A Genatosan Announcement

SEBIGEN - A NEW CREAM

SEBIGEN is the new name for the white, virtually odourless cream formerly known as Sebbix and intended for the treatment of seborrhoea and psoriasis of the scalp. SEBIGEN contains Purified fractions equivalent to Crude Coal Tar 10% together with Sulphur and Salicylic Acid, and being non-greasy it does not mat or clog the hair and is, therefore, readily used by women.

Basic N.H.S. price 2/3d. per 1-oz. tube.

GENISOL - A NEW PRODUCT

GENISOL is a new addition to our prescribable range of dermatological products and is a shampoo type preparation intended to be used either alone or in conjunction with SEBIGEN in the treatment of seborrhoea capitis, infantile scurf and psoriasis of the scalp. GENISOL contains Purified fractions equivalent to Crude Coal Tar 2% and Hexachlorophene 1% in a specially developed soapless shampoo base.

Basic N.H.S. price 2/0d. per 2-oz. bottle.

Safe · effective · economical

Sebigen and Genisol are made by Genatosan Ltd., Loughborough, Leicestershire

Transvasin

brings the esters of **NICOTINIC ACID**
SALICYLIC ACID
p-AMINO BENZOIC ACID

to the focal point of
soft-tissue rheumatism

The esters in Transvasin, a new preparation developed by Hamol S.A., our Swiss associates, readily pass the skin barrier in therapeutic quantities and enable an effective concentration of the drugs to be built up where they are needed.* Transvasin

not only induces vasodilation of the skin with a superficial erythema, but also brings about a deep hyperaemia of the underlying tissues. It is non-irritant, and can be safely used on delicate skins. It is now being widely prescribed with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible cream base ad	100%

*Therapeutische Umschau VIII, 1952, 10, 143

Transvasin is available in 1 oz. tubes, basic price 2/6 plus 9d. P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD., 11 WATERLOO PLACE, LONDON, S.W.1. WHITEHALL 8654/5/6
Transvasin is the registered trade mark of Lloyd-Hamol Ltd.

Will the planets contribute to medical knowledge?

Is there an answer to man's every affliction on this Earth? Or must we in the future, when space travel permits, seek remedies on other planets? Already this "good earth" has yielded up many marvels. It surrendered to the microscope when man discovered antibiotics. It gave us Terramycin after research workers had screened over 100,000 soil samples from all over the Earth. And in the future — well, who knows? The prospect of space travel to the moon or the nearer planets gets ever closer. But what will the medical man find when he first sets foot on another world? Will he be confronted by a vast new array of infections? Will he live to conquer these new enemies of health? And what then will be the role of such medicaments as today's powerful antibiotics? In this present era, "wonder drugs" such as Terramycin have a range of effectiveness against more than 100 infections. But will today's powerful weapons then be considered lacking? Will they be surpassed by even more wondrous "wonder drugs"? Or will the future reveal Terramycin as the ultimate in the antibiotic age? Stop for a moment and consider the future of man and the medical man. Dare we predict this future as confidently as we can now predict results with some of today's antibiotics? Or will the medical realities of tomorrow outpace even our wildest speculations?

Terramycin is the Trade Mark of Chas. Pfizer & Co., Inc., for their brand of oxytetracycline.

ONE HUNDRED AND TWENTY-FOURTH ANNUAL MEETING, BRIGHTON, 1956

President's Address

THE STATE OF GENERAL PRACTICE TO-DAY

BY

ALEXANDER HALL, O.B.E., M.D.

This is the last year in which the right to nominate the President of the Association lies with the host Division. My nomination and election to this high office should be taken not in any personal but in a representative sense. The general-practitioner members put forward the name of one of their number to signify their determination to reassert and justify once more the claim that their ranks form the front line of the Health Services of the nation, and thus to make manifest their willingness, nay eagerness, to accept the responsibilities implicit in that claim.

It is in these circumstances then that I come to-day to occupy the Presidential chair, and to my colleagues in this Division, to the Representative Body, and to the Council I tender my sincere thanks for the high honour they have bestowed on me.

"In all positions of honour men are excited to do their best." These words are taken from the address of Dr. Jenks, a veteran of Waterloo, who was President when the Association first met in Brighton in 1851: during my year of office I shall try to live up to this aphorism.

It is almost half a century since last the Association met in Brighton, and during this period a general practitioner has occupied the chair of President on only three occasions. During these years medical science has advanced in leaps and bounds; the impact of this remarkable progress on the practice of medicine has been dealt with by successive presidents and in the scientific sections of our Meetings. It might be profitable, therefore, to turn our attentions to other changes which have altered the conditions in which medical practice is conducted and consider whether present conditions can satisfy patient and doctor alike.

First are the changes within the profession. At the beginning of this century almost all doctors undertook general practice even though some by reason of special study or long experience had later gained such knowledge and wisdom of one branch of medicine as to make their opinion and advice sought after in a consultant capacity. With progress in medical science the demand for consultant or specialist advice increased, and many doctors, having reached consultant status, gave up their general practice of medicine. The two

types of practice continued to diverge until, with the advent of the National Health Service in 1948, organizational expediency brought in a more complete cleavage between consultant and general practitioner. The path to consultant status no longer leads through the experience of general practice in the homes of the patients, but through the academic avenues of the examination-room and the hospital corridor. The old type of general consultant has all but vanished.

Both general practitioner and consultant have their parts to play in the provision of a comprehensive health service for the nation, predominantly within the Act; but both are still free to practise privately outside it.

You would not expect otherwise than that after forty years in general practice, during which I have watched all these developments, my observations to-day will be directed to that branch of medical life which I have always found interesting and satisfying, if at times a bit exacting.

Role of the Family Doctor

However much the conditions of practice may have changed, the function of the family doctor remains the same. The term general practitioner strictly means someone who practises medicine, obstetrics, and surgery. As major surgery is no longer carried out in this country by general practitioners I think the term should be replaced by "family doctor." In some countries in the Commonwealth the consultant may act as a super G.P. to whom the patient can make a direct approach, but in this country on the family doctor alone primarily falls the overall responsibility of examining, diagnosing, and treating his patients. The more completely the family doctor can discharge these responsibilities the less frequently will occasion arise to refer patients to hospital. The hospital service was never meant to be, nor can it ever be, a substitute for the family doctor service. I believe, therefore, that the role of the family doctor, far from having become less important in the scheme of things, has had added to it many new responsibilities, important among which is that of knowing when and how best to make available to his patients the special knowledge and experience of his consultant colleagues. Spheres of specialization have become

more over and narrower, and thus the elucidation of a problem often calls for examination or investigation by more than one specialist. The integration of these opinions and the assessment of their significance therefore fall more heavily than formerly on the family doctor, who must survey the patient as a whole and be responsible for the continuity of his care.

From recent pronouncements it is clear that both the Association and the Government are aware that the role of the general-practitioner service is paramount and that it must be sustained as a first-class force. In a speech last year at Birmingham Mr. Iain Macleod, then Minister of Health, said that five principles had guided his thinking in office. He enunciated one of them in these words: "I think we ought to make—and for it to be seen that we are making—the general practitioner the king-pin of the whole of the National Health Services in this country." In his Presidential address to the Association in 1950 Sir Henry Cohen made this observation: "Until we have so reformed the conditions of general practice that students of merit wish to enter it we have not achieved our object." In the recent Guillebaud report there is general agreement that too much emphasis is being placed on the cure of the sick and too little either on prevention or on treatment at home.

These three pronouncements lead one to conclude that the general-practitioner service is not in good heart, that it needs resuscitation if it is to survive. It is failing to fulfil adequately its proper function in the national service. Existing conditions do not give it a fair chance to do so, with the result that much of the work which family doctors should normally undertake is passed on to the hospital or to local government clinics. This process of disintegration is progressive, and if not checked it will inevitably and rapidly lead to the disappearance of family or general practice as we have hitherto known it. Such a calamity ought to be prevented, but it can be prevented only if avoiding action is not too long delayed.

In a brief glance at the changes in the social and economic sphere can we find any hint as to why the community is ceasing to place the same reliance on the family doctor as it formerly did?

Health of the Worker

Health no longer means only the absence of disease, but implies a condition in which sound limbs and a sound mind can function to the best and happiest advantage. The term National Health Service implies that doctors should be as much concerned with the promotion of health as with the care and prevention of disease.

Gradually there has developed a growing appreciation by the Government of the value to the nation of the health of the individual as a "unit of productivity"—that is, as a worker. Voluntary effort, always well ahead of official action, had already done much to foster health, but Government interest and intervention increased, until with the coming into operation of the National Health Service Act it proclaimed its responsibility for the health and welfare of every citizen from the cradle to the grave. But it really provided a "disease" service, and at the same time created conditions unfavourable to the public health service. As Lord Adrian said in a recent address (*British Medical Journal*, May 26): "We praise the achievements of our

medical officers of health and urge them to greater efforts, but the great reorganization of our medical services seems to have passed over their heads and left them with innumerable minor tasks and little chance to make effective progress." The State thus took over from individuals the responsibility of providing medical services and with it the onus of maintaining their standard. Now 90% or more of the population avails itself of these services, and less than 10% of the cost is met from the national insurance contributions.

