following an emergency operation. In each case it was an operation on an elderly patient suffering from intestinal obstruction. The anaesthetic situation was as described by Dr. Hunter: intubation performed with suxamethonium and further relaxation provided by one of the "competitive blocking" relaxants. Maintenance of anaesthesia was with nitrous oxide and oxygen and intermittent pethidine, using controlled respiration with carbon dioxide absorption. In each case the end result was the same—failure to establish satisfactory respiration in spite of adequate doses of neostigmine preceded by atropine. The patients died some hours later

from circulatory failure. On the day on which Dr. Hunter's paper appeared I met my third case of this syndrome—which ended in the same fashion as the others.

I should like to emphasize that other causes of this condition were considered: the soda-lime was changed, carbon dioxide was allowed to accumulate, nikethamide and nalorphine were all tried. Necropsy showed no cerebral lesions. The patient looked the picture of "curarization"—that is, inadequate respiration with well-marked tracheal tug. There are two features which appear significant in these cases: (1) all responded in a normal manner to suxamethonium, and (2) all suffered from either intestinal obstruction or ileus.

Dr. Hunter has tentatively proposed that the condition may be due to a low blood potassium. It is known that when depolarization occurs after the injection of suxamethonium there is an outpouring of potassium ions from the muscle cells into the plasma, sufficient to cause a persistent substantial increase in the plasma potassium level.¹ The third case quoted above and one of Dr. Hunter's cases received stored blood, which is rich in potassium ions. This suggests that low blood potassium is not the answer. Could it be that some toxin formed in the lumen of obstructed bowel is synergistic with the "competitive" group of relaxants and this interferes with the normal depolarizing action of acetylcholine, as occurs with the toxin of *Bacillus botulinus*?²—I am, etc.,

Ely, Cambs.

Liquorice-all-sorts as Anastomotic Aid

SIR,—I was greatly interested in Mr. Peter Martin's use of liquorice-all-sorts (*Journal*, October 27, p. 999) as an intestinal splint to effect anastomosis between two pieces of intestine of different sizes. In 1905 Messrs. Arnold and Sons made me a number of gelatin bobbins, at my suggestion; they were the shape of a cotton-reel or spool. I also made myself a long gelatin tube of various sizes, and one could cut off the length desired with a scalpel dipped in boiling water. These enabled one, as Mr. Martin remarks, to easily join intestine of different sizes end to end—I got the idea from decalcified bone bobbins, which were too large for the cases Mr. Martin mentions. The gelatin cylinders dissolved, and on one or two occasions this failed to occur and they were found as collapsed soft masses in the faeces.—I am, etc.,

London, S.W.7.

T. YOUNG SIMPSON.

Medical Education

SIR,—Dr. H. Stewart Moore (*Journal*, October 20, p. 940) objects to the phrase, "He was laparotomized," which appeared recently in a "responsible medical journal," and he hopes that all professional journals might collaborate in refusing to print "such monstrous expressions."

I am not so sure that the coining of such new words is so undesirable. There are many examples in medical as well as non-medical phrases where a verb, arising from a noun, has been coined, and quite aptly so. Thus it is quite correct and proper to say that patient was electrocardiographed, rather than the longer wording—an electrocardiograph was taken of patient, and similarly that he was gastroscopied, bronchoscopied, cystoscoped, x-rayed. And one would not think of saying that the patient had a circumcision operation performed in preference to that he was circumcised. Digitalization and hospitalization, or, to keep to verbs being coined from the nouns, digitalized and hospitalized, are also time-saving in writing without offending the ears, as Dr. Moore asserts. I even welcome the expression, "patient was E.B.S'd," rather than "arrangements for patient's admission were made through the E.B.S." (Emergency Bed Service).—I am, etc.,

London, N.W.1.

M. D. RIPKA.

Pitfalls in Medicine

SIR,—It would be interesting to test the reaction of the average medical practitioner to the learned discourse on misdiagnoses so well illustrated by Dr. A. H. Douthwaite (*Journal*, October 20, p. 895, and October 27, p. 958). How much suffering could be avoided and how many lives prolonged are questions which come uppermost to mind. If the reaction of some ultra-conscientious doctor is one of despair one is reminded of a remark once heard, of a doctor who decided to retire because he had grown tired of guessing. The fact is that, even for a case which appears quite trivial, there must probably be x-ray examination, blood examination, sedimentation test, and renal and certainly rectal and other internal investigations, to mention only a few of them.

But one significant and very true observation and conclusion by Dr. Douthwaite is his allusion to the superior intelligence of the physician of bygone days who could arrive at a probable prognosis by the exercise of his senses—hearing, sight, smell, and touch. This reminds the writer of a teaching clinic he once attended at the Presbyterian hospital of New York held by Dr. Hermann Biggs, the commissioner. At this patients walked in and sat down, and the students were required to observe and notice all they could and give an opinion. With one patient there was hesitation, and after a while Dr. Biggs said, "Well, he looks 'sick,' meaning that he was obviously an 'ill' man. Whether such methods of teaching would pass muster in these days (the clinic referred to took place 43 years ago) is very questionable, but it had its value then.

However, Dr. Douthwaite relents in his epilogue quite nicely when he insists that a misdiagnosis must be glossed over at all costs in the presence of the culprit.—I am, etc.,

London, W.1.

BERNARD E. POTTER.

Student Mental Health

SIR,—I read with interest your summary and comments in regard to the First International Conference on Student Mental Health (*Journal*, October 20, p. 936). With the findings of the conference as to the need for further knowledge of the mental health of students, surely one of the most important occupational groups, one cannot too heartily agree. The problem, of course, involves both constitutional and environmental factors. I think it would be agreed that, even where evidence is lacking, a hereditary element enters into the majority of cases. In regard to this problem in eugenics there is at present little that can be done; we have to accept the fact that some students are constitutionally more prone to breakdown than others. The environmental side of the problem on the other hand is vitally important, because here much can be done in the way of prevention and treatment.

An analysis of cases of anxiety neurosis which occurred during the five academic years 1951–2 to 1955–6 has recently been carried out in the University of Aberdeen student health service. Though this has served to emphasize the complexity of certain aspects of the problem it has brought to light some clear and relatively straightforward findings. Perhaps the most outstanding feature is the high proportion of distressed students who were found to have been living a totally unreasonable life, lacking any sort of interest outside the course of study, and in particular (87% men and 96% women) failing to take any form of outdoor exercise. The question of "cause or effect" naturally arises. Does this way of life predispose to, or is it the result of, anxiety neurosis?

It would be unwise to dogmatize, but more often than not the main stress factors were found to be essentially "university"—associated with the academic and/or social aspects of university life. Much less frequently bad childhood conditions, broken homes, parental disharmony, or unhappy school life proved to be important factors. It is of interest that the majority of students stated that while still at school they had taken part in and enjoyed all sorts of

activities. Very few of them seemed to have been adequately prepared for their new environment; they arrived with no clear understanding of what the university expected of them or how to make the best of their student years. It is not without significance that, although this university provides quite exceptional, and very conveniently placed, recreational facilities, the total membership of the athletic union has never, in any one year, exceeded one-third of the total student body.

When watching young men and women energetically disporting themselves in God's good air, and afterwards, pleasantly tired, enjoying the camaraderie of the pavilion, I cannot help feeling that herein lies at least one answer to the problem of student mental distress. There are of course many sides to this question, but how to persuade young men and women coming to the university for the first time towards a healthier way of living than many of them now adopt is, I suggest, a medico-social problem well worth the consideration of all who have to do with students. The subject of "school to university" has received attention at high level, but discussion so far has centred mainly round the academic aspects of the problem: what to teach in the sixth form, etc. It would seem to me that the health (in its widest sense) aspects are equally important.—I am, etc.,

Aberdeen.

A. H. MACKLIN.

Twopenny-halfpenny Advertising

SIR,—Most of us have received the circulars with the 2½d. stamp which were the subject of letters from Drs. A. E. Penn and D. Saklatvala (*Journal*, October 20, p. 941). Personally, I was amused at the ingenuity of the drug firms.

Another firm sent me a superb portrait, a real photograph, of a very charming and beautifully dressed young lady. There was no indication on the front that it was an advertisement, but the name of the firm is printed in small letters on the back. I mentioned the matter to the representative at the exhibition in Brighton this year, complaining that they had not sent me her name, address, and telephone number. I certainly never omit opening any correspondence from that firm nowadays. I can prophesy a great future for the advertisers who take the daring plunge and send out a few nudes.—I am, etc.,

Stanley, Perth.

OWEN McDONAGH.

Chorda Tympani Syndrome

SIR,—Mr. A. Greville Young in his article, "Unilateral Sweating of the Submental Region after Eating" (*Journal*, October 27, p. 976), describes a most interesting case, allied in nature to the now well-known auriculo-temporal syndrome. I have described¹ an example of the latter syndrome, which was remarkable in being bilateral. The patient was a young man in whom appendicitis was followed by parotid buboes, one on either side of the face—both of which had to be opened. The scars led to the persistent flushing and sweating on eating, which may have been especially annoying to the patient, because his German surname meant "shame red." I occasionally alluded to this case at clinical medical meetings in London. Kinnier Wilson² in his book on neurology pointed out that the term Frey's syndrome was due to Madame Frey's "rediscovering" the syndrome. I alluded to allied syndromes in an article entitled "The Auriculo-temporal and Allied Syndromes" in my book, *Rare Diseases and Some Debatable Subjects*.—I am, etc.,

SIR,—May I suggest that the obvious treatment of unilateral sweating of the submental region after eating (chorda tympani syndrome) (*Journal*, October 27, p. 976) should be interruption of the chorda tympani in the middle ear?

The approach would be identical to that used by Rosen for mobilization of the stapes for otosclerosis.¹ Under local analgesia a small flap, consisting of part of the cutaneous lining of the posterior wall of the auditory meatus and the tympanic membrane, is reflected forwards, the chorda tympani cut where it leaves the Fallopian canal behind the handle of the malleus, and the tympano-meatal flap replaced.

This relatively minor operation can be performed by any otologist trained in the permeatal approach to the tympanic cavity. Disappearance of the submental sweating would confirm the theory of dysfunction of the chorda tympani in this syndrome. The operation would not leave any visible scar and would not impair hearing.—I am, etc.,

SIR,—Mr. A. Greville Young in his paper on the chorda tympani syndrome (*Journal*, October 27, p. 976) rightly rejects destruction of the lingual nerve as a form of treatment on account of its undesirable side-effects. These objections do not apply to the division of the chorda tympani alone, which can be done easily in the middle ear using Rosen's transmeatal approach.—I am, etc.,

Cardiac Diagnosis

SIR,—I have read with interest the review (*Journal*, October 27, p. 984) by Dr. Paul Wood of Dr. R. F. Rushmer's new book entitled *Cardiac Diagnosis: A Physiologic Approach*. While believing that the title might with advantage have been instead "Cardiac Physiology: An Approach to Diagnosis," and thereby have emphasized its physiological rather than clinical bias, I feel that the reviewer has been a little unfair in his criticism of it.

Dr. Wood says that "a physiologist has set out to teach the cardiologists the scientific basis of their subject," but in the preface to the book the author states: "... the text is intended for students of medicine in the broadest sense; from first-year medical students to experienced physicians who are interested in applying basic concepts to the recognition of disease processes." Further, the reviewer questions the restricted choice of pathological conditions which Rushmer discusses in Part V and comments: "No explanation is given for this curious selection." However, again in the preface, the author explains that "these discussions are intended to indicate how physiologic principles apply to the diagnosis of selected conditions rather than to provide a complete dissertation on heart disease."

One would like to think that expert cardiologists have no need for such a book, but many medical students and newly qualified practitioners, as well as teachers of physiology, will find in it much of great value in laying the foundations of an understanding of cardiology. This, as I see it, was Rushmer's aim, and his efforts are, I think, to be applauded.—I am, etc.,

Irradiation-induced Malignant Hypertension

SIR,—Drs. W. M. Levitt and Samuel Oram (*Journal*, October 20, p. 910) appear to have made a somewhat limited examination of the literature on the above subject when they state that, to the best of their knowledge, theirs is the first case of this kind to be recorded. Dean and Abels¹ described a similar case in 1944, and their case was summarized and the reference given in the *Quarterly Journal of Medicine* in 1953.²

It is more serious that Drs. Levitt and Oram have not mentioned that, when malignant hypertension follows abdominal radiotherapy for seminoma, both kidneys may already be badly damaged by the irradiation. To remove one kidney under such circumstances would bisect the patient's renal reserve, already failing, at one blow. This

statement is based on the following: (1) Abdominal radiotherapy used as routine prophylaxis after orchidectomy for seminoma is given on the assumption that metastases may be present in the abdominal lymph nodes. The irradiation usually includes both kidneys, although the upper third of each kidney is excluded from the field, as far as possible. Both kidneys commonly receive the same total dose. (2) In a study of 27 cases of radiation nephritis³ I described two cases as "late malignant hypertension," the syndrome developing many months after abdominal radiotherapy. I have since seen two more such patients, one very recently and still living, in each of whom malignant hypertension commenced four years after abdominal radiotherapy. Thus, out of 40 patients with radiation nephritis carefully studied during the past eight years, four have shown "late malignant hypertension" as distinct from the other clinical syndromes of radiation nephritis. Three of the patients with late malignant hypertension died within three months of the onset of symptoms, and necropsies were performed on two. In each case both kidneys were of normal size and all four kidneys showed histologically the picture of severe hypertensive nephrosclerosis. One case had bilateral perirenal fibrosis. Necropsy on the third patient was refused, but an intravenous pyelogram taken four weeks before death showed no deformity of either kidney.

It is valuable to have confirmation of the fact that, when one kidney is seriously disorganized by radiotherapy due to vigorous treatment of a localized tumour mass in the neighbourhood of that kidney, nephrectomy may cure a resulting malignant hypertension. It is unfortunate, however, that Levitt and Oram should record their case without adequate reference to the basis on which malignant hypertension may arise after abdominal radiotherapy, for their paper could mislead clinicians into unjustified and harmful surgery.—I am, etc.,

Breath-holding Test

SIR,—I was interested in Dr. S. A. Mason's views on the breath-holding test (*Journal*, September 29, p. 766). A few years ago I did this test on 52 patients with varying degrees of pulmonary fibrosis and dyspnoea, and the results led me to begin an article on "The ineptitude of the breath-holding test as an index of either the vital capacity, the maximum ventilatory capacity, or the ventilatory cost of standard exercise." In this study the breath-holding time had been measured in the sitting position after a single deep inhalation. The paper was put aside on finding that the results agreed very closely with those of a far more extensive study on 425 patients with pulmonary insufficiency by Gaensler, Rayl, and Donnelly,¹ who measured the breath-holding time after three consecutive deep inhalations. The interrelation between various ventilatory indices and the voluntary breath-holding time found by these workers and myself is given in the table of correlation coefficients below.

Author	Index	Correlation with Breath-holding Time (r)
Gaensler et al.	Vital capacity	0.28 ± 0.03
" "	Maximum ventilatory capacity (1)	0.38 ± 0.03
" "	Subjective dyspnoea	0.19 ± 0.03
Personal findings	Maximum ventilatory capacity (2)	0.17
" "	Ventilatory cost of standard exercise (3)	0.13
" "	Ventilatory reserve ((2)-(3))	0.12

(1) Obtained using the maximum voluntary ventilation test as described by Baldwin et al.² (2) Obtained using the expiratory flow rate test.³ (3) Obtained according to the method of Hugh-Jones and Lambert.⁴

Although the above table shows no significant correlation between the breath-holding time and the various ventilatory indices, there is no doubt that the breath-holding time is influenced by the oxygen and carbon dioxide tensions of

arterial blood,⁵ which are themselves dependent on so many physiological factors. Mirsky, Lipman, and Grinker⁶ found the mean breath-holding time to be significantly lower in patients suffering from anxiety states than in normals, and it may have been for this reason that Flack⁷ found the test to be useful in assessing the fitness of pilots for wartime operational duties. Apart from these physiological and psychological variables, Gaensler and his colleagues have shown that the breath-holding time can be almost doubled by practice and suggestion, and they state that the only conclusion that can be drawn from a greatly reduced breath-holding time is that the patient is uncooperative, poorly trained, or ill.

Whatever this test measures, it does not appear particularly sensitive in picking out patients who are likely to die under anaesthesia. Of the 52 poor-risk patients reported by Ruth,⁸ the breath-holding time was normal in 28 patients (two deaths) and subnormal in 24 patients (four deaths). In view of the many variables involved I cannot share Dr. Mason's optimism that this test is likely to prove useful in assessing anaesthetic risk, whether the breath-holding time be measured after a maximum inspiration or after a normal expiration.—I am, etc.,

Public Health Laundry Service

SIR,—As long ago as 1945 you published an inquiry about how to protect workers in a laundry against the fleas which came in with the washing¹; and in 1947 the *Spectator* published a letter which pointed out that the public health authorities were faced with a quite new problem in social hygiene. Until then the slum-makers had washed their clothing at home, but with full employment and very high wages they found that they could send it to the laundries. Ever since then bedclothes and body linen heavily contaminated with faeces, urine, blood, sputum, and every kind of discharge from every kind of disease has been packed off to the ordinary commercial laundries without any hindrance from anybody. The matter was raised again about a year ago in the *Yorkshire Post* with the object of persuading the West Riding County Council to establish a public health laundry service to undertake the washing of contaminated clothing, but the proposal was turned down.

The people who are liable to be infected by contaminated material in laundries are the workers who sort it and the customers whose clothing is mixed with it when it is washed. The sorters may pick up all sorts of infections themselves and they may start an outbreak of food-poisoning at home; the customers may be infected if the clothing that comes back from the laundry has not been efficiently sterilized. Obviously, all laundries ought to be inspected and controlled, but the difficulty seems to be that they are in a sort of no-man's-land between the Ministry of Health, the factory department of the Ministry of Labour and National Service, and the county councils. The factory inspectors are responsible for the prevention of accidents, and no doubt H.M. medical inspectors of factories go round periodically to make sure that the workers do not get dermatitis from the chemicals they use, but it does not seem to be anybody's duty to see that fouled clothing is kept out of the laundry (unless it is known to come from a case of scarlet fever or similar notifiable disease), or to make sure that it is sterilized before it is handled.

The general public appreciates that factories are inspected for the benefit of the workers and not for the benefit of the customers, but they often say that with health visitors.

medical officers of health, and a whole Ministry of Health it is a queer state of affairs if there is nobody at all to make sure that their linen comes back from the laundry not only clean but sterile. And it certainly does seem curious that after all these years there is nothing at all in the Public Health Act and subsequent regulations to make it the duty of the local authorities to protect the public by inspecting the laundries.

It is manifestly extremely difficult to make out where, among so many authorities, responsibility lies, but I think it is clear that the first and urgent requirement is public health laundry services to deal with all fouled clothing, and I hope the B.M.A. will take steps to get them established.—I am, etc.,

Wetherby, Yorks.

New Preparations

SIR,—Dr. C. D. Peters's letter on the subject of tranquilizers (*Journal*, October 27, p. 998) prompts me to make a suggestion which is not revolutionary in the publishing business. I need not stress the huge quantity of circulars we all receive, and the impossibility it is for a busy practitioner to digest their contents and weigh their extensive individual claims. The price, too, is never mentioned. Would it not be possible for the *Journal* to publish each week a list of new preparations with comments as to their efficacy and their price? In this way we would be well informed of worth-while new preparations, the astronomical and ever-rising N.H.S. drug bill would be reduced, and the bombardment from the drug houses subdued to the odd broadside, to the benefit of all.—I am, etc.,

Stroud, Glos.

W. G. B. HALLIDEN.

Allergy to Intravenous Iodine

SIR,—The following experience, apparently not unknown to radiologists in general hospitals, is described in the belief that it may be of assistance to anyone occasionally called upon to carry out intravenous pyelography.

A patient suffering from pulmonary tuberculosis complained of haematuria, and an intravenous pyelogram (I.V.P.) was considered necessary. Pressure was applied to the lower abdomen by a football bladder inflated under a tight band, and 20 ml. of "diagnol" (sodium acetate) 50% was injected intravenously into the right arm over a period of about two minutes. The patient noted the usual feeling of heat almost immediately, but within two or three minutes his eyelids were seen to be puffy and the face became flushed. A feeling of malaise followed, with alteration of the voice suggesting some constriction of the larynx. An x-ray taken at five minutes showed only the faintest excretion of the opaque medium from the right kidney, and none from the left, and subsequent films taken at 10, 15, 25, and 45 minutes showed none at all. It was, however, observed that the outline of both kidneys showed up more clearly than usual on all the films from 10 minutes onwards. On the assumption that the reaction was allergic, 5 min. (0.3 ml.) of adrenaline was given hypodermically during the procedure, but produced no immediate relief. The symptoms eventually disappeared in about three hours.

The question then arose as to why the opaque medium had not been excreted in the urine, and advice was sought from the radiologist of the neighbouring infirmary, who stated that he had had a similar result associated with an allergic reaction. At his suggestion, "urogratin" 76% was tried 10 days later; 1 ml. was given intravenously, and, as no reaction was observed in an hour, the rest of the ampoule was injected, using the same technique as on the first occasion. An excellent normal I.V.P. was obtained without untoward incident, the medium being excreted freely from both kidneys in the first five minutes. Although both brands of media contain iodine it would seem that a patient is allergic only to the whole molecule and not to any fraction of it, so that where one brand causes trouble it is possible that another of different molecular composition

may be used with safety. It has not been possible to discover why the medium is not excreted in the allergic case.

Thanks are due to Dr. C. Edwards, consultant radiologist to the North Staffordshire Royal Infirmary, for his advice.—I am, etc.,

Market Drayton, Salop.

J. S. MILLER.

BZ 55

SIR,—I would like to make this small contribution towards the reports which have appeared in your *Journal* in regard to the treatment of diabetes with BZ 55.

My report is upon the first 20 cases I have treated, 17 of whom have continued on BZ 55 for at least 15 weeks; in the other three patients in this series the treatment failed. The three "failures" were patients who asked if they might "try it." Their ages were 18, 37, and 39; the duration of their diabetes three years, twenty years, and twenty years, and their insulin requirements 60, 40, and 70 units daily respectively. Only one had ever been in ketosis. Of the remaining 17—the average age is 64 (ranging from 45 to 77)—six had been on diet and insulin (doses ranging from 20 to 92 units daily) and the average duration of the diabetes is four years. Only one has ever been in ketosis. Insulin was no longer required after starting BZ 55 in all but one case. Eleven had been on diet alone and the average duration of their diabetes is two years. Only one has been in ketosis.

All have responded satisfactorily as judged by diminution or disappearance of glycosuria and reduction of post-prandial blood-sugars. In 14 of these the control is as good as one could wish on any form of treatment. It is of interest to me that one case remained well stabilized despite severe sepsis of a foot, and that another (not included in this report) has remained well stabilized on BZ 55 prior to and following upon a below-knee amputation for gangrene of the foot.

I would like to take this opportunity of expressing my gratitude to Eli Lilly and Co., Ltd., for their generous supplies of BZ 55 and for their interest and help.—I am, etc.,

Chester.

PHILIP R. GRAVES.

Royal College of Surgeons Annual General Meeting

SIR,—We wish to call the special attention of all members and fellows of the Royal College of Surgeons of England to the annual general meeting to be held at the College in Lincoln's Inn Fields on Wednesday, December 12. The nature of this meeting has been recently revised and a programme arranged which should prove attractive to general practitioners and surgeons alike.

About 30 scientific exhibits by members and fellows illustrating aspects of medicine and surgery and the work of the departments of anatomy, pathology, physiology, and pharmacology in the College will be on view from 10 a.m. At 11 o'clock in the Great Hall (accommodating some 700) there will be a series of scientific cinematograph films. At 1 p.m. lunch will be available in the College, and at 2.30 p.m. there will be a ceremony of admission to the Honorary Fellowship followed by a Moynihan Lecture by Professor I. S. Ravdin, Professor of Surgery in Philadelphia and chairman of the Board of Regents of the American College of Surgeons.

The annual meeting of fellows and members at 4 o'clock will include a résumé of College matters and afford members and fellows the opportunity to discuss matters of general interest and to make recommendations to Council. Tea at 5 p.m. will be provided, and the day will end with a subscription dinner (informal dress), at 7 for 7.30, to which guests may be brought. Applications for tickets, £1 10s. each, accompanied by a cheque, must be sent to the deputy secretary at least a week in advance.

All general practitioners and specialists will be made very welcome and are assured of a profitable and friendly day.—We are, etc.,

A. LAWRENCE ABEL,
RUSSELL BROCK,
Vice-presidents of the
Royal College of Surgeons of England.

London, W.C.2.

Obituary

M. J. STEWART, C.B.E., M.D., LL.D.
F.R.C.P., F.R.F.P.S.

Professor Matthew J. Stewart, emeritus professor of pathology in the University of Leeds, and editor for many years of the *Journal of Pathology and Bacteriology*, died at his home at Stoke Poges, Buckinghamshire, on November 7. He was 71 years of age.

Matthew John Stewart was born at Dalmellington, Ayrshire, on May 4, 1885, the son of William Ritchie Stewart, F.S.A., and was educated at the local school and at Glasgow University, where he graduated M.B., Ch.B., with honours, in 1907, gaining the Brunton Memorial Prize as the most distinguished graduate of his year. After graduation he held the appointments of

house-physician and house-surgeon at the Western Infirmary, Glasgow, and resident medical officer at the Ruchill Fever Hospital, where he worked under Dr. John Brownlee. In 1909 he was appointed assistant pathologist at Glasgow Royal Infirmary. He became a member of the Royal College of Physicians of London in 1912.

Stewart began his long association with Leeds in 1910, when he was appointed clinical pathologist to the General Infirmary, a post he continued to hold until 1918. Over much the same period he was honorary demonstrator in clinical pathology in the university. During the first world war he served in the R.A.M.C., first as pathologist to the East Leeds War Hospital and subsequently in the north of France with the 59th General Hospital, where he did fine work among men suffering from the effects of mustard gas. In 1918 he was appointed professor of pathology at Leeds University and occupied the chair for the long period of 32 years, until 1950, when he retired. Academic sub-dean from 1923 to 1941, he was also dean of the Faculty of Medicine from 1941 to 1948 and Pro-Vice-Chancellor from 1939 to 1941, and he represented the university on the General Medical Council from 1942 to 1950.

Recognized at an early stage of his career as one of the leading pathologists in the country, he was president of the Section of Pathology and Bacteriology at the Annual Meeting of the B.M.A. in Newcastle-upon-Tyne in 1921, and at Winnipeg in 1930 he was a vice-president of the Section of Pathology, Bacteriology, Physiology, and Biochemistry. Between these two meetings, in 1924-5, he served as chairman of the Leeds Division of the B.M.A. From 1947 to 1950 he was a member of the Leeds Regional Hospital Board and of the Board of Governors of the United Leeds Hospitals. He was an honorary member of the Leeds and West Riding Medico-Chirurgical Society and of the Glasgow University Medico-Chirurgical Society—of both of which he was a past-president—and of the Faculty of Radiologists. In 1932 he was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, and six years later the University of Glasgow conferred on him the honorary degree of LL.D.

Professor Stewart was elected a Fellow of the Royal College of Physicians of London in 1924. Seven years later he gave the Croonian Lecture before the College, choosing for his subject "Precancerous Lesions of the Alimentary Tract." With Sir Arthur Hurst he was co-author of a book entitled *Gastric and Duodenal Ulcer* (1929). As a morbid histologist he was specially interested in malignant disease and in industrial diseases of the lung. A member of the Medical Research Council from 1935 to 1940, he served on its Industrial Pulmonary Disease Committee from its inception and on its Arsenic Committee. He was also a trustee of the Hunterian Collection and a consulting pathologist to the Imperial Cancer Research Fund. His services as an examiner in pathology were in great demand, and he examined for the Universities of Oxford, Cambridge, Manchester, Bristol, Aberdeen, Glasgow, Birmingham, Sheffield, St. Andrews, Wales, Belfast, and for the Conjoint Board, the Faculty of Radiologists, and the Czechoslovak Government.

Professor Stewart will long be remembered for his services to medicine as assistant editor and editor of the *Journal of Pathology and Bacteriology*, which under his direction became one of the leading pathological journals of the world. He was associated with the journal for 33 years, being appointed assistant editor in 1923 and editor—a post he held until this year—in 1934. The 69th volume of the journal (January–April, 1955) was inscribed in his honour on the occasion of his 70th birthday. In 1950, in recognition of his notable contributions to pathology, of his work on behalf of the Pathological Society of Great Britain and Ireland, and of his long tenure of the chair of pathology at Leeds, his friends decided to commemorate his unique service by making an appeal for funds for the foundation of a lectureship bearing his name and for a bronze plaque struck in his honour to be placed in the medical school at Leeds. The plaque was unveiled in 1952 by Professor H. R. Dean, and the residue of the money, nearly £2,000, is to be used to found a Matthew Stewart Lecture at the university. At a dinner earlier this year Professor Stewart's past and present colleagues on the committee of the Pathological Society of Great Britain and Ireland made a presentation to him and Mrs. Stewart in recognition of his devoted service to the society as editor of the *Journal of Pathology and Bacteriology*. After his retirement from the chair at Leeds, Professor Stewart, accompanied by his wife, went on a tour of Australia, New Zealand, and the United States of America. The University of Melbourne conferred on him the honorary degree of M.D., and while at Brisbane he delivered the Bancroft Oration at the university, taking as his subject "Medicine in Pepys's Diary." In 1951 he was appointed C.B.E.

Stewart was an authority on Pepys; he was also a Burns enthusiast and a member of the council of the Brontë Society. Among his hobbies was stamp-collecting, and he was a past president of the Leeds Philatelic Society. Other recreations were the study of mediaeval architecture and country walking. He married Dr. Clara Eglington in 1913, and she survives him.

We are indebted to Professor J. W. McLEOD for the following appreciation:

After a brilliant student career at Glasgow University Matt Stewart was associated in his hospital appointments with two chiefs of unusual outlook and attainments. These were the late Professor Samsen Gemmell and Dr. Brownlee, who was for many years in charge of the Ruchill Fever

Hospital and later the first statistical adviser to the Medical Research Council, and from these he doubtless got much inspiration. It was after working under these two men that Stewart came to the Leeds General Infirmary as pathologist in the years immediately preceeding the first world war. In his work for that hospital Stewart built up his outstanding prowess as a morbid anatomist and developed many valuable contacts with his clinical colleagues which in later years helped him, when dean, to preserve a sound balance between the demands of the clinical and the more academic departments in the medical faculty.

After his Army service in the first world war he was recalled to Leeds to take over the vacant chair of pathology and to build up the pathological services of the hospitals of that city. He set about this with characteristic energy and thoroughness, and already in 1919 lecturers in bacteriology and in chemical pathology had been appointed under him and an extension of accommodation begun by the conversion to bacteriological and biochemical laboratories of a commercial college adjacent to the medical school. The dean of the Leeds Medical School at this time was the late Professor J. K. Jamieson, and Stewart was associated with him as academic sub-dean. These two men worked in cordial co-operation and succeeded in interesting a number of benefactors in the development of the department of pathology. By the first of many benefactions which he made to the university, Lord Brotherton founded the chair of bacteriology in 1922. A few years later a great drive for funds to support cancer research was launched in Yorkshire, and in this the late Lord Moynehan took a leading part. This was highly successful and made possible the establishment of a third chair in the department, devoted to experimental pathology and cancer research. All these scattered sections of the department were finally united in an ample new building, the gift of the late Sir Algernon Firth. Thus within about fifteen years of the appointment of "M.J." to the professorship the department had passed from a state in which the whole pathological work of the Leeds General Infirmary and city was carried out in two very inadequate rooms adjacent to the post-mortem room in the Infirmary and one even less adequate room in the medical school (with some shared laboratory and lecture-room accommodation for teaching purposes) to the possession of a large building equal to any in the country. In this building the work was directed by three men of professorial rank working under Stewart as administrative head, the last expansion of the department being the creation of a chair in chemical pathology.

Stewart succeeded Jamieson as dean and occupied this position throughout the second world war and up till 1948, and it was in this capacity that his broad interest in medicine and equal interest in the academic and clinical aspects of the subject were particularly valuable. It was remarkable how often the promising younger men who were becoming prominent in the school had been directly associated with the work of the pathological department as demonstrators or as joint authors of scientific papers with the head of the department. How any one man could run a large department successfully while attending to the duties of the dean of a faculty and editing a large and important scientific journal was a puzzle to all his colleagues. His great abilities, his remarkable capacity for hard work, and the determination with which he sought his objectives played a large part, but perhaps not less important was his singularly likable personality, which showed itself above all in his vivid interest in everyone with whom he came in contact, from the last acquired laboratory boy to his most senior colleague.

We are indebted to Professor D. H. COLLINS for the following appreciation:

Matthew John Stewart, "Matt" or "M.J." as he was called by many in all walks of medicine, was a great man. He was an outstanding figure in British pathology. His influence has been widely felt throughout the United Kingdom and in the Commonwealth, especially, perhaps, in

Africa, Australasia, and Ceylon. Everywhere he seemed to have innumerable friends and correspondents who had been his former students or colleagues or who had become acquainted with him either as editor of the *Journal of Pathology and Bacteriology* or as an expert whose opinion had been sought in some difficult case. Indeed, there can be very few Britishers now practising pathology who do not remember him with affection and gratitude for some helpful, considerate, or just friendly activity, great or small, on their behalf.

Stewart himself often said that his principal contribution to the progress of medical science was his editorship of the *Journal of Pathology and Bacteriology*, in whose volumes his name first appears as assistant editor in 1923 and as editor for 22 years, from 1934 to the middle of this year. This was indeed a great contribution to medicine, for through diligence and concentration upon detail he succeeded in maintaining the highest possible standards of matter and presentation, and the journal has for many years held its place among the top-rank specialist journals throughout the world. Stewart had much to be proud of in this connexion, and those of us who have been privileged to work with him know how unremittingly he gave himself to this work. Manuscripts and proofs were always about him—in his room in the Pathological Institute, at his home, in the train, and even, though partly concealed, at some of the less interesting of the countless administrative committee meetings on which he sat.

But Stewart was too modest about his own original work. He wrote for publication only when he had something important to say. Some of us feel that he put on record too little of his vast experience, for so much of what he did publish remains of sound worth to-day. For instance, statistics from his Croonian Lectures on precancerous lesions of the alimentary tract are still often quoted. He had a lasting interest in giant-cell tumours of bone, and it was from Stewart's identification, 34 years ago, of the giant-cells with osteoclasts that the concept and the name of osteoclastoma arose. Gastric ulcer and carcinoma form another subject in which Stewart's original work is well known: his lifelong interest in it culminated, in 1953, in his Macewen Memorial Lecture at Glasgow on ulcer-cancer of the stomach. The third field of pathology in which Stewart was a great expert was that of industrial diseases of the lung. His opinion was widely sought in this respect. There were few cases of asbestosis in this country upon which he was not consulted, and he was writing widely on the pneumoconioses throughout the 1930s. It is very fitting that his name appears as joint author at the head of the first article in the next number, about to be published, of his beloved *Journal of Pathology and Bacteriology*. The paper is on carcinoma of the lung in haematite miners. It is gratifying to reflect that he was at least able to see the proofs of this paper, which stands as a becoming minor memorial, symbolically combining his contributions both to pathology and to medical journalism.

Three little vignettes from personal reminiscence may serve to portray a great character: first, twenty years ago, being summoned to him convalescing from an illness and sitting shivering at his bedside by a wide-open window, while he, the counterpane smothered in sheets of paper, patiently went phrase by phrase over an inept manuscript that I had submitted for editorial judgment, and the feeling of certainty as I came away that I had learnt from "M.J." in that hour so much more than anyone else could have taught me, not only about presenting scientific results but about the use of our beautiful English language; second, his genial figure moving around some social gathering, knowing everyone, and greeting his juniors especially with warming friendliness and a firm grip on one or other elbow; third, the deep satisfaction that I know he felt when, at the time of his 70th birthday in 1955, his assistant editors, taking independent action on the only occasion in history, inserted his own portrait into Vol. LXIX of the *Journal of Pathology and Bacteriology* and inscribed it "In honour of a distinguished pathologist and a great editor."