State-sponsored maternity and infant welfare schemes, the medical inspection of schoolchildren, and the provision of the N.H.S. Act all express a vast extension of the State's direct concern in matters of health and sickness, while public health regulations, Factory Acts, and housing schemes bear witness to the growing activity of central and local government in providing healthy conditions of living. Both sides of industry, too, have accepted responsibility in these matters. The trade unions have made adequate pay, limited working hours, and improvement in working conditions their special concern. From the purely health point of view I doubt if further reduction in working hours is desirable. We would not want the average man to work as long hours as does the average doctor; but full work makes a full life, and leisure is something which needs wisdom to fill it with profit to mind and body.

Industrialists have found that healthy and contented employees go hand in hand with increased output, and to this end have instituted research into working methods and conditions and medical services to detect and correct factors adverse to the health of men and women at their tasks, and recreational facilities to encourage health-giving activities in leisure hours. Rightly, too, the effects of loss of earning power to the individual have been mitigated by the introduction of unemployment, sickness, and industrial benefit schemes and by family allowances and pension schemes. Proper conditions of hygiene may be provided in both factory and home by legislation; adequate provisions of pay and leisure may be agreed by negotiation; but unless these conditions are appreciated and properly used much of their value is lost.

Responsibility of the Individual

The question arises whether the acceptance by the State of more and more of these responsibilities has not induced in the individual a diminished sense of his own personal responsibility to keep himself fit and eager to add his regular daily quota to the work-pool of the nation and to partake in the life of the community. But in so far as this diminished sense may be caused by a lack of knowledge rather than by a lack of willingness further education in health matters should help. From the vast sums spent on education could not more be usefully invested in instruction on the general principles of health culture, both physical and mental? The people of this country should consider whether they are developing an attitude of mind to the National Health Service which is more disease-conscious than health-conscious.

In this connexion may I quote the following from the statement on medical aspects of social security issued by the World Medical Association in 1952: "A powerful factor in recovery from illness and in restoration to health is the sense of personal responsibility of the patient for what happens to him. This is something indispensable in the doctor-patient relationship. In what is called the Welfare State, social security schemes loom large, and in these schemes the provision of (apparently) free medical services is important. The more the State does for the individual

in this direction, the less is the individual's sense of obligation and responsibility." Are we not daily seeing examples of this through the whole of the country? And as the B.M.A. presumably subscribes to the policy of the W.M.A. can we really feel that we are doing enough to keep this aspect before our patients and the government? The willingness with which the public shoulders an expenditure on entertainment, alcohol, confectionery, and tobacco many times greater than that spent on the National Health Service makes one wonder if the true value of good health is appreciated.

The Association's Journal, *Family Doctor*, shows how alive the Association is to the need for further education in health and hygiene, but it reaches such a small proportion of the population that its efforts need amplifying. Much more could be done in schools, but the essential source of information on health for each family should be the family doctor, who should take an active part in providing this as he does in providing expert care in time of sickness. Were this so, millions of lost working hours might be saved and expenditure of millions of pounds on hospital services might be avoided; more important than this, the sum of human happiness would be increased.

Changes in Attitude

The attitude of the public has changed in another way: many of those we care for have travelled widely during the wars. Apart from the greater number at risk, we are dealing with a more reasoning people who no longer accept blindly what the doctor tells them. They know that advice must be based on facts and that facts can be elicited only by proper examination. But there is still a blind and unreasoning faith in the "bottle of medicine," and, thanks partly to the lay press and "digest" articles, a pathetic belief that even the most stubborn ailments can be cured at once by antibiotics and other "wonder drugs." From people would stop talking about "wonder drugs." I wish similar sources many patients are encouraged to diagnose their own condition and, at the cost of much time and energy, have to be convinced how wrong they are. All this means that a consultation which is to be satisfying to both doctor and patient is a more time-consuming affair.

There are changes, too, in families, where it is not uncommon to find both man and wife have work which takes them from the home. The consequent lack of parental influence and control has often a profound effect on the physical, mental, and moral development of the children; nor is it without its drawbacks when illness overtakes the family.

Lastly, there have been changes in the facilities for conducting practice. As a means of transport the doctor-driven motor-car and even the aeroplane have replaced the leisurely horse-drawn vehicle which allowed ample time for chewing the mental cud between visits. The ubiquitous telephone has made the doctor more accessible to his patients, has added a sense of urgency to many calls which are in no way urgent, and by necessity of its being manned 24 hours a day has added greatly to the burdens of the doctor's household. But the family doctor at least has been emancipated from the silk hat and black coat, starched shirt, and striped trousers.

The complexity of modern methods of examination and treatment has necessitated larger accommodation in the consulting-room or surgery, and the multiplicity of instruments and appliances calls for greater expenditure. Whereas in industry the employment of new methods and new machinery usually leads to increased precision, with a saving in cost and time, in medicine new methods of diagnosis add to the cost and demand more time in their application and interpretation.

The Time Factor Paramount

This general review of the conditions in which we work brings out the overriding importance of the time factor. But can we say that in general practice throughout the country we are giving more time to each patient than was formerly the case? The various social changes and

changes in attitude which I have mentioned should not themselves have undermined the confidence of the community in the family doctor to which I have referred earlier. The essential cause for the lowered prestige of the family doctor lies, I believe, in the National Health Service.

Changed Relationships

First the Act altered the relationship between the doctor and the patient by introducing the State as a third party. This new type of eternal triangle is fraught with as many dangers as the more familiar type and has tended to make the relationship between the contracting parties less personal and more liable to lack that esteem and mutual trust which are essential if confidence is to be engendered. I know that in a State-provided scheme such intrusion is unavoidable. But in a statement in 1952 the World Medical Association amplified the second of its principles—"No intervention of third party between physician and patient"—as follows: "When medical care is provided as part of social security the State or the Local Authority or the Insurance Company enter into relationship with the patient and doctor. Such relationship must not involve interference with the essential freedom of either." Can we be really confident that this is the case in Britain to-day? For example, the closed area denies the freedom of the doctor to take up work—in the N.H.S.—where he wants, and hampers transfer from one area to another should health, family educational requirements, or other causes make such transfer desirable. In the N.H.S. it is virtually impossible for a doctor in the general-practitioner service to attain consultant status, and this, too, is not in line with Principle V of the World Medical Association, of which, I need hardly remind you, the B.M.A. is one of the principal member associations—indeed, the originator of it. Principle V is, "Freedom of the physician to choose the location and type of his practice."

Secondly, the manner in which the National Health Service was introduced was unfortunate. It was heralded as a free service in such a way as to lead to irresponsible demands, not only for time-absorbing service but for supplies which many expected to be forthcoming, not according to need as judged by the doctor, but as something which the patients' weekly contribution entitled them to receive on demand. The development of this "entitlement" complex led to full surgeries and high prescription rates. This made it more difficult to give that extra time which modern medical science requires. The erroneous belief of many patients that their insurance contributions pay for the whole of the benefits of the Health Service has altered their attitude to the whole profession and made them more prone to be litigious, although, of course, the free legal aid scheme has greatly encouraged this.

Thirdly—what was worse—the specialist services were heralded as something new and superior, and available to every citizen for the first time; by comparison the family-doctor service was thus presented as a second-rate affair with very limited capacities. Denial to the family doctor of diagnostic facilities in the x-ray department and the laboratory except through consultant and specialist exaggerated the apparent incompetence of the general practitioner, while the denial of his right of access to hospital beds even for midwifery completed the ignominy and altogether undermined confidence in him.

Naturally the public came to demand more and more specialist services, usually at or in hospital, nothing short of which, they were led to believe, was the best; and the qualifying student sought to enter the hospital services rather than the ranks of general practice, which has been given, rather than has gained, the reputation of being something short of the best. Consequently hospital departments became overcrowded with cases which, had the patient had confidence in his G.P., could equally well have been dealt with at home and in the consulting-room or surgery.

I think, therefore, we can fairly say that the reduced status of the family doctor emanated not from any essential

in the profession itself but from the treatment it received at the hands of those who introduced the N.H.S. But the profession is not altogether free from blame, because it was not always successful in distinguishing between principle and expediency. In large part the new health service was manned by the same doctors who were in practice before its inception. They were men and women with a sense of vocation who asked only to be allowed to get on with the job of looking after their patients.

When the Act was being framed the Association pointed out its many weaknesses and eventually secured some important modifications, but in the end political rather than medical considerations prevailed, and in 1948 the Association advised the profession to accept service under the Act, although it infringed principles the profession held sacrosanct, and resolved to seek reforms by amendments. Eight years of sustained effort by the Association still leaves us seeking many of these reforms.

The financial aspect was improved by the Danckwerts award, which was, after all, but a belated carrying out of the promises made by the Government in the Spens report. But money is a means, not an end, and if general practice is to take its rightful place again and attract recruits of the right calibre it must be made a worth-while and satisfying job in other and more fundamental respects. To this end the principles we established in 1948 must not be lost sight of.

To restore the prestige of the family doctor we are entitled to ask the Government for evidence of a change of policy; we want to be more than the king-pin of a lifeless mechanical service; we want to be the heart and soul of a living organism. We should be directed not by bureaucratic theory but by the guiding finger of practical experience and human understanding.

Problems to be Solved

Every family doctor should be encouraged to use his brain to try to solve the problems it has been trained to solve, and should be given the facilities which will make his work a matter of interest and not mere routine. Medicine is never at its best where conditions suppress the individuality of the doctor. Until every region in the country provides facilities for the family doctor to enlarge the scope of interest he can take in his patients, until the Ministry and others cease to belittle his capability to undertake midwifery—that intimate service which is often the foundation of that mutual trust so precious in family practice—until they show they remember his existence and use him as a medium for health education, as they failed to do in the matter of poliomyelitis vaccine, or for sounding live medical opinion, as they failed to do in the matter of the ban on heroin—until then we cannot assume any change in the attitude of the Government and the ubiquitous planners towards the family doctor.

If the Government continues to damn the general-practitioner service with faint praise or to present it to the country not as the dog but as the tail and a very short one at that, it is not letting it be seen that it is making the family doctor the king-pin of the whole of the National Health Service in this country.

The health services must fall within the general policy of the Government of the day, but, Mr. Bevan has said, the tragedy is that it has become the Tom Tiddler's ground of party politics. The services can well stand up to the ordinary variations of pressure in the political atmosphere, but there is always a risk of more violent disturbances developing and bringing with them conditions which encroach on the freedom of medicine. The Association and its members individually have a duty, not only to themselves but to the public, to preserve and foster the practice of medicine outside the National Health Service away from the cold blast of bureaucratic control. The greater the area of freedom provided by the private practice of medicine,

in which the doctor is his own master and able to mould his practice according to his own temperament and capacities, the greater will be the encouragement to maintain a general high standard and the stronger the deterrent to the introduction into the National Health Service of terms and conditions of service which we believe will make such standards unattainable.

It also remains the duty of the Association to detect and fight any tendency on the part of those who administer the health services towards regimentation or automation of the profession. Few administrators have more than little personal experience of general practice, and cannot conceive that ill-considered action on their part may seriously disrupt the doctor-patient relationship. Any attempt by the Ministry of Health to by-pass the general practitioner must be resisted.

First Line of Defence

What is the proper function of the general-practitioner service? It is to provide the first line of defence against ill-health and the force which supplies the first counter-attack when "operation sickness" has already begun. To sustain the service as a first-class force implies keeping the morale constantly at concert pitch, by ensuring proper working conditions and pay that family doctors may work in an atmosphere free from such hustle as robs both patient and doctor of mutual respect, and of time for proper consultation, free from limitation of facilities which makes him appear incompetent and deprives him of the interest of investigating and of the satisfaction of treating his patients, not as far as the machine permits but as far as his training and experience will allow. It also implies attracting a steady flow of recruits of the right type.

Students in their final year must be made more familiar with what general practice has to offer. They must have an opportunity of hearing about this and asking about that, not from a teacher, or even a dean, who cannot speak from personal experience, but from someone actively engaged in general practice and preferably someone with a certain amount of private practice. When they learn how very worth-while the work of the family doctor can be even the best students will not hesitate to join our ranks and help to make it even more so.

A patient is dependent on the sympathy and good faith as well as on the skill of his doctor, and the young doctor cannot be taught to give this full service; he can learn to do so only in the school of experience. In my view, after registration the sooner he takes up an ordinary assistantship and learns to assume responsibility under the wing of an experienced practitioner the better.

"It is therefore necessary that the doctor should be quite frank and positive in his statements, for uncertainty will never allay apprehension," said another of our past presidents, Dr. P. T. J. O'Farrell. Only with experience and with the appreciation of his own limitations will come to the young doctor that frankness and assurance which makes the patient trust him and willing to leave to him the decision on the need for specialist help. When this trust has been re-established, then and only then will the family doctor again fulfil his proper function and the undue emphasis on the hospital services be corrected.

With time and facilities to use his knowledge and experience the general practitioner can and willingly will accept further responsibilities in the health services of the country with satisfaction to both the patient and himself, and with relief to the hard-pressed and costly hospital services.

One thing should be made clear, and that is, if whatever steps are taken succeed in restoring to the family doctor responsibilities which at present are undertaken by the hospital services, he must not be grudged the same weapons with which to fight. These are frequently antibiotics which will inevitably increase the family doctor's prescribing costs; but this should not be held against him, as it relieves the hospital not only of the cost of the drugs but also of heavy maintenance charges.

To discharge these responsibilities requires much more than mere scholastic attainment, for the practice of medicine must be a constant adaptation to new conditions. While man's soul may remain unchangeable, is man physiologically the same as he was when this Association was founded? So many factors crowd on him to alter his biological individuality. The increased scale of the problems and their number which beset us in both our national and our family life, the supersonic tempo which makes life a scramble after livelihood, power, productivity, or progress, the urge to snatch the present opportunity in the uncertainty of the morrow arriving, from these a new pathology has developed under our own eyes and for which we ourselves are responsible. Even now we are hoist with our own petard. How much more will that be when the atomic age arrives?

To meet the spiral effect of these stress conditions many seek escape in the noise and excitement of modern social activities such as football pools, non-stop television, and boogie-woogie, while many others prefer to shelter under the umbrella of sedatives or stimulants. Wonderful and ever-changing as the products of the pharmacologist's laboratory are, by themselves they can but alleviate and postpone eventual breakdown, mental or physical. To help such people successfully to ride the storm and reach a safe anchorage the doctors' equipment must include human understanding based on sound moral principles and sympathy born of true charity, qualities of mind which remain unchanged throughout the centuries.

Conclusion

You who have so patiently listened to me may conclude that many of my views are reactionary. They are certainly the views of someone who "reacts" to what he sees to-day, the views of someone, in the words of a remarkable essay in *The Times Literary Supplement* earlier this year, who believes in "perhaps an old-fashioned society, inherited without much self-questioning, but nevertheless a society that cohered and had a dynamic and still offered opportunities to the young and the talented and the enterprising; not a society harried, hag-ridden by regulations and financially penalized. . . ." Medicine is in the middle of all this. It is losing its dynamic. Somehow or other this Association must bend its efforts towards not only preserving but also enlarging the area of freedom and dignity in the medicine that still exists within the framework of the National Health Service. If we cannot succeed in this, then I fear for the future of medicine and especially of General Practice. The decline in standards which I and others see is harmful to the public deluded into believing that the National Health Service is the best possible service because it is State-sponsored and is labelled free. We need men of conviction who do not lack the courage to express their opinions clearly, unpopular though they may be; we need a new dynamic in medicine. Let us see that it comes from within the Association.

In the first quarter of this year there were increases in almost all categories of nursing staff in both mental and mental deficiency hospitals, amounting to 270 in the first and 175 in the second. These figures were given by Mr. R. H. TURTON, Minister of Health, when he spoke recently to the Association of Hospital Matrons. The most welcome feature of all, said the Minister, was the increase in the numbers of both male and female student-nurses, an increase of 10%, and 109 more female student-nurses, an increase of over 5%. In mental deficiency hospitals the increase in male student-nurses was 16 (6%) and of female student-nurses 36 (8%). These increases had occurred before the recent salary settlement. Of particular interest was the notable increase in the number of male student-nurses in mental hospitals, which might be partly due to the deferment of National Service during training.

BEHAVIOUR IN VITRO OF SOME NEW ANTISTAPHYLOCOCCAL ANTIBIOTICS

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

AND

PAMELA M. WATERWORTH, F.I.M.L.T.

The numerous antibiotics now available could be regularly depended on for the treatment of almost any bacterial infection but for one factor. This is acquired bacterial resistance, and the species which has shown the greatest capacity for this, with the most serious consequences, is *Staph. pyogenes*. The literature abounds with reports of infection by strains of this organism resistant not only to penicillin but to streptomycin, the tetracyclines, and, less often, to chloramphenicol. It can also become resistant to erythromycin, which is at present the last line of defence against a return to the conditions of pre-penicillin days. That a strain resistant to this as well as to other antibiotics can kill patients as in the past is evident from the experience of Martin *et al.* (1954) at the Mayo Clinic.

It follows that the identification of further antibiotics capable of replacing those now in use for this purpose would afford very comforting security. The Antibiotics Clinical Trials Committee of the Medical Research Council decided recently to examine or re-examine the properties of certain antibiotics which might prove useful in this direction, and some of the work reported here was undertaken to provide information to that committee.* Only *in vitro* observations are reported, but these are capable of revealing properties of some consequence to therapeutic efficacy, and the comparison under identical conditions of eight different antibiotics affords some idea of their relative merits and of any relationships which may exist between them.

Antibiotics Examined

Erythromycin.—This was included because two of the other antibiotics studied are evidently related to it. The pure material used was kindly supplied by Eli Lilly & Co.

Spiramycin.—This antibiotic was discovered in the laboratories of Rhône-Poulenc. According to Chabbert (1955) its antibacterial spectrum corresponds closely to that of erythromycin, but the latter is 4 to 20 times more active. Staphylococci were readily made resistant to spiramycin, and were then resistant to the same concentration of erythromycin: thus in the resistant organism the difference in degree of activity of the two antibiotics disappears. Hudson, Yoshihara, and Kirby (1956) found very little cross-resistance: of 13 strains resistant to erythromycin, 11 were sensitive to spiramycin. These authors used spiramycin successfully in the treatment of pneumonia, as did Renoux, Dupoux, and Huet (1955). This antibiotic was kindly furnished by Dr. W. R. Thrower, of May & Baker Ltd.