C. E. BEVAN, M.B., D.T.M.&H.

Dr. C. E. Bevan, medical superintendent of the sanatorium at Saitta and consulting thoracic surgeon to the Government of Cyprus, was shot dead by terrorists while attending a patient at Amiandos, 45 miles from Nicosia, on November 8.

Charles Edward Bevan was born in 1905, a member of a Quaker family. From Emmanuel College, Cambridge, he went on to St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1931. He took the D.T.M.&H. of the English Royal Colleges in 1933, the B.Chir. in 1935, and the M.B. two years later. After qualification he held the posts of house-surgeon, house-physician, resident obstetric assistant, and casualty officer at St. George's, and resident medical officer at St. Andrew's Hospital, Dollis Hill. Entering the former Colonial Medical Service in 1933, he was posted to Nigeria, but left the service after two years to join the Friends' Ambulance Unit in Ethiopia during the Italian invasion of that country. Returning to the Colonial Medical Service in 1936, he became district medical officer in Cyprus, where he specialized in tuberculosis, a disease from which he had suffered as a young man. His untiring efforts to eradicate the disease from among the people of the island dated from his association with the late Dr. Noel Bardswell in a tuberculosis survey of Cyprus just before the outbreak of the second world war. In 1949 he was appointed tuberculosis specialist under the Colonial Medical Service, and for some years was head of the Jubilee Sanatorium at Kyterounda. An active member of the British Medical Association, he was honorary secretary of the Cyprus Branch in 1938-9 and again in 1952-3, and in 1954 he became president of the Branch. Dr. Bevan knew Cyprus and the Cypriots as few Englishmen can know them: he was at home in the island and loved its people, who have been deprived by this senseless assassination of one who had given much of his life to the promotion of their well-being.

Dr. Bevan was twice married. He is survived by his second wife and two daughters, and his friends in the medical profession will sympathize with them most sincerely in their tragic loss.

Dr. P. L. STALLARD, one-time principal medical and health officer, Great Indian Peninsula Railway, died at his home at Pyrton, near Oxford, on August 23, at the age of 76. Philip Lechmere Stallard was born at Powick, Worcestershire, on May 20, 1880. From Sedbergh School, and after a year spent in Paris, he went up to Gonville and Caius College, Cambridge, in 1899. Taking first-class in honours in the Natural Sciences Tripos in 1902, he remained in residence a fourth year to take the second part of the Tripos—again with honours—with physiology as his main subject. He was also a prizeman in Natural Science. He took his medical training at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1907, and obtained an appointment as house-surgeon and later as anaesthetist at the Seamen's Hospital, Greenwich. It was here he gained an interest in tropical medicine which led him to take the D.T.M.&H. and the D.P.H. in 1909, and to accept an appointment with the G.I.P. Railway in Western India. During his service in the India he held at various times administrative charge of the railway districts of Bina, Jhansi, Igatpuri, Lonavla, and Bombay, and was Principal Medical Officer in 1926-7. After his retirement to England in 1929 he settled down to an ophthalmic practice in High Wycombe—he had obtained the D.O.M.S. in 1924—and was ophthalmic consultant for the

Buckinghamshire, Bedfordshire, and Oxfordshire county councils from 1930 to 1949. His heart, however, had been unsound since 1917, and recurring minor warnings caused him to reduce his activities until, in 1953, a severe attack of coronary thrombosis forced him to give up work entirely. The end came suddenly as he entered his house after a short afternoon drive in his car.

H. R. R. writes: Stallard was a man whose exceptional intellectual brilliance was apparent to his friends even in the early days at Cambridge, and throughout his life he never failed to astonish all who sought his opinion by the soundness of his judgment and the depth of his knowledge. While still at Cambridge, and engaged in Natural Science, he amused himself by mastering French, German, and Spanish, and was familiar with the classics of these languages. Later, when serving in the East his interest in languages continued, and he taught himself, in the recreational intervals of a busy official life, Urdu, Arabic, Persian, and Turkish to the extent that he could translate selections from old Persian and other Oriental poets into beautifully phrased English verse, which gave much pleasure to such of his friends who were privileged to receive the little volumes he published for private circulation. He was in fact a master of English composition, and it was always a delight to receive a letter from him. His *Renderings from the Dewan of Khwaja Shamsuddin Muhammad Hafiz Shirazi*, published by Basil Blackwell and printed at the Shakespeare Head Press, contains thirty-two poems of rare merit translated from the original Persian of the Shirazi philosopher. During the early years of his service in the East the lack of precise standards in vision testing and physical examination of railway staff led him to a profound study of the subject. He spent several years in a careful analysis of the procedures in this regard on English, French, and German railways, and in the civil services and the armies of these countries. The result was a masterly and as yet unpublished demi-official report to the administration containing much original work on the functional capacity, efficiency and classification of staff with substandard vision, colour weakness, stereoscopic perceptive defects, and night blindness. The extent of the material studied may be judged from the bibliography, which covers sixty-nine books, periodicals, and official reports in English, French, and German, each of which was conscientiously examined by him in the original. This report formed the basis of the elaborate and unique system of physical examination of candidates and employees now in use throughout the extensive railways of India. His last two years in India were spent on special duty devoted to clarifying and coding the mass of medical and sanitary regulations which had accumulated with the growth of the railways during the preceding three-quarters of a century. Two impressive official volumes remain as a memento to his industry and cover the subject with Pepsian thoroughness and attention to detail. Just before settling down to practise in High Wycombe he spent most of his hard-earned leave touring the old Great Western; London and North-Eastern; London, Midland, and Scottish; and Southern railways, studying their medical services. The result of this work was published by the Government of India under the title *Notes on Medical Arrangements on Four Home Railways*, and circulated for the guidance of railway medical officers in India. Stallard's unusual talents were controlled by an acutely critical faculty. Combined with great modesty, this prevented him from publishing the results of his work with the freedom of many a lesser man. They lie buried in the pages of official files, but nevertheless continue to influence the work of the huge staff who operate some 43,000 miles of railway track and the safety of millions of its passengers. On the lighter side he could perform with credit on the violin and was a draughtsman of no mean ability. He was also a master craftsman in bookbinding. He married in 1910 Dorothea, daughter of the Rev. J. W. D. Bell, vicar of Pyrton, who survives him. They lost their only daughter at an early age. Stallard's many friends in England, his Indian colleagues, both medical and lay, and the staff of the G.I.P.

Railway who served with him under the old regime in India will deeply regret the passing of one whose character is well epitomized in the words of the Fifteenth Psalm.

By the sudden death of Dr. BENJAMIN HUTCHISON on October 30, after a relapse from an illness from which it was thought he had recovered, Lanarkshire has lost one of its most distinguished family practitioners and medical administrators. Benjamin Hutchison was born in Glasgow on October 21, 1886, and after a distinguished academic career at Glasgow University graduated M.B., Ch.B., with commendation, in 1908. Having completed the usual resident posts in the Victoria Infirmary and the Maternity Hospital, Glasgow, he entered general practice and finally settled in Cambuslang in 1911. During the first world war he served as a captain in the R.A.M.C. and was awarded the Military Cross, and in the second world war he was second in command of the Lanarkshire Home Guard, with the rank of major. For 45 years Hutchison carried on the work of a large mixed general practice single-handed until joined by his son after the second world war. He was one of the type of general practitioners now called old-fashioned, and tending to become extinct, who devoted his whole life to the welfare of his patients, not only in relation to their medical needs but also as a counsellor and friend. He was a man of robust health and vitality, and throughout his long and active career was never absent from duty until the onset of his first and last illness. Withal he had a very real understanding and sympathy which endeared him to his patients. Hutchison was an enthusiastic member of the British Medical Association for nearly 40 years, and was a past-chairman of the Lanarkshire Division and a past-president of the Glasgow and West of Scotland Branch. He was also intimately associated with the work of the Insurance Acts Committee and the Lanarkshire Medical Practitioners' Union, which was disbanded on the introduction of the National Health Service. Lanarkshire has produced many distinguished men who have risen to high office in the British Medical Association, but Ben Hutchison, though well known centrally, preferred to devote his main activities to serving his fellow practitioners in the home field. His main work in this regard began with the inception of the National Health Service. He had been strongly opposed to the conditions under which the profession accepted service under the new Act, but once it was an accomplished fact he devoted himself to making the Service work. He became the first chairman of the local medical committee in Lanarkshire and vice-chairman of the executive council and still held both these posts at the time of his death. He was also a member of the General Medical Services Subcommittee (Scotland) from its inception and served on its main subcommittees. In spite of these many commitments and the burden of work which they entailed, he also found time to serve for a period on the Western Regional Hospital Board, and at the time of his death was a member of the Scottish Medical Practices Committee. In addition, he had been for several years a member of the National Insurance Advisory Committee in London. In all these offices he played an important part in the moulding of the new legislation into a workable service, not only in the interests of his medical colleagues but mainly in what he regarded as the most important part, the interests and the welfare of the patient. He found a respite from his many activities in a lifelong interest in sport, including Rugby, golf, and fishing, and was a past captain of Cambuslang Golf Club. To those who enjoyed his personal friendship he has left the memory of a delightfully serene and sympathetic personality and of a loyal and affectionate friend. He is survived by his wife, a daughter, and two sons, the elder of whom is in the practice and the younger a major in the Royal Horse Guards at present serving in Cyprus. The funeral service in Daldowie crematorium on November 1 was attended by a large and representative gathering, a fitting tribute from those he had served so well. —J. C. M.

Dr. EUGEN BIRCHER, co-editor of the *Schweizerische Medizinische Wochenschrift* since 1927, died in Aarau on October 20 after a long illness. Eugen Bircher, the son of Heinrich Bircher, a distinguished surgeon and hospital superintendent, was born at Aarau on February 17, 1882. He qualified in medicine at Basle in 1906, proceeding to his M.D. two years later. After serving as an assistant at the surgical clinic in Basle, he joined his father at the surgical clinic of the cantonal hospital at Aarau, and eventually succeeded him as chief of the clinic. From 1932 to 1934 he was superintendent of the hospital. A leading figure in the medical affairs of his country, he served as president of the German-Swiss Medical Association and as vice-president of the Association of Swiss Physicians. He was interested in politics, both local and national, and from 1942 to 1955 was a member of the National Council of the Federal Assembly: here he was known as a man of broad views, refusing to be confined by narrow party interests. As an author Bircher wrote on military, political, and surgical subjects. His study of the Battle of the Marne established his reputation as a military historian; for some years he edited the *Allgemeine Schweizerische Militärzeitschrift*. His numerous medical papers were for the most part published in the *Schweizerische Medizinische Wochenschrift*, the journal which he helped to edit for so many years.

Medico-Legal

ALLEGED DELAY IN TREATING TUBERCULOSIS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On November 5, 1956, settlement was reached before Mr. Justice Donovan in the Queen's Bench Division¹ in an action brought against Dr. Claude Conway and Dr. Abraham Sless, of Brighton, by Miss Roberta Eleanor Maguire, of Brighton. Miss Maguire's case was that in 1949 and 1950 Dr. Conway and Dr. Sless were practising in partnership and that over a period of 14 months she attended their surgery as a patient. During that time she was exhibiting symptoms which must have given notice and warning to any reasonable doctor that the state of her chest ought to be investigated. No investigation was suggested, and 14 or 15 months later when an x-ray photograph was taken of her chest at the instance of a school medical officer it was found that she was in an advanced stage of adult pulmonary tuberculosis. It was then too late for any treatment except drastic surgery. Her right lung was grossly affected and the left lung also, but not so much.

Dr. E. W. T. Evans, consultant physician in charge of the chest department at Worthing Hospital, called on Miss Maguire's behalf, thought that if an x-ray photograph had been taken in January or February, 1950, it would have shown signs of tuberculosis. If a moderate degree of infiltration had been shown then it might have been cured by drugs or a minor surgical operation. He agreed that it was very unusual to find adult tuberculosis in a child of 13.

Dr. I. R. Clout, of Crawley, criticizing the medical record card of Miss Maguire's case kept by Dr. Conway, said that, though he would have expected to find a note of the diagnosis as well as of the treatment, the card did show colds, coughs, sore throat, and loss of weight, which in his opinion showed a debilitated, sick child treated over a year and requiring investigation. He did not agree that though some doctors would have referred the patient for x-ray examination others would have accepted responsibility and gone on with the treatment.

Miss Maguire's evidence was that in the winter of 1949, when she saw first Dr. Conway and later Dr. Sless for sore throats and colds, she was given medicine but never examined with a stethoscope. Next winter she was worse, and towards the end of the year was visiting the surgery almost weekly. On one

occasion Dr. Sless examined her with a stethoscope, but did not take her temperature or weigh her. She was once told she had bronchitis. On a visit to her home Dr. Sless, when told by her mother that Miss Maguire was tired and listless, said it was all fuss and nonsense and she should be made to eat and should go out and play. She agreed that she had gone swimming against her parents' wishes and without telling the doctor while she had a cough. She said that she had told both Dr. Conway and Dr. Sless and her school doctor when she had night sweats in the autumn of 1950.

Miss Maguire's form mistress gave evidence that in the winter of 1949 her cough had interrupted lessons, but it improved during the summer of 1950. Miss Maguire's mother said that she was not so worried about her daughter's coughs and colds in the winter of 1949-50 as in the following winter. Her daughter was not too shy to go to the doctor regularly. Mr. Maguire gave evidence that his doubts about his daughter's health arose before March, 1951.

Dr. Conway said in evidence that in 1949 he had 4,600 patients on his list and was then joined by Dr. Sless. He was deputy Treasury medical adviser for the area, carrying out examinations for various Ministries. Miss Maguire's medical card was in Dr. Sless's handwriting and dated November 15, 1949, and he first saw her on December 30 of that year. She could not have seen him without its being recorded. When he next saw her on March 17, 1950, she complained of a cough. He examined her general condition and found nothing unusual. He next saw her in September for an elbow injury and was not told by her mother that she was going downhill fast. If he had been told that he would have examined her at once and sent her to the children's hospital or clinic for further examination. He never suspected tuberculosis. He would not expect Dr. Sless to record a cold and a few odd sounds in the chest.

During Dr. Conway's evidence there was a short adjournment, after which Miss Maguire's counsel announced that the action had been settled on terms of the payment of an agreed sum by way of damages, to include £150 for special damages for expense incurred by the father, and a payment for costs by the defendants amounting to a complete indemnity against any claim the legal aid fund might have against Miss Maguire on any of the damages recovered. Mr. Justice Donovan approved the settlement.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Conway, and the Medical Protection Society instructed Messrs. Le Brasseur and Oakley to act for Dr. Sless.

Medical Notes in Parliament

Polio-myelitis Vaccination

Mr. SOMERVILLE HASTINGS (Barking, Lab.) on November 12 asked the Minister of Health for a statement on the recent campaign for inoculation of children against polio-myelitis and his plans for further inoculation in the future. Mr. R. H. TURTON stated that 176,200 children were vaccinated last May and June, including 27,000 who received only one injection. Nearly 1½ million children whose names were registered earlier this year would be given priority when vaccination was resumed. This should be in December for those children who had had one injection and in January for the others, but this further programme would depend on the rate of supply and testing of the vaccine.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) said there had been strong adverse criticism by the B.M.A. of the Minister and the Parliamentary Secretary for using the polio-myelitis campaign for party propaganda purposes at the Llandudno conference, and she asked for an undertaking that this would not be repeated. Mr. TURTON suggested that she must have been misinformed. He made no speech at the party conference, and he understood that the Parliamentary Secretary made no such reference as was alleged. Dr. SUMMERSKILL told him that if he read the *British*

Medical Journal he would see that it was the Parliamentary Secretary's speech, and he as Minister was responsible for what she said. For the second time this year the Minister had been criticized by the great majority of doctors.

Prescription Charge Complaints

Mr. V. COLLINS (Shoreditch and Finsbury, Lab.) asked the Minister if he would exclude from the proposed charges for prescriptions all prescriptions for diabetes and varicose ulcer patients. Mr. TURTON replied "No," but added that any person who on application to the National Assistance Board showed that he would suffer financial hardship in accordance with the board's standards would be able to obtain a refund. Mr. COLLINS said that this class of patient required prescriptions consisting of a number of items throughout their lives. Could the Minister suggest some way in which these people could be helped by having one prescription covering a variety of items? Mr. TURTON replied that diabetics were now paying 1s. whenever they had a form. Under the regulations it was being provided that where a doctor thought it medically advisable he could prescribe a larger quantity of the drugs or dressings for a patient, and the patient would only pay 1s. He had been in touch with the B.M.A., and had asked them to consider any further composite packs that might be desirable. If they discovered such packs they would see that these composite packs would be charged only 1s. when they were prescribed.

Mr. S. AWBERY (Bristol, Central, Lab.) asked the Minister if he would introduce the use of larger medicine bottles and instruct doctors to prescribe larger quantities of drugs, dressings, and medicines in order to obviate the extra cost to those who could not afford to pay the extra charges and who were anxious to avoid a means test. Mr. TURTON stated that the quantity prescribed was a matter for the doctor's decision in accordance with his view of the treatment needed. The charge would be made for each quantity prescribed at any one time, notwithstanding that it might be dispensed in more than one container.

Mr. LLYWELYN WILLIAMS (Abertillery, Lab.) asked for an estimate of the number of persons eligible on the ground of economic circumstances to receive medically prescribed items free of charge and of the number of these who were old-age pensioners. Mr. TURTON said that the prescription charge would be refunded without further inquiry to persons already receiving National Assistance, who on September 25 numbered 1,628,000, of whom 1,065,000 were receiving retirement or non-contributory old-age pensions. He could not form any reliable estimate of the number of other people who might apply and be found eligible for a refund.

Critics of the New Flour

Lieutenant-Colonel LIPTON (Brixton, Lab.) asked the Minister of Agriculture, Fisheries, and Food what further regulations on the composition of flour and bread had been recommended by the Food Standards Committee. Mr. HEATHCOAT AMORY said that the committee had only within the last few days received written observations from interested parties and had yet to take oral evidence. It would therefore be some time before they were able to make recommendations. Lieutenant-Colonel LIPTON said that housewives had no idea of the extent to which the quality of flour had been reduced. Mr. AMORY said he could not agree that the quality had been reduced. He believed the average quality was more wholesome than it was before the recent change in the extraction rate. Mr. HASTINGS said that many, if not most, of those who knew most about the food value of bread would not agree with the Minister that the quality of bread had not been reduced recently. Would the Minister look at the leading articles in the *Lancet* and the *British Medical Journal* and other papers at the time the change was made? Mr. AMORY replied that he believed that flour to-day probably contained the three essential nutrients to a greater extent than it did before the recent change.

¹ *The Times*, November 1, 2, 3, and 6, 1956.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 27 (No. 43) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Week Ending November 3

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 574, whooping-cough 1,538, diphtheria 4, measles 3,089, acute pneumonia 322, acute poliomyelitis 135, dysentery 458, paratyphoid fever 16, and typhoid fever 4.

Infectious Diseases

The variations in the notifications of infectious diseases in England and Wales during the week ending October 27 were small. The largest rises were 219 for measles, from 2,790 to 3,009, 83 for whooping-cough, from 1,469 to 1,552, and 32 for acute pneumonia, from 284 to 316; the largest falls were 68 for dysentery, from 636 to 568, 38 for food-poisoning, from 341 to 303, and 22 for scarlet fever, from 600 to 578.

The largest rises in the incidence of measles were 79 in Montgomeryshire, from 30 to 109 (102 of the 109 cases were notified in Newtown and Llanllwchaearn U.D.), and 55 in Lancashire, from 779 to 834; the largest fall was 61 in Cheshire, from 158 to 97. Only small changes were reported in the local returns of scarlet fever. The largest variation in the trends of whooping-cough was a fall of 38 in Lancashire, from 227 to 189. 9 cases of diphtheria were notified, being 3 more than in the preceding week; 6 of these cases were notified in Lancashire (Liverpool C.B. 4).

114 cases of acute poliomyelitis were notified; these were 25 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 15 (Liverpool C.B. 6, Manchester C.B. 4); London 14 (Battersea 2, Chelsea 2, Greenwich 2, Lewisham 2, Poplar 2), Cheshire 12 (Altrincham M.B. 2, Bebington M.B. 2, Sale M.B. 2), Middlesex 12 (Ealing M.B. 6).

The largest variations in the local outbreaks of dysentery were decreases of 55 in Lancashire and 51 in Yorkshire West Riding. The chief centres of infection were Yorkshire West Riding 96 (Rotherham R.D. 22, Leeds C.B. 19, Sheffield C.B. 11), Lancashire 75 (Rawtenstall M.B. 16, Rochdale C.B. 11), London 74 (Chelsea 15, Wandsworth 9), Essex 50 (West Ham C.B. 37, Ilford M.B. 9), Yorkshire East Riding 46 (Haltemprice U.D. 38), Staffordshire 37 (West Bromwich C.B. 20), and Worcestershire 20 (Oldbury M.B. 19).

The largest outbreak of food-poisoning in the country was 65 cases in Liverpool C.B.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

The Services

Wounded in Egypt.—Lieutenant A. J. Cavanagh, R.A.M.C., attached Parachute Regiment (Bedford).

Surgeon Rear-Admiral S. G. Weldon, C.B.E., R.N., has been appointed an Honorary Physician to the Queen in succession to Surgeon Captain D. H. Kernohan, R.N.

Colonel H. Sissons, O.B.E., T.D., R.A.M.C., T.A., has been appointed Honorary Colonel, 42 (Lancs) Inf. Div., R.A.M.C., in succession to Colonel J. F. O'Grady, T.D., R.A.M.C., T.A., tenure expired.

Colonel M. H. Summers, D.S.O., T.D., R.A.M.C., T.A., has been appointed Honorary Colonel 57 (Mx.) General Hospital.

A Supplement to the London Gazette has announced the following appointments in recognition of distinguished services in Malaya for the period January 1 to June 30, 1956:

C.B.E. (Military Division).—Colonel (temporary) J. C. Reed, O.B.E., R.A.M.C.

M.B.E. (Military Division).—Captain E. W. Brentnall, R.A.M.C.

Medical News

Royal Medal.—On the recommendation of the council of the Royal Society and with the approval of the QUEEN, Dr. DOROTHY HODGKIN, F.R.S., reader in x-ray crystallography at Oxford, has been awarded one of this year's two Royal Medals. The award, states the citation, is "for her distinguished work in the elucidation of structures of penicillin, vitamin B₁₂, and other important compounds by the methods of x-ray crystallography."

Gowers Memorial Medal.—We illustrate here the Gowers memorial medal which was presented to Sir FRANCIS WALSH, F.R.S., by Sir RUSSELL BRAIN, P.R.C.P., on Thursday evening, when Sir Francis delivered the first Gowers

memorial lecture at the Royal Society of Medicine (see p. 1168). At the lecture the chairman was Sir ERNEST GOWERS, whose father, Sir William Gowers, the lecture and medal commemorate. Sir Ernest is chairman of the board of governors of the National Hospitals for Nervous Diseases. The medal, which is in gold, was designed by Mr. T. H. PAGET, and bears on its obverse a likeness of Sir William Gowers based on contemporary photographs, and the words "Sir William Gowers, F.R.S., 1845-1915." It is understood that the lecture and medal will be awarded triennially.

Mental Hospitals.—The Board of Control's report on the condition of mental hospitals and other institutions for the mentally ill (excluding mental defectives) in England and Wales in 1955 states that at the end of the year the mental hospitals were overcrowded to the extent of nearly 18,000 patients and that the nursing shortage persisted. However, the figures showed some improvement on the previous year. The encouraging feature of the report is that the proportion of voluntary patients continued to rise, being 75% of the total admissions to designated mental hospitals during the year; in 1946 the comparable figure was 50.8%. At the end of 1955 a total of 150,856 patients were notified to the Board as being then under institutional care for mental illness. This figure includes 4,291 private patients and 1,108 "criminal lunatics," and represents a fall of 1,288 since the beginning of the year. Of the total admissions 41.6% were readmissions, and there was, as previously, little difference between the readmission rates for voluntary and certified patients. Sir FREDERICK ARMER is continuing as chairman of the Board, despite his retirement this week from the post of deputy secretary at the Ministry of Health.

Chair of Medical Entomology.—Dr. D. S. BERTRAM, Ph.D., reader in entomology at the London School of Hygiene and Tropical Medicine, has been appointed to the London University Chair of Medical Entomology tenable at the School. Dr. Bertram, who is 42, was educated at Glasgow University, where he graduated B.Sc. in zoology (with first-class honours) in 1935, proceeding Ph.D. in 1940. After holding appointments as lecturer and demonstrator in medical zoology and entomology at Glasgow and later the Liverpool School of Tropical Medicine, Dr. Bertram joined the R.A.M.C. as an entomologist in 1940. He was a prisoner of war in Germany from 1941 to 1945, and later in charge of the department of

DEATHS

Boftrell.—On October 20, 1956, at his home, Stanley Henry Reginald Bofftrell, L.R.C.S.Ed., L.S.A., aged 89.

Bryson.—On October 30, 1956, in an infirmary, Thomas Bryson, M.B., Ch.B., of Glasgow, and Kilmarnock, Ayrshire.

Davidson.—On October 27, 1956, at Hildenborough, Kent, the result of an accident, Guy Beaumont Davidson, M.B., B.Chir., D.Obst.R.C.O.G., of Philipotts, Hildenborough, aged 29.

Dunn.—On October 31, 1956, at 42, Upper Cheyne Row, Chelsea, London, S.W., Williamina Shaw Dunn, M.D., D.Sc., D.P.H.

Eardley.—On October 29, 1956, William Eardley, M.B., B.Ch., of Lindum House, Boothferry Road, Goole, Yorks., aged 92.

Glegg.—On October 29, 1956, William Little Glegg, D.S.C., M.B., Ch.B., D.P.H., B.Hy., of 135, Horston Road, Leicester.

Hardy.—On October 30, 1956, at Torquay, Devon, Thomas Mellor Hardy, M.D., of "Prospect," Barton Hill Road, Torquay, formerly of West Byfleet, Surrey.

Henpolette.—On October 30, 1956, at his home, Southdene, Regent Road, Jersey, John Emmanuel Reid Henpolette, M.B.E., F.R.C.O.G., M.R.C.S., L.R.C.P., formerly of Agra, India.

Simpson.—On October 29, 1956, Thomas Edward Norman Simpson, M.R.C.S., L.R.C.P., of West Hythe, Patchway, Bristol, aged 53.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Age of Puberty

Q.—We know that the heights and weights of school-children have improved within recent years. Is there any evidence that the age of puberty is earlier? What factors influence the age at which it occurs?

A.—There is a great deal of evidence that the age of puberty in girls, and also in boys, is earlier than formerly. Unfortunately none of the evidence comes from Britain, where up to about ten years ago very little attention was paid to the growth of children; but European and American statistics make it quite clear that the age at which the first menstrual period occurs (menarche) has got less by about a third of a year per decade continuously during the last hundred years. The average age of menarche in England now is approximately 13½ years. So far as we know age of puberty is not greatly affected by climate (contrary to what used to be thought); poor nutrition retards the age of puberty, and poor social environment does so as well. Various other factors influence the age of puberty, the chief amongst them being the factor of inheritance. A full discussion of these factors can be found in J. M. Tanner's *Growth at Adolescence* (Blackwell Scientific Publications, Oxford, 1955).

Foreign Bodies in Children's Ears

Q.—What is the best way of removing foreign bodies such as beads, beans, etc., from children's ears? Do any of the new plastic adhesives make it possible to attach a match-stick or similar instrument to the object to facilitate its extraction?

A.—The danger of foreign bodies in the ear lies mainly in their removal. In the case of children a general anaesthetic must be given if the child is nervous and unable to hold its head perfectly still during examination, and if the foreign body is too large to remove by syringing. Only a practitioner with considerable experience in otoscopic examination and in the intra-meatal manipulation of instruments should attempt to remove a foreign body from the ear, and it should be carefully examined before any such attempt is made. Small free objects are best removed by syringing; it should be remembered in so doing that beans and peas are hygroscopic and swell when moist, and in such cases syringing with alcohol is recommended. Hard bodies, such as beads and buttons, may damage the tympanic membrane if driven against it by forcible syringing and should be removed by the aural curette; this is best passed along the roof of the meatus between the foreign body and the meatal wall and the body rolled outwards along the floor. It is useless to try to grasp cylindrical bodies with forceps in the meatus.

Partially impacted foreign bodies may be freed and removed by means of a fine aural hook in the same manner as the aural curette; secondary otitis or swelling from trauma may be a contraindication to their immediate removal. If firmly impacted, it may be necessary to remove foreign bodies by operation, in which case an incision is made in the post-audicular groove, the membranous meatus is freed and incised, and the body disimpacted and removed. It may occasionally be necessary to enlarge the bony meatus by paring down its walls with a gouge.

There is no record known of the use of plastic adhesives for removing foreign bodies from the meatus.

"Mist. Menses"

Q.—I have been asked by the warden of a hostel for pupil-midwives to prescribe a mixture for the relief of dysmenorrhoea. Apparently a number of the pupils suffer considerable distress from premenstrual and first-day pain. I am given to understand that at one London hospital a mixture known as "Mist. Menses" was prescribed in such cases. What does your expert suggest?

A.—Although this is, or was, traditional in some hospital nurses' homes, the wisdom of providing a stock mixture—sedative, antispasmodic, or both—for the home sister to dole out to nurses with dysmenorrhoea is, to say the least, doubtful. Each girl or woman with dysmenorrhoea deserves individual attention from her doctor, including questioning, examination, explanation, reassurance, and in some cases reference to a specialist. Even pupil-midwives are not free from misconceptions regarding the phenomena of menstruation; and, although most are in their early twenties, a few are older women in whom an organic cause for the symptom may be present.

Child Guidance Clinics

Q.—(1) What are your experts' views on the usefulness of child guidance clinics? What facilities not easily obtainable elsewhere do they offer? (2) What staff is required to run a child guidance clinic, and what accommodation is necessary? About how many cases a year can such a clinic deal with? I have in mind a town with a population of about 100,000.

A.—A CHILD PSYCHIATRIST writes: (1) Although child guidance clinics are becoming more systematic and organized in diagnostic, therapeutic, prophylactic, and experimental work it is not yet possible to assess their value in terms of improved general mental health, reduced frequency of breakdown in adult life, and influence upon the amount of antisocial and delinquent behaviour. However, most psychiatrists agree that the conditions occurring during infancy, childhood, and adolescence are, generally speaking, more amenable to treatment than those met with in adult life, and are convinced of the immediate value of child guidance in relieving distressing symptoms or behaviour, in improving adjustment, and in freeing the developing personality of the child from the influence of distorting attitudes and circumstances. Clinics provide facilities for the assessment of physical, emotional, intellectual, and social stresses and their relation to symptom formation, disturbed behaviour, and deviations of personality in infancy, childhood, and adolescence; and for the relief of many of these stresses through the advice, guidance, and help given to parents, teachers, etc., and through the direct treatment of the child by psychotherapeutic methods or by placing the child in a suitable alternative environment. There is a growing realization amongst those concerned with the education, physical health, care, and supervision of children that emotional factors play an important part in the child's development, adjustment, and response to stress, and that a better understanding of these factors would assist considerably in their work. The modern clinic should be prepared to meet this growing need and to advise and help when questions of mental hygiene arise during the work of infant and child welfare clinics.

(2) Conditions vary considerably from area to area as far as the responsibility for the provision of staff and accommodation is concerned and for the general administration of the unit. The recommendation of the committee on maladjusted children¹ on staffing has been accepted by most as a reasonable ideal: nevertheless, for a population of 100,000 inhabitants the needs suggested above could be more adequately met by a team consisting of one full-time psychiatrist, one full-time psychologist, and two full-time psychiatric social workers. The most satisfactory arrangements so far as local authority clinics are concerned is for

the unit to be accommodated in offices set aside for the purpose and not shared by other workers; a minimum of an office for each member of staff, a fairly large play-room, a waiting-room, and a general office is required. The turnover of cases will depend upon the policy adopted by the clinic, but in an area of 100,000 inhabitants between 100 and 200 new cases could be examined each year in addition to cases attending for regular treatment.

A MEDICAL OFFICER OF HEALTH writes: (1) There is no doubt about the value and usefulness of child guidance. There are two components of child guidance in its broadest sense which may be combined or associated together in a child guidance clinic. The first concerns the clinical treatment of those children called maladjusted, who show evidence of emotional instability or psychological disturbance and require special educational treatment in order to effect their full personal, social, and educational adjustment. The second component includes the duties of a school psychological service. The function of this service, which is primarily non-medical in character, is to assess the abilities and aptitudes in an educational sense of children throughout their school life so as to obtain the best results from the education provided. A child guidance clinic of this dual character can provide a centre for the diagnosis and treatment of emotional and behaviour problems occurring in the child at home and in school, and it can also provide guidance in the purely educational sense both to the child and to the teaching staff of the school. In its psychiatric aspect the clinic can prevent delinquency, and in this respect can give valuable advice to magistrates and to juvenile courts, and later on in the life of the child give advice on aptitude for employment. It is recommended that child guidance clinics should work in close association with juvenile courts and with the children's departments of local authorities.

(2) The minimum staff required is a psychiatrist, an educational psychologist, and a psychiatric social worker. The psychiatrist should be one with a special interest in child psychiatry. A clinic taking about 100 new cases per year will need the services of a part-time psychiatrist, a psychologist working half-time, and a full-time social worker. In a clinic taking 300 new cases per year the minimum staff needed would be one full-time psychiatrist, two full-time psychologists, and three full-time social workers. The clinic should be run in close association with the school health service and with the general practitioners in the area. In addition the consultant services of a paediatrician are valuable, and it is recommended that the services of a speech therapist should be available as required. The accommodation necessary will depend on the size of the clinic, but it should be sufficient to ensure privacy for each member of the staff to interview parents and children. The suggested minimum would be a waiting-room, individual rooms for each psychiatrist and psychologist, and accommodation for the social workers. In addition to this there should be two play-rooms for play therapy and observation, together with the necessary office and record accommodation. The accommodation should be as informal and as homely as possible, and it is desirable that the building should be as unobtrusive as possible. It is estimated that a child guidance team of one full-time psychiatrist, two psychologists, and three social workers can adequately serve a population of 45,000 schoolchildren.

Mescaline

Q.—Has mescaline any therapeutic value?

A.—Mescaline is the best studied of those drugs with a central stimulating action which because of their effect on imagery have been called "phantastica" or hallucinogenic drugs. Its chemical constitution is of interest because of its close relation to adrenaline and similar substances occurring

in the normal human body. In view of the frequent occurrence of "depersonalization" under mescaline intoxication, Guttman and Maclay¹ suggested its use for treating this symptom, but their results have not been confirmed by other observers. Small doses have lately been used as a help to provoke the production of "subconscious" material which was apparently forgotten or "repressed" from consciousness. Other means of releasing such material are available and more effective than mescaline. Aldous Huxley's recommendation of mescaline in place of alcohol as a general stimulant has no medical support.

To sum up: mescaline has no therapeutic value in spite of its considerable interest as a research tool.

Fungal Infections of the Urinary Tract

Q.—What treatment is suggested for a monilial pyelitis? The patient in question had a tuberculous kidney removed some years ago, but repeated examinations of catheter specimens of urine have failed to reveal any tubercle bacilli (guinea-pigs were inoculated), and the most recent specimen has yielded an almost pure culture of *Monilia albicans*. There are some small stones in the remaining kidney.

A.—Yeast-like fungi in the urine are more often of the genus *Torula* than *Candida* (*Monilia*), and a frequent predisposing condition is glycosuria: when this exists its abolition is often enough to cure the infection. The precise identity of the organism is of little consequence in treatment, since all yeast-like fungi are entirely unaffected by sulphonamides and antibiotics. This leaves only the urinary antiseptics other than true chemotherapeutic agents, and I am not aware that any of these has been shown to be effective against this class of organism except hexamine. The action of hexamine, which itself is inert, is due to the liberation from it in an acid medium of small quantities of formaldehyde. This liberation is minimal unless the pH of the urine is reduced to below 6.0, and preferably to about 5.0. Sufficient ammonium chloride should therefore be given to attain this degree of acidity in the urine (as verified by an appropriate indicator, or, better, with a pH meter) together with 10 gr. (0.65 g.) of hexamine three times a day. It may prove impossible to eradicate this (or any other) infection permanently if there are, as stated, calculi in the remaining kidney.