E129.—This is an antibiotic produced by submerged fermentation of a new species of *Streptomyces*, isolated in the Fermentation Research Division of Glaxo Laboratories Ltd. from a sample of soil collected in Jericho, Jordan. It has been extensively studied in these Laboratories, and shown to have a spectrum similar to that of erythromycin.

*Some of the antibiotics examined have become available only since this committee last met, and it is not to be understood that the committee has considered all of them, or decided on undertaking clinical trials of any.

a low toxicity, and full therapeutic action in mice on infection by *Staph. pyogenes*, *Str. pyogenes*, and *Str. pneumoniae*. It is known to be a mixture of several substances, and recently one of these, Factor B, has been separated from it. For a supply of both E129 and Factor B we are indebted to Dr. J. Ungar, of Glaxo Laboratories Ltd.

Cephalosporin P.—This is one of several interesting antibiotics shown by workers at Oxford to be formed by a species of *Cephalosporium* isolated from the sea near a sewage outfall in Sardinia by Brotzu (Florey, 1955). Its antistaphylococcal activity was studied by Ritchie, Smith, and Florey (1951). *In vitro* activity was high and toxicity very low: on the other hand, the therapeutic effect was much inferior to that of the tetracyclines, and resistance was readily acquired *in vitro*, although no evidence was obtained that this occurred *in vivo*. We are greatly indebted to Sir Howard Florey and Dr. E. P. Abraham for the gift of some pure cephalosporin P.

Micrococin P.—This antibiotic is formed by an organism of the *B. pumilis* group isolated from soil in East Africa by Fuller (1955), who found it to be highly active *in vitro* against Gram-positive organisms and *Myco. tuberculosis*, of low toxicity, and therapeutically active in mice against *Str. pyogenes*. We are much indebted to Dr. A. T. Fuller and Dr. D. R. Bangham for a supply of this substance and for much further information about it. The named used has been proposed for it by Abraham, Heatley, Brookes, Fuller, and Walker (1956), since it appears to be nearly identical with the antibiotic micrococin, originally described by Su (1948) and by Heatley and Doery (1951).

Albomycin.—The properties of this antibiotic discovered in the U.S.S.R. were recently described by Gause (1955). It is credited with a wide range of activity and extensive therapeutic powers demonstrated both experimentally and in the clinical field. Perhaps the most remarkable claim made in this paper is that albomycin is 10 times as active as penicillin against staphylococci *in vitro*. A supply of this drug had been obtained through the British Embassy in Moscow for the treatment of a patient who was not in fact given it, and we were fortunate in obtaining it for laboratory study. The labels on the ampoules bore the numbers VI-56, K-13855, 235.

Novobiocin.—This antibiotic, best known as "albamycin" (Upjohn Company), which has been independently discovered in three laboratories and given six names, has had its generic name changed from streptonivcin to novobiocin: other trade names are "cathomycin" (Merck) and "cardelmycin" (Pfizer). An account of its properties is given in a series of five papers (Smith *et al.*, 1956; Hoeksema *et al.*, 1956; Wilkins *et al.*, 1956; Taylor *et al.*, 1956a, 1956b); its most striking properties are a high degree of activity against various Gram-positive organisms, especially staphylococci, and the remarkably high blood levels attained and maintained for many hours after oral administration. An experimental study at the Mayo Clinic (Martin *et al.*, 1955) confirms these findings and the therapeutic activity of the drug in mice. A series of papers in the April, 1956, issue of *Antibiotic Medicine* reports clinical trials, with generally promising results. Staphylococci can develop resistance to it rather rapidly *in vitro*. Persistence in the blood appears to be due in part to protein binding and in part to biliary excretion and reabsorption: little is excreted in the urine. We are indebted to the Upjohn Company for a supply of this antibiotic.

Vancomycin ("vancocin") is formed by *Streptomyces orientalis* n.sp., isolated from a soil sample obtained in Indonesia examined in the Lilly Research Laboratories. We are indebted to Eli Lilly & Co. for a supply of this substance, and for an account of their observations on its properties (McCormick *et al.*, 1955-6; Ziegler *et al.*, 1955-6; Griffith and Peck, 1955-6). It is active chiefly against Gram-positive cocci and is bactericidal. Attempts to induce resistance to it in staphylococci resulted in only a fourfold to eightfold change in sensitivity. It has a low toxicity, and has been administered intravenously and intramuscularly to

human subjects, attaining concentrations in the blood which should suffice for therapeutic effect and being excreted in the urine. Intramuscular injection causes pain.

Methods

The medium used for all purposes was ox heart extract peptone broth or agar, pH 7.4.

Preparation of Antibiotic Solutions.—The more soluble antibiotics were dissolved in sterile distilled water: the original solutions of micrococin P and of E129 and Factor B were made in ethanol.

Minimum Inhibitory Concentrations were determined on plates containing doubled dilutions of the antibiotic, divisions of which were inoculated with a 1-mm. loopful of an approximately 1/500 dilution of a 24-hour broth culture. These were read for presence of growth visible to the naked eye after 24 hours at 37° C. Blood (0.5 ml. saponin-lysed horse blood to 15 ml. medium) was added for tests with pneumococci and streptococci.

Tests of Bactericidal Action.—Broth containing 10 µg. of the antibiotic per ml. was inoculated with 0.01 ml. of a 24-hour broth culture per ml. and kept in a water-bath at 37° C., surface viable counts being made at 0, 2, 4, 8, and 24 hours.

Habituation.—Previous experience in this laboratory has shown that this process is more rapid in broth than on agar. Broth containing doubled dilutions of antibiotic was heavily inoculated, and transfer made daily with a 6-mm. loop (= ± 0.025 ml.) from the highest concentration showing growth to a further range of tubes. This was repeated 16 times, unless a high degree of resistance developed at an earlier stage.

Studies of Cross-resistance.—Organisms so habituated were tested for sensitivity to other antibiotics by the method used for determining minimum inhibitory concentrations.

Effect of pH.—Broth was adjusted to pH 5.5, 6.5, 7.5, and 8.5 by the addition of N-HCl or NaOH, antibiotic was added in different concentrations, and tubes were inoculated with 1 drop of an approximately 1/500 dilution of staphylococcus broth culture: these were read for turbidity after overnight incubation.

Effect of Inoculum Size.—Broth tubes (4.5 ml.) containing doubled dilutions of antibiotic were inoculated with (1) 1 drop (± 0.02 ml.) undiluted broth culture, (2) 1 drop broth culture diluted 1/500 in saline.

Results

Minimum Inhibitory Concentrations

The results obtained with 55 strains of *Staph. pyogenes* are given in Table I (a few of these strains were omitted in some of the tests). The antibiotic to which the majority were most sensitive is micrococin P. Next in activity is

TABLE I.—Number of Strains of *Staph. pyogenes* Inhibited by Antibiotics

Antibiotic	Total Strains Tested	Concentration (µg./ml.)

* In reading these results, the presence of one or two colonies of a resistant variant was ignored.

erythromycin: spiramycin was 16 to 32 times less active, and E129 had about a quarter and Factor B about a half the activity of erythromycin. The order of activity of the remainder was novobiocin > cephalosporin P > vancomycin > albomycin. The last-named was the only antibiotic to which any of these strains were highly resistant. Even

some of the sensitive strains either included a small minority of resistant cells or developed resistant variants very rapidly: the growth of one or two colonies only in such tests has been ignored in compiling Table I.

Similar tests were done with 12 strains each of Group A *Str. pyogenes* (Table II) and of *Str. pneumoniae* (Table III). Erythromycin is the most active against each of these species; of the performance of the others, that of spiramycin is decidedly better than against staphylococci, but

* One strain in each case not inhibited by 0.12, 2, or 1 µg./ml. respectively of erythromycin, spiramycin, and vancomycin: not tested further.

cephalosporin P and novobiocin show differences in the opposite direction. Albomycin is consistently and highly active against *Str. pneumoniae*, but has no action on *Str. pyogenes* (it also failed to inhibit 12 strains of *Str. viridans* in concentrations up to and including 128 µg./ml.). The remainder behave similarly against all three species: Factor B is again somewhat more active than E129.

Tests were also done with single strains of nine species of Gram-negative bacilli, and the only one of these antibiotics with a substantial action on them was albomycin. Its minimum inhibitory concentrations in µg./ml. were: *Bact. coli*, 0.5; *Bact. aerogenes*, 0.5; *Bact. friedländeri*, 0.12; *Salm. typhi*, >128 (seven strains tested); *Salm. paratyphi* B, 0.25; *Salm. typhimurium*, 0.12; *Sh. sonnei*, 0.25; *Proteus mirabilis* and *Ps. pyocyanea*, >128 (four strains of each tested). Thus the extraordinary contrast between the sensitivity of pneumococci and resistance of streptococci finds a parallel in the behaviour of paratyphoid and typhoid bacilli.

Of the remaining antibiotics, cephalosporin P, micrococin P, and vancomycin had no demonstrable action on any of these nine species: the remainder inhibited some of them in concentrations less than 32 µg./ml. in only one instance. This was the inhibition of *Proteus* (three strains) by novobiocin at 4 µg./ml.

Bactericidal Action

Only six of the antibiotics proved to be bactericidal in a concentration of 10 µg./ml. Of what may be called the erythromycin group, E129 and Factor B were rather more active than erythromycin and much more so than spiramycin, active than erythromycin and much more so than spiramycin, in the presence of which there was an initial rise in the count. Novobiocin was rather less active than erythromycin; and vancomycin, after the first two hours, gave the lowest survivor counts of all (Table IV).

TABLE IV.—Percentage Mortality of *Staph. pyogenes* in Broth Containing 10 µg. of Antibiotic per ml. at 37° C.

Antibiotic	2 Hours	4 Hours	8 Hours	24 Hours
Erythromycin	9	25	74	98
Spiramycin	+5	+74	+15	78
E129	88	90	95	99
E129, Factor B	70	87	94	99.4
Novobiocin	48	67	68	96
Vancomycin	63	95	99.5	99.99

In the presence of cephalosporin P, micrococin P, and albomycin there was growth, slow up to eight hours but profuse overnight. According to Ritchie *et al.* (1951) cephalosporin P is bactericidal: the difference between their results and these is undoubtedly an effect of inoculum size. The inoculum in these experiments was about 5×10^6 per ml.: a test with cephalosporin P was repeated using 5×10^6 , 5×10^4 , and 5×10^3 per ml., and with each of these the 24-hour count was zero or near it. It also seems that micrococin P is an antibiotic the effect of which depends much on inoculum size. This is even more true of albomycin, in the presence of which a large inoculum of staphylococci yields highly resistant variants within a very short time. Various other attempts were made to demonstrate bactericidal action in albomycin, including the use of shaken cultures (its action being said to depend on oxygen) and of *Bact. friedländeri*, which is highly sensitive and does not rapidly produce resistant variants on solid media, but in every experiment free growth took place overnight.

Effect of Inoculum Size

The effect of a 500-fold difference in staphylococcus inoculum size on capacity to inhibit growth in broth was only twofold for erythromycin, spiramycin, and E129, and fourfold for Factor B, novobiocin, and vancomycin. For cephalosporin P it was eightfold, for micrococin P more than sixteenfold, and for albomycin, in an experiment with *Bact. friedländeri*, more than 8,192-fold (dilute inoculum inhibited by 0.03, undiluted not by 128 µg./ml.). The test could not be done with *Staph. pyogenes* and this antibiotic for reasons given later.

Effect of pH

Erythromycin and spiramycin are decidedly more active in an alkaline medium, but E129 has a constant activity at pH 5.5-7.5 and is less active at pH 8.5 (Fig. 1). This difference suggests a fundamental dissimilarity between E129 and the other two.

Of the remainder, vancomycin and micrococin P are little affected by pH; cephalosporin P and novobiocin are less,

FIG. 1.—Effect of pH on bacteriostatic activity.

The 1930's witnessed the rapid build-up of evidence that the incidence of leprosy in Eastern Nigeria was not only generally high but in some localities phenomenal. At new settlements at Uzuakoli and Oji River experience at Itu was repeated, and far more patients sought admission than could be accommodated. In 1937 detailed information about specific localities began to be available. In that year a survey of the Abua clan by one of us (T. F. D.) revealed

492 patients with active leprosy among a population of 14,515 (34 per 1,000). That one small group, and one unusually health-conscious, could have so high an incidence was as surprising as it was disconcerting. This survey was quickly followed by many others, and, although lower figures were sometimes recorded, in a number of instances the incidence was far higher, figures of 50, 100, and even 150 per 1,000 being recorded. By 1942 it was evident that a formidable amount of leprosy existed in the region. By then the vigorous efforts of missionary societies were evolving methods of leprosy control which aroused Government interest, and led directly to the creation in 1945 of the Nigeria Leprosy Service, which has cared for many thousands of patients and undertaken very intense and extensive leprosy control measures.

Unusual Features of the Disease

Leprosy in Eastern Nigeria, especially as encountered on surveys between 1937 and 1948, has certain unusual features. In comparison with its manifestations in some other parts of the world, it is a relatively mild disease. The patient with mutilations and serious complications is generally rare. Even though severe and moderately severe infections have been more than sufficient to fill settlements to capacity, they represent only a minority of the total. Often more than 50% of patients in a locality have shown only one or very few lesions, which involve little physical discomfort and no disability.

The relative distribution of the various types of the disease is also of interest. Frank lepromatous cases rarely represent more than 10% of the total. The proportion is often smaller. The more flamboyant forms of tuberculoid leprosy are also uncommon, the bulk of infections consisting of tuberculoid leprosy of low intensity, and a smaller but considerable group of indeterminate character.

Furthermore, the disease is not particularly selective where sex and age are concerned. There is often little difference in incidence between the sexes. Infection is not by any means confined to childhood and youth; indeed, the frequency of apparently recent infections in the later age groups has attracted the attention of those familiar with leprosy elsewhere (Lowe and Smith, 1949).

Finally, the generally good response to treatment is also noteworthy. It was apparent before the days of sulphone therapy.

Decline in Leprosy Incidence

These features of the disease are interesting pointers to its natural history in Nigeria. They become even more interesting in the light of events during recent years. From 1948 onwards evidence began to appear that in some heavily infected localities the incidence of leprosy was declining. The following are two examples of this.

Ndi Oji Abam, Owerri Province

At one isolated group of villages (Ndi Oji Abam, Owerri Province) a careful survey early in 1941 brought to light 369 cases of active leprosy in a population of 3,057, an incidence of 121 per 1,000. Excessive though it was, this amount of leprosy represented by no means the whole story. In addition to those who showed unmistakable signs of active disease there were others who showed suspicious but uncertain lesions, and yet another group who presented scars and ulcers from the application of caustics to what they themselves regarded as leprosy lesions. The people here were extremely co-operative, and it proved possible to maintain a relatively close watch on events after the survey. During subsequent years new cases of active leprosy among the resident population became evident, as follows:

1941	37	1946	12	1951	9
1942	45	1947	20	1952	8
1943	71	1948	13	1953	10
1944	19	1949	16	1954	8
1945	26	1950	5		

In a few instances these cases were discovered by the examination of contacts, but most came forward for treat-

ment on their own initiative, presenting extremely early lesions. The high degree of co-operation given by the people is attested by two further intensive surveys, undertaken in 1947 and 1955. The former of these brought to light only 18 persons who had developed leprosy since 1941 and had not bothered to seek treatment on their own. In all cases the infection was slight. They are included in the figures for 1946 and 1947. The most recent survey, in January, 1955, revealed only 8 cases previously unknown. Four are included in the total for 1954.

Thus the stream of new infections evident between 1941 and 1943 then began to decline and had become a trickle by 1950, since when it has remained at low level. As a result of this and the symptom-free discharge from treatment of many patients, the amount of active leprosy in this area has declined enormously—522 cases at the end of 1943 comparing with 216 in 1947 and 49 at the end of 1954, a fall of over 90%.

Bende Clan, Owerri Province

This is a very different area from Ndi Oji Abam, although they are separated by less than 20 miles. It was the first administrative centre of British rule in the area, and has had flourishing contacts with surrounding clans for over half a century. The people are mainly traders and so are often away from home, sometimes travelling long distances. They also have a relatively high standard of living.

Survey work in such an area is necessarily less certain than in an isolated community, but in two surveys, in 1943 and 1951, a high level of accuracy was in fact achieved. During this period, in a population of 3,500, the incidence of leprosy declined from 31 to 5 per 1,000. In the second survey only three previously unknown cases were found. It was possible to transfer the three remaining lepromatous cases to the central settlement. In this clan leprosy has almost completely died out in a period of ten years.

These are examples of a process that has in fact been going on in many areas to a greater or less degree, and during the past six years a mass of evidence has accumulated of a decline in the incidence of the disease that is widespread and is gaining in momentum each year. Its scale is indicated by the fact that, whereas in the three provinces of Onitsha, Owerri, and Rivers 30,630 patients with active leprosy were taking treatment in December, 1948, by the end of 1954 the number had dropped to 14,770, a decline of over 50%.

Causes of the Decline

In the community, as in the individual, leprosy usually takes a very chronic course, and with one exception, to which reference is made later, the few examples of a decline in the disease have taken decades to develop. A decline in incidence on the scale now apparent in Eastern Nigeria, occurring in so short a period, is a most unusual phenomenon. When one comes to examine the influences that may be responsible, it becomes evident that several are at work, and that they are operating in a most complex manner, so that what has probably been decisive at one time and place does not apply at another. The subject is a very large one, and it is possible here to examine very briefly only a few of its main features.

Has There Been a Leprosy Epidemic?

The rather curious association of a very high incidence, an essentially mild disease, and a rapid decline over a short period of years has been reported before—namely, in the case of the epidemic of leprosy in the island of Nauru in the early years of this century (Bray, 1930). The question immediately arises whether what has been witnessed in Eastern Nigeria is a similar outbreak, but on a far larger scale, and in particular whether the very high incidence recorded around 1940 was the result of an epidemic that had developed during the preceding 20 to 30 years and was then not far from its peak. However reluctant one may be to accept such a hypothesis, there is a great deal of evidence in favour of it.