Menthol Cigarettes

Q.—A patient has asked me to prescribe menthol cigarettes for him. He tells me that before the war they were used by people forbidden to smoke. I would appreciate some information about them.

A.—Cigarettes containing menthol were at one time available in Britain for discouraging smoking. They were not supplied through pharmacists but were advertised in the lay press, and those wishing to stop smoking were asked to write for the "cure." They were extremely expensive, costing about five guineas for a few cigarettes. It is not known whether they were effective or if they are still available. A trick often played on pharmaceutical apprentices was to place a long crystal of menthol in an ordinary cigarette. The effect of smoking such a cigarette is certainly most unpleasant.

Medicated cigarettes are usually made from one or more of the following herbs: stramonium, belladonna, lobelia, hyoscyamus, digitalis, mullein, sage, eucalyptus, or coltsfoot leaves, cascarilla bark, phellandrus fruit, or cubeb berries. Cigarettes containing menthol could be made with some of these as a basis. Alternatively, thin blotting paper could be soaked in a solution of menthol in methylated spirits, and when dry this could be used to make cigarettes. It is usual to add about 2% of potassium nitrate to aid combustion.

Intra-arterial Transfusion

Q.—What are the indications for, and what is the rationale of, intra-arterial transfusion?

A.—The chief indication for intra-arterial transfusion is a degree of shock so profound that an adequate volume of blood cannot be given sufficiently quickly by the intravenous route. The rationale is that intra-arterial transfusion immediately raises the mean intra-arterial pressure and improves the blood supply directly to brain, heart, and other internal organs. Perhaps the commonest example of the use of intra-arterial transfusion is the cardiac surgeon's insertion of a needle for transfusion into the aorta when cardiac output is impaired in the course of a cardiac operation.

Infirmity Mice

Q.—Do house-mice sometimes spontaneously desert buildings they have long occupied, and, if so, are the reasons for this understood? A large infirmary, previously much afflicted with mice, is said now to have none. The only change in environment noted has been the installation of seven television sets, and some people have suggested that this might account for the migration of the mice.

A.—It would be nice to attribute some useful function to television sets, but, until controlled experiments have been carried out, television will have to find other functions to justify its existence.

There does not appear to be any authenticated case of a mouse population spontaneously deserting a large town-building where there was an adequate supply of food. In the hospital mentioned in the question it is possible that control measures, aided by the local cat population and perhaps unnoticed changes in the handling and storage of possible food materials, have brought about a marked decline in the mouse population.

The British house-mouse is derived from a Central Asian wild species. In Britain there appear to be three fairly distinct groups; the "town-mouse" of our houses, shops, and warehouses; the "rural-mouse" (not to be confused with the various species of field mice and voles); and the "wild house-mouse." The rural mouse lives in and about farm buildings, whereas the wild one keeps to the hedges and fields and rarely invades buildings. A farmhouse may be free from mice during the summer months, but a high population may develop with the onset of autumn. If the hospital is in rural surroundings it is more than likely that very shortly the mice will again become obvious.

Potency and Effectiveness of Adrenaline

Q.—How long does 1 in 1,000 adrenaline solution retain its potency? How can one test this? Does adrenaline in an ampoule retain its potency longer than if kept in a rubber-capped bottle? Recently I needed to give 100 minims (6 ml.) of 1 in 1,000 adrenaline from a bottle to relieve an asthmatic who the day before had been relieved by 1 ml. from an ampoule. Could this discrepancy have been due to loss of potency of the adrenaline in the bottle? It had not changed colour.

A.—One-in-a-thousand adrenaline solution, if protected from light and stored in a cool place in well-filled glass containers complying with the tests for the limit of alkalinity, should retain its potency. In practice, however, adrenaline in rubber-capped bottles is often found to be discoloured after six months, while adrenaline in ampoules, if the ampoules are left in their boxes, retains its potency for much longer. Loss of potency is due to oxidization. Apart from animal assay, the only practical way of judging the potency is by carefully looking for any colour change: active adrenaline is colourless; a pink colour later turning to brown indicates loss of activity.

Since the 100 minims (6 ml.) of adrenaline was colourless, the difference in dose from the previous day was almost certainly not due to loss of potency but to the condition of the patient. The effective dose of adrenaline depends on the severity of the attack. It is quite understandable that an asthmatic on one day might be relieved by 1 ml. of adrenaline, but that on the following day, with the condition worsening, 6 ml. of adrenaline given at the rate of 1 minim (0.06 ml.) per minute might be required and tolerated without side effects.

Heredity in Diabetes

Q.—To what extent is diabetes mellitus an inherited disease? In a family of seven children four have already developed diabetes (two boys and two girls); one of the remaining children was killed in the war. There is no knowledge of the disease in earlier generations on either side. What is the likelihood of the two remaining unaffected children developing the disease, and what is the outlook for the next generation?

A.—Diabetes mellitus is probably not homogeneous genetically. The insulin-sensitive form of early onset behaves as if due to one or more recessive genes with reduced penetrance.¹ The empiric risk for a brother or sister of an affected child, the parents being unaffected, is about 1 in 20.

The remarkable history in the inquirer's family, however, suggests recessive inheritance without any reduction of penetrance. The risk in this family for the remaining two children may well be as much as 1 in 4, but the risk is lessened by the extent to which the children have already passed a fraction of their lifetime risk. The outlook for the next generation in this family is a risk of 2-5% for the children of the affected members of the sibship, and of 1-2% for those of the unaffected members.

NOTES AND COMMENTS

Schools for Mentally Backward Children.—Dr. D. M. ZAUSMER (Barnehurst, Kent) writes: In your expert's answer to the inquiry on where information about schools for mentally backward children may be obtained ("Any Questions?" November 3, p. 1070) there is no mention of child guidance clinics. I would suggest that a doctor concerned with an E.S.N. child should first consult the psychiatrist of his local clinic. In addition to the special day and residential schools for E.S.N. pupils mentioned in the answer, there are also special classes for such pupils in some ordinary schools. Other provisions include home tuition in certain cases and remedial teaching by educational psychologists at child guidance clinics.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Alitology, Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. Spreading smooth and even...

A little Ef-Cortelan Skin Lotion goes a long way. Just one drop will spread smoothly and evenly to cover an extensive area. It does not stick, sting or stain—brings only swift, soothing relief in inflammatory, exudative and allergic skin disorders.

Why the spreading power of Ef-Cortelan Skin Lotion is so important.

- More intimate contact with the tissues makes the $\frac{1}{2}$ % lotion as effective as a 1% ointment
- It spreads *smoothly* without a hint of friction.
- It is economical in use

GLAXO EF-CORTELAN SKIN LOTION

(0.5% and 1% hydrocortisone alcohol in non-greasy fluid base) In 20 cc. squeeze bottles.

ALSO AVAILABLE: EF-CORTELAN SKIN OINTMENT NO. 1 (non-greasy); EF-CORTELAN SKIN OINTMENT NO. 2 (greasy). In potencies of $\frac{1}{2}$ %, 1% and 2½%. OINTMENT and LOTION WITH NEOMYCIN.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX BYRON 3434

Does man really have a limited expectation of life?

Is there indisputable evidence that man's term upon this Earth is limited? Could it be that what today is a normal age span will tomorrow seem ludicrous? Admitted, at present a body seems to wear out. But does it really? Or does bodily decline go hand-in-hand with mental stagnation? There have, of course, from time to time been reports from foreign climes of extreme longevity—extreme, that is, compared to normal. And even here in Britain the average expectation of life has risen steadily, thanks to the surgeon, the physician and the march of medical knowledge. But, even so, our allotted time is still only a little more than the traditional 'three score and ten'. We may, of course, cheat the grave by some ten, twenty or perhaps thirty years. But can we in the future live on and on and on? *Who is to say that another age will not produce the elixir of life?* What reasoning precludes "spare parts" for men's anatomy, not merely mechanical prostheses but living, sensate, organs and limbs? And why shouldn't there be new horizons for future medical men to see over? After all, this age has given us antibiotics. Man's life span has been increased by such "wonder drugs" as Terramycin. May not the future hold even broader broad-spectrums? Today we can only hope and search and use those weapons which best help us to fulfil our Hippocratic oath. But think on these things. For who, other than you, can give a man his birthright—the right to live?

Terramycin is the Trade Mark of Chas. Pfizer & Co., Inc. for their brand of oxytetracycline.

LONDON SATURDAY DECEMBER 1 1956

PRESENT THERAPEUTIC STATUS OF CORTISONE AND ITS DERIVATIVES, WITH SPECIAL REFERENCE TO RHEUMATIC DISEASES*

BY

HOWARD F. POLLEY, M.D.

Section of Medicine, Mayo Clinic and Mayo Foundation,† Rochester, Minnesota, U.S.A.

The multiple and various applications of cortisone and certain of its derivatives and of corticotrophin currently give these hormones a field of action and versatility "wider than that of any other therapeutic agent" (Hench, 1956). Their specific hormonal value is recognized by their use in about 20 hormonal, endocrinal, or metabolic conditions. The non-specific hormonal effects have been useful in more than 90 so-called non-hormonal conditions. In such circumstances the effects of administration of these hormones are suppressive rather than curative; but the effects are none the less valuable for purposes of treatment or further investigation. As Hench has stated, it is now no longer *if* but when, how, and for what purpose these hormones should be used.

Chief among the non-specific effects of adrenocortical hormones which have been useful clinically are their anti-inflammatory, antirheumatic, and anti-allergic activities. A few examples are given in Table I. The

physicians should learn to use the available hormones as effectively as possible and should obtain the consultation and supervision of experienced specialists whenever indicated.

Improved use of adrenocortical steroids has developed chiefly along two interdependent approaches. One has been by way of the various modifications of methods of administering the hormones. In a sense this has been an approach dictated by necessity, since existing measurements of adrenal cortical and pituitary function (Mason, 1955) were of limited usefulness for presumed non-hormonal diseases. Certain practical aspects of the currently advocated methods of administration are discussed below. The other approach to improved use of the hormones has been made by various chemical modifications of the steroid nucleus. This has resulted already in a number of synthetic steroidal compounds with varying degrees of metabolic and anti-inflammatory activity.

CHEMICAL DEVELOPMENTS AND STUDIES OF EFFECTS

Evolution of Antirheumatic Steroids

Cortisone, the first adrenocortical steroid found to have antirheumatic and other physiological effects, was given to patients with rheumatoid arthritis in 1948 (Hench *et al.*, 1949), and hydrocortisone, or cortisol, in 1949 (Hench *et al.*, 1950). Hydrocortisone has a more certain action than cortisone when administered locally (Young *et al.*, 1954); but it is equal to cortisone in the production of undesired metabolic effects when given systemically (Ward *et al.*, 1952). In 1954, 9 α -fluorohydrocortisone was found to have an antirheumatic effect about 10 times that of cortisone, but also an effect on electrolytes about 50 times that of cortisone (Ward *et al.*, 1954; Thorn *et al.*, 1955). In the same year prednisone and prednisolone were found to have antirheumatic effects about four to five times those of cortisone (milligram per milligram) without an enhanced effect on electrolytes (Bunim *et al.*, 1955).

Trials of other compounds have included Δ -1,9 α -fluorohydrocortisone, a combination of prednisone and 9 α -fluorohydrocortisone which did not prove superior to either of these analogues (Thorn *et al.*, 1955); prednisone aldehyde, which seems to have less antirheumatic effect than prednisone (L. E. Ward, unpublished data); and aldosterone, which in doses used did not have antirheumatic properties, although it did affect electrolytes.

TABLE I.—Usefulness of Cortisone and Its Derivatives and Corticotrophin in "Non-hormonal" Conditions*

Clinical Effect	Clinical Application: Examples
Anti-inflammatory and antirheumatic	Rheumatic fever Rheumatoid arthritis Systemic L.E. Diffuse myositis Early periarteritis nodosa Acute bursitis Iritis, certain other ocular inflammations Pemphigus vulgaris Acute thyroiditis Non-tropical sprue Chronic ulcerative colitis
Anti-allergic	Status asthmaticus Allergic ocular conditions Severe seasonal pollenosis Serum sickness Sensitivity reactions to drugs
Antitoxic	Snake and insect venoms Acute delirium tremens Acute viral hepatitis Severe bacterial and other toxæmias (e.g., peritonitis)
Regulatory: to regulate haemic equilibrium	Effect on eosinophils in eosinophilic pneumonia Involutionary effect on lymphoid tissue in lymphomas, leukaemias Acute haemolytic anaemia; thrombocytopenic purpura
Regulatory: to inhibit mesenchymal fibroplasia	Control of formation or re-formation of adhesions, strictures, contractures, scar tissue

* From Hench (1956), with additional examples.

hormones also may have regulatory effects on haemic equilibrium and mesenchymal fibroplasia.

Much additional investigation is needed to answer important questions pertinent to the broadening clinical applications and potentialities of these hormones. But

*Read at the Annual Meeting of the British Medical Association, Brighton, 1956.

Undoubtedly other compounds will be introduced as a result of further intensive chemical modifications of significant portions of the steroid nucleus.

Prednisone: Metabolic Studies

Controlled metabolic balance studies in which the effects of prednisone are compared with those of cortisone or hydrocortisone have shown that prednisone has many similar and only a few different effects compared with other antirheumatically active synthetic or naturally occurring adrenocortical steroids (Ward *et al.*, 1955).

Case 1.—A woman of 51, who had had severe rheumatoid arthritis for one year, was given orally 20 mg. of prednisone daily for 36 days. It was then discontinued for 12 days, after which time hydrocortisone (free alcohol) was administered orally in a dose of 80 mg. daily for 24 days. This was followed by 20 mg. of prednisone again for six days, 17.5 mg. for six days, and 15 mg. for six days. Prednisone and hydrocortisone, in the doses used, produced marked and essentially equal antirheumatic effects.

During administration of prednisone the concentration of sodium, chloride, and carbon dioxide in the plasma remained essentially unchanged (Fig. 1). Plasma potassium increased slightly, although perhaps not significantly. The haematocrit reading increased appreciably and the body weight decreased about 5 kg., both of these changes occurring principally during diuresis of sodium and chloride in the first 12 days of the administration of prednisone.

In contrast, during the administration of hydrocortisone the average plasma concentration of sodium increased slightly and that of chloride decreased slightly, that of potassium decreased notably, and that of carbon dioxide increased greatly. The haematocrit reading and body weight remained essentially unchanged during this period.

Nitrogen balance studies (Fig. 2) revealed that, in comparison with the periods when the hormones were not being administered, the excretion of nitrogen was slightly increased during the first course of prednisone as well as when hydrocortisone was given. During the second

FIG. 2.—Effects of prednisone and hydrocortisone on balances of total nitrogen, calcium, and inorganic phosphorus in same patient as in Fig. 1. The daily intake is measured downward (but not blocked in) from the 0 line and is represented by the distance from the 0 line to the bottom line of the column. The average daily excretion (faecal, hatched column; urinary, clear column) is charted upward from the bottom line. Each column represents a six-day period. A negative balance is indicated by the position of the top of the column above the 0 line, a positive balance by the top of the column below the 0 line.

FIG. 1.—Effects of prednisone and hydrocortisone on concentration of electrolytes in plasma, on haematocrit, and on body weight determined in the course of a metabolic balance study on a woman aged 51 with rheumatoid arthritis.

course of prednisone, the nitrogen balance was in approximate equilibrium.

Calcium and phosphorus balances fluctuated irregularly during periods of administration of the hormones; interpretation of the results is difficult on the basis of these data. In general the amounts of calcium lost during the periods when prednisone and hydrocortisone were given were slightly less than in control periods when these hormones were not given.

The effects of 20 mg. of prednisone daily and of 80 mg. of hydrocortisone daily on the sedimentation rate were approximately the same (Fig. 3)—in each instance a prompt, significant decrease to normal. This paralleled the antirheumatic response.

With each of the hormones, total blood lipids increased substantially.

Urinary corticosteroids were increased less with 20 mg. of prednisone a day than with 80 mg. of hydrocortisone daily. Urinary 17-ketosteroids promptly decreased to zero during both periods of administration of prednisone, suggesting inhibition of adrenocortical function at least in respect to those substances metabolized to 17-ketosteroids. The slightly increased level of 17-ketosteroids found during the use of hydrocortisone presumably resulted from metabolism to 17-ketosteroids of part of the administered hydrocortisone.

Undesirable Hormonal Effects

Prednisone (or prednisolone) can produce most, if not all, of the so-called unwanted effects resulting from the use of cortisone, hydrocortisone, or corticotrophin. Effects which have been observed with doses of prednisone or prednisolone even smaller than those usually advocated include euphoria, insomnia, increase of appetite, facial rounding and other deposits of fat, acne, petechiae, hypertrichosis, loss of nitrogen, osteoporosis (with or without fractures), increase of blood fats, aggravation of peptic ulcer, inhibition of normal

reactions in inflammation or infections, and inhibition of pituitary and adrenocortical function.

Thus, although retention of sodium and depletion of potassium may be less when prednisone is administered than when cortisone is administered, chemical alterations of steroid structure to date have not materially solved the problems of hypercorticism.

STUDIES OF HYPERCORTICISM

But what is hypercorticism? The term describes exaggerated physiological hormonal effects; but as used clinically it represents more than a simple excess of cortisone. Hypercorticism from cortisone, for example, is a composite of exogenous hypercorticism plus endogenous hypocorticism and hypopituitarism, while hypercorticism from corticotrophin is a composite of endogenous hypercorticism plus endogenous hypopituitarism. Also involved are the effects on other glands and tissues (Slocumb, Polley, Ward, and Hench, unpublished data).

Hypercorticism was reported in 19 of the first 23 patients with rheumatoid arthritis who were given adrenocortical and anterior pituitary adrenocortical hormones at the Mayo Clinic (Hench *et al.*, 1950). It was more severe in those who had received relatively high doses for more than 50 days than in the other patients and also was more severe in women, especially post-menopausal women, than in men.

Features of Chronic Hypercorticism, and Distinction from Rheumatoid Arthritis

With prolonged administration of excessive hormonal doses, a state of chronic hypercorticism is likely to develop. In rheumatoid patients, particularly, this follows the initial period of stimulating effects and includes not only the familiar manifestations of overdosage but characteristically includes the cyclic occurrence of varying degrees of fatigability, emotional instability, and generalized muscular and articular aching (Slocumb, 1953; Slocumb and others, unpublished data).

FIG. 3.—Effects of prednisone and hydrocortisone on the sedimentation rate of erythrocytes, concentration of blood fats, and urinary excretion of corticosteroids and 17-ketosteroids in same patient as in Figs. 1 and 2.

These symptoms often become accentuated toward the end of the span of time between doses of the hormone. The next dose or increases in dosage may partially improve the symptoms of chronic hypercortisonism, but only temporarily. Successive increases in dosage accentuate the cyclic variability of symptoms and may complicate the course of symptoms resulting from chronic hypercortisonism.

Detailed clinical analysis indicates that the muscular and articular aching of chronic hypercortisonism is unlike the discomfort of the increased articular inflammation associated with a flare of rheumatoid arthritis. In chronic hypercortisonism, synovitis is minimal or not increased. Symptoms of a rheumatoid flare are referable to joints and fibrous tissue; but the musculo-skeletal symptoms of chronic hypercortisonism are more diffuse and generalized, being referable more to muscles than to joints and fibrous tissue, and associated with generalized hypersensitivity and hyperalgesia.

Rest may worsen temporarily the fibrositic symptoms of a rheumatoid flare, but rest benefits the diffuse cyclic aching of chronic hypercortisonism. Physical therapy or salicylates are helpful for a rheumatoid flare but do not adequately relieve symptoms of chronic hormonal overdosage.

The sedimentation rate may increase in chronic hypercortisonism as well as in a flare of rheumatoid arthritis, and thus it is not of differential value in this problem.

A patient's remark to the effect that "my arthritis is getting worse" requires careful analysis to permit a proper decision for lowering the hormonal dosage or for raising it temporarily.

Severe Mesenchymal Reactions in Chronic Hypercortisonism

Severe diffuse mesenchymal reactions also may develop. These may simulate systemic lupus erythematosus or periarteritis nodosa. In a group of 128 rheumatoid patients with chronic hypercortisonism were 18 patients (14%) who had L.E. cells in plasma or bone marrow or both. Among these 18 patients, fever in excess of 100° F. (37.8° C.) occurred in more than 50% at some time during the reaction, nephritis occurred in 50%, transfusion reactions in 33%, leucopenia in 28%, encephalopathy in 22%, serositis in 17%, purpura in 17%, hypersensitivity to sunlight in 11%,

FIG. 4.—Photomicrograph of characteristic panarteritis found on muscle biopsy from the calf of a man aged 56 who had had rheumatoid arthritis for 17 years and severe chronic hypercortisonism beginning four years before this biopsy. The inflammatory reaction in endothelial, intimal, medial, and adventitial tissues is histologically indistinguishable from that characteristically present in patients with periarteritis nodosa before steroid therapy. (Haematoxylin and eosin. $\times 150$.)

pneumonitis in 11%, false-positive results of serological test on the blood in 7%, and phlebitis in 7% (Frerichs, 1954).

Severe mesenchymal reactions simulating periarteritis nodosa were observed in five rheumatoid patients who had diffuse panarteritis histologically characteristic of periarteritis nodosa (Fig. 4), peripheral neuritis, vascular occlusion, cutaneous ulcers, nephritis, fever, leucocytosis, and hypertension.

In incidence or severity, or in both, these various mesenchymal reactions were more pronounced in the 128 patients with chronic hypercortisonism than in either of two control groups of rheumatoid patients (105 without hormonal treatment and 166 without hormonal excess) observed during the same period.

Chronic hormonal excess seems to disarm or modify in some manner the mesenchymal tissue reactions of patients with rheumatoid arthritis and produces an incidence or severity, or both, of reactions that would not have been anticipated without excessive hormonal treatment. In some instances these severe mesenchymal reactions have been irreversible and death has resulted. In any event the seriousness of chronic hormonal overdosage is increased by severe mesenchymal reactions.

Studies on Plasma 17-hydroxycorticosteroids

Studies of hydrocortisone (cortisol) or levels of 17-hydroxycorticosteroids in the plasma of patients with rheumatic diseases have been undertaken to help determine

FIG. 5.—Plasma 17-hydroxycorticosteroid (17-OHCS) levels in a woman aged 48 who had had severe rheumatoid arthritis for 17 years. This patient had taken orally 40 mg. of hydrocortisone daily for 14 months and had developed most of the signs of chronic hypercortisonism in the 12 months preceding abrupt cessation of steroid therapy on October 21 at 6 p.m. The solid line with black dots shows for comparison the mean value of plasma 17-OHCS found during the day in normal patients. The solid line with clear dots shows the slightly higher mean value found in patients with rheumatoid arthritis.

some of the mechanisms and effects of hormonal treatment (Hench, Wu, Mason, Slocumb, Polley, Ward, and Mayne, unpublished data). Included in these studies have been certain observations on the plasma levels of 17-hydroxycorticosteroids in patients with rheumatoid arthritis and chronic hypercortisonism.

Fig. 5 shows the levels of 17-hydroxycorticosteroids in plasma found as a result of abruptly stopping administration of hydrocortisone to a 48-year-old post-menopausal woman who had had severe rheumatoid arthritis for 17 years. This patient had taken 40 mg. of hydrocortisone daily for 14 months, and in the 12 months preceding cessation of the treatment most of the signs of chronic hypercortisonism had developed. Although no obvious clinical signs of adrenal insufficiency appeared when the hydrocortisone was stopped

abruptly at 6 p.m. on October 21, the level of 17-hydroxycorticosteroids in the plasma was practically zero for almost 24 hours thereafter.

The level was low on October 22 at 6 p.m., and on October 26. Normal values for plasma 17-hydroxycorticosteroids were found on November 1, 11 days after administration of hydrocortisone was stopped; but excretion of 17-ketosteroids in the urine was still negligible (1.1 mg. per 24 hours), and the clinically evident features of chronic hypercortisonism persisted for five months after treatment with the excessive doses of the hormone was stopped.

Further studies of levels of 17-hydroxycorticosteroids in plasma in rheumatoid and other patients are in progress. However, up to the present there still are no laboratory tests available which would substitute for careful clinical study of patients for whom adrenocortical steroids may be indicated.

OBSERVATIONS ON THE CLINICAL USES OF ADRENOCORTICAL HORMONES

Detailed clinical observations are needed to make treatment with adrenocortical hormones or corticotrophins as satisfactory as possible. Results of such observations over a period of more than six years of increasing use and experiences with these potent preparations have been, as stated above, one of the principal factors in improving current use of these hormones for many conditions.

The choice of hormone and doses to be used will vary with the severity of the disease, the anticipated duration of treatment, the age and sex of the patient, the presence or absence of associated medical conditions which might affect the risk of hormonal treatment, and the experience of the physician.

Indications, Dosage, and Contraindications

Since adrenocortical steroids or corticotrophin is indicated for only certain diseases, and especially only certain rheumatic diseases, an accurate diagnosis is of first importance. When the presence of a disease for which steroid therapy may be useful has been determined, the next aspect to consider is whether the stage of the disease will permit the desired alteration through hormonal treatment. Corticosteroids can affect favourably only the reversible stages of the tissue reactions of the particular diseases—that is, the pathological physiology, not the pathological anatomy of a disease. Attempts to modify the irreversible changes of a

disease process by administration of steroids are generally disappointing and often result in the use of excessive hormonal doses which induce hypercortisonism, with its additional therapeutic problems.

Appropriate dosage of steroids is another important factor to be considered in hormonal treatment. Use of inadequate amounts for fulminating processes may lead to just as unsatisfactory results as the use of too large a dosage for low-grade chronic diseases when long-term hormonal administration may be needed. In general, steroid therapy is used in combination with such other treatment as may be indicated by the particular disease process.

The presence or absence of contraindications to use of adrenocortical steroids also must be considered. These deterrents may be either absolute or relative. Absolute contraindications are few: a psychotic episode or severe emotional instability or severe psychoneurosis, Cushing's syndrome, tuberculosis which is active or has been quiescent only a few years or less, and certain infectious diseases not readily controlled by antibiotics, especially those of viral origin such as acute anterior poliomyelitis and viral encephalitis.

Relative contraindications include other severe or moderately severe infections, diabetes mellitus, duodenal or peptic ulcer, pregnancy, convulsive disorders (except spontaneous hypoglycaemia), less severe degrees of psychoneurosis, osteoporosis, cardiovascular-renal disease, including hypertension, glomerulonephritis, coronary artery disease, and tendency to thrombotic or thrombo-embolic phenomena (Hench and Ward, 1954). In the presence of these conditions the indications for steroid therapy are measured against the potential disadvantages in each patient for whom it is considered.

Treatment With Relatively Large Doses for Acute Conditions

For acute self-limited disease with potentially serious damage as a result of an unchecked inflammatory reaction, it usually has seemed best to give large suppressive doses for the relatively brief period in which hormonal treatment is needed.

In acute rheumatic fever, 200 to 300 mg. of cortisone daily for four to six weeks or so may be needed. When control of the inflammatory reaction is established, the dose is gradually tapered off, but larger doses are resumed if signs of inflammation recur.

FIG. 6.—Chart showing certain aspects of the course of illness in a woman aged 29 who had had symptoms and signs of systemic lupus erythematosus for 18 months. At the time of a severe crisis with encephalopathy, hydrocortisone was administered orally in doses of 400 mg. daily for nine days and 20 units of corticotrophin (A.C.T.H.) intravenously for one day. The patient responded adequately to this treatment and the hormonal dosage was reduced to 35 mg. of hydrocortisone daily within three weeks.

Systemic lupus erythematosus is another instance in which large hormonal doses may be needed for relatively brief periods of crisis. Fig. 6 shows diagrammatically the use of 400 mg. of hydrocortisone daily for nine days plus 20 units of corticotrophin intravenously on one day, to control a severe crisis of systemic lupus erythematosus with encephalopathy in a 29-year-old woman who had had symptoms and

FIG. 7.—Chart of same patient as in Fig. 6 showing use of large doses of prednisone for another severe crisis of systemic lupus erythematosus two and a half years later, when patient was 32 years old. Doses of prednisone ranged from 60 to 70 mg. daily for 28 days, but as improvement occurred the dosage was gradually decreased to 8 mg. daily in the ensuing three to four weeks.

signs of that disease for 18 months previously. Within three weeks after this crisis had subsided, the hormonal dosage had been successfully reduced to 35 mg. of hydrocortisone daily; and hormonal treatment was discontinued completely in another three weeks.

The patient experienced another crisis two and a half years later (Fig. 7), at which time she was treated with prednisone

in large doses—up to 70 mg. daily—followed by gradual decrease to 8 mg. of prednisone daily after three to four weeks.

Prolonged Treatment for Chronic Conditions such as Rheumatoid Arthritis

The problems of steroidal treatment for responsive chronic diseases are peculiar in that treatment may need to be greatly prolonged. Hormonal treatment for rheumatoid arthritis will serve as a suitable example.

Most rheumatologists are agreed that cortisone and related hormones are no more universally indicated for all patients with rheumatoid arthritis than is subtotal gastrectomy for all patients with duodenal ulcer or even insulin for all patients with diabetes mellitus, although in each instance the treatment is of great value when indicated properly.

When hormonal treatment is undertaken for rheumatoid arthritis the schedule of dosage as well as choice of hormone should be individualized. It also should be flexible within each patient's anticipated range of tolerance. This limitation involves use of relatively small hormonal doses. Optimal antirheumatic effects without hypercortisonism are facilitated by avoiding large, stimulating initial doses. Use of the smallest possible dose of the hormone at the start of, as well as during, treatment is advised (Ward *et al.*, 1953). Very gradual reductions of the doses—for example, only 2.5 to 5 mg. of cortisone or only 0.5 to 1 mg. of prednisone—are undertaken at varying intervals in accordance with the response. Most patients with rheumatoid arthritis should anticipate that sooner or later the inflammatory manifestations of their disease can be controlled adequately without supplemental hormonal treatment.

Increasing experience with long-term administration of adrenocortical hormones to patients with rheumatoid arthritis has led to the realization that tolerable doses are smaller than those previously considered satisfactory. These doses vary particularly with the patients' age and sex.

For post-menopausal women, 20 to 30 mg. of cortisone or 3.5 to 5 mg. of prednisone daily is usually maximal. For

FLEXIBLE PATTERN WITHIN INDIVIDUAL TOLERANCE

Gradual adjustment of dose from onset. No fixed doses or "periods"

FIG. 8.—Example of flexible pattern of steroid dosage for long-term hormonal administration as used in rheumatoid arthritis. An initial dosage of 40 mg. of cortisone daily is shown. The development of a prompt antirheumatic or stimulating effect indicates the desirability of a prompt initial decrease in dosage as shown in the dotted-line insert. Small gradual reductions of dosage are undertaken in accordance with the patient's progress, but without fixed periods. For some flares, increases of dosage may be needed temporarily; for other flares, only a delay in further reduction of dosage is needed. Ultimately, the dosage for many patients with rheumatoid arthritis may be reduced to zero and control of the disease maintained, at least temporarily, with other basic treatment as indicated.

pre-menopausal women the upper limit has been in the range of 30 to 37.5 mg. of cortisone or 5 to 6.5 mg. of prednisone daily. For adult men, 37.5 to 50 mg. of cortisone or 6 to 9 mg. of prednisone may be maximal if hypercortisonism is to be avoided. In the light of current information it seems unlikely that the effects of doses within these limits are explained by the replacement of an absolute endogenous adrenocortical deficiency.

The improvement in antirheumatic effects reported sometimes on changing from one corticosteroid to another apparently results from relative differences in the dosage used or other factors in treatment rather than qualitative differences in antirheumatic effects of prednisone (or prednisolone), and cortisone (or hydrocortisone).

Use of corticotrophin to "stimulate latent adrenal cortical function" has not seemed to facilitate recovery of both adrenocortical and pituitary function sufficiently to be a routinely useful adjunct.

Individualized Treatment Schedules

An adjustable and flexible but gradually decreasing pattern of hormonal dosage may be used to reduce as well as to prevent hypercortisonism (Fig. 8).

Doses preferably are divided into equal or approximately equal amounts given regularly every six or occasionally every eight hours. Temporary increases of doses, or delays in further reductions, may be indicated for flares from time to time. But ultimately, on this programme, exogenous treatment with hormones is discontinued and the patient's disease is controlled, at least temporarily, with such other basic treatment as is indicated.

Variable and often unsatisfactory responses may be attributed to suboptimal divisions of total daily doses which do not take into account the differences of the intervals in such ordinary schedules as "night and morning" and "with meals," and the like.

When needed for different patients, more individualized symptomatic control may be provided by adjustments of dosage within the limits of the regular six-hour or eight-hour schedule (Table II).

TABLE II.—Alternative Plans for Division of Total Daily Dose

Time	Various Divisions of Daily Dose of 30 mg.			
	Patient 1	Patient 2	Patient 3	Patient 4
6 a.m.	7.5	10	10	10
Noon	7.5	5	7.5	10
2 p.m.	7.5	5	5	10
6 p.m.	7.5	10	7.5	
Midnight				
Alternative hours:	7 a.m.—1 p.m.—7 p.m.—1 a.m.			7 a.m.—3 p.m.—11 p.m.
	8 a.m.—2 p.m.—8 p.m.—2 a.m.			8 a.m.—4 p.m.—12 p.m.

Results of Optimal Hormonal Usage in Rheumatoid Arthritis

Wide variability of rheumatoid inflammation in different patients, variance of indications for use of hormones, and diversity among the plans for hormonal treatment have made it difficult to correlate the data of various authors with regard to the results of hormonal treatment for rheumatoid arthritis (Ward *et al.*, 1953). Experience at the Mayo Clinic indicates that doses are well tolerated by 50 to 60% of the patients for whom hormonal treatment seems indicated, and that their signs of active rheumatoid inflammation can be satisfactorily controlled thus to the degree of 75%, more or less. In an additional 25 to 35% of such patients the results are worth while, with relief from their symptoms to the degree of approximately 50%; but management of patients

in this group is more complicated. There remain about 15% of the patients with rheumatoid inflammation for whom hormonal treatment seems indicated; but for these prolonged satisfactory control of signs is difficult if not impossible to obtain with present methods of utilizing adrenocortical and pituitary adrenocortical hormones.

SUMMARY

The potency of adrenocortical hormones and their newer effective synthetic analogues is great and generally beneficial for more than a hundred acute or chronic hormonal or non-hormonal diseases, but knowledge of how the hormones work and the safest way to use them is still far from complete. Benefits from present-day use of the hormones must still be weighed against the disadvantages, which vary for each disease and patient for whom the hormonal treatment might be helpful.

Physicians, as well as their patients, should anticipate the future development and availability of antirheumatic, anti-inflammatory, and anti-allergic hormonal preparations with increased effectiveness and fewer unwanted side-effects. However, the stage has now been reached where employment of the several potent hormonal compounds at present available can be useful and reasonably safe for a number of potentially serious diseases.

For optimal therapeutic value, use of these hormones should be supervised by physicians who have familiarized themselves with its intricacies in the same thorough manner that they would consider necessary in undertaking any complicated medical or surgical treatment.

The prednisone used in this study was generously supplied by the Schering Corporation, Dr. Edward Henderson, Medical Director.

PART II. FACTORS IN PREGNANCY AND LABOUR INFLUENCING PERINATAL MORTALITY

Here some of the factors shown in Table V to be of importance in perinatal mortality are discussed from the clinical aspect.