1. Conditions were extremely favourable for a leprosy epidemic to develop. It is well known that leprosy is most likely to spread not among entirely primitive communities but among communities in which the social and economic changes of civilization have begun to operate. Even as recently as the early years of this century, each of the multitudes of villages in the Region was very much an isolated unit, with neighbouring villages probably hostile. Travel was not to be undertaken lightly. There was no central African authority, and, although leprosy was known and was often dealt with ruthlessly, in some places there was greater laxity. Then with bewildering rapidity the country was opened up. The fear of travel disappeared. Education spread rapidly, but hygiene and standards of living lagged far behind, especially during the years of depression in the 1930's. It is impossible to imagine a situation more likely to encourage the spread of leprosy.

2. The people are themselves of the opinion that leprosy did spread very greatly during this period. Personal opinion is of course highly unreliable as evidence, but in this case it does deserve some respect, for the Ibo is a very efficient diagnostician where leprosy is concerned, and, as generally very little clothing was worn during the years concerned, there was ample opportunity to observe the disease.

3. The relative rarity of the patient bearing the stigmata of a long-standing infection calls for explanation. Either many patients died before this stage was reached or the disease was formerly much less common.

4. It is customary to gauge the activity of leprosy in a community by its incidence among children as compared with that among adults. This simple and obvious method is reliable enough when conditions affecting the immunological status of the community are relatively stable, but it breaks down under unstable epidemic conditions. Here in parts of Eastern Nigeria leprosy is very common both in children and in adults, and the frequency of the unstable indeterminate and borderline varieties of leprosy among the higher age groups is particularly suggestive. It is what one would expect in the earlier stages of an epidemic with all age groups susceptible.

Taken together, these strands of evidence are weighty, and receive added strength from experience during the past 10 years. If an epidemic of leprosy did develop in many areas during the third and fourth decades of this century, it is not to be expected that the excessive incidence found in it is not to be expected that the excessive incidence found in a number of surveys could in fact continue at that level. Some decline would be expected with the development of resistance to *Mycobacterium leprae* in the population, and resistance to the tuberculoid form, with a corresponding disease to exhibit the tuberculoid form, with a corresponding decrease in the indeterminate group. A total decline with a relative increase in tuberculoid leprosy has been noted in certain areas.

Even if it is true that an acute epidemic of leprosy has appeared in parts of Eastern Nigeria, its inevitable decline offers only a partial and very inadequate explanation for the observed facts. Leprosy may decline naturally, but in this case the process has undoubtedly been hastened by other influences.

Influence of Tuberculosis

Lowe, working in Eastern Nigeria, drew attention to the immunological relationship between leprosy and tuberculosis (Lowe and McNulty, 1953). There seems to be little doubt that tuberculosis is also a factor in the situation. The opening up of the country which facilitated the spread of leprosy also encouraged the spread of tuberculosis inland from coastal areas. It is significant that the areas of highest leprosy incidence have never been found in close relationship to ports and townships on the main routes of communication. Tuberculosis of the lungs is still a relatively uncommon disease in many rural areas, but its spread, followed by the development of allergy to tuberculin, has probably influenced the natural course of leprosy through the production of a concomitant allergy to lepromin in a proportion of those infected. It is very difficult to

assess the importance of tuberculosis as a factor in the general decline of leprosy. A positive reaction to tuberculin is often found in leprosy patients who are negative to lepromin. Pseudo-reactions to tuberculin are not uncommon. It has even been suggested that *M. leprae* may be one of the agents responsible for them (Lowe, 1955). The impression remains that, even if tuberculosis is having a limiting effect on leprosy in and around ports and townships, its effects in remoter rural areas are not yet sufficient to have contributed much to the decline of leprosy already observed in such areas.

Improved Living Conditions

Another, and very welcome, factor in the situation is the considerable rise in the standard of living of the people, which began towards the end of the war and has steadily gained in impetus. Far more clothing is worn and opportunities for contact are thereby lessened. Standards of housing have improved, sometimes greatly, though it may be doubted whether this is as yet sufficient to have had any significant influence. Of greater importance is the advance in child health that has undoubtedly occurred, and the spread of medical facilities, which have reduced the incidence of diseases causing abrasion of the skin—for example, yaws and scabies. Opportunities for the spread of *M. leprae* by contact are certainly fewer than they were, and the healthier population is better able to withstand infections of all kinds.

Influence of Leprosy Control Measures

Finally, it is necessary to consider the influence of leprosy control measures on the natural course of the disease. In doing so it is first worthy of note that in many localities there was no need to stimulate an awareness of the infectivity of leprosy. This already existed, enshrined in taboos relating to contact with patients and demonstrated in efforts to expel patients from the community and, in one or two instances, in the provision of segregation villages for them. The original requests for leprosy surveys came because these efforts had broken down and the disease had got out of hand. Although in some places prejudice against leprosy was so strong that the very idea of doing anything to help patients was abhorrent, this did not apply in areas of very high incidence, and here it was not difficult to establish treatment centres and local segregation villages and organize preventive work, often at negligible cost and with the co-operation of the entire community, both patients and non-patients. The fact that the entire community often participated needs to be stressed. Once started, the idea of local anti-leprosy schemes spread, and between 1938 and 1943 many centres were established, which have continued up to the present, their number growing each year, and together dealing with many thousands of patients. The effect of all this effort may be reviewed from the two standpoints of treatment and isolation.

In Eastern Nigeria leprosy has been particularly amenable to treatment, and good results were achieved with hydnocarpus oil during the years when it was the mainstay of treatment. The resolution of tuberculoid lesions was generally hastened, and large numbers of patients with this type of leprosy were discharged in an inactive condition. On lepromatous cases its effect was very much slower, and, although some did gradually resolve, in other cases it succeeded in doing little more than keep the patient alive. Judged by its action on the two stable forms of the disease, it may be concluded that hydnocarpus oil had very little effect on the spread of leprosy, for the non-infective tuberculoid cases resolved and the infective lepromatous cases continued to stay infective for a long time. Where, however, patients displaying the unstable indeterminate varieties of leprosy are concerned its action may very well have been of importance. It is thought by many workers that these varieties of leprosy play an important part in the evolution of lepromatous leprosy (Lowe and Chatterji, 1941). In Nigeria our experience has been similar. In such patients the virtue of hydnocarpus oil was evident, for, once under

treatment, they rarely degenerated into the lepromatous type of the disease. Through its action on such patients in particular, hydnocarpus oil must have contributed to the decline of leprosy.

The virtue of the isolation of open cases is self-evident. Over the past 20 years several thousands of these have been isolated at settlements in Eastern Nigeria, and this must inevitably have had its effect on the disease. In addition, particularly in Owerri and Rivers Provinces, during the past 15 years approximately 10,000 patients have been isolated for longer or shorter periods in local segregation villages, this number including most of the known cases likely to be infective in the localities concerned. Even though this group of patients enjoyed considerable freedom, and visits home were sometimes frequent, they were for a considerable part of their time removed from the compounds where they formerly lived, and many opportunities for infecting others were thereby prevented. The virtue of the system as an anti-leprosy measure was commented on by Cochrane (1953). There seems to be no doubt about its importance.

Since 1949 the most important leprosy control measure of all has come into play with the general adoption of sulphone treatment. This area provided the first large-scale experiment in the use of oral 4:4'-diaminodiphenylsulphone (D.D.S.) in the field, initiated by the enterprise of Drs. Lowe and Bland. In Onitsha Province it has been reported on by Garrett (1951) and Garrett and Corcos (1952). Since 1951 oral D.D.S. has been the standard treatment for leprosy at all centres, and its effects are now manifest. The long-standing lepromatous cases whose infection lingered on under hydnocarpus treatment are for the most part now discharged. Treatment is extremely popular, attracting patients at an earlier stage of the disease than ever before. Early lepromatous cases speedily become bacteriologically negative. The general public is increasingly leprosy-conscious, and prejudice in localities long resistant to local leprosy control measures has finally succumbed. Relapses hitherto have been unimportant, and there have been no grounds for losing the confident outlook that sulphone treatment engendered. Here, then, is a potent anti-leprosy weapon rendered especially powerful because, thanks to an existing organization, it proved possible to apply it at many centres simultaneously.

The only clue to the relative importance of the four influences antagonistic to leprosy, which have been discussed briefly here, lies in the speed with which change has occurred. Circumstances are unusual, but it is extremely unlikely that natural regression of the disease, the spread of tuberculosis, or a rising standard of living can, either singly or collectively, have produced such profound effects in the space of seven years. They have doubtless played their part, but there seems to be little room for doubt that intense and widespread leprosy control work has been of great importance, that the effort of many devoted leprosy workers has borne fruit, and that the cost of the Leprosy Service to the British taxpayer through the Colonial Development Fund has entirely justified itself.

Summary

Leprosy is a disease of major importance in Eastern Nigeria, where it has a number of unusual features: (a) its incidence as encountered in surveys between 1937 and 1948 was generally high, sometimes phenomenally so; (b) its character is usually mild; (c) highly infective lepromatous cases form only a small minority of total infections, and indeterminate cases are common; (d) the disease affects all age groups; and (e) since 1948 signs of a decline in incidence have steadily increased, and a large-scale reduction in the disease is now evident.

The facts suggest that an epidemic of the disease has occurred which is now waning. In its decline the influence of tuberculosis, improved living conditions,

and leprosy-control measures is probable, and the relative importance of these factors antagonistic to the disease is briefly discussed.

Thanks are due to the Director of Medical Services, Eastern Region, Nigeria, for permission to publish this paper.

LETTERER-SIWE SYNDROME IN ADULTS

REPORT OF TWO CASES

BY

A. W. TAYLOR, M.Sc., M.B., M.R.C.P.
Clinical Pathologist, Kent and Sussex Hospital,
Tunbridge Wells

Descriptions, from both clinical and pathological aspects, of the commoner lymphatic node tumours are abundant, and their recognition now presents no great difficulty. It is amongst the rarer members of this group of tumours that the greatest difficulty in accurate diagnosis is often encountered. Robb-Smith (1938) has attempted the task of clarifying a most confused group of conditions, and it seems desirable that cases of the rarer types of lymphoid tumours should be recorded, not merely because of their rarity, but in order that the adequate study of such cases may eventually make their clinical and pathological recognition easier.

The cases described below are of the rare Letterer-Siwe syndrome in adult life: they showed several of the clinical features described by Robb-Smith in this condition, with other features not hitherto recorded. The presenting symptoms in each case consisted of a severe macrocytic anaemia with steatorrhoea.

Case 1

The patient, a married woman aged 39, was admitted to hospital in January, 1947, for the investigation of a severe anaemia with nausea, anorexia, and rapid loss of weight. A short bout of diarrhoea lasting a few days had occurred

CHART I.—Case 1.

in September, 1946. She was seven months pregnant. Investigations showed a very severe macrocytic anaemia with haemoglobin 24% (Chart I), red cells 1,400,000 per c.mm., with a mean cell diameter of 7.9 μ . A fractional test meal showed the presence of free acid. Marrow biopsy revealed a typical megaloblastic picture. A diagnosis of macrocytic anaemia of pregnancy was made and treatment included blood transfusion, crude liver injections of 2 ml. twice a week, and proteolysed liver and iron by mouth. The patient made a rapid recovery, being discharged from hospital early in March, 1947, with a haemoglobin of 100%. A healthy female child was born in April.

In January, 1948, there was a gradual return of the earlier symptoms of anaemia and loss of weight; the patient now began to suffer from diarrhoea, with frequent pale, watery, offensive motions. She was readmitted to hospital in February, 1948. Her weight was 5 st. 11 lb. (36.7 kg.). The haemoglobin was 46%, red cells 2,000,000, mean cell diameter 8.6 μ . A fractional test meal again showed the presence of free acid; serum calcium was 10 mg. per 100 ml. Total faecal fat was 39.6%—free fatty acid 27.5%, soaps 9.3%, neutral fat 2.8%. A revised diagnosis of idiopathic steatorrhoea was made, and treatment was begun with crude liver injections, 4 ml. daily. Vitamin B, calcium, and iron were also given, and the patient was put on a low-fat, low-carbohydrate, high-protein diet. Response to therapy was good, and the patient was discharged in April with a haemoglobin of 82%, and red cells 4,800,000, having gained a stone (6.4 kg.) in weight. The maintenance dosage of liver was 2 ml. of crude liver weekly. The low-fat high-protein diet was continued.

In December, 1950, a severe generalized eczematous dermatitis occurred, which remained troublesome for some weeks.

By March, 1951, the skin condition had greatly improved, but the patient was now complaining of pains in the back, legs, and right shoulder. Examination showed tenderness over the mid-dorsal spine, and an x-ray film showed wedging of the eighth dorsal vertebra. Serum calcium was 8.4 mg. per 100 ml., serum phosphorus 3 mg. per 100 ml., and serum alkaline phosphatase 14 units. This localized osteoporosis, as it was thought to be, was treated with high dosage of vitamin D, and the pain and disability disappeared completely within a month.

In August small irregular raised nodules, purplish in colour and painful to the touch, began to appear in the skin of her legs and arms. Biopsy of a skin nodule was performed, and sections showed a low-grade tumour of lymphatic or reticulo-endothelial tissue. It now seemed possible that the whole picture might be that described by Robb-Smith as reticulum-celled medullary reticulosis (Letterer-Siwe syndrome) of adults.

In October a sternal marrow biopsy showed a slight increase in eosinophil myelocytes, but nothing else abnormal. By December generalized lymphatic node enlargement appeared. Her weight fell to 5 st. 10 lb. (36.3 kg.) with increasing general weakness. Soon after this, periods of increasing general weakness. Soon after this, periods of pyrexia of Pel-Ebstein type began and the weakness and pyrexia became even more pronounced. In January, 1952, her weight was 4 st. 11 lb. (30.4 kg.). Abdominal pain of severe colicky type with flatulence and occasional diarrhoea also appeared.

The patient was readmitted to hospital in January. Biopsy of an epitrochlear lymphatic node was performed and the picture, described below, was that of a malignant tumour of lymphatic tissue.

A course of nitrogen mustard was given without any evidence of clinical improvement, although the enlarged lymphatic nodes showed some reduction in size. The pyrexia, cachexia, and abdominal pain continued, and although there was no sign of further lymphatic node involvement, skin metastases, or bony metastases, her condition steadily deteriorated and death occurred on May 7, 1952.

Biopsy Reports

Skin Nodule.—Biopsy in September, 1951, showed a subcutaneous nodule of densely cellular infiltration, the predominant cell being a fairly well differentiated histiocyte-like cell. There was evidence of active growth in frequent mitotic division figures.

Epitrochlear Node (Fig. 1).—Biopsy in January, 1952, showed the normal gland architecture to be completely destroyed by a malignant neoplasm, the features of which were those of a primary lymphatic tumour. The picture

FIG. 1.—Case 1. Photomicrograph of section of epitrochlear lymph node ($\times 900$).

varied in different areas of the node, some areas showing predominance of quite well differentiated histiocyte-like cells similar to those seen in the skin biopsy, while larger areas show a pleomorphic picture. Reticulin staining showed a diffuse and considerable increase in reticulin. The general picture was that of a "reticulum-cell sarcoma" as defined by Willis (1948). In the Robb-Smith classification the picture was that of reticulum-celled medullary reticulosis.

Summary of Necropsy Findings

The body was extremely wasted. A few petechial haemorrhages were scattered over the skin of both lower limbs. There were a few small indurated nodules in the skin in both infraclavicular regions. The peritoneum contained about 2½ pints (1.4 litres) of milky fluid. The liver (weight 28 oz.—790 mg.) showed diffusely scattered very small white areas. The spleen (weight 5½ oz.—156 mg.) was also studded with very small white areas (1–2 mm. diameter). The mesentery was crowded with numerous lymphatic nodes up to half an inch (1.3 cm.) in diameter, with large, hard, matted masses of nodes at the root of the mesentery merging with similar retroperitoneal masses. Other organs showed no macroscopic abnormality.

Histology

Both spleen and liver (Fig. 2) contained numerous sharply defined irregularly scattered areas of infiltration by a

FIG. 2.—Case 1. Photomicrograph of section of liver. ($\times 550$).

neoplasm showing the characters described above in the lymphatic node biopsy. In many of these areas partial or complete necrosis had occurred, but particularly in areas adjoining blood vessels a very cellular picture was seen, the predominant cell being a histiocyte-like cell. The periphery of the pancreas was infiltrated by the same tumour tissue, although here necrosis was widespread and almost complete. Several lymphatic nodes from mesentery, porta hepatis, and inguinal and infraclavicular regions showed replacement of normal lymphoid structure by tumour tissue, very much of which was completely structureless and necrotic, though a few small islands of recognizable tumour tissue with the same predominantly histiocytic cell picture had survived. The mesentery, apart from the numerous enlarged lymphatic nodes, showed diffuse infiltration by necrotic tumour tissue, and many grossly dilated lymphatics.

The affected dorsal vertebrae showed no recognizable infiltration, and areas of fibrous tissue represented the original lesions.

Comment

The history falls naturally into three periods. Firstly, a severe macrocytic anaemia of pregnancy in 1947; next a period of three years from 1948 to 1951 during which the clinical picture was that of idiopathic steatorrhoea associated with a macrocytic anaemia; and, finally, the last phase from mid-1951 to 1952 during which generalized spread of a lymphatic node tumour occurred, involving peripheral lymphatic nodes, skin, and bone.

Case 2

A man aged 39 was admitted to hospital on November 5, 1951, suffering from a severe anaemia. He had been well up to a month before, except for two short bouts of diarrhoea and vomiting in July and August, 1951. He had never been abroad. On examination nothing abnormal was found beyond the anaemia and a general pigmentation of skin. There had been no obvious loss of weight. Blood examination showed a very severe macrocytic anaemia, with haemoglobin 34% (Chart II), erythrocytes 1,340,000, and a

mean cell diameter of 7.8 μ . Treatment with a refined liver preparation, 2 ml. daily, was begun, but there was no response after 10 days, and a transfusion of 4 pints (2.3 litres) of blood was given. Meanwhile a fractional test meal showed the presence of free hydrochloric acid. Faecal fat estimations showed 50% total fat with normal split/unsplitted ratio. A crude liver preparation was substituted for the refined liver, but no response was obtained, and on December 6 liver therapy was discontinued and folic acid, 25 mg. daily, was given. Response was rapid, a good reticulocyte crisis being obtained, and the patient was discharged on January 16, 1952, with a diagnosis of idiopathic steatorrhoea. His blood picture was nearly back to normal.