TABLE V.—Clinical Associations of Major Causes of Perinatal Mortality in 337 Consecutive Necropsies Expressed as the Percentage Incidence

Cause of Death	Toxaemia and Hypertension	Maternal Age of 35 or More	Ante-partum Haemorrhage	Diabetes	Post-maturity (42 Weeks or More)	Labour of 24 Hours or More	Other Complications of Vaginal Delivery	Caesarean Section	Proportion of Primiparae	Multiple Pregnancy	Total Cases
Ante-partum death with maceration only	44*	30*	15*	6.6	1.6	—	—	—	55	11*	61
Intra-partum asphyxia (premature)	28	22	17	Nil	—	11	45	5.6	66	11	18
Intra-partum asphyxia (full-time)	19	19	5.4	2.7	25*	35*	41*	2.7	65	11*	37
Birth trauma (premature)	16	37*	11	Nil	—	16	53*	Nil	65	32	19
Birth trauma (full-time)	22	28*	Nil	—	11	39*	72*	5.5	65	11*	18
Ante-partum asphyxia	42*	31*	53*	5.5	2.8	—	—	—	59	14*	36
Pulmonary syndrome of newborn	22	14	20	Nil	—	7	25	28*	53	11	36
Intraventricular haemorrhage	18	36	9	—	—	12	27	27	45	9	11
Pneumonia	11	16	5.5	—	16	11	F.T. 25.* Prem. 50	F.T. 25.* Prem. 12	47	Nil	F.T. 11. Prem. 8
All births	17	12	3.3	0.3	11	17	10	4.5	67	2.6	10,028
Premature births	27	21	12	0.0	—	11	26	8	57	20	593
Full-time	16	11	2.7	0.3	12	17	9	4.3	59	1.6	9,435

* Statistically significant.

Maternal Age

There was some increase in the perinatal mortality rate when the mother was over 30 years of age and a sharp rise over the age of 35 years both in primiparae and in multiparae (Table VI). This relationship of maternal age to foetal loss is of course well known (cf. Crosse and Mackintosh, 1954).

TABLE VI.—Perinatal Mortality Rate in Different Maternal Age Groups Based on 10,028 Consecutive Births at U.C.H. Between 1948 and 1955

	Maternal Age in Years					
	Less than 20	20-24	25-29	30-34	35-39	Over 40
No. of births	387	2,772	3,622	2,076	972	199
Percentage death rate	1.8	2.7	2.7	3.9	6.3	8.6

Table V shows that babies in the maceration-only, ante-partum asphyxia, and birth trauma groups had a significantly high proportion of mothers over 35 years. In the case of birth trauma both premature and full-time babies were involved. Any other associations of high maternal age apparent in Table V were not statistically significant. It can be seen that high maternal age leads to foetal loss mainly in the ante-partum stage, but that it also increases

*Part I of this paper was printed in last week's issue (p. 1191).

the possibility of fatal birth trauma. The way in which high maternal age operates remains obscure. Toxaemia is a known association of pregnancy in mothers over 35 years (Eastman, 1950) and analysis of our figures suggested that while this association could account for some of the deaths in the group of ante-partum death with maceration only it could not account for the increased loss of babies from ante-partum asphyxia and birth trauma with high maternal age. However, the figures relating to this analysis were not statistically significant.

Over the age of 35 birth trauma was not related to any particular complication of labour. Most of the common difficulties were encountered. In particular, birth trauma after an apparently normal labour bore no relationship to maternal age.

Toxaemia and Hypertension

We have based our definition of these conditions on that of Eastman (1950)—that is, blood-pressure readings of at least 140 mm. Hg systolic and/or 90 mm. Hg diastolic on two or more occasions not less than 12 hours apart and before the onset of labour.

The incidence of maternal toxaemia and hypertension was significantly raised in the groups of ante-partum death with maceration only and ante-partum asphyxia. Any other apparent associations in Table V were not statistically significant.

Toxaemia and hypertension are a known cause of premature labour, but once born the "toxaemic" premature baby is no more at risk than the premature infant born of a non-toxaemic mother. This is shown by the fact that the incidence of maternal toxaemia and hypertension in premature neonatal deaths was 17%, compared with 27% in all premature live births. Indeed, these figures suggest that the risk is less, possibly because "toxaemic" babies tend to be small for their age and therefore more mature for a given birth weight than other premature infants. It is worth noticing from Table V that toxaemia and hypertension do not appear to be a cause of the mysterious pulmonary syndrome of the newborn, except in so far as they cause premature labour.

Prematurity apart, the risk of toxaemia and hypertension to the life of the baby appears to operate only in the ante-partum period.

Ante-partum Haemorrhage

For this we have taken Browne and Browne's (1955) definition of haemorrhage from the genital tract occurring before the onset of labour and after the 28th week of pregnancy. The incidence of ante-partum haemorrhage was significantly raised in the groups of ante-partum death

with maceration only and ante-partum asphyxia. It is of interest that there was an apparently raised incidence of ante-partum haemorrhage in the pulmonary syndrome of the newborn, although the increase was not statistically significant, possibly owing to the relatively small numbers involved.

The nature of the bleeding showed a marked difference in the two groups. In the nine cases of ante-partum haemorrhage associated with foetal maceration only, eight had a small loss, usually extending over a period of days or weeks, the other being a case of type I placenta praevia.

On the other hand, in the 19 cases of ante-partum haemorrhage resulting in foetal ante-partum asphyxia, 15 were severe accidental haemorrhages, one followed an external version, one followed a fall, and only two consisted of slight repeated bleeding. Because of this difference the occurrence of ante-partum haemorrhage in both the maceration-only and the ante-partum asphyxia group does not diminish the validity of their separation into two pathological categories.

Post-maturity

A baby has been considered post-mature when pregnancy has been prolonged 14 days or more beyond the expected date of delivery. The increased risk to the baby of post-maturity is well known (*British Medical Journal*, 1955). Table V shows that in our cases the only significant risk to the baby consisted of an increased liability to intra-partum asphyxia.

The increased rate of fall of oxygen saturation of umbilical-vein blood after the 40th week of pregnancy (Walker, 1954) led us to examine the effect of other factors likely to increase placental insufficiency in post-mature pregnancies. We regard the chief factors to be toxaemia and hypertension and a labour lasting more than 24 hours.

Without these complications, the risk to the baby from post-maturity was no greater than in all non-premature deliveries (Table VII). When, however, the post-mature pregnancy was associated with a labour over 24 hours, a

TABLE VII.—Effect of Toxaemia and Hypertension and Labour Lasting More than 24 Hours in Post-maturity. Ante-partum Deaths are Excluded from All Groups

	Post-mature Pregnancies Only		Full-time and Post-mature Pregnancies	
	No. of Births	Percentage Perinatal Mortality Rate	No. of Births	Percentage Perinatal Mortality Rate
Cases with toxaemia and hypertension	217	3.1	1,543	1.4
Cases with a labour lasting more than 24 hours	237	4.2	1,626	1.8
Cases with neither toxaemia and hypertension nor a labour over 24 hours	745	0.9	6,266	0.9

significantly greater risk to the baby was apparent, while with maternal toxaemia and hypertension the increased risk was of borderline significance ($0.1 > P > 0.05$).

Labour over 24 Hours

Table V shows, as might be expected, a high incidence of labours lasting more than 24 hours in the "full-time" intra-partum asphyxia and birth trauma groups but not in the corresponding premature groups. It is obviously important in considering length of labour in cases of intra-partum foetal death to calculate duration of labour up to the death of the baby and not to its birth. Similarly in assessing the effect of obstetric manoeuvres, manipulations performed after the death of the foetus should be excluded. It is obvious that, post-maturity apart, prolonged labour will extend the period of foetal hypoxia that normally occurs and predispose the infant to intra-partum asphyxia. The association of labour over 24 hours with fatal birth trauma may be due to excessive moulding of the head, especially when disproportion delays delivery, or to injuries occurring during efforts made to save the baby's life.

It is of interest that there was no apparent association between prolonged labour and foetal pneumonia.

Complications of Vaginal Delivery

Under this heading are included forceps delivery, breech delivery, breech extraction, other malpresentations, impacted shoulders, and disproportion, all of which may prove traumatic to the baby. Prolapse of the cord and intra-partum haemorrhage, which are apt to interfere with the supply of oxygen to the foetus, are also included.

The incidence of all complications was significantly raised in the "full-time" intra-partum asphyxia, "full-time" and "premature" birth trauma, and "full-time" pneumonia groups (Table V). There was a suggestion that these complications were also associated with the "premature" intra-partum asphyxia and "premature" pneumonia groups, but the figures were not statistically significant. Obviously, complicated labour may lead to birth trauma, but its association with intra-partum asphyxia seems at first sight to throw doubt on the need to separate these two pathological groups. However, in most cases of intra-partum asphyxia, in which complications of vaginal delivery occurred they were not of the potentially traumatic variety but those apt to interfere with the foetal oxygen supply. This distinction is set out in Table VIII, in which the figures for full-time babies are significant ($P < 0.001$), but not those for premature babies.

TABLE VIII.—Incidence of Potentially Traumatic and Non-traumatic Complications of Vaginal Delivery in Babies Dying of Birth Trauma and Intra-partum Asphyxia

	Full-time				Premature			
	Birth Trauma		Intra-partum Asphyxia		Birth Trauma		Intra-partum Asphyxia	
	No.	%	No.	%	No.	%	No.	%
Potentially traumatic complications	14	78	7*	19.5	10	50	6	33
Non-traumatic complications	4	22	29	80.5	10	50	12	67
Total	18	100	36	100	20	100	18	100

* Two of these seven cases had a secondary degree of birth trauma.

Therefore, to separate the intra-partum asphyxia and birth trauma groups, rather than merge them into one category of "intra-partum stress," may enable the obstetrician to decide which particular event in labour was responsible for the death of the baby.

In the premature babies the relatively high incidence of non-traumatic delivery in the birth trauma group is explicable by the widely held view that the delicate premature structures are easily damaged by the normal stresses of labour.

Of the six cases of potentially traumatic delivery in the "premature" intra-partum asphyxia group, four had a complication apt to produce asphyxia, one was an uncomplicated breech delivery, and in one foetal distress occurred. Further, in four of the cases doubt exists whether the foetus was still alive when the potentially traumatic delivery occurred. One baby had a slight degree of birth trauma insufficient in itself to account for death.

In all four cases of pneumonia in full-time babies associated with complications of vaginal delivery, these were of the potentially traumatic variety. It is clear that manipulations might result in the introduction of infection. It is likely, however, that these manipulations were associated with pneumonia merely because they were often performed for foetal distress, which is in itself an association of pneumonia. The apparently raised incidence of complicated labour in premature babies with pneumonia was not statistically significant.

Caesarean Section

Table V shows the incidence of caesarean section to be raised in the pulmonary syndrome of the newborn, intra-ventricular haemorrhage, and "full-time" pneumonia

groups. The increase is statistically significant in the case of pulmonary syndrome and "full-time" pneumonia and of borderline significance in intraventricular haemorrhage. All babies in this last category born by caesarean section had, in addition to their cerebral lesion, evidence of the pulmonary syndrome of the newborn.

The pneumonia group is characterized by three features: (1) the association with caesarean section is confined to the full-time babies; (2) the operation was performed for foetal distress in labour in three out of four cases, and in the fourth case an obvious source of infection was present; and (3) the membranes had ruptured before delivery in all three cases showing foetal distress. These circumstances suggest that pneumonia is particularly apt to follow foetal distress occurring at term after the membranes have ruptured and that the association of pneumonia with caesarean section is therefore merely coincidental.

Babies dying of the pulmonary syndrome and born by caesarean section differed from the pneumonia group in that 8 out of 10 were premature. The incidence of caesarean section was raised in the pulmonary syndrome in both full-time and premature babies. Another difference between this group and the pneumonia category is that in all 8 cases of premature pulmonary syndrome the operation was performed before the onset of labour when the membranes were intact. The indications for operation were equally divided between ante-partum haemorrhage, and toxæmia and hypertension.

The association of caesarean section with the pulmonary syndrome of the newborn could be due to the operation itself, especially in relation to prematurity, or to the complications for which the operation was performed (although apparently not toxæmia and hypertension) or to both combined. In any case the precise way in which these factors could operate remains obscure.

Multiple Pregnancy

Table V shows the incidence of multiple pregnancy to be raised in all ante-partum deaths, in "full-time" intra-partum asphyxia and birth trauma, and in premature babies dying of birth trauma, although this last figure is not statistically significant. The presence of multiple pregnancy does not increase the risk of premature babies dying of asphyxia during labour or in the neonatal period from any cause.

The additional hazard of multiple pregnancy in labour is well known. Its influence in ante-partum deaths is not so clear, although the association of toxæmia with multiple pregnancy (Eastman, 1950; Browne and Browne, 1955), may play a part. The mothers of all cases in the ante-partum asphyxia group had toxæmia and hypertension. Of the seven babies in the group of ante-partum death with maceration only one was born of a toxæmic mother, another set of twins was associated with maternal hereditary thrombasthenia, and the remainder were born after normal pregnancies.

Of the 24 twins that died in the intra-partum and post-partum periods, 12 were first-born and 12 second-born. This is at variance with the often expressed view that second twins are more at risk, particularly because of birth trauma and intra-partum asphyxia. In fact, both these pathological groups contained exactly similar numbers of first and second twins.

Diabetes

There were 29 cases of maternal diabetes in our 10,028 deliveries, 6 of whom were delivered by caesarean section at 37 to 40 weeks for other maternal complications. The remainder were allowed to go into spontaneous labour (which occurred in 70% by 39 weeks). There were no neonatal deaths, but seven stillbirths, the foetal loss being 24%. This is similar to the foetal loss of 27% reported by Peel (1955), who favours termination of pregnancy before the end of the 37th week and whose fatal cases included a proportion of deaths from hyaline membrane in the neonatal period.

Of our seven stillbirths, three were examples of ante-partum death with maceration only, two of ante-partum asphyxia, one of congenital malformation, and one of intra-partum asphyxia. This last death was directly attributable to the large size of the baby.

PART III. CLINICAL PICTURES IN BABIES DYING IN THE NEONATAL PERIOD

This section is concerned with the correlation of clinical and post-mortem findings and the differential diagnosis of the common conditions causing death. 221 neonatal deaths were studied. They occurred among 9,250 full-time and 593 premature babies born in the Obstetric Hospital, together with 201 infants, all premature save one, admitted from home or other hospitals after birth.

The main causes of death and their distribution according to the babies' birth weights are shown in Table IX. Over four-fifths of the deaths were accounted for by the pulmon-

TABLE IX.—Mortality by Birth-weight Groups, and Cause of Neonatal Deaths, Among Babies Born in U.C.H. Obstetric Hospital and Those Admitted After Birth, 1948-55

Birth Weight (g.)	Live Births	Deaths		Causes of Death Expressed as Percentage of Total Deaths						
		No.	%	Pulmonary Syndrome	Intra-ventricular Haemorrhage	Pneumonia	Intracranial Birth Trauma	Congenital Malformations	Other	
Up to 1,000	52	49	94	23	12	18	16	2	29	
1,001-1,500	89	46	51	44	15	4	15	2	13	
1,501-2,000	203	35	17	43	20	3	14	9	6	
2,001-2,500	449	27	6	26	0	15	19	19	21	
Over 2,500	9,251	64	0.7	9	2	17	24	28	20	
Total	10,044	221	2.1	27	10	12	18	15	18	

ary syndrome (27%), birth trauma (18%), congenital malformations (15%), pneumonia (12%), and intraventricular haemorrhage (10%). Excluding congenital malformations, it was found that the clinical pictures of these four conditions were often similar and consisted essentially of one or more of three symptom-complexes. These were poor condition at birth, respiratory difficulty, and cerebral irritation.

Poor Condition at Birth

More than half the babies showed this feature. The diagnosis was made when the infants were limp and cyanosed, without the usual response to external stimuli; many also showed pallor of the skin. Respiration consisted at first of irregular gasps, and usually their onset was delayed for more than 30 seconds after birth. The clinical course of fatal cases took one of three forms. Some infants died after a period of gasping. In others, irregular gasping gradually or rapidly gave place to normal rhythmical breathing, but after a varying period respiratory difficulty returned. Other babies developed rhythmical breathing, but persistent respiratory difficulty was shown by the grunting character of the respirations. In the last four years of the eight under survey, resuscitation has been attempted by the administration of intragastric oxygen and rocking. Prior to that time oxygen was given by nasal catheter, except in the severest cases, when the intratracheal route was used.

Respiratory Difficulty and Cyanosis

This occurred sooner or later in every case, and was shown at first by unduly rapid respirations. An expiratory grunt was often present. Later there was marked irregularity of respiratory rhythm with apnoeic periods, and, finally, the gasping respirations of severe hypoxia developed.

Cyanosis, either persistent or in attacks, was often present from an early stage. This central cyanosis has to be distinguished from the peripheral type. Cyanosed extremities are common in normal babies during the first few hours of

life, and result from slow peripheral circulation and polycythaemia. The pink colour of the skin of the trunk and normal respiratory movements should prevent confusion with central cyanosis. However, if doubt persists, one limb may be warmed and the skin will then become pink if the cyanosis is peripheral in origin.

Examination of the chest in cases with respiratory difficulty showed varying degrees of inspiratory recession of the lower ribs and sternum, impaired percussion note over the lungs, diminished air entry, and sometimes inspiratory rales.

Cerebral Irritation

The major sign in this group was convulsions, often associated with other indications of cerebral irritation. Less commonly, signs of cerebral irritation occurred without convulsions. These signs included excessive wakefulness, contrasting with the normal baby, who sleeps when not feeding, restlessness, irritability when disturbed, shrill high-pitched cry, tense anterior fontanelle, and alterations of muscle tone, usually spasticity of the limbs or trunk muscles, but sometimes hypotonia.

Convulsions were 17 times more common in premature infants, with an incidence of 4.2% compared with 0.25% in full-time babies. Although sometimes merely a terminal phenomenon, they often occurred 24 hours or more before death.

In only 24% of fatal cases of cerebral irritation was post-mortem evidence of intracranial trauma found, while in 63% the only abnormal findings were in the lungs. In most of the latter group the cerebral signs are probably attributable to the effects of hypoxia and carbon dioxide retention on the brain and cerebral vessels. Among the infants who develop a tense fontanelle are some in whom right-sided cardiac failure, which is accompanied by an increase of cerebrospinal fluid pressure (Friedfeld and Fishberg, 1934), seems to be an important factor. These infants have enlarged liver, and in non-fatal cases of cerebral irritation we have sometimes observed a diminution of liver size and a lessening of fontanelle tension to precede improvement in the babies' condition.

Pulmonary Syndrome of the Newborn

The pulmonary syndrome accounted for 27% of neonatal deaths. Approximately 10% of the babies had a birth weight of over 2,500 g., and these formed 10% of all deaths in full-time infants. Pulmonary syndrome showed its highest incidence as a cause of death (43%) in babies weighing from 1,000 to 2,000 g. at birth. The condition was particularly common after caesarean section and caused 45% of neonatal deaths following this method of delivery.

One-half of the babies were in poor condition at birth, and thereafter showed persistent respiratory difficulty. The condition of the remainder usually deteriorated within 12 hours of birth; indeed, only 3 of the 53 premature infants—two with extensive pulmonary haemorrhage and one with hyaline membrane—first developed symptoms over the age of 12 hours. From the corresponding figure for the age of 12 hours, it will be seen that birth trauma, which are given below, it will be seen that birth trauma, which are given below, it will be seen that the pulmonary syndrome is the least likely diagnosis of the pulmonary syndrome. A sign in favour of a diagnosis of pulmonary syndrome was the blood-stained frothy mucus often produced by infants in whom the main lesion was pulmonary haemorrhage or oedema.

The incidence of cerebral signs was noteworthy. Of the 59 cases, 20 (34%) developed convulsions and a further six cerebral irritation without convulsions. This illustrated the difficulty in differential diagnosis of pulmonary syndrome from intracranial birth trauma. Cerebral irritation in the former condition was more likely to occur over the age of 12 hours, whereas in birth trauma the opposite was true; but this fact is of little value in diagnosis of the individual case.

Donald and Steiner (1953) have described a sequence of radiological changes in the lungs which indicate the presence of a hyaline membrane. However, in our series, such membranes were found in 42% of babies with intraventricular haemorrhage and in 44% of premature infants with intracranial birth trauma. Therefore the presence of characteristic radiological changes of hyaline membrane does not exclude the presence of other pathology. In our opinion the main value of radiology is twofold. Firstly, in babies who recover from respiratory difficulty, it may indicate whether or not a hyaline membrane was present. Secondly, it will exclude the presence of congenital malformations, such as diaphragmatic hernia, which is mentioned below, and also of a pneumothorax.

Deaths occurred after an illness lasting from a few hours up to nearly three days; only one baby was alive at the age of 3 days, and she died 12 hours later.

Intraventricular Haemorrhage

This condition accounted for approximately 10% of the neonatal deaths, but was confined almost entirely to babies weighing less than 2,000 g. at birth. A similarity between the clinical picture of this condition and that of the pulmonary syndrome was to be expected, because 62% of primary deaths from intraventricular haemorrhage showed evidence of the pulmonary syndrome as well. However, it might be thought that all cases of intraventricular haemorrhage would show cerebral signs, especially a tense anterior fontanelle, but in our experience such signs have been no more frequent than in the pulmonary syndrome occurring alone.

Approximately half the babies were in poor condition at birth, and in 18 out of the 21 the onset of respiratory symptoms was before 12 hours of age. Two-thirds (14 out of 21) died in the first 24 hours of life and it was rare for survival to exceed three days, although one baby lived for 13 days, having occasional cyanotic attacks from the age of 2 days.

It will be clear that there was no distinguishing feature clinically between babies dying from intraventricular haemorrhage and those with the pulmonary syndrome.

Pneumonia

Pneumonia occurred in 12% of deaths, and was seen most often in previable and full-time babies. Three-fifths of the infants were in poor condition at birth, but some appeared to recover after resuscitation, only to develop further respiratory difficulty after an interval of up to several days. Five of 11 full-time and 3 of 16 premature infants (30% of the total cases) were free of respiratory distress in the first 12 hours of life.

It is important to note that cerebral signs were a feature in 9 of the 27 cases, 6 of whom had convulsions.

Over half the babies (15 out of 27) died in the first day, half (8) of these being previable. Seven babies (25%) lived over three days, but five were full-time infants, so that this tendency to longer survival probably does not represent a true difference from cases of pulmonary syndrome occurring mostly in premature babies.

Possible predisposing factors to pneumonia in these infants were investigated. The mothers of five babies suffered from an acute infection during or immediately preceding labour, while in another five cases the membranes had ruptured more than 18 hours before delivery. Three more babies were known to have had foetal distress during delivery, and another 11 were in poor condition at birth. Thus in 24 out of 27 deaths from pneumonia there had been maternal infection, rupture of the membranes for a considerable period before birth, or evidence of foetal hypoxia which might have led to the inhalation of infected material during delivery. After the first five and a half years of the period under survey, we considered that maternal infection, premature rupture of the membranes, foetal distress, and poor condition at birth should be indications for the

administration of prophylactic antibiotics to the baby, even in the absence of clinical signs. Finally, in view of the difficulty of making a clinical diagnosis of pneumonia, all babies who showed respiratory difficulty after birth were treated with antibiotics in addition to any other method used. Penicillin and streptomycin were given by intramuscular injection.

Before following these principles a primary diagnosis of pneumonia was made in 23 out of 154 deaths (15.6%), whereas subsequently the figure has been 4 out of 67 deaths (6%). Further, two of the last four babies with pneumonia died within 15 minutes of birth before antibiotics could be given.

Intracranial Birth Trauma

This was found in 18% of deaths. Among full-time babies the majority (13 out of 15) were in poor condition at birth and eight died in the first hour of life. In contrast, although 19 of the 25 premature infants were in poor condition, only two died within an hour. The common causes of death within an hour of birth were intracranial birth trauma and intra-partum asphyxia. A history of a forceps delivery, especially if a difficult one, breech delivery, or breech extraction was found to be strongly suggestive of intracranial birth trauma.

Among cases surviving over one hour, less than half of the premature babies developed cerebral irritation, but respiratory difficulty was a constant feature and almost always the presenting sign, frequently dating from birth (in three the first symptoms occurred after the age of 12 hours). The clinical picture was therefore indistinguishable from that of the pulmonary syndrome, intraventricular haemorrhage, or pneumonia. The majority of full-time infants surviving more than one hour developed cerebral signs, but again always accompanied by respiratory disturbances. The birth histories of these babies were of much less help in diagnosis, because the delivery had been apparently normal in many cases.

Three-fifths of the 40 babies died in the first day, and only three survived for more than three days.

Differential Diagnosis of the Pulmonary Syndrome, Intraventricular Haemorrhage, Pneumonia, and Intracranial Birth Trauma from other less Common Conditions

It will be clear that it is often impossible to distinguish between birth trauma, the pulmonary syndrome, pneumonia, and intraventricular haemorrhage in premature babies, and between the first three in full-time infants. However, the four conditions may be confused with less common abnormalities, including some congenital malformations which may cause respiratory difficulty in the first three days of life. The differential diagnosis from certain malformations is particularly important. Oesophageal atresia and diaphragmatic hernia, for example, are often amenable to immediate surgical treatment.

Oesophageal atresia should be suspected when an infant brings up an excess of frothy mucus for several hours after birth or when the mother has had hydramnios. Diaphragmatic hernia usually causes marked displacement of the cardiac impulse and absent air entry on the affected side of the chest, but sometimes the condition is revealed only by radiology. Congenital heart disease should be considered when there is central cyanosis out of proportion to the degree of respiratory difficulty, or dyspnoea with rales in the lungs and enlargement of the liver.

In another small group of babies poor condition at birth is due to foetal haemorrhage from placental incision during caesarean section for anterior placenta praevia (Butler and Martin, 1954). Correct diagnosis is important, because blood transfusion may be life-saving.

Finally, two rare conditions—bilateral renal agenesis and massive adrenal haemorrhage—have caused difficulty in diagnosis. Renal agenesis may be suggested by the characteristic facies (Potter, 1952), but adrenal haemorrhage is not usually suspected during life.

Prognosis

In view of the difficulty in distinguishing between the pulmonary syndrome of the newborn, intraventricular haemorrhage, pneumonia, and intracranial birth trauma in life, the prognosis of these conditions individually is uncertain. The problem in practice is to estimate the prognosis of a baby showing respiratory difficulty which may be due to one of these four conditions.

In premature infants the birth weight is an important factor in prognosis. Mortality in birth-weight groups in the present series is shown in Table IX and requires no further comment. The second factor is the time that the baby has survived. In general, prognosis is much improved when the fourth day of life is reached. Thus in fatal cases, 87% of 31 full-time babies and 96% of 113 premature infants died before the end of the third day. The next factor is the degree of inspiratory recession of the lower sternum. Severe recession, producing a funnel-shaped deformity, was usually unfavourable. Finally, the occurrence of convulsions was a bad prognostic sign, especially in premature infants, the mortality being 79% as opposed to 42% in full-time babies (Table X). The total death rate from convulsions in the

TABLE X.—Mortality in Babies With Convulsions

	Full-time	Premature	Total
Total No. of cases	24	33	57
Died	10	26	36
Percentage	42	79	63

neonatal period was 63%, which compares unfavourably with that of Burke (1954), whose rate was 37.5%, but the proportion of premature infants was two and a half times greater in our series.

Conclusion

It has been shown that the four conditions (pulmonary syndrome of the newborn, intraventricular haemorrhage, pneumonia, and birth trauma) which caused two-thirds of all neonatal deaths in our series could not usually be distinguished in life. In a few cases consideration of the birth history and the signs shown by the baby, including their time of onset, strongly indicated the correct diagnosis. A vital task for the doctor confronted with a baby showing respiratory difficulty in the first hours of life is to exclude the presence of certain congenital malformations which may be amenable to surgical treatment.

It is important to note that cerebral irritation, even with convulsions and a tense anterior fontanelle, does not necessarily mean that intracranial trauma has occurred, and that such cases may not be hopeless.

Finally, it will be clear that, congenital malformations having been excluded, all babies showing respiratory difficulty, with or without cerebral irritation, in the first few days of life should receive any specific therapy that is known for the four conditions mentioned above. Thus, in addition to symptomatic treatment, all such infants should be given antibiotics in case pneumonia is present, and vitamin K (1 mg.) to try to prevent or diminish haemorrhage. Similarly, all will have to receive any treatment that may be discovered in the future for the pulmonary syndrome of the newborn.

SUMMARY

The post-mortem and histological examination of 406 stillbirths and neonatal deaths has enabled these deaths to be divided into 11 pathological categories forming a classification of perinatal mortality. The importance of necropsy is discussed. Each pathological group is defined and the diagnostic features are described.

The introduction of the term "pulmonary syndrome of the newborn" to include hyaline membrane, intra-alveolar haemorrhage, and pulmonary oedema is explained. Strict criteria for the diagnosis of intra-

RELIEF OF NEUROLOGICAL SYMPTOMS AND SIGNS BY RECONSTRUCTION OF A STENOSSED INTERNAL CAROTID ARTERY

cranial birth trauma have been used, and the value of distinguishing such cases from the intra-partum asphyxia group is stressed. A diagnosis of prematurity or previability is considered undesirable, and was made in only 2% of the present series.

The clinical associations of each category are enumerated, and the aetiology is discussed. In most cases there was a specific association between a given pathological group or groups and at least one feature of pregnancy or labour. Thus, the classification is not merely academic, but should also be of practical value to the obstetrician and paediatrician. It is felt that the general adoption of such a system throughout the country would assist the collation of valid statistics on the causes of perinatal mortality.

In addition to the classification of death, certain factors in pregnancy and labour have been re-examined in order to determine in what way and at which stage they cause foetal and neonatal loss.

Finally, a study has been made of some clinical aspects of babies dying in the first week of life. The pulmonary syndrome of the newborn, birth trauma, pneumonia, and intraventricular haemorrhage, which together caused two-thirds of the neonatal deaths, could not usually be distinguished during life. Successful prophylaxis of pneumonia during the latter part of the period covered by this study is described.

Our thanks are due to Dr. R. E. Bonham Carter, Professor G. R. Cameron, F.R.S., Professor W. C. W. Nixon, and Dr. B. E. Schlesinger for their advice and encouragement. A special acknowledgment is also due to the late Dr. R. H. D. Short for his contribution to the study of foetal and neonatal mortality at U.C.H.

"English is now more widely used and studied throughout the world than it, or any other language, has ever been before. It has been estimated that over half of the literate population of the world speak English as a first or second language, or use English as an indispensable instrument for vocational purposes, or are studying (or have studied) English. It is increasingly the international language of science and technology. In recent years about half of the world's output of literature on scientific research has been published in English. To a degree hitherto unknown it is recognized, and not only in the Western world, as the language of opportunity, of affairs, and of international communication."—Annual Report (1955-6) of the British Council.

Clinical History

The patient, aged 56, was captain of a large ocean liner. In October, 1955, he felt a sudden lack of control of the right arm and leg, accompanied by tingling over the right side of his body which felt strange in a way he could not describe. He could walk during this episode and the symptoms cleared after about ten minutes. Two weeks later a second and similar attack occurred, lasting this time for less than five minutes, and two weeks after that his third attack occurred.

On January 23, 1956, five minutes after getting up from bed and while shaving, he suddenly lost control of his right arm and leg and found that his speech had become slurred. He could walk, but he staggered to the right; he was able to get back into bed. Neither in this nor in the three previous attacks did he suffer from impairment of consciousness or visual disturbance. He was transferred to the Royal Perth Hospital in Australia, where Dr. J. C. Anderson saw him and reported as follows: "On examination: slight cyanosis, pulse 100 a minute; right upper limb showed weakness of grip and of flexion but good power of extension. Right lower limb showed weakness of all movements with poor co-ordination in heel-to-toe test. Knee-jerks present, plantar response flexor. Tongue, no deviation. Eyes, pupils equal and react to light. Cardiovascular system, heart sounds muffled, blood pressure 150/80. Three hours later his speech was completely coherent and he was able to write clearly. All the cranial nerves appeared normal except for a dulling of sensation over the right cheek and forehead. Slight deviation of mouth to the right. Knee-jerks, right brisker than left. Plantar response flexor. Blood pressure 165/110."

Six hours later—that is, nine hours after his initial examination, Dr. Anderson reported: "Condition deteriorating.

Slurred speech, tongue protrudes to the right. Unable to write, but grip good. Unable to perform finger-to-nose test satisfactorily. Numbness of the right side of the face more marked. Weakness of right leg as noted at initial examination. Blood pressure 170/110."

He was then admitted to the neurosurgical unit of the Royal Perth Hospital, where the surgeon and physician in charge expressed the view that he was suffering from intermittent arterial occlusion as the cause of his symptoms. He was rested, and during the next 48 hours a steady and noticeable recovery in the power of his limbs took place, also in his ability to speak. As the weakness cleared he experienced a tingling sensation in the fingers of his right hand, particularly the middle finger, and touching this finger provoked a tingling sensation. This was a symptom that he had noticed before. A telephone discussion was held between Perth and Melbourne, where Dr. A. Schweiger expressed the opinion that the condition was probably a partial occlusion of the internal carotid artery. The patient was by this time so much better that it was thought advisable to return him to his home country before undertaking further investigations. He was accordingly flown home to England and was admitted to the Dreadnought Hospital under the care of one of us (C. E.).

On examination he showed evidence of difficulty in speaking fluently, and he complained that he could not write satisfactorily, and in particular that he found it difficult to sign his name and that his signature bore no resemblance to the normal. He also found difficulty in walking because he had not full control of his right leg. The right finger-to-nose test showed slight incoordination and there was impairment of skill in rapidly executed finger movements of the right hand. His gait showed a slight disturbance of rhythm due apparently to a minimal relative increase in tone of the muscles in the right leg, and the right knee-jerk was slightly brisker than the left. Rapid movements with the right foot were impaired.

The central nervous system was normal in response to all other routine tests, with flexor plantar responses and completely normal sensory responses everywhere. His blood pressure was 160/100. It was thought that the left internal carotid pulse was much decreased in volume when compared with the right, and it was difficult to feel at all. All the other peripheral pulses were normal. The cardiovascular system showed no other abnormality; there was no evidence of atherosclerosis elsewhere, his retinal vessels were normal in appearance, and his electrocardiogram showed nothing abnormal. Physical examination of his other systems revealed nothing abnormal.

The E.S.R. (Wintrobe) was 15 mm. in one hour. On lumbar puncture cerebrospinal fluid pressure was not raised and the fluid was of normal content, with protein of 28 mg. per 100 ml. and less than 1 cell per c.mm. The Wassermann and Kahn reactions were negative and the routine blood count was normal.

The patient was then transferred to the West End Hospital for Neurology and Neurosurgery, where an electroencephalogram showed a 10 c/s alpha rhythm disturbed in all leads by 22 c/s activity. There were runs of 5 c/s waves showing symmetrically over both temporal lobes and there was no evidence of any single focal abnormality. Plain skull x-ray films were normal and a left common carotid arteriogram was performed by Dr. A. Fisher; this was reported on by Dr. Douglas Gordon as follows: "Complete filling of both internal and external carotid vessels, but the branches of the latter were relatively large and of the former narrow, tortuous, and numerous. At the lowest point in the neck capable of being included, a small filling defect was seen partially blocking the internal carotid artery. There was a localized dilatation of the internal carotid artery immediately distal to the filling defect." The patient was then transferred to St. Mary's Hospital for operation by one of us (C. R.).

Operation

On March 21, 1956, the patient was anaesthetized and the body temperature reduced to 28° C. (82.4° F.) by surface cooling (Dr. Alan Cheate). In our view hypothermia is a valuable aid to surgery of the carotid arteries; without it the prolonged clamping of these vessels which may be needed in this type of operation can produce permanent cerebral damage, but with hypothermia it is safe to occlude one carotid artery for a long period and the surgeon has adequate time to reconstruct the internal carotid artery. It is of course unnecessary to use hypothermia when a carotid artery is completely occluded before operation.

The bifurcation of the common carotid artery was exposed and the common, internal, and external carotid vessels were dissected free. A sufficient length of these vessels was freed to allow the application of clamps well away from the lesion. The constriction in the internal carotid artery could easily be felt and the artery at this point was adherent to the adjacent vein. The diseased segment of artery was resected; it consisted of a crescent-shaped plaque about 1 cm. long in the main axis of the internal carotid artery, and it projected into the lumen so that this was reduced to less than 20% of its normal calibre. The common, internal, and external carotid arteries were of normal appearance above and below this stenosed segment. Continuity was restored by a direct anastomosis between the common and internal carotid arteries; it was not necessary to ligate the external carotid artery. A satisfactory pulse returned to the internal and external carotid vessels and the wound was closed. Anticoagulants were not used.

Post-operatively the patient rapidly recovered consciousness and his body temperature reached 36.9° C. (98.5° F.) in five hours. At this time a superficial examination of his central nervous system showed no obvious abnormality. The next morning, 24 hours after the beginning of his operation, a full examination of his central nervous system was made and the findings were remarkable. The most striking thing was the fact that the patient had signed his name about fifty times on his morning paper in his joy at finding that he could write normally for the first time since the onset of his major symptoms two months before. And his pleasure at this, plus the usual euphoria seen after operations under hypothermia, produced an elation which can seldom have been equalled.

All the abnormal physical signs which had been present the day before had disappeared; his speech was as normal as was his handwriting. The right finger-to-nose test was normal and he was able to perform rapid fine movements with both his hands. The increased tone in the right leg had disappeared and his knee-jerk was now normal. He made satisfactory progress and left hospital ten days after the operation.

Five weeks later he was examined for his employers, the shipping company; he had no abnormal physical signs of any kind in his central nervous system and he did not complain of symptoms. His handwriting continued to be fluent and normal. He was certified as medically fit to resume charge of the liner he had captained, but his employers considered it unsound business to allow this when so many passengers and crew had known that he had had a "stroke." Accordingly he was promoted to a higher ranking shore-based administrative post in the company.

The pathologist's report (Dr. H. C. Barrett) on the portion of carotid artery was: "Part of the carotid artery in which there is a semilunar valve-like structure protruding into the lumen. Microscopically this is seen to be a hyaline thickening of the intima. The two recesses on either side of this membrane have been the site of both an old and a recent haemorrhage. Although there are a few small collections of round cells, mainly in the media, this structure is probably not inflammatory. It is consistent with a post-traumatic lesion."

The electroencephalogram was repeated on October 3 and showed improvement. The 5 c/s waves were no longer present and the 22 c/s activity was limited to the anterior halves of the hemispheres.

Discussion

The first point of interest is the lesion in this artery. This was considered by the pathologist to be traumatic in origin, but there was no history of injury. One of us (C. R.) believes that this lesion was a localized plaque of atheroma, both because of its appearance and because of its situation at the common site near to the origin of the internal carotid artery.

The next and most striking finding was the immediate disappearance of well-marked pyramidal signs and symptoms once a normal flow through the internal carotid artery had been re-established. The explanation of this and of the temporary episodes of disturbance of function in the central nervous system which occurs in patients with a partial occlusion of the internal carotid artery is of interest. In our view the most likely explanation is that the narrowing of the lumen reduces the internal carotid blood flow. In our patient this, coupled with a greater reduction of flow due to haemorrhage into the arterial wall at the time of the onset of his major attack, was enough to maintain the symptoms and signs of pyramidal insufficiency but not enough to cause complete death of the cerebral cells.

The same type of explanation will account for the transitory attacks which occurred earlier in this patient, in the patient reported by Eastcott *et al.* (1954), and in those reported by other authors, including Chambers (1954) and Millikan and Siekert (1955). In these the narrowing of the carotid reduces the flow. Under ideal conditions this is sufficient to maintain normal cerebral function, but when the flow is further reduced by such events as a change of posture or a reduction of blood pressure transitory symptoms of cerebral ischaemia may result. Others have postulated that these attacks of transitory carotid ischaemia are due to spasm of the carotid vessels. It is possible that this may occur, but in the presence of an organic reduction in the size of the internal carotid artery a further reduction in flow by some general or local cause other than spasm is more likely. Another explanation is that thrombi may form on the narrowed part and peripheral emboli result, but this again is unlikely in view of the short duration and repeated occurrence of similar attacks.

We believe that the correct treatment of a patient with a partial occlusion of the internal carotid artery is surgical because of the disability it causes and because of the great risk of complete carotid occlusion; this view is shared by Denman, Ebner, and Duty (1955). By this means we have completely relieved three patients, greatly improved two others, and six patients with complete occlusions have been made no worse by exploration of this vessel; there has been no mortality. The alternative is to treat these patients with long-term anticoagulant therapy. We believe that this measure should be used after operation to reduce, if possible, the occurrence of further thrombosis in this vessel or elsewhere.

An important step in the diagnosis of this lesion is the correct interpretation of the carotid arteriogram. This should always show the bifurcation of the common carotid artery, and as much attention should be paid to this region as to the intracranial vessels.

The actual operation is aimed at restoring the flow through the internal carotid artery. This may be achieved by either a direct anastomosis, a thrombo-endarterectomy, or an arterial graft or transplant, depending on the type of abnormality which the surgeon encounters. We have employed each of these procedures with success in patients requiring reconstruction of the carotid arteries. In our view hypothermia is a valuable aid to this type of surgery, but the body temperature need not be reduced below 28° C. (oesophageal temperature).

Summary

The case of a man with a partial occlusion of the left internal carotid artery is reported; as a result he was unable to sign his name, suffered from difficulty in speaking, and had abnormal pyramidal signs and symptoms in his right upper and lower limbs. These neurological abnormalities had been present for eight weeks. Reconstruction of the internal carotid artery was followed by immediate and complete relief of his neurological abnormalities. We believe that this is the first report of the complete recovery of definite and persistent neurological symptoms and signs due to internal carotid obstruction. In 1954 a similar case was reported by Eastcott, Pickering, and Rob, but in this case the neurological abnormalities were intermittent and not persistent.

TREATMENT OF ULCERATIVE COLITIS WITH LOCAL HYDROCORTISONE

BY

S. C. TRUELOVE, M.D., M.R.C.P.

Assistant Physician, Nuffield Department of Clinical Medicine, the Radcliffe Infirmary, Oxford

A number of reports exist indicating that oral cortisone is a useful agent in the treatment of ulcerative colitis. In a controlled therapeutic trial carried out through the co-operation of many physicians, it was found that patients treated with oral cortisone were nearly three times as likely to be in clinical remission at the end of six weeks' treatment as patients in the control group (Truelove and Witts, 1955). In view of the fact that cortisone and, more particularly, hydrocortisone have been found useful when applied locally in several eye conditions, joint conditions, and skin diseases, it seemed worth while assessing the value of local treatment in ulcerative colitis.

Hydrocortisone is an active principle of the adrenal cortex and is the principal corticosteroid found in human plasma. Under ordinary conditions it is present in the blood and other body fluids at a concentration of about 5-10 µg. per 100 ml. Under conditions of stress, or following injection of corticotrophin, its concentration may rise to 50 µg. per 100 ml., or even higher. Hydrocortisone appears to act directly on the tissues of the body, where it is constantly being broken down into inert metabolites. When cortisone is given orally or by injection it acts because it is converted into hydrocortisone. For cortisone to be locally effective the appropriate enzyme for this conversion must be present in the tissues being treated. For local application hydrocortisone has the additional advantage over cortisone that it is water-soluble, though not to a high degree. (The foregoing paragraph is based on the findings presented in a number of scientific papers, such as those by Nelson *et al.* (1951), Nelson and Samuels (1952), Cote and Delbarre (1953), Hellman *et al.* (1954), Silber and Porter (1954), and Peterson *et al.* (1955). A good general account is included in an article by Gope (1955).)

TABLE I.—*Brief Clinical Details and Results of Treatment in the First Six Patients Treated With Local Hydrocortisone (Each Course of Treatment Lasted Three Weeks).*

Case No.	Previous History	Immediately Before Treatment	Response to Treatment	Progress During One Year Follow-up Period
1. Female aged 30	In 1951 began to pass blood and mucus per rectum, and had bouts of diarrhoea. In 1954, inflamed rectum and lower sigmoid colon up to 25 cm. found on sigmoidoscopy. Then treated with corticotrophin and went rapidly into remission, which lasted several months. Symptoms recurred; treated with oral cortisone, she again went into remission for several months; then began to pass blood per rectum, without diarrhoea	<i>Clinical:</i> Passing blood per rectum twice a day <i>Sigmoidoscopic:</i> Very active inflammation of rectum with less severe changes above recto-sigmoid junction	<i>Remission:</i> Excellent response. Rapidly became symptom-free. Much improved but not entirely normal	Remained almost entirely well. Occasional passage of trace of blood per rectum. Sigmoidoscopy showed mild inflammation up to 20 cm. from anal margin, thereafter shading off into normality
2. Female aged 38	In Feb., 1953, had a sudden attack of diarrhoea with blood in motions, lasting for 5 months. Thereafter fairly well, but would often pass blood and mucus per rectum, although without diarrhoea. In Sept., 1955, recurrence of diarrhoea, with 5 motions a day containing much blood. This settled down to two motions a day with blood and mucus present	<i>Clinical:</i> 2 motions a day with blood and mucus present <i>Sigmoidoscopic:</i> Marked changes in rectum up to 18 cm. from anal margin	<i>Remission:</i> Excellent response. Rapidly became normal. Much improved but not normal	Remained almost entirely normal, with mild inflammation in lower half of rectum only, for 8 months, when she suddenly relapsed with diarrhoea and gross blood in stools. After 5 weeks of these symptoms she was again treated with local hydrocortisone (see Treatment 20 in Table II)
3. Male aged 34	In March, 1955, gradual onset of diarrhoea with 5-10 motions a day, with occasional blood present. Symptoms had eased off somewhat before present treatment began	<i>Clinical:</i> 4 unformed motions a day with much mucus. Colicky abdominal pain preceding each motion. Barium enema showed involvement of transverse and descending colon <i>Sigmoidoscopic:</i> Moderate inflammation extending as far as could be seen	<i>Remission:</i> Excellent response. 2 stools a day, rather soft but otherwise normal Improved but not normal	Remained symptom-free regarding bowel action for 11 months, but with mild inflammation of colonic mucosa extending as far up as could be seen with a sigmoidoscope. 2 months after end of treatment developed ischio-rectal abscess, treated by surgical drainage; healed well. After 11 months bowel symptoms recurred, treated with local hydrocortisone hemisuccinate sodium (to be reported)
4. Female aged 30	In August, 1952, gradual onset of diarrhoea with 6 motions a day containing blood and mucus. After 1 year had a complete remission lasting 3 months, but symptoms then recurred. Admitted in Feb., 1954, with 6 motions a day containing blood; haemoglobin, 66%; and evidence, on barium enema, of ulcerative colitis affecting transverse and descending colon. Improved on general medical treatment, but diarrhoea recurred, and in 1955 was treated with oral cortisone with improvement but not complete relief. Barium enema showed widespread involvement of colon	<i>Clinical:</i> Intermittent diarrhoea with blood present in stools <i>Sigmoidoscopic:</i> Moderate inflammation extending as far up as could be seen	<i>Remission:</i> Excellent response. Entirely normal symptomatically. Much improved. Slight hyperaemia only	Remained well for 6 months, although sigmoidoscopic appearances were those of moderate activity. After 6 months had a sharp clinical relapse, which was treated with local hydrocortisone (see Treatment 15 in Table II)
5. Female aged 42	Since 1952 has passed large quantities of mucus and blood per rectum each time bowels were opened and at other times also. No diarrhoea. Barium enema showed evidence of ulcerative colitis affecting the rectum and sigmoid colon	<i>Clinical:</i> No diarrhoea but passing considerable amounts of blood and mucus with every motion, and also at other times <i>Sigmoidoscopic:</i> Severe inflammation extending as far up as could be seen	No change No change	Treated with corticotrophin gel by intramuscular injection; passed into complete clinical remission, with much improved sigmoidoscopic appearances. After 7 months' remission relapsed and was treated with oral cortisone combined with "salazopyrin," with gradual remission
6. Female aged 35	In 1943 developed ulcerative colitis, for which she was discharged from the Women's Auxiliary Air Force. In remission from 1945 to 1949, when symptoms recurred and she was in hospital for 2 months. Fairly well until June, 1955, when diarrhoea recurred with up to 12 motions a day containing blood and pus. Barium enema showed involvement of descending and sigmoid colon. Treated with oral cortisone with slight improvement only	<i>Clinical:</i> 6 unformed motions a day with blood present, and also passing blood at other times <i>Sigmoidoscopic:</i> Moderate inflammation extending as far up as could be seen	No change No change	Treated with systemic corticotrophin gel with little effect. Then treated with salazopyrin with no effect. Subsequent slight improvement, but had 6 stools a day until 8 months after present study began, when she went gradually into remission and has since been symptom-free

Present Investigation

With these considerations in mind it was decided to use hydrocortisone for the local treatment of ulcerative colitis. It was supplied for trial by Glaxo Laboratories in bottles containing 250 mg. of hydrocortisone (free alcohol) dissolved in 50 ml. of 50% ethyl alcohol, in which it is much more soluble than in water. For therapeutic use one of these bottles was emptied into a standard intravenous infusion bottle containing 500 ml. of normal saline. The hydrocortisone is soluble enough to be held in this dilution, and the resulting solution of 4.5% ethyl alcohol in saline was judged not to be an irritating fluid for the colonic mucosa. The infusion bottle containing hydrocortisone was suspended close to the patient's bed and the hydrocortisone dripped into the rectum through a standard blood transfusion giving-set, slightly modified to carry a rubber catheter for insertion into the rectum. The use of a controllable drip mechanism permits the solution to be run into the rectum at a slow and steady rate, so that the chance of its acting as an enema is much reduced. The method described was also easily mastered by those patients who

treated themselves in their own homes, and none of them experienced any difficulty in applying the treatment.

The patients now reported on were all mild or moderate cases of ulcerative colitis. Patients with the severe form may have much superadded infection with pyogenic bacteria. In view of the fact that cortisone encourages the spread of pyogenic infections, it was thought advisable to confine the local use of hydrocortisone, at any rate initially, to less severe cases. Although the hydrocortisone was used in low concentration compared with what has been found optimal in skin diseases, there are reasons to suppose that the concentration used would be adequate for local action in the colon. The mucosa of the colon is covered with a single layer of epithelial cells as opposed to the numerous layers of cornified cells covering the skin. The colon absorbs water and saline avidly, and hence the hydrocortisone would be drawn into contact with, or actually into, the mucosa in the process. (It has recently been shown by Liddle (1956) that $\Delta^9\alpha$ -fluorohydrocortisone ($\Delta^9\text{FF}$) can be used to study the absorption of hydrocortisone by virtue of its capacity to suppress the normal secretion of corticotrophin and thus reduce blood levels of endogenous

hydrocorticoids to nearly zero. By this method, 26% of hydrocortisone was absorbed from the rectum compared with 2% from the skin, although Liddle specifically mentions that absorption across an inflamed mucosa has not been measured.) With these points in mind, a solution containing hydrocortisone at a concentration approximately 1,000 times that found in body fluids seems sufficient to have some local effect.

The treatment was given each night and was carried out with the patient in bed immediately before settling down for his night's sleep. On the first night one-quarter of a bottle was given—that is, approximately 125 ml. of liquid containing 60 mg. of hydrocortisone. During treatment the amount was increased up to half a bottle each night. The length of each course was originally three weeks, but later this was reduced to two weeks.

Results

Two groups of patients are here reported on. First, a group of six patients who were treated in October, 1955, and who have been observed for one year since. These patients were studied with particular care, for at least one sigmoidoscopic examination with biopsy was carried out before treatment and further biopsy examinations were made at weekly intervals during treatment, and on isolated occasions during the period of follow-up, by means of a special biopsy instrument (Truelove *et al.*, 1955). Their

course of treatment lasted three weeks. Secondly, an additional 15 treatments, each of two weeks' duration, have been given to patients without such close study and with shorter periods of follow-up. These 15 treatments include four instances of repeat treatments on patients who had previously responded to this form of therapy but had subsequently relapsed.

The results for these two groups are shown in Tables I and II. It will be seen that the patients often went into clinical remission during treatment, the net result of the total of 21 treatments being clinical remission in 14 cases, improvement in 1 case, and no change in six cases.

Almost all the patients who went into clinical remission with the treatment did so with great rapidity, commonly during the first few days of treatment. It is well known that symptoms may rapidly abate in any patient with ulcerative colitis, but the occurrence of very rapid remission in two out of every three patients within a few days of starting a particular form of therapy is decidedly exceptional, even if we allow for the fact that most of the patients in the present study had only mild symptoms. Rapid clinical remission was not confined to those patients with mild symptoms. For example, the patient described under Treatment No. 15 was experiencing a sharp attack of symptoms with gross bloody diarrhoea, rapidly falling haemoglobin, general malaise, and a sigmoidoscopic picture of acute inflammation. She nevertheless had complete

TABLE II.—*Results of Next 15 Courses of Treatment With Local Hydrocortisone (Each Course of Treatment Lasted Two Weeks).*

Treatment No.	Previous History	Immediately Before Treatment	Response to Treatment	Subsequent Progress
7. Male aged 46	In October, 1955, developed dull abdominal pain with fever and sweating lasting about a week. Since then has been passing 2 stools a day, watery, with much mucus present and occasional blood. Barium enema shows evidence of ulcerative colitis in rectum and sigmoid colon	<i>Clinical:</i> 2 liquid motions a day, with much mucus and occasional blood <i>Sigmoidoscopic:</i> Marked hyperaemia, granularity, numerous petechiae and shallow erosions, as far up as could be seen. Mucosal fragility much increased	<i>Remission:</i> Excellent response. After a few days was passing one normal stool a day Much improved, but mild hyperaemia and granularity still present	Remained symptom-free for 3 months, then had relapse and was again treated with local hydrocortisone (see Treatment 14)
8. Female aged 28	In March, 1955, had one week's diarrhoea with 7-8 loose motions a day containing blood; gradual improvement followed. Aug., 1955, bloody diarrhoea recurred, then gradually cleared up. Recently has been constipated but passing much blood and mucus per rectum, with occasional diarrhoea	<i>Clinical:</i> Passing considerable amounts of blood and mucus per rectum. Much lower abdominal pain <i>Sigmoidoscopic:</i> Well-marked hyperaemia, granularity, and exudate with the mucosal fragility much increased. These changes extended beyond 23 cm. from the anal margin	<i>Remission:</i> Good response. Steady improvement and was normal after one week Greatly improved. Mild hyperaemia and granularity only	Remained well for 6 weeks, but developed acute sinusitis which was followed by relapse of ulcerative colitis with passage of blood per rectum, abdominal pain, and sigmoidoscopic evidence of activity. Oral cortisone brought good response. Remained almost symptom-free on oral cortisone at the end of study
9. Female aged 36	Two years' history of passing blood and mucus per rectum every few days. Usually constipated. Lower abdominal pain	<i>Clinical:</i> Passing blood and mucus per rectum, but without diarrhoea <i>Sigmoidoscopic:</i> Marked inflammation of the rectum, becoming mild above rectosigmoid junction	<i>Remission:</i> Symptom-free in a few days Much improved—nearly normal	Symptom-free (6 months' follow-up)
10. Male aged 28	In Jan., 1954, had diarrhoea with 6 motions a day containing blood and mucus. Diarrhoea stopped after 6 weeks, but intermittent rectal bleeding persisted. Sept., 1954, 7 weeks' diarrhoea. Dec., 1954, period of severe rectal bleeding. Feb., 1956, bleeding per rectum recurred followed by diarrhoea with up to 12 motions a day and loss of 1 stone (6.4 kg.) in weight. Barium enema showed evidence of ulcerative colitis from rectum to transverse colon	<i>Clinical:</i> Diarrhoea with blood and mucus present. Barium enema showed widespread involvement of colon <i>Sigmoidoscopic:</i> Hyperaemia and well-marked granularity of the mucosa extending up as far as could be seen	<i>Remission:</i> Became symptom-free in a few days. Gained 1 stone (6.4 kg.) in weight	Remained symptom-free for a month, then relapsed with 4 unformed stools daily containing small amounts of blood. Again treated with local hydrocortisone (see Treatment 21)
11. Female aged 57	Recurrent attacks of diarrhoea with blood and mucus since 1917. Recent attack began 2 months before present treatment, with diarrhoea of up to 18 stools a day with blood and mucus present. Anaemic and treated with blood transfusion before hydrocortisone therapy was begun. Also suffered from chronic pyelonephritis with hypertension	<i>Clinical:</i> Severe bloody diarrhoea as described in previous column <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity of mucosa with numerous tiny erosions. Much purulent exudate. Mucosa very fragile with bleeding on slight trauma. These changes extended as far as could be seen	<i>Remission:</i> Rapid response to treatment; became symptom-free in a few days Greatly improved, but still showing hyperaemia with mildly increased fragility of mucosa	Recurrence of diarrhoea with blood in stools. These symptoms persisted until end of present study

TABLE II.—Continued.

Treatment No.	Previous History	Immediately Before Treatment	Response to Treatment	Subsequent Progress
12. Female aged 51	Five months' history of passing blood and mucus per rectum but without diarrhoea	<i>Clinical:</i> Passing much blood and mucus per rectum up to 8 times a day <i>Sigmoidoscopic:</i> Marked hyperaemia of mucosa as far up as could be seen, with increased fragility and patchy exudate	<i>Remission:</i> One normal stool a day without blood or mucus Much improved. Slight hyperaemia and slightly increased fragility	Remained perfectly well (6 months' follow-up)
13. Female aged 30	In 1955 had a severe attack of ulcerative colitis associated with pregnancy, and was treated in hospital for 5 months with corticotrophin followed by oral cortisone, followed by salazopyrin. Was symptom-free on discharge in Dec., 1955. Remained in clinical remission and with sigmoidoscopic findings within normal limits (apart from some residual scarring) until April, 1956, when sharp relapse began possibly related to change of diet	<i>Clinical:</i> Three loose stools a day with much blood and mucus present <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity with purulent exudate present. Numerous mucosal petechiae. Mucosal fragility much increased	No change Not done	Symptoms persisted in spite of variety of treatments, including oral cortisone, salazopyrin, and blood transfusion
14. Male aged 46	See Treatment No. 7	<i>Clinical:</i> For past two weeks had 3 loose stools a day with much mucus present <i>Sigmoidoscopic:</i> Hyperaemia and granularity with numerous petechiae present	<i>Remission:</i> Immediate response, to treatment with 1 normal stool a day after first instillation Much improved but residual hyperaemia and granularity present	Remained well for 3 months, then began to pass 3 loose stools a day with much mucus present. Treated with local hydrocortisone hemisuccinate sodium (to be reported)
15. Female aged 30	See Case 4 (Table I)	<i>Clinical:</i> Six unformed stools a day with much blood present. Hb has fallen from 95% to 75% in past fortnight <i>Sigmoidoscopic:</i> Marked hyperaemia with very extensive petechiae and purulent exudate. Extreme mucosal fragility	<i>Remission:</i> Immediate response to treatment. Diarrhoea less after 1 day. No bleeding after 2 days. One motion a day without blood after 3 days Much improved but still showed hyperaemia and granularity	Remained symptom-free (5 months' follow-up)
16. Male aged 46	Intermittent attacks of bloody diarrhoea since 1949. Three admissions to hospital. Two weeks before present treatment he had diarrhoea with small amounts of blood and pus present and with much lower abdominal pain	<i>Clinical:</i> Diarrhoea, with small amounts of blood and pus present in stools and lower abdominal pain <i>Sigmoidoscopic:</i> Well-marked hyperaemia, granularity, and mucosal fragility as far up as could be seen	<i>Remission:</i> Abdominal pain ceased after 2 days and diarrhoea after 5 days. Thereafter had entirely normal motions	Remained well (5 months' follow-up)
17. Male aged 46	Attacks of ulcerative colitis since 1953, for which was twice admitted to hospital. On second occasion in Dec., 1955, when he improved on treatment but continued to get 4-6 motions a day with occasional blood and mucus present. These symptoms persisted until present treatment began	<i>Clinical:</i> 4-6 loose motions a day with occasional blood and mucus present <i>Sigmoidoscopic:</i> Marked hyperaemia with numerous petechiae and purulent exudate. Mucosal fragility increased	No change: At first improved and became almost symptom-free, but symptoms recurred during treatment No change	Symptoms persisted in spite of a variety of treatments
18. Male aged 24	Developed first attack of ulcerative colitis in Dec., 1955. In Feb., 1956, was admitted to hospital with 15 motions a day containing much mucus and blood. Barium enema showed changes throughout the whole descending colon. Treated with corticotrophin with much improvement but without going symptom-free. Thereafter treated with oral cortisone as out-patient, but became rather worse with 6-7 motions a day containing small amounts of blood. Oral cortisone was tailed off at beginning of hydrocortisone treatment	<i>Clinical:</i> 6-7 motions a day with small amounts of blood present <i>Sigmoidoscopic:</i> Marked hyperaemia, granularity, and purulent exudate. Mucosal fragility much increased	Improved: One normal motion each morning; no further bowel action until evening, then he passed small amounts of mucus and a little blood No change	Mild symptoms persisted in spite of treatment with salazopyrin, which was apparently beneficial
19. Female aged 62	Four months' passage of mucus per rectum with occasional blood and increasing frequency of defaecation	<i>Clinical:</i> 5 motions a day containing blood and mucus. Intermittent fever up to 101° F. (38.3° C.) <i>Sigmoidoscopic:</i> Well-marked hyperaemia and granularity	No change No change	Treated with systemic corticotrophin. Deteriorated. Developed severe fungus infection of mouth. Then gradually improved and was almost symptom-free at end of present study
20. Female aged 38	See Case 2 (Table I)	<i>Clinical:</i> Diarrhoea with gross blood and mucus in stools <i>Sigmoidoscopic:</i> Severe inflammation extending up to 20 cm. from anal margin and then shading off into normality	<i>Remission:</i> Symptom-free after a few days Much improved but not normal	Remained well for 2 months, then began to pass blood and mucus per rectum. Treated with local hydrocortisone hemisuccinate sodium (to be reported later)
21. Male aged 28	See Treatment No. 10	<i>Clinical:</i> Diarrhoea with 4 unformed motions a day, containing blood <i>Sigmoidoscopic:</i> Marked inflammation as far up as could be seen	No change No change	Treated with oral cortisone until end of present study, with improvement after 6 weeks

symptomatic relief in three days from the onset of therapy, which was self-administered at home.

The sigmoidoscopic changes throughout treatment corresponded roughly to the clinical response, in that all the patients experiencing a clinical remission showed an improved sigmoidoscopic picture, which the others did not. However, in only one patient did the sigmoidoscopic appearances become entirely normal, although in some of the others the abnormal changes were slight at the end of treatment.

By contrast, the histological appearances of biopsy specimens taken throughout treatment showed no such corresponding improvement. In general, the mucosal changes appeared much the same at the end of treatment as at the beginning, even among those patients experiencing complete symptomatic relief and with greatly improved sigmoidoscopic appearances. In some cases the surface epithelium appeared more gravely disturbed during treatment than before it. Whether this was due to the effects of the hydrocortisone itself or whether the vehicle of 4% ethyl alcohol was exerting a noxious influence is at present uncertain.

The patients who passed into clinical remission were liable to suffer from recurrence of symptoms during the follow-up period, although a relapse during the first few weeks after stopping treatment was not common. Among those who responded well to the treatment the sigmoidoscopic picture often showed some worsening after treatment was stopped, but this might occur without simultaneous clinical relapse. Four patients who relapsed clinically some months after a successful first treatment were treated a second time. In the case of the first three patients so treated, the second course of treatment was rapidly effective in suppressing symptoms, but the fourth patient showed no response to the second course.

It might be supposed that local treatment applied by a rectal drip would be effective only in patients in whom the disease was limited to the rectum or lower colon. In other words, the treatment might be efficacious only in those varieties of ulcerative colitis which have been labelled "haemorrhagic proctitis" and "recto-sigmoiditis." Many of the patients fell into these categories, as was to be expected in view of the fact that severely ill patients were excluded from the study. However, not all these patients with limited disease responded to the treatment, and, by contrast, there were other patients with radiological evidence of widespread involvement of the colon who did respond. The geographical extent of the disease is therefore not the important element in determining response to treatment. The reason for this becomes plain when we consider the extent to which substances dripped into the rectum will spread through the colon.

Extent of Spread of Rectal Drip

In order to determine how far along the colon the hydrocortisone solution travels when it is dripped into the rectum with the patient supine, each of the first six patients treated was examined radiologically after a dilute suspension of barium sulphate had been dripped into the rectum under similar conditions. It was found that a suspension of 15 g. of barium sulphate in 250 ml. of normal saline was sufficient to yield clear radiographs. The patient set up the rectal drip with the dilute barium suspension while lying on the x-ray table and remained there until the radiological examination was completed some three and a half hours later. The barium sulphate suspension was dripped into the rectum at the usual rate, and radiographs were taken at the end of the administration, followed by additional radiographs at intervals of one hour, two hours, and three hours after its completion.

The barium sulphate suspension was found to travel extensively through the colon, in all cases travelling as far up at least as the splenic flexure and, in some, across the transverse colon and into the ascending colon. A typical

radiograph taken one hour after the conclusion of the rectal drip is shown in the accompanying illustration. This wide spread is presumably due to the occurrence of non-propulsive contractions of the colon such as have been demonstrated both in animals and in man (Templeton and Lawson, 1931; Adler *et al.*, 1941). It demands only the application of simple physical principles to see that if the anal sphincters remain closed during such contractions any liquid contents are likely to be widely dispersed through the colon. It is clear that if a local treatment can be found which is efficacious against ulcerative colitis it can be applied effectively by rectal drip over the bulk of the colonic mucosal surface, provided the patient is not rectally incontinent.

Discussion

The present study has shown that about two out of every three patients with mild or moderate symptoms of ulcerative colitis experience complete symptomatic relief when treated with nightly instillations of hydrocortisone into the rectum. The clinical response has shown a well-marked pattern. Either the patient responds swiftly to the treatment so that symptomatic relief is obtained in the first few days or he is left unchanged by it. Whether this difference reflects any fundamental difference in the nature of the disease in different patients is entirely uncertain. However, it is a pattern of response which has commonly been observed when hydrocortisone has been employed as a local treatment on the skin, in the eyes, and in joints. For example, Sulzberger and Witten (1954) reported a study of the effect of hydrocortisone in 252 patients with skin diseases, in many of whom the lesions were symmetrically bilateral, so that one side of the body could be treated with an inert

Radiographic appearances one hour after dripping a weak suspension of barium sulphate into the rectum with the patient supine.

ointment and used as a control. In those patients who showed a good response to hydrocortisone the effect was quickly apparent, visible improvement occurring in 24 to 48 hours.

Although the sigmoidoscopic picture showed improvement during therapy in all those patients going into clinical remission, only one patient had entirely normal sigmoidoscopic findings at the end of treatment. A more marked discrepancy was seen in the case of the histological picture of the mucosa as judged by examination of small specimens taken for biopsy from the neighbourhood of the recto-sigmoid junction, for it was exceptional to find improvement. This finding emphasizes that this form of treatment can be regarded only as a means of symptomatic relief and that the disease continues in those who pass into complete clinical remission. However, this is probably true of all forms of medical treatment in present use, and Truelove and Richards (1956) have reported that more than half of the biopsy specimens taken from patients in clinical remission show evidence of inflammation.

The fact that the present form of treatment is in no sense a cure of the disease should not be taken to mean that it is useless. If symptoms can be promptly checked in a considerable proportion of patients, particularly by the use of a method which they can carry out in their own homes, it is a valuable addition to therapy. So far, there has not been sufficient opportunity to see whether repeated short courses of local hydrocortisone administered as soon as symptoms recur will keep patients in a good state of general health for a prolonged period. Four patients in the present study who relapsed some months after a successful course of treatment were treated a second time, with rapid relief of symptoms in three of them. It is highly desirable that further experience along these lines be gained.

Although the results now reported seem reasonably favourable, it is not claimed that the form of hydrocortisone used is necessarily the best for local treatment. Hydrocortisone (free alcohol) has a very limited solubility in water and was therefore supplied by the manufacturers in solution in 50% ethyl alcohol. This was diluted 10 times with saline, but, even so, it is conceivable that the resulting weak alcohol solution which acted as a vehicle for the hydrocortisone was not entirely innocuous to the inflamed mucosa. A form of hydrocortisone which is freely soluble in water may therefore prove to be superior for local use in ulcerative colitis. One such preparation, hydrocortisone hemisuccinate sodium, is being tried at present.

It will be appreciated that the opinion expressed that the present study has shown local hydrocortisone to be frequently effective in bringing about symptomatic relief in mild attacks of ulcerative colitis is no more than a presumption based on clinical judgment. It is conceivable that the rectal drip might aid in the relief of symptoms merely by lubricating the colon and thus minimizing the damage caused by defaecation, just as preparations such as "isogel" and "normacol" may be useful in mild cases of ulcerative colitis. Alternatively, those who believe ulcerative colitis to be a psychosomatic disorder will find a ready explanation of the apparent benefit in the use of any treatment which is novel. Yet a third possibility is that a rectal drip of hydrocortisone is no more than an inconvenient and expensive way of allowing hydrocortisone to be absorbed to exert its systemic effects. These possibilities could be assessed by a properly designed therapeutic trial. Such a trial may be advisable, but at present it seems best to form clinical judgments on various preparations of hydrocortisone so that the one found to be most efficient can be put to a formal test in due course.

Summary

A group of patients suffering from ulcerative colitis in a stage of mild or moderate severity have been treated by the introduction of a solution of hydrocortisone into the rectum by means of a slow drip. Those who were

severely ill were not included. Treatment was given nightly, originally for three weeks, latterly for two weeks.

Twenty-one courses of treatment have been given to 17 patients, four having been treated twice.

In 14 instances rapid clinical remission occurred, this change occurring in the first few days after starting treatment. In one instance the patient was much improved but not in complete clinical remission. In the remaining six instances the treatment had no effect.

The sigmoidoscopic changes roughly corresponded with the change in clinical state, for all those patients going into clinical remission showed an improved sigmoidoscopic picture, although in only one instance did the sigmoidoscopic findings become entirely normal.

By contrast, the histological findings met with in small biopsy specimens did not in general show a corresponding improvement.

The effect of the treatment is not permanent, although a successful immediate outcome may be followed by a period of clinical remission lasting at least for several months. In the case of four patients who suffered clinical relapse some months after an excellent response to treatment, the institution of a second course of treatment brought about clinical remission in a few days in three of them, so that repeated courses of treatment whenever symptoms recur may prove to be effective in some of those patients who respond to the first course of treatment.

This method of treatment appears to be a useful addition to the treatment of ulcerative colitis, particularly as it can be carried out by patients in their own homes.

I am grateful to Glaxo Laboratories for making a gift of the hydrocortisone; to Miss Shirley Thomas, who assisted at the sigmoidoscopic examinations and in other ways; to Mr. D. Jerome, of the Dunn School of Pathology, who prepared some of the histological specimens through the courtesy of Professor Sir Howard Florey; to Dr. M. A. Jennings, of the Dunn School of Pathology, who examined some of the specimens; and to my radiologist colleague, Dr. K. Lumsden, who arranged for the special barium enema examinations to be carried out. It is a pleasure to record my appreciation of the first six patients treated. They were plainly told that the treatment was experimental and that if they took part they would undergo repeated sigmoidoscopy with biopsy; none refused treatment.

OBSTRUCTION OF THE SUPERIOR VENA CAVA IN CARCINOMA OF BRONCHUS

BY

LEON SZUR, M.B., D.M.R., D.M.R.D.

AND

L. L. BROMLEY, M.Chir., F.R.C.S.

Of the Medical Research Council Radiotherapeutic Unit and the Department of Surgery, Hammersmith Hospital

The increasing incidence of carcinoma of the bronchus in recent years, and the undisputed fact that only a small proportion of patients can be permanently cured, makes the palliation of some of the grave symptoms of this disease assume great importance. One of the most unpleasant complications of carcinoma of the bronchus is obstruction of the superior vena cava, and the purpose of this article is to report our experiences in the management of 107 patients with this condition seen at Hammersmith Hospital during the four-year period November, 1949, to October, 1953.

There seems little doubt that the superior vena caval syndrome is more commonly encountered now than it was in the past. Hinshaw (1949) remarked on its rarity when he reported that, in analysing 85,000 consecutive admissions to the White Memorial Hospital in Los Angeles, he could find only four examples of the condition. McIntire and Sykes (1949) reviewed the literature up to 1946; they report Fischer's (1904) collected series of 252 cases and add a further 250 cases from the literature from 1904 to 1946. Furthermore, the aetiological background of the syndrome has undergone a gradual change. Many conditions have been identified as the cause of superior vena caval obstruction; among those most frequently encountered have been aortic aneurysm, carcinoma of the bronchus, chronic mediastinitis (syphilitic, tuberculous, or of unknown aetiology), carcinoma of the thyroid, malignant lymphoma, metastatic carcinoma, and thrombosis with no apparent underlying cause. Whereas aneurysm of the aorta, including the complication of perforation of the wall of the sac into the right atrium or superior vena cava, was apparently the commonest cause reported in the older literature, clearly carcinoma of the bronchus now accounts for the majority of cases, certainly in Great Britain.

In a previous article (Bromley and Szur, 1955) we outlined the work of the Bronchus Tumour Clinic at Hammersmith Hospital and reported that during the four-year period (1949-53) 732 patients were seen. Among these were 107 who presented with superior vena caval obstruction—that is, 14.6%. It is interesting to note that Roswit *et al.* (1953), reporting 38 cases, state that these represent 15% of their series of carcinoma of the bronchus.

Clinical Features

The majority of patients presented with pulmonary symptoms antedating those of superior vena caval obstruction, but in a small number the latter were the first indication of the presence of carcinoma of the bronchus. The main complaint of the patients was dyspnoea. This may have been present for some time, but it had rapidly worsened with the onset of caval obstruction. In addition, the patients complained of a sense of fullness in the head, swelling of the neck, and puffiness of the face. Headache, vertigo, and drowsiness were symptoms often present; these

were possibly the result of increased cerebral venous pressure. The classical physical signs were present in all cases in varying degree. These included venous engorgement of the neck; congestion of the face with suffusion of the conjunctivae; frank oedema of the face, neck, and often of the arms; as well as evidence of a collateral circulation (Fig. 1). These symptoms and signs were aggravated by lying flat, some patients finding the horizontal position untenable for more than a few moments.

The diagnosis of superior vena caval obstruction in our patients was made primarily on clinical grounds. Infra-red photographs were taken to demonstrate collateral channels in some patients (Fig. 2) and in a few angiography was performed (Fig. 3). Estimation of the venous pressure in upper and lower limbs was not made, as we did not feel that this procedure was essential for diagnosis or a necessary aid to the planning of treatment.

The age incidence of the 107 patients (90 males, 17 females) suffering from superior caval obstruction is shown (Fig. 4). It will be seen that over 70% occurred between the ages of 45 and 64. Table I shows the side and site of

TABLE I.—Side and Site of the Primary Growth

	Total	Main Bronchus	Upper Lobe Bronchus	Lower Lobe Bronchus	Middle Lobe	Not Known
Left	22	5	14	3	—	—
Right	85	26	44	10	1	4

the primary growth. Although some authors report a slight preponderance of left-sided carcinomas, the majority agree that right-sided primaries are the predominant cause of this syndrome, and our series shows a proportion of nearly 4:1. The right main bronchus and right upper lobe accounted for 65.4%.

Bronchoscopy was performed in 70 patients and was not accompanied by any serious morbidity. In 58 of these it was done before treatment was started and in the remaining 12 during or at the end of treatment. It was our agreed policy to carry out bronchoscopy in all patients before their assessment at the bronchus tumour clinic. The reason for this was to determine the extent of the primary growth, to obtain evidence of the degree of tracheal or carinal deformity, if such existed, and, finally, to secure histological confirmation. This was the only group in which bronchoscopy was not always possible or desirable. In 37 patients bronchoscopy was not done. This was because they were too gravely ill (a few being almost moribund) or it was considered that the procedure might be hazardous owing to the presence of gross venous congestion of the head and marked respiratory embarrassment. Also, in several cases, histological confirmation was readily obtainable by cervical node biopsy.

The results of the bronchoscopies can be summarized as follows: positive histological evidence was obtained in 20 patients; in 37 there was strong presumptive evidence of malignant disease of the lung; in 13 the examination yielded no positive information. It is interesting to compare this with a series of 66 patients with carcinoma of the bronchus who had radical radiotherapy followed by pneumonectomy (Bromley and Szur, 1955). In the overwhelming majority of these, histological proof was obtained at the first bronchoscopy, whilst in the group under discussion this could be obtained in only 29%. The reason why it was so often unobtainable, even in the presence of advanced carcinoma of the bronchus, was that tracheal and carinal deformity and rigidity of the main bronchi made a full examination technically impossible.

Histology

Table II shows the histological findings. The absence of positive histological proof in about a third is explained by the difficulties in investigating this group of patients as previously outlined. The majority of the patients died at

home and necropsy was performed in only 38. In these, however, a bronchial carcinoma origin was confirmed in every case, and thus we feel that it is unlikely that more than a very few could have been due to any other condition, although this cannot be entirely excluded. Whilst it is

though a few of them were in a very advanced condition. Indeed, it is our impression that superior vena caval obstruction is one of the few emergencies of radiotherapy and that on occasion remarkable relief of symptoms can be achieved in a short time. Only five received radical treatment, based

FIG. 1.—Typical appearance of a patient with superior vena caval obstruction.

FIG. 2.—Infra-red photograph showing collateral venous channels on the anterior chest wall.

regretted that a high proportion remained without confirmation of the diagnosis, it does not seem likely that this affects the conclusions which can be drawn from the series as a whole.

TABLE II.—Histology of the Growths in 107 Patients

Not Known	Squamous	Oat	Adeno-carcinoma	Anaplastic and Others
38	12	27	—	30

It will be seen from Table II that most of the patients were affected by undifferentiated forms of carcinoma (oat or anaplastic). Only 12 out of 69, proved histologically, could be classified with certainty by the pathologists as squamous growths. This is 17%; and should be compared with the usual incidence of about 60% reported in most general series of carcinoma of the bronchus.

Radiotherapy

In view of the distressing nature of this syndrome it was our policy to treat all patients who presented with it, even

FIG. 3.—Venous angiograms: (A) before and (B) after treatment, showing return to patency in the superior vena cava.

on multiple small fields and careful beam direction. These patients were in exceptionally good general condition. In most of the others a four-field set-up was used; in only a few were two fields employed. The main aim of the treatment was to relieve the superior vena caval obstruction; the primary site of the growth bore only secondary consideration in planning the fields. In the great majority of the cases, however, it was possible to include the right main bronchus and the upper lobe stem in the maximum tumour dose area. Field sizes were usually 15 by 10, 15 by 7.5, or rarely 20 by 10 cm. The apparatus then available provided a kilovoltage varying between 190 and 250. The half-value layer in all cases was 2 mm. of copper. In some patients treatment could not be completed because of further deterioration of their condition or death. The dose generally aimed at was about 3,000 to 4,000 r in about three to four weeks. It was not considered desirable to stop treatment as soon as the symptoms were relieved, as is advocated by some radiotherapists, because it was our belief that continued treatment to a higher dosage makes the likelihood of a recurrence of the obstruction much less. However, we tried to avoid any significant skin reactions or radiation oesophagitis.

Results of Treatment

The effects of treatment on the caval obstruction can be shown as follows: (1) No change or continued deterior-

FIG. 4.—Age incidence in the 107 patients.

ration occurred in 33 patients. (2) Improvement took place in the remaining 74—(a) half of these (37) were classified as showing considerable improvement in their symptoms, with complete disappearance of the signs of caval obstruction; a small number of them were able to return to full employment; (b) the other half showed slight or moderate improvement; in the majority of these the clinical signs of caval obstruction disappeared. Thus 69% of the patients responded to the treatment and, so far as the caval obstruction was concerned, derived benefit from radiotherapy. The symptoms of the underlying primary tumour were often improved to a great extent but seldom completely disappeared.

Table III shows the survival time in months from the start of treatment. It will be seen that 80 (74%) of the patients died within the first six months and only three survived

TABLE III.—Survival Time in Months from the Start of Treatment

-1	1-3	3-6	6-9	9-12	12+
14	37	29	17	7	3

longer than a year. The longest survivor lived for 18 months. It is difficult to assess whether the treatment actually prolonged the life of the group as a whole, although it undoubtedly did so in individual cases. Rosenbloom (1949) reports the fate of nine untreated cases: eight died within 10 weeks and one survived 14 weeks. Although his is a small series and it is not possible to draw any definite conclusions from it, it seems probable that the expectation of life after the onset of caval obstruction is to be measured in weeks rather than in months.

Recurrence of Obstruction.—Of those patients who showed considerable improvement, 31 had no recurrence prior to death, 5 developed a recurrence, and in 1 there was insufficient information to arrive at an assessment. Of the 37 patients who showed slight or moderate improvement, 28 had no further deterioration of the symptoms or signs of caval obstruction, 8 did show evidence of progression of the syndrome after an initial phase of improvement, and in 1 there was insufficient information to arrive at an assessment.

Nature of the Obstruction

We were interested to find out, if possible, the anatomical cause or nature of the obstruction. Necropsy was done in 38 patients, but information about the state of the vena cava and its tributaries was complete enough to form an opinion in only 23. Understandably, the majority of necropsies were performed on those who had not responded to treatment and died in hospital. Table IV shows the

TABLE IV.—Findings at Necropsy in 23 Patients

Direct Infiltration by Primary	Thrombosis	Pressure of Primary or Glands	Normal Superior Mediastinum
4	8	13	6

findings in 23 patients. It will be seen that some patients had the superior vena cava affected by more than one of the possible causes for the obstruction. It was interesting to find that direct infiltration of the vessel with growth in its lumen was noted in only four. The six who had a normal superior mediastinum all belonged to the considerably improved group.

Discussion

In Great Britain carcinoma of the bronchus is undoubtedly the commonest cause of superior vena caval obstruction and probably accounts now for at least 80% of the cases. This great vein is anatomically so placed as to be particularly vulnerable to pressure effects from an intrathoracic malignant growth. This is due to its close relationship to the right main bronchus and to the right paratracheal group

of glands which receives a considerable volume of the lymph drainage from both lungs. The obstruction of the vein leads to the establishment of a collateral circulation in which, amongst others, the azygos, the internal mammary, and the superficial thoracic veins participate. In most patients the collateral circulation is inadequate, and this accounts for the signs and symptoms of the condition.

The fully established clinical picture is so characteristic that it can be readily diagnosed. Whilst investigations are often necessary and histological confirmation is of great value in proving the underlying aetiology, it is our belief that unnecessary time should not be spent on a variety of diagnostic procedures. The patient is often in so poor and advanced a condition that treatment is urgently indicated. Some of the investigations may be carried out at a slightly later stage, when the symptoms and signs have been at least partially relieved. For example, bronchoscopy in the early stages may be a procedure that carries a certain degree of risk. In our series it was performed only in 58 patients before the start of treatment and in only 20 was positive histological proof obtained. It might, therefore, be regarded as almost an academic investigation, and should be done only if there is no obvious risk to the patient or if there is real doubt about the underlying cause of the obstruction.

Radiotherapy is generally, though not universally, accepted as the treatment of choice for the relief of caval obstruction (Price Thomas, 1950; Brooks *et al.*, 1951; Roswit *et al.*, 1953; Hilton, 1955). Of our 107 patients, 74 (69%) improved with treatment, half of these showing marked improvement with complete disappearance of the symptoms and signs of their caval obstruction. The continued deterioration in the remaining 31% did not appear to be accelerated by the treatment given. As the treatment was planned to be palliative, skin reactions and irradiation oesophagitis were avoided. Of the 74 patients who benefited by treatment, 59 (79%) had no recurrence of the obstruction prior to death, the latter being usually due to metastases or intercurrent infection. Whilst it is difficult to assess whether the treatment prolonged the survival time in many cases, there is no doubt that the quality of the remaining life was considerably improved. Clinicians who have seen patients with superior vena caval obstruction will agree that the mode of death in this condition is most distressing and that, on the whole, less suffering is experienced when death is due to generalized metastases. When first seen 21% of our patients already had clinical or radiological evidence of extrathoracic metastases; almost all had extensive intrathoracic disease. Our experience in the management of this condition has confirmed our belief that treatment should be given to all patients even though the expectation of life is very short.

The majority of the patients had tumours situated in the right main and right upper lobe bronchi and there was a very high incidence of anaplastic growths. A case might be made, therefore, for very close observation of patients who fall into these categories and who are not suitable for thoracotomy or radical irradiation. Radiotherapy might be regarded as having a place early in the development of such a tumour, either on diagnosis or at the earliest appearance of caval obstruction. In this way the misery of the fully developed syndrome might be avoided.

Summary

Of 732 patients seen at the Bronchus Tumour Clinic at Hammersmith Hospital, 107 presented with superior vena caval obstruction. These were treated with irradiation. Clinical, pathological, and radiotherapeutic details are described and the results of treatment presented. Benefit was derived from this treatment in 69%, and in four-fifths of these there was no recurrence of the obstruction prior to death. It is concluded that treatment should be attempted in all patients suffering from this condition.

We should like to express our gratitude to Dr. Constance Wood and Mr. W. P. Cleland, who were responsible for the general guidance of the work of the clinic; also to Dr. P. B. Woodyatt, who treated many of these patients.

CLINICAL TRIAL OF BUCILIZINE HYDROCHLORIDE FOR VOMITING OF PREGNANCY

BY

M. PETER DURHAM, M.B., F.R.C.S., M.R.C.O.G.
Consultant Gynaecologist and Obstetrician, Royal Victoria Hospital, Folkestone

Many drugs have been used in attempts to relieve nausea and vomiting of pregnancy. Except in sporadic cases the results are disappointing, which is not surprising when the cause of this condition continues to be obscure. In mild degree these symptoms are accepted by most patients as a necessary evil; in moderate degree they cause considerable distress; in severe degree hyperemesis gravidarum results, a condition which may threaten life and which requires urgent treatment.

Bucilizine hydrochloride ("vibazine") has the chemical formula 1-(p-chlorobenzhydryl)-4-(p-tertio-butylbenzyl)-diethylene-diamine dihydrochloride and is an antihistaminic of low toxicity (Schiller and Lowell, 1956). It has been shown to be effective in cases of allergy (Blatt, 1955), post-operative vomiting (Klein-Vercautere, 1954), and motion sickness (Chinn, 1955), and it seemed likely that it might be equally efficacious in vomiting of pregnancy.

In carrying out a clinical trial to investigate this, cases of moderate degree were chosen, the response of those of mild degree being too difficult to elucidate and the occurrence of those of severe degree being too rare to obtain sufficient material. An occasional case of severe nausea with slight vomiting and a few cases of hyperemesis gravidarum, which occurred during the time of the investigation, were included.

Material

Between January 25 and December 11, 1955, 1,267 new patients attended the antenatal clinics at Willesborough, Folkestone, and Buckland Hospitals; 33 of these had symptoms severe enough to include them in the investigation. During the same time three patients were seen in their own homes. One patient is included twice in the series, excessive vomiting occurring at the eighth and again at the thirty-seventh week. The age of patients varied from 18 to 36 years. Their distribution according to parity is shown in Table I, according to symptoms in Table II, and according to stage of pregnancy in Fig. 1.

TABLE I.—Parity of 36 Patients

Gravida	1	2	3	4	6	7
No. of cases	17	11	4	2	1	1

The duration of vomiting before treatment was between 3 and 70 days, the average being 30 days. One patient complained of it for 120 days! The severity varied from vomiting twice a day to vomiting "everything." Of those cases occurring between the sixth and ninth weeks, 50% had been vomiting for a week, 25% for two weeks, 25% for

four weeks. In the group between the tenth and fourteenth weeks, the majority of patients had been vomiting three to four times daily for at least four weeks. Most of the patients treated after the thirty-fifth week had suffered throughout pregnancy from intermittent vomiting, which had become severe shortly before treatment.

Acetone was detected in the urine in eight patients; unfortunately it was not tested for in some cases.

FIG. 1.—Distribution of patients according to stage of pregnancy.

Treatment

Prior to treatment all patients were examined to exclude an organic cause for vomiting. At the beginning of the investigation the dose of buclizine hydrochloride prescribed was 50 mg. nocte, this being supplemented after three days by 25 mg. mane if the response was not satisfactory. Later, 50 mg. nocte and 25 mg. mane was prescribed at the outset, as this was found more effective. Twenty patients were treated with 50 mg. nocte, 13 with 50 mg. nocte and 25 mg. mane, two in-patients and two out-patients with 50 mg. nocte and 25 mg. t.d.s., and one in-patient and one out-patient with 25 mg. t.d.s. One patient of her own accord found she obtained the best result by taking 25 mg. nocte and 50 mg. mane. The only contraindication to these higher doses seemed to be that sleepiness was induced in some patients in the daytime.

Six patients were treated in hospital. Four of these were admitted on account of the severity of their vomiting, one for treatment of bronchiectasis, and one for social reasons.

The duration of treatment varied from five days to three months, the average being two weeks.

Results

An analysis of the results is shown in Table III. The time interval between the onset of treatment and patients

TABLE III

Result	No. of Cases
Complete relief	19 (53%)
Marked improvement	5 (14%)
Improved	7 (19%)
No effect	2 (5.5%)
Worse	3 (8.5%)

experiencing relief was short in most cases, many patients stating that they were greatly relieved the following day. An analysis of the number of days between the onset of treatment and response is shown in Table IV.

The distribution of the results according to the stage of pregnancy is shown in Fig. 2. Of the two patients who did not experience any effect, the mental approach and environment of one were unstable and difficult. No treatment proved of any avail other than separating her from her home surroundings. The other patient stated that she

FIG. 2.—Results according to stage of pregnancy.

continued to vomit all the time regardless of any treatment, but at no time was her general condition affected. Of the three patients who stated they were worse following therapy, one vomited violently four hours after taking buclizine hydrochloride and did not take any further tablets, one thought her vomiting was more violent during her week's treatment, and one felt ill but took the tablets for only three nights. Unfortunately there was no opportunity to analyse the last patient's statement, as her frame of mind was such that she departed from the out-patient department with her notes.

One patient in the successful group complained that her vomiting was more violent after the first two nights, but she then experienced relief and was pleased to continue with the treatment.

In the successful group two patients had a previous history of hyperemesis gravidarum. One had had a therapeutic termination for hyperemesis at the second month in 1950, and, during her second pregnancy in 1951, treatment in hospital for 14 weeks from the sixth week had been necessary. During the present pregnancy promethazine hydrochloride had already been tried; buclizine hydrochloride was started at the ninth week and continued until the seventeenth week, but at no time was admission indicated. The dosage at first was 25 mg. t.d.s. and 50 mg. nocte, but eventually it was found that 50 mg. on waking in the morning and 25 mg. at midday gave the desired result.

The other patient had been admitted during her first pregnancy at the sixth, twenty-second, and twenty-sixth weeks for hyperemesis. During the present pregnancy a buclizine hydrochloride was started at the eighth week on a dosage of 50 mg. nocte and 25 mg. mane. Treatment was continued for three months, during which time she vomited on only four occasions. After the first week it was found that 50 mg. nocte was sufficient.

In six patients who had received treatment for seven to ten days, vomiting recurred at the end of the course. In five this was controlled as soon as treatment was restarted; in the sixth, a patient at the eighth week of pregnancy, vomiting ceased spontaneously after three days, no further treatment being required.

Comment

In drawing any conclusion from a survey into the value of a drug for vomiting of pregnancy it is essential to remember that the aetiology of this condition is not understood and is probably multiple. It is well known that many patients suffering from vomiting will improve after reassurance, and may improve on inert therapy.

All the patients in this survey were given their tablets direct from the hospitals concerned. In most cases it proved impossible to keep from them the fact that the medicine prescribed was not in general use, as normally patients are referred to their own doctors for drugs.

Even after taking into account the possible improvement resulting from "suggestion therapy," the high percentage of patients benefiting would appear to indicate a good thera-

peutic response to buclizine hydrochloride. Many of these patients had previously been treated with other drugs, including antihistamines.

The only adverse factors were drowsiness, when 50 mg. nocte and 25 mg. t.d.s. were prescribed for out-patients, and the incidence of violent vomiting in two patients mentioned.

Summary

The results of a clinical trial into the value of buclizine hydrochloride ("vibazine") for excessive vomiting of pregnancy are analysed.

Thirty-six patients out of 1,267 attending antenatal clinics were treated.

The results showed that 53% of the patients were completely relieved, 14% were much improved, 19% were improved, 5.5% were the same, and 8.5% were worse.

I wish to thank Mr. John Buttery for allowing me to include patients under his care and Messrs. Pfizer Ltd., Folkestone, Kent, for making this clinical trial possible by their generous supply of vibazine.

BAD GASTRECTOMIES

BY

V. J. KINSELLA, M.D., F.R.C.S., F.R.A.C.S.

Hon. Surgeon, St. Vincent's Hospital, Sydney

The first gastrectomy for ulcer was performed in 1881, by Rydygier in Poland. The main modifications of the operation were worked out in Europe in the nineteenth century and appeared in the European textbooks in 1900. The modification which I use to-day was described by Krönlein, of Zürich, in 1885. In those early days, before the placement of stoma and loops was well understood, various forms of obstruction were encountered. To deal with these Braun, of Königsberg, described in 1892 an anastomosis between afferent and efferent limbs, which now bears his name. Kappeler, of Münsterlingen, in 1898 described an improvement, a "suspension method" designed to prevent rather than to cure, in which the afferent limb of the loop is fixed above the stoma in such manner that kinking is prevented and the stomach empties its contents into the efferent limb. The stitches used for this suspension are now called after Kappeler.

A Keen Rivalry

By the end of the nineteenth century operative techniques had been established, and then began a critical long-term evaluation of end-results which covered the first two decades of the century. In 1906, at a surgical congress in Berlin, Rydygier showed in good digestive health, and 25 years after operation, the first patient ever to have had gastrectomy for ulcer. A keen and critical rivalry sprang up between the great European schools of gastric surgery, most of them directed by pupils of Billroth. Wedge resections, sleeve resections, gastro-enterostomy, pylorotomy, and extended resection battled for the mastery. By 1920 the advocates of extensive gastrectomy, led by Finsterer, Eiselsberg, and Haberer, had won the day, and this operation.

because of its excellent late results, was accepted as the operation of choice for intractable ulcer, whether gastric or duodenal.

But surgeons in Britain and America questioned it. C. H. Mayo expressed the opinion that "if a surgeon threatened me with a partial gastrectomy for a small duodenal ulcer he would have to run faster than I can." Judd and Nagel, of the Mayo Clinic, in 1926, devised their excision of duodenal ulcer with modified pyloroplasty. Rose and Carless, in 1927, advocated gastro-enterostomy, with excision of gastric ulcers and inversion of duodenal ulcers. Clare in 1923 advocated gastro-myotomy; Braithwaite in 1926 gastro-cholecystostomy. For penetrating ulcers Carson and also Roberts, in 1927, advocated jejunostomy, and Moynihan devised a combination of gastro-enterostomy with jejunostomy, although he used gastro-cholecystostomy in some patients. During this period gastrectomy was tried, at least in those ulcers which were not penetrating the liver or pancreas. But, in general, the mortality was high. Thus *St. Bartholomew's Hospital Reports* (Vol. 69) revealed a primary mortality, from 1919 to 1931, of 16.9% in partial gastrectomy for peptic ulcer.

In 1926 Finsterer attended the annual meeting of the B.M.A. in Nottingham and advocated gastrectomy for ulcer. Unfortunately, he also attempted to demonstrate his highly specialized techniques torn from the proper setting in which they had been elaborated, and met with failure, as have others in like circumstances. In 1928 he added a personal appeal to Hurst on behalf of this operation. He reported that gastrectomy could be done even for the so-called inoperable ulcers penetrating liver and pancreas (if the viscera were separated and the base of the ulcer left behind), and that, even including these, since 1919 he was able to achieve a mortality of 2.6% in 532 patients (4% in the 175 gastric cases and 2% in the 357 duodenal cases), 87 of them between 60 and 78 years of age. In support he quoted Eiselsberg's mortality of 3% in 449 patients. These two surgeons were indeed worthy disciples of their great master, Billroth. But Finsterer met with a cold reception. Hurst (1929) wrote of gastrectomy for duodenal ulcer that "the operation is so formidable, and the mortality is likely to be so high, that it is very improbable that it will ever gain wide popularity." Moynihan (1928) was even more emphatic, and wrote that gastrectomy for duodenal ulcer "is dangerous even in the hands of its warmest advocates; a mortality of 5 to 10 per cent. [sic] is, in my judgement, prohibitive . . . there is certainly not a great degree of freedom from the only serious sequel, gastro-jejunal ulcer. My own unequivocal and most confident opinion is opposed to it. It is one more evidence of the familiar Teutonic capacity for finding a difficult way of doing easy things. I regret that the wise and cautious judgement, the sanity of outlook, and care for the individual patient, which hitherto have always characterized British surgery, have not rendered all our surgeons immune from rash and most intemperate persuasions by Continental and transatlantic operators." Lewison was probably one of the "transatlantic operators." Moynihan, in quoting mortalities, ignored the masters and went instead to Louria, an American visitor to Haberer's clinic in Graz. Haberer's mortality was high, because he attempted total resection of the difficult ulcers, even those penetrating liver and pancreas. Meantime Finsterer had avoided such dangerous steps, by the method of resection-with-exclusion for duodenal ulcers, and of peeling the stomach off the base of the ulcer in gastric cases—methods which still have their place to-day.

By the way, there is no justification for calling the first of these methods "Bancroft's operation." Finsterer (1918) first described it, including the excision of "as much as possible of the [antral] mucosa." Later he taught that, even without this, the acid could be sufficiently reduced if enough stomach were resected towards the cardiac end. Neglect of the masters has, as we shall see, wrought much harm to gastric surgery. It is of interest to speculate about the number of stomal ulcers caused by overlooking this particular point.

The Treatment of Choice for Ulcer

But time and a critical testing of results justified the Viennese surgeons. After a delay of about 25 years, gastrectomy became at last established in Britain as the operation of choice for ulcer, thanks to the superiority of its results and to the efforts of younger surgeons, such as Ogilvie. At the same time, in the U.S.A., the younger surgeons at the Mayo Clinic were able to dispel the doubts of its great founder and to report that the late results were excellent in 95% of cases (Deller, 1948). Meantime Moynihan can be taken as representative of the transition period. In spite of his condemnation of gastrectomy for duodenal ulcer he described it as an "almost flawless operation" for gastric ulcer (1926), and later he reported (1930) that he had "yet to meet a case in which the ultimate result was disappointing, and secondary operations are almost unknown."

Such was the position when my own series began in 1937. At that time I felt that the long-term follow-up could only prove what was already well known—namely, the excellence of the end-results. But the position changed. When gastrectomy became accepted as the treatment of choice for intractable ulcer, it was widely taken up by general surgeons, irrespective of their training and special interests, of their knowledge of gastric pathology and surgery, and of their sympathy with the complex related problems of technical and psychological reconstruction. In this way the development of gastric surgery has suffered, in comparison with cerebral, pulmonary, and cardiac surgery. These have enjoyed the benefits of a proper specialism, including a proper and rigorous training for their practitioners, who undertake the work only in response to a special vocation. A veritable rash of reports of small series appeared in the literature. Immediate mortalities of 8%, 10%, and 15% were not uncommon. Surgeons went ahead without effective tuition and without a proper understanding of the operation. The more gifted of them, by a method of trial and error, succeeded in detecting and eliminating their worst faults, finally achieving good results. Thus Hedley Visick (1948) had a mortality of 12% in his first 75 patients and of 3.3% in his last 480 patients, his overall mortality being 4.5%. There were no deaths in his last 123 cases, and there can be little doubt that in these he treated the efferent loop more circumspectly than in those patients who suffered from his "question-mark deformity." His figures exclude emergency operations, and in only one-third of his patients had the ulcer penetrated all coats of the viscus.

But what about the survivors? Soon the end-results came under scrutiny. Widespread dissatisfaction was manifested, for it was evident that a new disease was coming into being. The results of the great masters were not being duplicated.

Two Schools of Thought

So to-day, once again, we find gastrectomy flanked by two schools of thought: on the one hand the supporters of the operation, who get good results and would retain it; on the other its critics, who would supplant it because their results are bad.

Porritt (1952) writes: "95% of patients who have a gastrectomy are satisfied." This corresponds with the experience reported many years ago by Finsterer, who found "symptoms of the small stomach" in 7% of patients, and these usually avoidable by taking frequent small feeds. Ogilvie (1925) wrote: "I have spoken of gastrectomy as a uniformly successful operation. I have found it so. My friends have found it so. Their patients and mine are a happy crowd and are never tired of saying so. The unhappy ones are equally vocal, but they are so rare that they hardly cloud the picture." "Recurrent ulceration at the stoma . . . I have seen no instances" (except when the antrum and its mucosa were mistakenly left). Tanner (1951) finds partial gastrectomy "100% successful for gastric ulcer and 97-98% for duodenal ulcer." Hollenbach (1950) in his last 1,148 cases found the end-results to be good in 90%; there

were no recurrences, but 39 patients had gastro-jejunitis, necessitating second resection in 4, and a few complained of palpitations and heat relieved by lying down for 20 minutes. According to Maingot (1955) the final results "leave little to be desired." Barclay and McIntyre (1954) find that post-gastrectomy complaints are rare.

My own experience after 280 gastrectomies for ulcer (Kinsella, 1955) is that the results, twelve months and later, when the operation had been properly performed, are uniformly successful. A few patients still complain of bile vomiting, sometimes with headaches; a few others had occasional bouts of vomiting small amounts of clear or food-stained slimy fluid, sometimes in the early morning when cleaning their teeth or following coughing; a few others were intolerant of certain foods. In all these cases the records revealed that the same symptoms were present before operation. It must be strongly stressed that a post-gastrectomy follow-up, perhaps delegated to a registrar, is of little value unless correlated with a carefully and fully recorded pre-operative history, aimed particularly at the analysis of gastric symptoms. It should be remembered that when an appendix is removed for pain in the right iliac region, and when the pain persists after operation, the patient always dates the pain from the operation. Partial gastrectomy cannot cure a migraine or gastro-duodenal-jejunitis or food allergies. But nevertheless patients are delighted that their pain has gone, that meals and sleep can now be enjoyed, and that work, interrupted for years, can now be resumed.

But, as mentioned already, there are other clinics in which the late results have been bad; in some so bad that the operation, in spite of its substantial background, is given up and patients are subjected to new and untried methods. Thus Gilbert and Dunlop (1947) found 5 patients in 45 so disabled after gastrectomy that they were totally unfit for employment. Grayton-Brown and Wood (1955) found that 20% of their patients suffer from "considerable disability . . . daily attacks of nausea followed by vomiting of bile . . . accompanied by considerable loss of weight and lack of energy." Such reports could easily be multiplied.

Causes of Bad Results

An analysis of the literature thus reveals a dichotomy of opinion about late results. It would be of still more value if the search could throw light upon the cause of the bad results, so that they may be avoided. Barclay and McIntyre (loc. cit.) suggested that bad results are frequent in England because of the faulty nutrition of the people. But this is unlikely, for the people are not so badly nourished; some English surgeons get good results and some Australasians bad ones. Ogilvie (loc. cit.) has "come to believe that the bad results of gastrectomy are the results of bad gastrectomy." The high primary mortalities often reported support this conclusion. But does the literature throw any light upon the details at fault? I believe that it does, thus providing further evidence for the truth of Ogilvie's opinion. I have already mentioned the efferent-loop obstruction, or "question-mark deformity," recognized and pointed out by Visick himself. But there are many other examples in textbooks and journals.

Among the textbooks we may select *Abdominal Operations*, by R. Maingot, published in 1955. He describes two modifications of the Billroth II operation: with full-width and with part-width stoma. The description of the first type is defective in that the principle of Kappeler has been ignored, thus ensuring at least partial obstruction of the afferent jejunal loop at the point where it meets the lesser curvature of the stomach. This obstructive kink is clearly seen in Fig. 15-25 showing the completed operation. It is the main cause of the so-called "dumping syndrome." (Maingot secures good results in his personal series because he, like Ogilvie, uses the second method, not the first. In the second method the principles of Kappeler have already been incorporated by Hofmeister and Finsterer. But, as we

shall see later, it is even possible to misuse this second type of anastomosis.) This criticism of the latest and best British textbook applies *a fortiori* to the others.

Likewise Custer, Butt, and Waugh (1946) found that "dumping" followed the full-width stoma, but was only mild and transient with the half-width stoma. They recognized that the jejunum is the source of the symptoms, but express themselves as puzzled by the fact that all the patients show rapid emptying of the stomach into the efferent loop but only a few experience dumping. They have forgotten the more important afferent loop.

Mimpriss and Birt (1948), in a series of 130 patients, lost one from an obstructive kink at the lesser curvature and saved two others by immediate re-operation; a fourth was relieved of dumping by late re-operation. They then refer to the method which would have prevented these complications and attribute it to Maingot, writing in 1948. It is the suspension method described by Kappeler just 50 years previously.

Capper and Butler (1951) report a 12% incidence of early "dumping," and give an excellent description of it, showing, in their own patients, the obstructive kink of the afferent loop at the lesser curvature, the dilated and hypertrophied bowel proximal to this, the symptomatic relief due to temporary release of the obstruction when lying down, and the associated discharge into the stomach of large quantities of bile, which may or may not be vomited. They then cause their patients discomfort by introducing mercury into the stomach, and argue from this that the normal mechanism of dumping is the drag upon the stomach remnant by the heavy jejunal loop. This conclusion is quite invalid, because the specific gravities of mercury and of jejunal loops are quite different. A heavier jejunal loop, floating in the fluid contents of the abdomen, would not drag if its greater weight were compensated by a greater volume. Moreover, "dumping" occurs after total gastrectomy. The jejunal loop causes the symptoms, not because it is a heavy loop dragging on the stomach, but because it is an obstructed loop; and if it is obstructed it causes the symptoms whether the stomach is there or not. The obstruction is the essence of the matter. The loop is heavy because it is obstructed, not obstructed because it is heavy; and the obstruction, not the heaviness, causes the symptoms. However, they hit upon a happy solution: they design an operation to suspend the heavy loop, and incidentally they undo the obstruction. In fact they have, 53 years later, rediscovered Kappeler's suspension method.

Goligher and Riley (1952) find that 75% of their patients suffer from dumping, 12.5% severely. They recognize that distension of the jejunal loop is the cause. They conclude that the efferent limb of the loop is responsible, because "dumping" appears even when there is no reflux into the afferent limb. Custer *et al.* forgot the afferent limb altogether. Goligher and Riley have not forgotten it, but they have forgotten that it can be distended through obstruction as well as through reflux. Their skiagrams show barium passing back into the afferent limb of the loop and stopping sharply at the point of obstruction, unable to trickle down towards the duodeno-jejunal flexure. Other skiagrams show bulging of the jejunum opposite the stoma, suggesting partial obstruction of both afferent and efferent limbs. It is evidently possible to obstruct the afferent limb even when using the Hofmeister-Finsterer method.

Schofield and Anderson (1953) report that "a new disease is being created," and give some inkling of the method of creation. They describe their operation as an "antecolic Polya-gastrectomy with a Hofmeister valve." Actually the Polva operation is retrocolic with no valve, and the Hofmeister is also retrocolic. Although they include only the early post-gastrectomy syndrome, they find a "large proportion" of bad results. In their series (number of cases unspecified) they find seven patients with such severe "dumping" that re-operation is required for afferent-loop obstruction. They perform an anastomosis between the afferent and efferent limbs of the jejunal loop and call this "the

procedure of Illingworth (quoted by Muir, 1949)." As we have seen, it was devised by Braun in 1892. It was useful in the early teething stages of gastrectomy, but nowadays it should no longer be necessary. The "new disease" of Schofield and Anderson was understood, treated, and prevented in the nineteenth century; forgotten, and then recreated. But it has not yet been recognized by the twentieth-century surgeon as very largely the product of his own technical failure; instead he has ascribed the fault to the operation itself.

Wells and McPhee (1954) introduce their article with the remark that "very little is known about the late results of the operation ten or more years after surgery." This is astonishing, in view of the history of the operation as briefly outlined at the beginning of the present article. (I have myself seen a patient who was quite symptom-free, so far as his stomach was concerned, after partial gastrectomy by Lorenz of Vienna forty years ago.) The authors go on to describe 24 cases treated by "high gastric resection with an antecolic Polya operation, and Finsterer-Lake valved anastomosis." They state that "such cases are quite representative of the modern technique." At least the terminology is representative of modern confusion. The operation described by Polya was retrocolic with a full-width stoma, and the Hofmeister-Finsterer ("Finsterer-Lake" so-called) is retrocolic with a valved anastomosis. The authors go on to report their five patients with recurrent ulcers out of 25 treated by a "limited Polya" operation; and their six patients with recurrent ulcers out of 11 treated by a "limited Billroth I." That the limited operation is followed by frequent recurrence was stressed by Finsterer and others in the first two decades of this century.

Placement of the Jejunal Loop

The jejunal loop, in full-width stoma operations, should pass in a slight, even curve from the duodeno-jejunal flexure to a point on the lesser curvature immediately below the oesophagus, about 2 cm. above the stoma, where it is fixed by Kappeler stitches. These should fix the anterior and posterior surfaces of the jejunum to the corresponding surfaces of the stomach, so that, as the jejunum descends, it lies in the same plane as the gastric surfaces. This is necessary to avoid minor obstruction by kinking or torsion of the afferent limb of the loop, as, for example, if the apex of the loop were fixed to the anterior surface of the stomach. Moreover, if this loop is too long it may kink; if it is too short the tension will result in the gradual cutting out of the suspension sutures, if nothing worse. From this point above the stoma, which should be the summit of an even curve, the jejunum should continue in the same straight line, downwards and to the left, past the stoma and into the efferent loop. This is the normal anatomical direction of the first loop, as can be seen in pre-operative skiagrams, and it should be maintained whether in gastrectomy or in gastro-enterostomy. Disregard for this direction will result in minor obstructions, as in the series reported by Holt and Robinson (1955). So also will rotation at the stoma, produced, for example, by an oblique incision into the jejunum. Finally it is desirable to place the omentum so that the limbs of the loop cannot adhere either to each other or to the incision in the abdominal wall.

Before the Kappeler stitches are inserted the slight kink in the afferent loop may be seen. If the stitches are properly inserted they do not merely result in displacing this kink to a higher level, but they convert it into an even curve.

Substitute Operations and Basic Pathology

There are many ways of doing each of the many steps in gastrectomy, and the number of possible combinations of these is very large indeed, but only a few of these will give consistently good results. Those clinics in which the results of gastrectomy are bad are faced with the necessity either of eliminating the detailed steps which have contributed to their bad results or else of inventing a new approach. New approaches may be divided into two groups.

In the first group are operations of increased difficulty and magnitude, in which a separated loop of jejunum or colon is used to replace the stomach. The most fantastic of these comes from Japan (Tomoda, 1952); it is for use after total gastrectomy. It includes five anastomoses, two of which are fashioned so as partially to obstruct the new "stomach," a jejunal loop, which therefore gradually distends, and can be triumphantly shown in the skiagrams as large as the original stomach. The natural aim of treatment is thus reversed and function is made to await upon form. The words of Moynihan applied to gastro-enterostomy 30 years ago may well apply to gastrectomy to-day. "In this operation, as in all others, the keynote of success is simplicity. The great variety of suggestions as to 'new methods,' many of them uncouth, shows beyond doubt that the principles underlying the operation have not been adequately appreciated" (1926). These operations violate the principle that, in a given operation, increased difficulty and complexity lead to increased mortality and morbidity.

In the second group an effort is made to conserve much, or even all, of the stomach. A gastro-enterostomy or a pyloroplasty is done. To prevent the grave hazard of recurrent ulcer surgeons may do nothing (for example, Wells and McPhee), or add vagotomy, or the worse than doubtful hazard of radiotherapy. Holt and Robinson (1955) describe their gastro-enterostomy as horizontal and isoperistaltic, which means that the first loop of the jejunum is displaced from its normal downwards and outwards course, so that difficulty in emptying results, and 19 of their 110 patients suffer from the vomiting of bile. These authors remark that "not the least" advantage of their method is that it can be used by surgeons of limited experience. It appears that the sufferer from peptic ulcer is to be denied the advantage of specialism which is given to those who suffer from disease of the urinary tract, of the bones and joints, of the thoracic organs, or of the brain.

But even more important than the technical defects in these methods is the fact that they have been-fashioned in disregard of basic pathology. Their authors consider only the acid-peptic factor. But this is not the basic factor, for ulcer is found in the less acid parts, and even when there is no acid. The basic cause is an organ defect, or, more properly, a defect in part of an organ. "Organ" must, of course, be taken to include not only the local tissues but also their vascular and nervous connexions. The exact nature of this defect is unknown, but it is known that chronic gastritis is in some way associated with it. The results of Aylett's operation will therefore be bad. As for radiotherapy, there is little hope that it will prevent ulcer in the ulcer-prone areas, for it does no more than temporarily substitute gastro-duodenitis for acid, one ulcer factor for another.

Already the harvest of recurrences is beginning. In Melbourne, even after 12-18 months, Grayton-Brown and Wood (1955) report 4 recurrences in 79 patients. In Liverpool, Bennett-Jones and O'Domhnaill (1955), after a short follow-up, found 11 patients with symptoms of recurrent ulceration, 7 of these needing re-operation, out of 95 patients who had had gastro-enterostomy with vagotomy. All the reports now coming to hand show not only a high recurrence rate, but also an excessive incidence of other complications, following the use of this method. A similar crop of recurrences and hour-glass deformities is, for the reasons given above, likely to follow the sleeve resections now being advocated by Grayton-Brown (1955) for high gastric ulcers. This operation was tried by Riedl in 1904 and by Payr in 1909, and soon given up.

The basic soundness of partial gastrectomy lies in its removal of the ulcer-prone part of the organ. And this is indeed the best that can be done, until we learn the cause and prevention of the disease or until medicine can effect a cure. But partial gastrectomy is a precision operation and more than an anatomical exercise. It differs from most other major operations in the extent and delicacy of the

reconstruction which must follow the ablation, and which demands of the surgeon a special sympathy with the object of his work.

Chronic Gastritis and End-results

Although this article deals with technique and end-results, reference should be made to chronic gastritis, because it has this in common with the technical niceties, that end-results are jeopardized by neglecting its importance.

In patients with ulcer the symptoms come from (1) the ulcer; (2) the diffuse gastro-duodenitis which so often accompanies ulcer, especially gastric, and sometimes simulates it; and (3) the mind of the patient. Many physicians and surgeons have failed to understand the fundamental importance of chronic gastro-duodenitis in diseases of the stomach and duodenum. This failure is due to the fact that they have relied upon the naked eye, either direct or through the gastroscope, for the diagnosis, not realizing that the disease is essentially microscopical. The disease may ruin the health or take the life of the patient and still remain imperceptible to the naked eye. These clinicians have falsely argued that the changes indicating chronic gastritis (the excessive cellular infiltration, with deformity and destruction of the epithelial and glandular elements) may be present without symptoms and are therefore without significance. The same argument could be applied to carcinoma in many organs, to ulcer, to gall-stones, and to chronic nephritis. Such a defective comprehension of gastric diseases leads in some cases to faulty selection, and in others to post-operative disappointment, because the symptoms due to diffuse chronic gastro-duodenitis may not disappear after operation.

Summary

There are two schools of opinion in regard to the late results of partial gastrectomy for peptic ulcer. The history and recent literature are briefly surveyed in an effort to explain this divergence. This survey confirms the opinion of Ogilvie that "the bad results of gastrectomy are the results of bad gastrectomy."

The commonest fault in technique is an improper placement of the afferent loop. This results in the so-called "dumping syndrome." The proper placement of the loop is described.

Substitute operations aimed at conserving ulcer-prone tissue are based upon an inadequate conception of the pathology of ulcer and will result in an excessive crop of recurrences and other complications. Substitute operations which include replacement of stomach by isolated loops of bowel are unnecessary and should therefore be abandoned.

In gastric surgery bad results and confusion reign to-day because insufficient attention has been paid to the old masters who fashioned the operation.

Gastric surgery should be left to those surgeons who have received a special training over and above that required for the general surgeon. Gastrectomy involves a more extensive and delicate reconstruction than that required in most major operations, and for this a special sympathy is required.

PERONEAL MUSCULAR ATROPHY WITH MENTAL DEFECT AND MYOPATHY IN SIBLINGS

BY

ROBERT GIBSON, M.D., D.P.M.

Clinical Director, Manitoba School, Portage la Prairie,
Manitoba

Peroneal muscular atrophy is characterized by the gradual onset and slow advance of atrophic weakness in certain groups of muscles. The disease begins in adolescence. According to Bell (1935) the mean age at onset is 10.93 years where neither parent is affected, but 18.95 years where one parent is affected. Atrophy of the peroneal and anterior tibial groups, with bilateral foot-drop, is an early finding in the disease. Progressive wasting spreads gradually, to involve the muscles of foot and leg, terminating at the knee or in some cases at the lower third of the thigh and producing the "inverted champagne-bottle" leg. Involvement of hands and forearms occurs some time after the onset of the disease in the legs, and here also can be seen a slow spread up to the elbows. Reflexes are generally diminished or absent following the atrophic weakness of muscles. Sensory changes include impairment of vibration sense, with often some diminution of postural and tactile sensibility. Mental defect is a frequent accompaniment, the grade of defect varying from moron to imbecile.

The disease is most commonly dominant in its transmission and only occasional instances have been described of its transmission by an unaffected carrier. In some cases a recessive mode of inheritance has been suggested, although Pratt (1953) has pointed out that the absence of disease in either parent may be due to low penetrance.

In the family under review three out of five siblings are affected with a progressive muscular atrophy beginning in the feet and legs and associated with a marked degree of mental defect. In order of birth the defective members are the first, second, and fourth. The third and fifth members are regarded as normal physically and mentally. At school the affected offspring were unable to progress beyond the lowest grades, 2, 3, and 4 respectively. On removal from school they were incapable of gainful employment and were kept at home until the burden became too great for the surviving parent. Both the remaining siblings, with no physical abnormality, satisfactorily completed their school grades and were gainfully employed as stenographers until marriage.

The family history, which has been extremely difficult to obtain and is admittedly incomplete, provides no

apparent evidence of similar mental or physical disability in parents or grandparents. The parents were not blood relations. The father died at the age of 67 from chronic nephritis, whilst the mother at the age of 66 was described as alert physically and mentally. Paternal and maternal grandfathers died at 57 and 84 respectively after apparently healthy lives. Paternal and maternal grandmothers, on the other hand, died at the early ages of 25 and 24 respectively, and no accurate information is available of their state. The possibility cannot be excluded that one or other may have carried the disease in a mild initial phase, and that low penetrance in their offspring may have accounted for absence of the malady in a parent of the affected siblings. An examination was carried out on two of the affected siblings.

Case 1

The patient, a man aged 39, showed no obvious physical abnormality until the age of 7 years, when awkwardness in walking was noticed. Schooling began at 6; and at 15, not having advanced beyond grade 4, he was removed from school as incapable of further progress. At home his combination of mental retardation and slowly increasing physical disability prevented him from obtaining work; his only activity was acting as a voluntary organblower in his church. On admission to the Manitoba School in 1945 the abnormalities found were wasting of the feet, claw-toes, pes cavus, and a noticeable slenderness of the limbs, together with an extensor plantar response on the right side. His I.Q. on the revised Stanford-Binet scale was 46. A year after admission it was recorded that his physical health was good and that he was working well in the laundry.

On present examination it became clear that considerable extension of the disease had occurred. There was drop-foot with inversion on both sides, and the feet were fixed in a position of pes equinovarus and pes cavus. The toes were fixed in a position of extension at the metatarso-phalangeal joint and flexion at the interphalangeal joints, giving the claw-toe appearance. Atrophy of the small muscles of the feet was accompanied by destruction of muscle tissue up to the knee, involving all compartments of the leg and producing the "rooster" leg. In spite of loss of movement at the ankle-joint the patient could move around fairly well with a steppage gait. In the upper extremities the hands were extensively involved, with pronounced wasting of the thenar, hypothenar, and interosseous muscles. Abduction and adduction of the fingers were virtually impossible, opposition of the little finger was lost, and opposition, abduction, and adduction of the thumb were grossly impaired.

Movements at the wrist-joint were weak and reduced in range, as were pronation and supination. In addition, the pectoralis major on both sides was the seat of extensive atrophy involving the sterno-costal portions. The face had also become involved. It was expressionless, with smoothed-out wrinkles and slightly open mouth. The patient could not blow out his cheeks properly or purse his lips for whistling, and his transverse smile showed weakness of the zygomatics. Closure of the eyes was weak, closure of each eye separately was impossible, and raising of the eyebrows was impaired. Apart from facial involvement the only other abnormality in the field of the cranial nerves was a bilateral nystagmus on lateral gaze. There was no ataxia. With the exception of the ankle-jerk deep reflexes were present; abdominal and cremasteric reflexes were present but no plantar response could be elicited. Sensation showed only slight loss over feet and legs, mainly impairment of vibration and delayed recognition of passive movement. Sphincters were unaffected. Vasomotor disturbance was apparent in the coldness and cyanosis of the right hand, brought on by exposure to cold. The x-ray report indicated osteoporosis and claw-feet. The E.E.G. was reported to be within normal limits.

Case 2

This sister, now aged 44, of the patient in Case 1 was not thought abnormal in any way until she went to school at the age of 6. She proved unable to make any progress with school work and never got beyond the second grade. Physical involvement apparently developed later, its onset probably so insidious that the relatives failed to observe difficulty in walking until not long before her admission to the Manitoba School in 1946. On admission it was noticed that her gait was unusual, and examination showed that the toes did not fully extend, the ankle-jerks could not be elicited, although the knee-jerk and other tendon reflexes were brisk, and the plantar response was doubtful enough to give rise to suspicion of upper motor neurone damage. After admission the patient was found capable of simple routine employment. Her intelligence quotient, estimated on the revised Stanford-Binet scale, was 34.

On present examination the disease process was found to have made considerable extension. Drop-foot, inversion, and pes cavus were present on both sides. Movement of the toes was practically impossible, apart from the left great toe, slight extension of which was possible at the metatarso-phalangeal joint. Slight movement was still possible at the ankle-joint. The gait was of steppage type. Wasting of the small muscles of the feet was accompanied by a generalized atrophy of leg muscles, not so marked as in her brother, and by atrophy of thigh muscles extending up to the lower third of the limb. In the upper extremities the hands were extensively involved. There was pronounced wasting of the interosseous, thenar, and hypothenar muscles, with loss of abduction and adduction in the fingers and thumbs. Movements at the wrist-joints were weak and diminished in range, and pronation-supination was impaired. Paresis was evident in the face, but was less advanced than in her brother's case.

Movements of the orbicularis oculi were weak: the patient was unable to close her eyes tightly or to shut them separately. Similar weakness was present in the region of the mouth. She could not blow out her cheeks, whistling was impossible, and involvement of the zygomatics had produced a transverse myopathic smile. Apart from the facial, none of the other cranial nerves showed obvious abnormality. Precision of movement was impaired owing to weak paretic muscles, but otherwise no ataxia was present. In the sphere of reflexes ankle-jerks were absent, knee, biceps, triceps, and radial jerks were exaggerated, and abdominal reflexes were barely elicitable. The right plantar response was absent, but on the left side, where movement of the great toe was still possible, the response was unmistakably extensor. With regard to sensation the patient complained of a feeling of pins-and-needles in the legs. Vibration was impaired over hands and feet, and minor degrees of passive movement could not be appreciated in the affected digits. Vasomotor changes were apparent in the frequent coldness and cyanosis of extremities, whilst callosities under the great toes were the possible forerunners of trophic sores. The x-ray report indicated osteoporosis with claw-feet. The E.E.G. showed extensive abnormality with paroxysmal characteristics, the pattern consistent with the presence of widespread organic brain damage.

Case 3

It was not possible to examine this sibling, and repeated attempts to trace him through his normal sisters have been unsuccessful. He was the eldest, and if still alive, which is doubtful, would now be 47 years of age. It is recorded of him that he could not learn at school and that he was troubled with his feet and legs in the same way as his brother and sister. When last heard of he had been admitted to an institution as a case of creeping paralysis.

Discussion

The patients examined had peroneal muscular atrophy, with typical involvement of both upper and lower extremities and the mild sensory loss characteristic of the disease. In

both cases, and in the third sibling, whose description accords with the disease, mental defect of imbecile or low moron grade was an accompaniment. This was in striking contrast to the mental state of the physically normal members of the family. In Case 2 mental defect was noted, moreover, some considerable time before physical signs became apparent.

Additional features were present. In Case 1 there was extensive bilateral atrophy of the costo-sternal portion of the pectoralis major. Wasting of this muscle in peroneal muscular atrophy has been mentioned by Brain (1947). Both patients showed involvement of the face. This is not a common accompaniment, but its occasional presence has been remarked on by Kinnier Wilson (1940). The same authority records the incidental occurrence of nystagmus and epilepsy. In both cases earlier examination indicated abnormal plantar responses. With increasing atrophy of muscles, however, it is now only possible to elicit an extensor response unilaterally in one member. In this connexion Perkoff and Tyler (1953) have noted that certain pedigrees are characterized by spasticity and increased tendon reflexes, evidence of spinal cord lesions involving the pyramidal tracts. Ford (1952) has also recorded the occurrence of hereditary spastic paraplegia with peroneal muscular atrophy.

In the differential diagnosis various rare syndromes have to be considered. A similar distribution of atrophy occurs in familial hypertrophic polyneuritis, Gower's distal myopathy, and in the syndrome described by Roussy and Levy (1926). The lack of palpable thickening of the peripheral nerve trunks, the absence of ataxia, and the presence of such myopathic features as atrophy of the sterno-costal portion of pectoralis major and involvement of the facial musculature would appear to contraindicate familial hypertrophic polyneuritis. Sensory and reflex anomalies are sufficient to exclude Gower's distal myopathy, whilst the absence of cerebellar ataxia is against a diagnosis of the equally rare hereditary ataxia with muscular atrophy of Roussy and Levy.

Summary

Three out of five siblings have been recorded as having a progressive muscular wasting beginning in the feet and associated with marked mental defect. In the two cases examined the pattern was characteristic of peroneal muscular atrophy, with some additional features only occasionally described in the disease.

I am indebted to Dr. H. S. Atkinson, medical superintendent of the Manitoba School, for permission to make use of the institutional facilities.

A move is being made to establish a national body to co-ordinate the work of societies concerned with the welfare of deaf children. A resolution to this end was passed unanimously at a recent conference in London of the Deaf Children's Society and other organizations working in this field. Delegates at the conference represented the Scottish Association of the Deaf (Edinburgh and Glasgow branches), the North Western Deaf Children's Association, the South Wales Parents' Association for Parents of Deaf Children, the Oxford and Districts' Association for Parents of Deaf Children, and the Herefordshire and Worcestershire Association for Parents of Deaf Children. A preliminary committee was formed to draw up a constitution and was given full terms of reference to deal with the setting up of the national body.

AN ALTERNATIVE APPROACH TO THE PROSTATE

PRELIMINARY REPORT

BY

G. T. WATTS, F.R.C.S.

Senior Surgical Registrar, Professorial Surgical Unit, Queen Elizabeth Hospital, Birmingham

Since the introduction in 1945 of the retropubic operation for prostatectomy by Millin (1947) many surgeons have come to regard it as the standard procedure. That it had certain drawbacks, however, was shown by the continued use of the suprapubic and other routes by others. These various operations were well discussed by Winsbury-White (1948) and by J. Cosbie Ross (1954).

The two other most favoured alternatives to these operations are the perineal and per-urethral routes, each with its own complications and presenting difficulties of execution to any except the most expert.

It was found that the principal drawback to the retropubic operation was the difficulty in closing the capsule after removing the gland; this was not obviated when using a vertical incision into the prostatic capsule, as when it was opened the tension retracting the side of this incision caused the lower end of it to split down further and made it very difficult to close. Another drawback was the difficulty of seeing the ureters easily. The Wells operation was found to be much more satisfactory and simple to perform, except when securing haemostasis, when it was impossible to guarantee a good view of the prostatic bed; on the other hand, the ureters were easily seen and it was possible to inspect the interior of the bladder without the necessity of using a cystoscope beforehand.

Bearing this in mind, the procedure described below was adopted; this gives all the advantages of the Wells operation and also allows the same excellent view of the prostatic bed as is obtained in the Millin operation. Closure is easy, since the incision is a vertical one and can be closed with an ordinary needle-holder and half-circle needle; also, as is shown below, there is no tension that is likely to cause a split downwards at the bottom of the incision. Haemostasis is easier by this route than by any other tried.

Operative Procedure

Preparation for the operation is the same as that normally followed for prostatectomy. Catheterization should be kept to a minimum; therefore we do not routinely empty the bladder or cystoscope the patient. Unfortunately many of the patients were admitted with acute retention of urine, having already been catheterized several times. Intravenous pyelograms and blood chemistry estimations are carried out and arrangements for transfusion are made, although this last should not normally be necessary. Operation is carried out under general anaesthesia with the patient in the supine position; a slight Trendelenburg tilt is occasionally helpful, but not absolutely essential.

The usual skin incision is employed, preference being given to the transverse one, but there is no necessity to use this. The muscles are retracted and the peritoneum is pushed up in the normal way. Next, the bladder is freed below by swab pressure to display the puboprostatic ligament and the upper part of the gland. Then, while the bladder is gently drawn up by the pressure of a gauze swab, a thread suture is inserted to encircle the vein coming up on the front of the gland. The ligament should not be torn while this is done

or there will be troublesome bleeding. The stitch should also be deep enough to take a firm bite into the capsule of the gland; this serves to prevent the capsule splitting downwards later on and causing difficulty in its repair. This suture is left long as a guide when the wound is closed.

The bladder is picked up about 1½ in. (4 cm.) above the prostate and opened with a scalpel. Any urine inside is sucked out and the incision extended with scissors, downwards to the prostate and upwards enough to allow the introduction of a self-retaining retractor such as the Millin type. Two catgut stay sutures are inserted at the bottom of this incision on either side, passing through the muscle layers only

Diagram illustrating technique of the operation.

and not through the mucosa. The prostate is infiltrated with a solution of normal saline (about 20 ml., to which a few drops of adrenaline may be added with advantage). This makes separation of the adenoma easier and reduces bleeding. A small silver probe is inserted into each ureter as a guide to its position in the next stage (this is easier if the last ½ in. (1.3 cm.) of the probe is bent to a right angle). A circular incision of ½ in. (1.3 cm.) radius is then made around the internal urethral meatus, using the diathermy needle. Posteriorly a notch is cut back between the ureters. When the correct depth has been reached a plane of cleavage appears, usually at about ½ in. (0.6 cm.). At this stage the probes are removed from the ureters.

The incision is continued forwards in the midline to the bottom end of the incision in the anterior bladder wall and

over the front of the prostatic capsule between the stay sutures to within ¼ in. (0.6 cm.) of the thread suture inserted earlier (see Fig.). The adenoma is freed on all sides, using a long pair of scissors and dissecting forceps, until it is held only at its apex by the urethra; as this is being done the prostatic vessels are seen on each side and are clamped and coagulated by diathermy. The adenoma is then drawn gently up with a vulsellum and the urethra divided under direct vision. A gauze pack is inserted into the prostatic bed and left for a few minutes. It is then withdrawn and any bleeding points are coagulated. A whistle-tip catheter is passed through the urethra. The wound is closed with a continuous plain No. 1 catgut suture through the prostatic capsule and the muscular layers of the bladder only. It is started at the bottom of the incision in the prostatic capsule, and, after reaching the top, returns as a second layer invaginating the first. A few further sutures are used over these for reinforcement and the stay sutures are tied together. The cave of Retzius is drained for forty-eight hours. The wound is then closed in the usual way.

The bladder is washed out with a solution of sodium citrate before the patient is returned to the ward and a few ounces of the solution are left in the bladder for the first few hours. The bladder is subsequently washed out only if necessary, and the urethral catheter is removed in about forty-eight hours, or when the urine is clear.

In cases where long-standing distension of the bladder has made it likely to be atonic, the catheter is sometimes left in a little longer; some of these cases respond very well, however, to small oral doses of carbachol.

Illustrative Case Records

Case 8.—This patient, aged 53, first presented with clot retention of urine and a history of haematuria for seven months; he had had frequency of micturition day and night for several years and a very poor stream. He refused operation and was treated as an out-patient by his own doctor for a week by catheterization. At operation a large benign gland with a prominent middle lobe was removed, together with six bladder stones. The urine was infected with *Staphylococcus aureus*, which was sensitive to penicillin. Urine was passed on the second day without any difficulty within two hours of removal of the catheter. The infection cleared rapidly on penicillin.

Case 9.—After a partial gastrectomy for a high lesser-curve ulcer, this patient, aged 78, developed acute retention of urine on the third post-operative day. Owing to his age and the absence of previous urinary symptoms he was catheterized repeatedly, but still failed to pass urine after ten days. At operation a small adherent gland was removed.

TABLE I

Case No.	Age	History	Hb (%)	Previous Cath.	Blood Urea (mg./100 ml.)	Infection (Pre-operative)	Anti-biotics	P.U. (Days)	Wt. of Gland (g.)	Pathology
1	73	Many years' difficulty. D/N=12/4. Acute retention 1 day	82	+				3	40	Benign
2	88	Several years' frequency. Acute retention 2 days	104	+	33	+	S, A, O	4	90	"
3	84	Several years' frequency. Acute retention 2 days	78	+	48	+	S	3	—	Adenocarcinoma
4	82	1 month's frequency and difficulty. Acute retention 2 days	94	+	28	+	S	3	50	Benign
5	65	Several months' frequency. Acute retention 3 days		+		+	S, C	2	60	"
6	70	2 years' frequency. Acute retention 5 days	114	+	51			2	42	"
7	72	No frequency. Acute retention 8 days	77	+	27			5	26	"
8	53	Gross frequency. 7 months' haematuria	98	+		+	P	2	90	Benign; bladder stones present
9	78	Acute retention 3 days after partial gastrectomy	86	+	45	+		3	17	Adenocarcinoma
10	63	Cardiac failure 1 year, with pre-renal uraemia. Acute retention 2 days	50	+	265			3		Benign with calculi
11	69	Acute retention 1 day		+	41	+	S	2		Benign
12	61	Several years' frequency. Acute retention 1 day	74	—	54			4		"
13	81	Acute retention 2 days	70	+	83			2	90	"

P=Penicillin. S=Streptomycin. A=Chlortetracycline. C=Chloramphenicol. O=Oxytetracycline.

Urine was passed on the third post-operative day, within two hours of removal of the catheter. The infection of the urine (*Streptococcus faecalis*) was resistant to all antibiotics but cleared spontaneously within a few days of operation. Histology showed an adenocarcinoma of the gland.

Case 10.—This patient, aged 63, was under treatment for cardiac failure and chronic bronchitis; there was gross oedema and venous congestion, and when first seen he was uraemic, with a blood urea of 190 mg. per 100 ml., and semi-comatose. Catheterization, however, showed that, although there had been a past history of frequency and difficulty in micturition, the uraemia was due to renal failure. A week later the urinary output improved and he developed acute retention of urine. He was then slightly more conscious, although his blood urea had risen to 265 mg. per 100 ml. At operation a very small adherent fibrous gland, containing calculi, was removed. Urine was passed on the third post-operative day, but the bladder was somewhat atonic and it was necessary to give carbachol orally for a week before normal micturition was fully established. The cardiac and renal functions improved slowly but steadily.

Case 11.—On admission this patient, aged 69, had acute retention of urine due to a large diffuse hypertrophy of the prostate; there had been no urinary symptoms until a few days before admission. He had been catheterized several times. At operation a large gland was found and enucleation was easy. Urine was passed on the second post-operation day, within two hours of removal of the catheter; an infection with *Staph. aureus* cleared spontaneously after operation. (Streptomycin was given, but it was later found that the organism was resistant to this antibiotic.)

Discussion

The operation described above compares favourably with other standard routes. The results of the cases so treated are summarized in Table I. There have been no operative deaths in this series, despite the fact that patients up to the age of 88 (Case 2) and with blood urea levels as high as 265 mg. per 100 ml. (Case 10) have been treated. The greatest difficulty has been caused by infection from pre-operative catheterization. No other complications have occurred to date, although it is of course possible that pyelonephritis, renal failure, and reactionary or secondary haemorrhage could occur in these cases under propitious circumstances. The improved exposure, of course, makes the likelihood of haemorrhage much less than in either the retropubic or the suprapubic route. Suprapubic leak has not been a problem, owing to the fact that it is much easier to close this incision than a retropubic one; it is more difficult to close, in fact, than an ordinary suprapubic cystotomy. In no case has control of micturition been impaired.

The indications for this operation are the same as for any form of prostatectomy, as the advantages of both suprapubic and retropubic approach are combined. There does not seem to be any type of prostate which cannot be dealt with by the anterior route. The only contraindications are those affecting the patient's general health, although here again the greater ease with which the operation is carried out gives the surgeon a much wider scope. Infection, though troublesome, is not a contraindication, and often appears to

settle much more rapidly after the operation than would be expected merely from the administration of antibiotics—for example, Cases 9 and 11, where the organisms were "resistant." A brief analysis of the results is given in Table II.

The only other operation which allows a view of the bladder and prostatic bed is that described by Ogier Ward (1948, 1949), but the prostatic capsule is not opened in front and the field of view is much more restricted than in the operation described above. It is felt that the advantages of this operation lie principally in the fact that it is simple to perform and less likely to give rise to trouble in the hands of the general surgeon than the other more complicated operations at present in use.

Summary

A new but simple method of exposing the prostate was sought to combine the advantages of the retropubic and suprapubic routes. In the former, difficulty in closing the capsule is a problem, but there is an excellent view of the prostatic bed. In the latter, closure is easy but haemostasis difficult; there is, however, a good view of the bladder and ureters.

In this operation both bladder and prostatic capsule are opened by a vertical incision. A suture at the lower end prevents a split downward. Incision of the bladder mucosa, enucleation of the adenoma, coagulation of vessels, and division of urethra are all done under direct vision. Closure is by continuous suture.

The results of a small series of cases are given which compare favourably with those of other methods in current use. There were no complications.

The advantage of this approach is that all steps are taken under direct vision and the operation is therefore made much easier.

I thank Professor F. A. R. Stammers and Mr. Hugh Donovan for their help while I was preparing this paper; Mr. D. M. Morrissey for his constant encouragement; Mr. J. B. Leather, Mr. A. Innes, and Dr. C. F. Hawkins, who kindly allowed me to operate on their patients; and, not least, Sister Jones, on whom fell the burden of post-operative care.

The World Federation for Mental Health has now published the proceedings of its eighth annual meeting, held in Istanbul, August, 1955, under the title "Family Mental Health and the State." The proceedings are divided into seven parts, the first being devoted to the inaugural ceremony with the addresses of welcome by Dr. BECHET UZ, Turkey's Minister of Health and Social Welfare, and Professor F. K. GÖKAY, Governor-Mayor of Istanbul, and the presidential address on the peaceful use of human power by Dr. F. FREMONT-SMITH. The second section, on mental health and family life, has papers on normal, delinquent, and handicapped children. Contributors are Dr. K. SODDY, Dr. E. NOYAN and Dr. H. BILGINER, Professor N. KUNTER, Dr. J. RIOCH, Dr. A. REPOND, Professor A. C. PACHECO E SILVA, and Dr. P. DOUSSINET. Dr. R. SPITZ's contribution on emotional stress and its consequences makes the third section. The fourth section is on education, the contributors being Mr. C. HAMBRO, Dr. B. ARKAN, and Mr. M. ENÇ. Section five deals with cultural change and mental health, Dr. MARGARET MEAD introducing a panel session with speakers from Turkey, Thailand, Lebanon, Israel, Iran, Yugoslavia, Cyprus, and Malaya taking part. Finally there are reports of the work of the United Nations and its specialized agencies, and an account of the closing session. A copy of the report may be obtained from the W.F.M.H., 19, Manchester Street, London, W.1, price £1.

ADHESIVE STRAPPING FOR UMBILICAL
HERNIA IN INFANTS

CLINICAL TRIAL

BY

J. C. HAWORTH, M.B., M.R.C.P., D.C.H.

Senior Medical Registrar, Children's Hospital, Sheffield

The infantile type of umbilical hernia is a common condition. Its frequency has been estimated as about 1:6 in English babies (Woods, 1953), and 40% of American negro babies are affected (Crump, 1952). While it is a benign condition so far as complications are concerned, strangulation being very rare, it is often a cause of much anxiety on the part of the mother both because of the disfigurement and because various symptoms such as "wind" and "colic" are attributed to it. It is known that almost all these hernias disappear spontaneously during the first few years of life (Browne, 1952; Crump, 1952; Gross, 1953; Woods, 1953), but in spite of this there is a difference of opinion amongst authorities concerning methods of treatment, or indeed whether any treatment is necessary at all. Whereas it is generally agreed that operation should be delayed until it is fairly certain that natural resolution is not going to occur (3 years of age was suggested by Barrington-Ward, 1947), there is little agreement about the advantages of mechanical reduction by the aid of adhesive strapping. Barrington-Ward (1947), Browne (1952), and Gross (1953) stated that adhesive strapping hastens disappearance of the hernia, but Woods (1953) felt that strapping is not only useless but in fact delays natural cure.

This paper is the report of a clinical trial carried out over a period of two and a half years to determine whether the application of adhesive strapping to umbilical hernias affected the natural cure rate.

Method

Only babies who were less than 12 months of age when they were first seen were accepted for the trial, and babies whose hernias had previously been kept efficiently reduced were excluded. (Elastic adhesive plaster and "pennies and binders" were not considered efficient methods of reduction.) Alternate cases were strapped and the others, who were not treated in any way, served as controls.

Only true umbilical hernias were included in the trial. Cases of supra-umbilical or linea alba hernias or babies with cutis navel were excluded. Mongols, cretins, and babies with general muscular hypotonia were also excluded. With some of the smallest hernias it was sometimes difficult to be sure whether a hernia was present or whether there was merely a cutis navel. Hernia was diagnosed only if the protrusion at the umbilicus could be reduced easily by digital pressure and a defect in the linea alba was palpated.

The size of each hernia was measured as accurately as possible from the skin of the abdominal wall to the highest point of protrusion. Protrusions of $\frac{1}{4}$ in. (6 mm.) or less were described as "small" and those of more than $\frac{1}{4}$ in. as "big." The smallest diameter of the oval defect in the linea alba was also measured by comparing its size by palpation with the size of holes of known diameter bored in a wooden gauge.

The method of strapping was that described by Gross (1953), using two pieces of 2-in. (5 cm.) non-elastic plaster and threading a tongue cut in one through a hole cut in the other. The skin was first painted with tincture of benzoin to increase adhesion, and the plasters were applied so that there was a gap between them at the back. An

assistant reduced the hernia by pinching the skin into a vertical fold over the hernia and the plasters were then pulled tight. A strip of 3-in. (7.5-cm.) plaster was then applied on top of the 2-in. (5-cm.) plasters. All cases were strapped for four weeks, although the plasters were changed after two weeks, the reduction of the hernia being maintained while this was done. After four weeks the strapping was removed, but if the hernia was still an appreciable size the strapping was reapplied for a further two weeks and occasionally for another two weeks after that. Thus no case was strapped for more than eight weeks. If, however, only a minimal protrusion was seen when the strapping was removed after four weeks, no further strapping was applied, but the hernia was observed until it disappeared.

Cases used for the final analysis were those in which (1) the hernia had disappeared before 12 months of age—that is, the "successes"; and (2) the hernia had not disappeared by 12 months of age—the "failures."

Results

Of the 100 cases which qualified for the final analysis, 80 were successes and 20 failures; 51 babies had their hernias strapped and 49 served as controls. There were 66 males (34 strapped and 32 controls) and 34 females (17 in each group).

Analysis of Cases Using Measurement of the Hernial Protrusion.—Table I shows the results. Unfortunately the "big" and "small" hernias are not evenly matched in the two groups, but the numbers are large enough to show

that, whereas the difference in the rate of disappearance of the small hernias in the strapped and control groups was slight, 87% and 75% respectively having resolved by 6 months and 100% and 96% by 12 months of age, the big hernias in the strapped group had a much higher success rate than the controls. At 6 months of age 67% of the strapped group had resolved, whereas only 9% of the control group had done so. At 12 months the figures were 80% and 43% respectively. These figures are statistically highly significant.

Analysis of Cases Using Measurement of the Umbilical Defect.—Table II shows the results in the two groups when analysed in relation to the diameter of the defect. Here the numbers are evenly matched in the strapped and control groups, and they show that the hernias with the small defects tended to resolve slightly quicker than those with

big defects; the latter, however, resolved much more rapidly in the strapped group than in the control. The figures of resolution at 6 months of age, however, where the differences appear to be greatest, are not quite significant statistically. Table III shows the correlation between the size of the protrusion and the size of the defect. It is seen that three-fifths of the big protrusions came through

TABLE III.—Correlation Between Size of Protrusion and Size of Defect

Size of Defect	Size of Protrusion	
	Big (> $\frac{1}{4}$ in.)	Small ($\frac{1}{4}$ in. or Less)

strapped when they were 1 to 2 months old. Neither of the two babies first strapped when over 6 months of age had resolved by 12 months, and when followed up after 12 months neither had resolved at 14 and 28 months respectively.

"Failures."—There were 20 failures in the two groups. One big hernia in the control group had resolved when seen at 14 months of age. The remaining 19 hernias had not resolved at the time of writing, and Table V shows the

TABLE V.—Ages of the "Failures" When Last Seen

Age in months ..	12-17	18-23	24-29	30-36
No. of cases ..	8	3	7	1

ages of the babies when they were last seen. Of the seven failures in the strapped group, two, as already mentioned, were strapped when over 6 months of age. One other case had a supra-umbilical hernia in addition to the umbilical hernia, and a thin band of fibrous tissue separated the two defects; the umbilical hernia, which had previously been big, became much smaller after it had been strapped for four weeks, but it had not quite gone when the baby was 12 months old, the supra-umbilical hernia showing no alteration in size. One case developed pertussis and another chronic bronchitis after the hernias had almost resolved with strapping, but the severe cough in both cases caused recurrence and further strapping was without effect. In two other cases the maximal protrusion was through the upper edge of the umbilical scar, and the hernias were probably what Browne (1952) has called "semi-umbilical." According to him these have a poor prognosis so far as spontaneous regression is concerned. One other similar baby in the strapped group, however, had resolved by 9 months of age. Three of the failures in the control group also had severe coughs, but the remainder were uncomplicated.

Complications of Strapping.—On the whole the babies in the strapped group tolerated the strapping well. Occasionally a mother would complain that her baby seemed to have discomfort when the strapping was first applied, and in two cases strapping had to be abandoned

because of excessive discomfort or soreness of the skin. These cases were, of course, excluded from the trial. Of the 51 babies who had strapping applied for four weeks or more, 13 suffered from mild excoriation or skin sepsis.

Discussion

The results of this investigation confirm the belief that umbilical hernias in infants have a great tendency to disappear spontaneously during the first few months of life, but they indicate that the natural cure rate depends upon the size of the hernial protrusion. Table I shows that by the age of 12 months nearly all (96%) untreated small hernias had disappeared, whereas less than half (43%) of the big hernias had resolved by the same age. In Woods's (1953) series of umbilical hernias 93% underwent spontaneous resolution in the first year of life, and she thought that severity did not influence the prognosis.

The results also indicate that adhesive strapping greatly increased the cure rate of the big hernias, but had little or no effect on the small ones. The percentage of successes in the strapped group might have been higher if two of the babies had not developed a severe cough. Woods (1953) pointed out that an umbilical hernia may first appear during pertussis or recur after apparent cure. It will be seen that there was no baby with the usual type of umbilical hernia who did not develop a cough, and whose hernia was strapped before 6 months of age, that was not cured by 12 months. Of the 13 failures in the control group, 3 developed a cough and 10 were uncomplicated.

The results of this clinical trial therefore demonstrate that: (1) If an umbilical hernia in a baby protrudes more than $\frac{1}{4}$ in. (6 mm.) and is efficiently reduced by adhesive strapping for at least four weeks, there is a much greater chance that the hernia will have resolved by 6 or 12 months than if no treatment is given. (2) Strapping after 6 months of age is probably useless. (3) No advantage is to be gained by strapping a hernia which protrudes only $\frac{1}{4}$ in. (6 mm.) or less, and possible skin irritation makes it inadvisable to do so.

The sex ratio of two males to one female in this series of 100 cases of umbilical hernia is unusual, and no similar sex ratio has been found in other series reported in the literature. For instance, Barrington-Ward (1947) wrote that umbilical hernia "is usually found in the female." Gross (1953) recorded a ratio of two females to one male, while Paterson and Gray (1927), Carter (1932), and Crump (1952) recorded an equal sex incidence.

Summary

A clinical trial was conducted to determine the efficacy of adhesive strapping for umbilical hernias in infants.

It was found that, while nearly all untreated umbilical hernias had resolved by 12 months of age if the protrusion was small, if the protrusion was more than $\frac{1}{4}$ in. (6 mm.) in size strapping greatly increased the cure rate. Strapping of big hernias before the baby is 6 months old is advocated.

In this series of 100 cases the proportion of males to females was two to one.

I am indebted to Dr. T. Colver, Professor R. S. Illingworth, and Mr. R. B. Zachary for kindly referring babies to me and for much helpful advice in the preparation of this paper. I am also grateful to Dr. J. Pemberton, of the Department of Social and Industrial Medicine of the University of Sheffield, for his help in testing the significance of the results. A number of family doctors in Sheffield referred cases to me, and to these I should also like to express my thanks.

Medical Memorandum

Rupture of the Rectovaginal Septum at Parturition

Isolated rupture, at parturition, of the rectovaginal septum without involvement of the perineum is a very rare obstetrical accident. In this condition the sphincter mechanism remains intact in contrast to the more common injury to the septum which is due to extension into it of a third-degree perineal laceration.

McNulty (1952), in a series of 75 cases of third-degree laceration occurring in a total of 14,080 patients, makes no reference to rupture of the septum; neither does Hofmeister (1952) in his paper on repair of rectovaginal injury occurring at parturition, or Dodek (1954) when writing about similar accidents. Kerr and Moir (1949) mention an instance of rupture of the rectovaginal septum in a patient with a breech presentation at the Glasgow Royal Maternity Hospital. Eight years ago I saw an identical case at the Royal Maternity Hospital, Belfast, when one foot presented through the vagina and the other through the anus. A similar accident is described by Lesh (1952) as occurring with the first of twins. The only record in English that I can find of rupture of the rectovaginal septum occurring in a vertex presentation is that of Melody (1953), although French and German writers have described such incidents. Melody (1953) describes a case occurring in a woman following delivery of her second child by outlet forceps and medial episiotomy. The entire delivery, he states, was easily effected and there was no extension of the episiotomy. On inspection of the posterior vaginal wall, however, a complete rupture of the rectovaginal septum was discovered which extended for a distance of 10 cm. without involvement of the episiotomy or of the anal sphincter.

CASE REPORT

The patient was a primigravida aged 36 who had had a completely normal antenatal period. Labour began at the 38th week. The os became fully dilated after 14 hours. Advance was slow in the second stage. This had been attributed to lack of co-ordination due to the patient having received "omnupon," $\frac{1}{2}$ gr. (22 mg.), and scopolamine, 1/30 gr. (2 mg.), in the four hours preceding delivery. When the head had been on the perineum for half an hour it was decided to deliver with forceps. During the preliminary vaginal examination a peculiar tight band was felt posteriorly in front of the head, near the introitus, but this caused only a momentary hesitation and it was decided the impression was created by a tight fourchette. After medio-lateral episiotomy a live male infant weighing 7 lb. 1 oz. (3.2 kg.) was delivered, using only moderate traction. There was no extension of the episiotomy. It had been intended to repair the incision with subcuticular figure-of-8 catgut sutures, starting posteriorly. It was not until the second of these was being inserted that anything unusual was noted.

An abnormal white appearance in the depths of the wound led to further exploration, which showed that the rectovaginal septum had split for a distance of 4 in. (10 cm.) in the midline posteriorly. The apex of the tear was in the posterior fornix and its distal portion extended into the episiotomy. The white appearance was due to the rectal epithelium. The rectal mucosa and muscularis were closed with a continuous row of intestinal chromic catgut. Another continuous row of the same material approximated the perirectal fascia as a separate layer. In the lower part of the wound the perineal body was reconstituted with interrupted catgut. The vaginal mucosa was then closed with interrupted sutures. This was simple at the apex of the tear, but where the septal split met the episiotomy the vaginal epithelium was badly lacerated and its vitality must have been grossly impaired by the necessity for the introduction of many stitches in different directions. The only comforting factor was the presence of a firm mass of

perineal tissue between the patchy, saggulated vaginal epithelium and the rectal mucosa at this level. The perineal skin was closed with three nylon sutures.

Obstipation was obtained by means of a low-residue diet for five days. An attempt to sterilize the bowel was made by giving streptomycin by mouth for the first two days as well as phthalylsulphathiazole, 10 g. daily for the first week. Penicillin and streptomycin were also administered parenterally. The bowels moved on the fifth day, following which all therapy was stopped and a normal diet resumed. The patient remained afebrile in hospital and was discharged, doing well, on the 13th day along with her baby, which then weighed 7 lb. 3 oz. (3.26 kg.) and was being artificially fed.

On the 20th day she was seen again because of pain in her perineum. She had developed a small abscess in the anterior part of the episiotomy wound, which at the time of examination had started to discharge with consequent lessening of pain. The discomfort ceased quickly and the perineum healed rapidly following the discharge of a small piece of catgut.

A post-partum examination was made at the sixth week. No evidence of the tear could be seen. The calibre of both rectum and vagina felt normal. The episiotomy was well healed, with no discomfort. Involution was satisfactory. Bowel action had always been normal.

COMMENT

Melody (1953) attributed the accident in his case to loss of mobility of the vaginal tube upon the rectum, due to scarring and fixation following Whitehead's haemorrhoidectomy. Other cases have been attributed to vaginal stenosis following circumcision and to rupture of a retro-uterine haematoma.

In this instance, however, there has been no previous involvement of the rectovaginal septum in trauma or inflammation of any sort, and no reason can be advocated for the unusual accident. The patient afterwards volunteered the information that because she was "so small inside" she always had some difficulty with coitus. In retrospect it is obvious that what had been thought to be fourchette was really a fold of the tight rectovaginal septum stretched to the point of rupture. If its significance had been realized, delivery probably would have been effected by caesarean section.

The main problems which the case poses are (a) the method of repair of the actual injury, and (b) the method of delivery in future pregnancies. The second problem is the more easily answered: I feel that all future deliveries should be by caesarean section. With regard to the principles of the repair of such a tear, opinions differ. I cannot see the necessity of sacrificing the sphincter mechanism by converting the wound into a typical third-degree laceration. The advantages are better access at the time of operation and a reduction of sphincteric tone during convalescence. The latter, however, can be readily obtained by other methods. Any anatomical advantage gained by producing a third-degree tear is offset by the increased trauma that has been caused and by the marked increase in bleeding which will occur. Since the introduction of powerful antibiotic and chemotherapeutic agents, the question of colostomy should not, in my opinion, arise—yet such was mentioned by several colleagues in discussion of the case. The similar injuries described by Kerr and Moir (1949) and Melody (1953) all healed satisfactorily without colostomy and without conversion into a third-degree laceration.

Reviews

STORY OF A STRUGGLE

More from the Primeval Forest. By Albert Schweitzer. (Pp. 128. 6s. 6d.) London: Adam and Charles Black. 1956.

The story of a struggle seldom fails to fascinate, and here there is struggle and difficulty enough to make a tale fascinating, together with all the thrill of ultimate achievement. Through his work in many fields Dr. Schweitzer has become something of a legend already during his lifetime; by many he has been idolized in a way which renders objective assessment of his work difficult, and it can be no disparagement to make up this book are similar to those which have been overcome by many hundreds of medical missionaries. Rather does the insight which he gives into their work make their achievement the more memorable.

The world has never failed to be amazed that Dr. Schweitzer should have chosen to use his talents in the "primeval forest." This book goes some way towards enabling one to understand his choice, for it reveals the intense interest he has in human nature, the satisfaction he obtained in building his hospital and superintending its work, and the feeling he has that the work is supremely worth while. The narrative consists of an account of his second period at the hospital at Lambaréne which he established in 1913 and left in 1917. Returning in 1924, he found it in a state of decay and rebuilt it, and then, finding the premises inadequate for the work as it developed, he decided 18 months later to construct an entirely new one. The labour involved was great and there were many difficulties, but the book ends with the main buildings complete and Dr. Schweitzer embarking for leave in Europe feeling that it is "incomprehensible that I am leaving the natives that I am so fond of them one becomes in spite of all for months. How fond of them one becomes in spite of all the trouble they give one." There are many anecdotes giving insight into the thoughts and feelings of the people with whom Dr. Schweitzer dealt. On one occasion, while himself piling timber, he asked an African visiting the hospital to help him. "I am an intellectual and don't drag wood about," came the reply.

Unfortunately the pleasure in reading the book is marred by the appalling English into which it is translated. The Germanic construction of sentences usually remains, the present tense is used almost throughout, and there are several simple errors; thus the town Buea appears as Buca, and "recuperate" as "recruit." The tale, however, lives; it has considerable vitality and will interest all who have practised medicine in the Tropics.

A. W. WOODRUFF.

OBSTETRICAL ANAESTHESIA

Anesthesia for Obstetrics: Labor—Delivery—Infant Care. By Robert A. Hingson and Louis M. Hellman. (Pp. 344+ xvi; illustrated. £5.) Philadelphia, Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

The number of books on this subject which have appeared during the last year or two must reflect a considerable surge of interest on the part of both anaesthetists and obstetricians. This is to be welcomed, and must be but one of the results of the publicity which has been given to recently available information on the frequency with which death or near death occurs in these circumstances. It is now realized that anaesthesia is probably the most important factor involved in death during operative obstetrics. From the point of view of efficacy, too, the current methods of analgesia and anaesthesia still leave a lot to be desired. None is both wholly safe and wholly effective.

The present book is an extension of one, the third edition of which appeared eight years ago, written by Drs. Lull and Hingson. Dr. Hingson is now joined by another obstetrical colleague, Dr. Hellman, and between them they have produced a comprehensive, vigorous, provocative, and informative monograph. Anaesthetists in particular will recognize Dr. Hingson's vivid and attractive personality on every page. While the authors of course stress those methods of which they have had special experience, they do not, like some other American writers, ignore or dismiss too briefly methods, such as "trilene and air," more popular in Britain. A full description will be found of Dr. Hingson's own portable, miniature anaesthetic machine for administering non-explosive mixtures of cyclopropane, which is likely to be useful not only in obstetrics but in other fields as well. Particular views are naturally put forward on many subjects, but they are always admirably supported by evidence—usually statistical. The section at the end deals with infant pathology and morbidity, as well as with maternal and infant resuscitation. Details are given, too, of the organization of an anaesthetic service for a busy obstetrical department.

This book will not please everybody, for it presents its often unorthodox material boldly, but it is certain to stimulate every reader whatever his views. The illustrations, index, and general production of the book are all excellent. Drs. Hingson and Hellman have made a major contribution to this still comparatively undocumented field of anaesthetics.

W. W. MUSHIN.

RADIOLOGY OF THE DIGESTIVE TRACT IN INFANTS

Radiology of the Alimentary Tract in Infancy. By Roy Astley, M.B., M.R.C.S., D.M.R. (Pp. 287+viii; illustrated. 50s.) London: Edward Arnold (Publishers) Ltd. 1956.

Paediatric radiology has made great strides in recent years, and in no particular field has it proved more useful than in the congenital anomalies presenting as surgical problems in the newborn. Dr. Astley, in writing of the radiology of the alimentary tract in infancy, has helped greatly in clarifying the conditions, and, although the book is intended primarily for radiologists, paediatricians will find much of value. The book follows a caudad course from the oesophagus to the rectum, and there is a final chapter on miscellaneous conditions involving liver, spleen, pancreas, mesentery, omentum, and retroperitoneal and pelvic structures. Many of the conditions described are rarities, but nevertheless merit inclusion; others are commonplace but still often too little understood. The sections on the oesophagus and diaphragm are particularly good. Common sense pervades the text, and it is clear that radiology is considered throughout as an aid to diagnosis rather than a convenient method of by-passing full clinical examination and investigation. Its limitations are fairly stated. Many interesting findings are reported, including cases of rumination which were associated with gastro-oesophageal incompetence and partial thoracic stomach. There are excellent references at the end of each section, and these are followed by illustrative case histories and practical comments. The book is well produced and the illustrations and their accompanying captions are clear and concise. The author and publishers are to be congratulated on their contribution to paediatric literature.

WILFRID GAISFORD.

The second edition of *Techniques and Procedures of Anaesthesia*, by John Adriani (Blackwell Scientific Publications, Oxford, price 66s.), has brought up to date this very popular technical manual. The compressed and tabulated material is naturally based on the American practice of anaesthesiology. It will nevertheless serve as a means of ready reference in this country, particularly to junior anaesthetists. It is essentially a book on how and not on when and why. Within these limits this is a first-rate book.

SATURDAY DECEMBER 1 1956

A CRISIS OF CONFIDENCE

The legal advisers to the Minister of Health disagree with the legal opinion of Sir James Millard Tucker on the nature of the Government's obligation to carry out the recommendations of the two Spens Committees. The argument for the profession was carefully and at length set out in a document of 6,500 words published in the *Supplement* of July 28. The Government's reply is a letter of 94 words from Sir John Hawton (*Supplement*, p. 201). There are times when brevity is a merit. There are also times when it is mere discourtesy, and this is one of them. The Ministers give the profession the lawyer's advice to take the matter to the courts. The Ministers evidently stick to the completely untenable interpretation of the Spens recommendations that they applied only to the time of entry into the N.H.S., to the view, in other words, that the readjustment to the post-war value of money related only to the post-war year of 1948. The profession will have only one interpretation of the present Government's attitude and action—that it has broken faith with it. Mr. Turton, it is true, is doing little more than follow the line laid down by his predecessors, starting with Mr. Bevan, in trying to wriggle out of the recommendations made in the two Spens reports. It is now crystal clear that the Government's original acceptance of these was insincere, and until now the profession has for nearly nine years been reluctant to believe that was the case. But the fact is that it was, and has been so all along the line of a series of Ministers of Health who have done little else but try to make political capital out of the medical benefits they think they have bestowed on the country. We have had amply demonstrated to us that medicine and politics do not mix, something the profession has always instinctively known but has been rather reluctant to admit without trial. Maybe the trial was necessary to bring home the painful truth that in medical politics the professional

politician and his expert administrators know a few more tricks of the trade than those medical men who devote themselves unselfishly in their spare time to serving the profession in this intricate field. That the N.H.S. has operated without any major breakdown is due solely to the fact that the long tradition of the medical profession has ensured that the patient would not suffer. The present crisis is something far deeper than a mere question of payment for work done in accordance with Governmental promise. It is a crisis of confidence between Medicine and the State. It brings to the fore the question of the soundness of the National Health Service in its present form. It is this, more, perhaps, than the remuneration of doctors, that demands investigation by the profession from the base upwards.

What is to be done? The British Medical Association is faced with a grave task, to tackle which will require all its long experience and expertness in this field. The B.M.A. is no more free from faults than any other great organization founded on the principles and practices of a free democracy, which include freedom to think, to speak, to assemble, to criticize; and freedom to disagree. But the Association is the only professional organization that can and does represent each and every branch of medicine. The medical profession has established the Association to do certain jobs, and has seen that it is equipped to do them. Of course it needs the assistance of other groups of medical men, whether organized in societies, corporations, or colleges; it needs their help, their wisdom, the variety of their outlook and experience. But in what may turn out to be a long struggle to put right those things that are so patently wrong in the medical services of this country—and more particularly in the relationship between Medicine and the State—there should be one spearhead of attack if the attack is to be driven home and effective. Unity does not mean singing in dull unison, but it does mean singing in harmony. There is urgent need for still closer consultation between those representing consultants and those representing general practitioners with the Association that represents them both, so that policies may be co-ordinated and action be made strong and organized by the body set up by the profession to maintain its honour and interests.

Those entrusted by the profession with the negotiations over pay that have been going on since February this year met on Wednesday this week. At the time of going to press we do not know what immediate steps they will recommend in face of the

present impasse. But their mandate is unambiguous—to insist upon the carrying out of the Spens recommendations. As the Government persists in its obstinate refusal to do this, then the Association will have to decide upon what should be done forthwith as a short-term measure; and then, we suggest, upon the long-term measures that may well embrace much more than the question of how much doctors should be paid for their work. Whatever is decided, the public may be assured—if such assurance is really necessary—that the sick and the suffering will be cared for as they always have been. Doctors all over the country will be infuriated by the cavalier treatment meted out to them, will be disgusted by this present flagrant breach of faith, even though not surprised by it. But the solution of the immediate and cognate problems will call for cool heads, calm reasoning, determination, and unity of purpose. These, we may be confident, will not be lacking under the leadership of the Association.

POISONING BY COAL GAS

A striking increase in the number of deaths due to coal-gas poisoning has been recorded during the last 25 years in Great Britain. In 1931, for example, there were 175 deaths, while in 1955 there were 891, and the increase has been at a fairly steady rate throughout the intervening years. Two years ago an article in this *Journal* by Dr. Keith Simpson,¹ the forensic pathologist, drew attention to what he called "a disquieting toll of life that has for many years been accepted as a natural risk of urban existence." The need for further investigation of these deaths was recognized, and in March, 1955, the Council of the B.M.A. empowered the Science Committee² to set up a subcommittee "to inquire into the problem of accidental death and ill-health from coal-gas poisoning, and to make recommendations." The subcommittee's report, recently approved by the Council, is summarized in the *Supplement* this week.

The figures set out by the subcommittee show that in Great Britain the number of deaths in 1955 was about 5 times the number in 1931, and the increase fell most heavily on older people, for deaths of people aged under 65 increased 2½ times, whereas deaths of people aged 65 and over increased 7½ times. The meaning of these figures is somewhat obscured, however, by changes in the population and by the increase

in the supply of gas. The number of people aged 65 and over increased about 1½ times, rising from about 7½% of the population to 11½%. At the same time the amount of gas sold increased by about 86%. While the relative increase in numbers of old people, who are naturally more liable than the young and active to be the victims of coal-gas poisoning, and the larger supply of gas would cause a greater exposure to risk of death from this cause, the actual numbers of deaths seem to be much greater than would be expected. For instance, the number of deaths per 10⁶ therms sold was 126 in 1931 and 345 in 1955, with a fairly steady increase in between. Thus a part of the increase remains unexplained, and it is all the more puzzling in view of the efforts made by the gas boards to ensure that faulty apparatus is replaced as soon as it is detected. Some data on mechanical defects classified by the Ministry of Fuel and Power for the two quinquennia 1934–8 and 1946–50, and tabulated by the subcommittee, intensify rather than solve the mystery. They show that between these two periods external escapes of gas causing death increased by 74.5%, or by about the same amount as the supply of gas increased. These are accidents for which the supplier rather than the consumer is responsible. By contrast, much the largest increase in causes of death was taps being left open (lighting and cooking burners 311%, cooking ovens 187%, fires 172%). These are accidents for which the consumer is responsible. In between are various causes for which both parties share some responsibility in varying degree, most notably deaths associated with defective internal pipes, meters, and fittings, which increased by 191%. Though the toxicity of coal gas varies slightly from time to time, it cannot account for these changes in the numbers of deaths. Nor does a likely explanation seem to lie in any increase in what have been called the four D's of carbon monoxide poisoning—the decrepit, the diseased, the drugged, and the drunk.³ Possibly increased consumption of barbiturates may have played a part now that better standards of living combine with high taxation to make drunkenness so much rarer than formerly. Further study might be worth undertaking by necropsy in a series of cases to find out what pathological conditions commonly contribute to the carelessness that underlies so many of these accidents. Simpson¹ has recorded some pertinent data.

In a thorough review of preventive measures, most of which are of necessity more the concern of engineers than medical men, the subcommittee draws attention to the local authorities' obligation to look after the health and welfare of old people. "There

² *Ibid.*, 1955, 2, 370.

³ Fiddes, F. S., *ibid.*, 1956, 2, 697.

is no doubt," says the report, "that any changes required to make gas appliances safer and more handy for these people would be a justifiable expense." Health visitors can be encouraged to keep an eye on the hazards of gas appliances in the houses they visit, and the report specially emphasizes, too, the need for "close co-operation between the gas authorities and the many statutory and voluntary organizations which at present are concerned with the welfare of old people."

TEMPORARY THROMBOTIC STATE

As mortality and morbidity from thrombosis continue to increase, the problem of the temporary thrombotic state gains ever greater importance, especially since it has been shown that the fatal thrombus is seldom the only evidence of recent intravascular thrombosis in the body. Man's survival depends on the ability of his blood to remain in a fluid state within vessels. Once blood is removed from the blood vessels it will clot if left in its natural state. Two problems require analysing. First, how is the blood kept from clotting in the blood vessels, and, secondly, how can we recognize an incipient breakdown in this mechanism?

Several factors play a part in the prevention of intravascular coagulation. The most important of these is the presence of a healthy and intact vascular endothelium. The endothelium is probably not a passive lining but has a vital function in preventing coagulation; it may actively stimulate coagulation when damaged.¹ No less important than this factor is the maintenance of a normal circulation rate. Stasis is a recognized and potent stimulus to intravascular thrombosis. J. N. Morris and his colleagues^{2,3} have recently analysed the relationship of occupation to coronary thrombosis and shown that when physical activity was high and therefore stasis was rare the incidence of coronary thrombosis was significantly less. It may well be that the sedentary state or poor posture, with their consequent blood stasis, may be more important than has been hitherto recognized. P. Nolf⁴ suggested that in the normal circulation fibrin is continually forming on the walls of the blood vessels and that a fibrinolytic mechanism then dissolves this deposit. It is worth remembering that fibrin once formed is a most potent antithrombin.⁵ Circulating anticoagulants such as antithrombin,⁶ heparin, and antithromboplastin⁷ are concerned in preventing such a mechanism. The defibrination syndrome of pregnancy shows that such a mechanism as Nolf suggested can in fact occur without the vessels clotting completely.⁸ This view has also received support in recent analyses of the pathogenesis of atherosclerosis and in electron-microscopic studies of atheroma and normal intima.^{9,10}

Interest has recently turned to agents which may increase the coagulability of the blood. The chylomicrons obtained from rat chyle and its active fraction phosphatidyl ethanolamine have been found to shorten the

coagulation time of plasma.^{11,12} This work is of great importance in considering the relation between fat intake and increased tendency to thrombosis.¹³ The finding of abnormal lipoprotein ratios in cases of coronary thrombosis suggests that fat metabolism and the thrombotic state are closely related,¹⁴ but there is no experimental evidence that an increased intake of fat or phospholipids can produce thrombosis *in vivo*. Recent work on serum-induced thrombosis in animals has suggested that factor VII (convertin, S.P.C.A.), or some similar but at present undetermined protein fraction, when present in increased amounts, may precipitate intravascular thrombosis.^{15,16} An increase in the level of factor VII is associated with states that are known to have a high incidence of thrombotic complications.¹⁷ Infection, neoplasms, especially visceral carcinoma,¹⁸ parturition, operations, and trauma are all well recognized as states associated with increased tendency to thrombosis. In animals it has been found that in hypotension the blood becomes hypercoagulable, and coagulation may occur.¹⁹ Platelets have been shown to have an increased adhesiveness in certain states, though it is doubtful if this is due to any abnormality of the platelets themselves, but rather to a property conferred on them by factors in the blood.²⁰ This observation may, however, provide evidence of a tendency to thrombosis.

At present no coagulation test is available which reliably diagnoses the incipient or established thrombotic state. L. Poller²¹ has shown that where clotting times have been estimated in a heparin-sensitized system they are reduced after surgical operations. Further elaboration or modification of known clotting tests such as this may provide the answer, but caution is necessary before they are adopted as routine techniques. Unconscious variations in the technique of venepuncture can shorten *in vitro* clotting times, and this makes analysis of any series a difficult procedure. Many factors complicate this problem. A delicate balance probably exists between the blood trying to clot on one side and various anticoagulant mechanisms on the other. Only one factor need be either more or less active for thrombosis to occur.

GENERAL-PURPOSE OR SPECIALIZED SOCIAL WORKERS?

The World Health Organization renders a singular service to its members by carrying out comparative studies of systems of health care operative in various countries, mainly with the object of demonstrating good and interesting features which might be more widely applied, especially by those whose institutions are in the formative stage. In 1950 W.H.O. and the Rockefeller Foundation, through their European offices, sponsored a study which aimed at defining "the type or types of health and social workers best suited to meet the needs of families with the greatest measure of efficiency and economy." For various reasons it was decided to make a comparative survey of the personnel and activities of the health and social services of England and France. The two countries have much in common in their social and economic development, and yet there is a remarkable contrast in the solutions found by each to the problem of meeting the health and welfare needs of its people. In broad terms, the French social services depend largely upon the general-purpose, or "polyvalent," social workers, while the English make use of a great variety of specialized workers. The report¹ just published has been prepared jointly by Monsieur P. Laroque and Sir Allen Daley. In trying to make effective comparisons between the two countries they met many difficulties. Nevertheless, the survey is intrinsically valuable as a descriptive account, by competent observers on the spot, of contrasting and in some ways complementary systems of health and social work.

The findings of the survey range widely: they include a brief, well-written account of the medical, social, and welfare services in the two countries, and the appropriate legislation; and the authors make a study, based on field work, of the general needs of families in relation to the duties of social workers. A comparison of the ways in which the social workers are brought into action raises interesting points. In England about a quarter of the cases are reached through routine notification and another quarter at the request of the family concerned. The social worker herself takes the initiative in 22% and the family doctor in 14%. Transfers from other social workers account for nearly all the rest. The data from France are not exactly comparable, but routine notifications account for more than half the interventions of the social worker. It is unusual for the *assistante sociale* to be called in by the doctor in attendance. In general, the French social worker is more isolated than the English, but she has fewer duties of a medical nature to perform, except, perhaps, in giving injections. In both countries maternity and infant welfare is the predominant reason for service. In the second place come problems about financial resources, housing, and health. Purely psychological problems occupy a secondary place, although of course they are likely to be discussed on routine visits.

One of the most important questions considered in this report may be summed up in the words "polyvalence or specialization." This is indeed the central theme of the study, but the conclusions are equivocal.

In fact, the difference between the two countries is not so big as had been believed; there are a great many specialized social workers in both countries, and the investigation has not shown any essential differences between the technical methods used by the two types. The report concludes that the action of the specialized *assistante sociale* operates earlier, takes less time, and gets to the root of the problem. The resources at her disposal are greater, but her action is generally remedial and is more effective than that of the general-purpose *assistante*. On the other hand, so far as preventive action is concerned, the specialized worker is likely to be less effective, because she is called in only after trouble has arisen: she cannot nip it in the bud. The general-purpose social worker, however, cannot do all that the specialist can, because her training does not give her the technical knowledge necessary to handle remedial work of any complexity. Yet she is better able to see the family as a whole.

As one might expect, the report tried to make some assessment of the relative efficiency of the French and English social-service systems, but no valid conclusions could be drawn. "In France, as in England, the action of social workers has contributed to a steady and marked improvement in the material and moral condition of the people, and it is to-day an essential part of the health and welfare system, even though it is not possible to assess the relative efficiency of the methods applied in either country." To some readers it may seem disappointing that the report is so inconclusive. Nevertheless, it is rich in factual information, and as a descriptive analysis it is a model of clear writing. The fact that the authors, who must have had to deal with a great mass of basic material, have resisted the temptation to put forward half-digested conclusions makes the report all the more useful as a work of reference.

PRESSURE SUITS IN MEDICINE

Pilots of highly manoeuvrable aircraft are sometimes exposed to a linear centrifugal force acting in the long axis of the body. This force is termed "positive G," because it is measured as multiples of the normal terrestrial gravitational force. Its principal effect is that, at a certain level of intensity, which varies slightly between different individuals, the blood becomes located in the vascular bed of the splanchnic area and lower limbs, with ultimate cessation of the circulation. This undesirable effect can be reduced by the application of controlled external pressure designed to restrict the capacity of the caudal peripheral vascular bed, and it has been for long successfully studied by aviation medical research departments in the armed Forces.

The induced hypotensive state, whether caused by drugs, spinal anaesthesia, or sympathectomy, becomes comparable when the patient is erect and subject to an appreciable gravitational force. This might happen if it became necessary during the course of a surgical operation to change the position of a patient in whom a hypotensive state had been created. P. A. Restall and F. H. Smirk¹ showed that the effects of a deliber-

¹ Restall, P. A., and Smirk, F. H., *Brit. Heart J.*, 1952, 14, 1.

² Gardner, W. J., and Dohn, D. F., *J. Amer. med. Ass.*, 1956, 162, 274.

¹ *Health and Social Workers in England and France*, 1956, Geneva.

ately induced hypotensive state could be controlled provided the external pressure was applied to the body up to the heart level, and provided the external pressure was not so great as to interfere with the venous return. W. J. Gardner and D. F. Dohn² have now described the use of a "pressure suit," mainly to combat fall in blood pressure during surgical procedures. "It consists," they report, "merely of two sheets of vinyl plastic sealed at the edges to form a large inflatable bladder. This is placed beneath the patient, the edges are folded over so as to enclose him from the rib margin to the ankles, and it is drawn snug by lacing. A manometer is attached to a tube leading from the upper part of the bladder; to a second tube leading from the lower end, a tank of gas is attached from which the bladder may be inflated in a matter of seconds."

Whether such a device will find a wide application in surgery is problematical. Induced hypotension as a routine aid to surgery is not favoured in Britain by the majority of anaesthetists and is now reserved for operations, particularly intracranial and plastic, at which bleeding may be expected to cause difficulty to the surgeon or danger to the patient and when efficient control by orthodox methods is uncertain. Probably most anaesthetists would prefer to retain pharmacological control of the hypotensive state rather than mechanical through an apparatus which must be somewhat cumbersome if it is to be efficient. Many surgeons might endorse this view, for they already find their access to the patient's body becoming increasingly restricted by the presence of apparatus. However, a light pressurized suit might be particularly useful during the post-operative period, when hypotension is present, until the blood pressure reaches a stable level. It could remove some of the need for special nursing of these cases, permit activity to be less restricted, and avert the severe headache that is sometimes an unpleasant sequel.

REHABILITATION IN THE R.A.F.

The Royal Air Force is this year celebrating the completion of its first fifteen years of organized rehabilitation. The first comprehensive scheme ever to be introduced on a national scale, it was born during the grim summer of 1940 as a result of the initiative of Sir Reginald Watson-Jones, supported by the then Director-General Sir Harold Whittingham, Mr. H. Osmond-Clarke, Dr. H. E. Moore, and Group Captain C. J. S. O'Malley as the leading participants. The stimulus was the desperate need for air crew in those days, and a residential centre where intensive full-time treatment could be given was opened at the Palace Hotel, Torquay, with accommodation for sixty patients. When the centre received a direct hit from a bomb, which killed some of the patients, other centres had been opened elsewhere, so that by the end of the war ten existed, by no means limited to the treatment of air crew. Through these 62,210 in-patients passed during the five years 1941-5; 77% of them were returned to full duty and only 4.8% required invaliding. Fortunately the impetus did not die with the end of the war, and there are to-day three centres active with a total of 600 beds.

The scope has been extended beyond purely orthopaedic and traumatic problems, for nearly 10% of the cases are medical, general surgical, or psychiatric. The bulk of the medical cases comprise patients recovering from pneumonia and bronchitis or suffering from bronchiectasis, and graded rehabilitation may be helpful also in building up the exercise tolerance of patients recovering from rheumatic fever. Return to full activity can be hastened after operations such as appendicectomy or herniorrhaphy. Patients with depressive or anxiety states and post-concussional syndromes have also been through these centres, with encouraging response. The principle of the residential centre, based on the dictum of "segregation and unification of control" enunciated by Sir Robert Jones, has been maintained so that full-time treatment can be given. The patient can thus receive the optimum of four to five hours' treatment daily. During his stay the whole range of physical treatment can be applied as well as training in a trade and social resettlement. These centres permit the safe transfer of patients from hospital at the earliest possible moment, thus keeping hospital waiting-lists to a minimum and returning patients to work most rapidly. By this means some 70% of all patients are to-day being returned to full duty and only 5% are being invalided—figures comparable to those obtained during the war. Even the patients in this 5%, which includes severe cases of poliomyelitis, multiple fractures, and chronic neurological and arthritic disorders, have an excellent chance of achieving the best possible social resettlement, because discharge from the Service can be dovetailed into the return to civilian occupations. Indeed, eight out of ten of those invalided are at work, 84% of them in the jobs decided on at the resettlement clinic before discharge.