He remained in good health on 5 mg. of folic acid twice daily until the end of 1953, when he was readmitted with a relapse of his anaemia and diarrhoea following the stopping of folic acid a month before. Again he responded well to folic acid and was discharged.

On March 2, 1954, he was readmitted to hospital with a two-months history of increasing dyspnoea and cough, with pyrexia and loss of weight. He was gravely ill and had the physical signs of a bilateral bronchopneumonia. Anaemia was not present. No response to antibiotics was obtained, and on radiological grounds a tuberculous bronchopneumonia was suspected. He was transferred to a sanatorium, where he died a few days after admission.

Necropsy Findings (April 3, 1954).—The body was that of a young man showing marked absence of subcutaneous fat. The lungs showed a well-established bronchopneumonic consolidation of gross miliary pattern. The hilar nodes were enlarged, especially on the right side. The liver was enlarged and appeared to be fatty and toxic. The spleen was enlarged and congested, and the mesenteric lymphatic nodes were grossly enlarged.

Histology.—The lungs showed bronchopneumonia. Metastases of a malignant reticulum-cell tumour were present, with central necrosis. There were also scattered miliary areas of recent monilia infection with giant-cell reaction. The reticulum-cell tumour showed well-differentiated histiocyte-like cells predominating, with rather frequent mitotic figures and occasional multinucleated and atypical cells (Fig. 3). Hilar and mesenteric nodes showed extensive deposits of the same reticulum-cell tumour as that described in the lung metastases. Much necrosis was present (Fig. 4). The liver had very frequent small miliary metastases of the same reticulum-cell tumour (Fig. 5).

FIG. 3.—Case 2. Photomicrograph of section of lung showing metastases of a malignant reticulum-cell tumour. ($\times 620$.)

FIG. 4.—Case 2. Photomicrograph of section of mesenteric node showing the same reticulum-cell tumour as Fig. 3. ($\times 340$.)

Summary

Two cases of Letterer-Siwe disease in adults are recorded, with early involvement of mesenteric lymph nodes, giving rise to the sprue syndrome with severe macrocytic anaemia responding only to folic acid. The clinical picture and the pathology of the disease are discussed.

My thanks are due to Professor Payling Wright for helpful criticism; to Dr. J. McMurray for the necropsy report of Case 2, and for providing necropsy material; and to Dr. B. B. Hosford for his co-operation.

Comment

Death was due to bronchopneumonia following pulmonary, hepatic, and lymph-node metastases of a malignant reticulum-cell tumour, probably arising in the mesenteric lymph nodes.

Discussion

While the cause of idiopathic steatorrhoea (as of sprue) is as yet unknown, it has been recognized for some time that a small proportion of all cases of steatorrhoea are caused by simple obstruction of mesenteric lacteals by a widespread mesenteric lymphadenitis. Ryle (1936) described how such obstruction may occur from tuberculous mesenteric nodes with the production of the sprue syndrome, and Hurst, Payling Wright, and Ryle (1942) describe the history and necropsy of such a case. Hamilton Fairley and Mackie (1937) described a sprue-like syndrome in adults associated with lymphoma, lymphadenoma, and lymphosarcoma of mesenteric nodes, and caused, as they suggest, by defective intestinal absorption from lymphatic obstruction. In two of their four cases anaemia was present, macrocytic in one and normocytic in the other.

For neoplastic disease of mesenteric nodes to produce the sprue syndrome without other evidence of disease it is necessary that the neoplastic condition be a low-grade one, of slow growth, occurring primarily in mesenteric nodes, remaining localized in that area for a considerable interval before becoming generalized and manifesting itself in peripheral lymph nodes or elsewhere. These conditions existed in the two cases here described. That the presenting symptom in Case 1 was that of macrocytic anaemia of pregnancy is not surprising, since pregnancy is a recognized precipitating factor of both sprue and idiopathic steatorrhoea (Morgensen, 1937). That the two cases here described were under observation for four years and two years respectively without developing palpable peripheral lymphatic nodes, hepatosplenomegaly, or other signs of generalized spread indicates the slow-growing, relatively benign nature of the neoplastic process; and careful study of biopsy and of the necropsy material from these cases has led us to place them in Robb-Smith's category of reticulum-celled medullary reticulosis (Letterer-Siwe syndrome). While this condition has most often been recorded in children (Wallgren, 1940; Varga *et al.*, 1948), where it may be confused with aleukaemic leukaemia, Robb-Smith has observed the condition in adults, in whom a very different clinical picture is produced; the condition runs a much more chronic course, is associated with lymphatic node enlargement, splenomegaly, severe anaemia, and pyrexia; and symptoms of steatorrhoea have been observed. This condition merges with the lesions of the lipoidoses and eosinophil granuloma of bone, in which the distinction between a chronic inflammatory condition and the true neoplasia is difficult, and, on the other hand, with the more obviously malignant "reticulum-cell sarcoma" of Willis (1948). Willis's Case XII in particular shows some striking similarities to the cases here described.

EFFECT OF MITRAL VALVOTOMY ON RENAL FUNCTION

BY

JOHN HAMMOND, M.B., M.R.C.P.

Research Assistant

JOHN MACKINNON, M.D., M.R.C.P.

Formerly Research Fellow

AND

WILLIAM WHITAKER, M.D., B.Sc., M.R.C.P.

Formerly Senior Lecturer in Medicine

University Department of Medicine, Royal Hospital, Sheffield, and Regional Cardiovascular Unit, City General Hospital, Sheffield

After surgical intervention some patients with mitral stenosis complicated by congestive heart failure improve to such an extent that they no longer require treatment. Merrill (1946) and Mokotoff *et al.* (1948) suggested that the abnormal renal circulation, which has been demonstrated in patients with chronic rheumatic heart disease both with and without congestive heart failure (Merrill, 1946; Aas and Blegen, 1949; Davies and Kilpatrick, 1951; Werkö *et al.*, 1955), was directly responsible for impairment of salt and water excretion in these patients and for the development of heart failure. Therefore it seemed desirable to investigate renal function before and after mitral valvotomy and to attempt to relate any changes to those in the clinical state.

Material and Methods

Fifteen patients, of whom all but one were female, were studied before and after mitral valvotomy.

The clinical state of the patients was assessed both before and after operation, using the grades of disability defined by Baker *et al.* (1952); these may be briefly summarized as 0, no disability; 1, slight disability; 2, moderate disability; 3, severe disability; and 4, total incapacity. The first post-operative assessment of the clinical state was made six months to one year after operation.

Observations on the renal circulation were made about two hours after a meal with the subjects propped up

comfortably in bed at an angle of approximately 45 degrees. The renal plasma flow was measured by sodium *para*-amino-hippuric acid clearance and glomerular filtration rate by inulin clearance, using the technical method described by Dick and Davies (1949). Measurements were made during two accurately timed periods of urine collection of approximately 20 minutes. The filtration fraction, that fraction of the plasma passing through the kidney which is filtered by the glomeruli, was calculated by dividing the glomerular filtration rate by the renal plasma flow. The renal blood flow was calculated from the renal plasma flow and the haematocrit reading.

The diuretic response to ingested water was tested before and after operation in five patients (Cases 1, 2, 8, 10, and 11). Fluids and food were withheld from 6 p.m. on the preceding evening. Between 9 and 9.15 a.m. the patient drank a litre of water and emptied the bladder at 9.15 a.m. The bladder was emptied every 15 minutes for the next four hours and the volume of each 15-minute specimen was measured. From these volumes the maximal rate of urine flow in millilitres per minute and the volume excreted in the first two hours were calculated.

These investigations were carried out a few days before and from two to five weeks after valvotomy.

Results

The effect of mitral valvotomy on the renal circulation, water excretion, and the clinical state is shown in Tables I and II.

TABLE I.—Effect of Mitral Valvotomy upon Clinical State and Renal Circulation

Case No.	Age and Sex	Follow-up (Months)	Clinical State (Grades 0 to 4)	Haematocrit (%)	Renal Blood Flow (ml./min.)	Renal Plasma Flow (ml./min.)	Glomerular Filtration Rate (ml./min.)	Filtration Fraction

a=Before operation. b=After operation.

1. *Effect upon Clinical State.*—Before operation five patients (Cases 5, 6, 7, 10, and 13) were in grade 4, six (Cases 2, 3, 4, 11, 12, and 15) in grade 3, and four (Cases 1, 8, 9, and 14) in grade 2. All except three were reassessed one year after operation. One of these three (Case 4) had improved from grade 3 to grade 1 nine months after operation and another (Case 12) had improved from grade 3 to grade 2 six months after operation; both patients subsequently failed to attend for follow-up. The third patient (Case 7)

TABLE II.—Results of Water Diuresis Tests Before and After Mitral Valvotomy

Case	2-hourly Volume (ml.)	Maximal Diuresis	
		Rate (ml./min.)	Time (minutes)

Normal range (Taylor, 1955)	702 to 1,338	9.7 to 16.9	48 to 104

first appeared slightly improved, but died nine months after valvotomy with congestive heart failure. Six of those followed up for at least one year (Cases 1, 3, 8, 9, 12, and 14) improved by one grade, but four of them (Cases 1, 8, 9, and 14) were only moderately disabled (grade 2) prior to operation. A decrease in disability of two grades was observed in six patients (Cases 2, 4, 5, 10, 11, and 15) and a decrease in disability of three grades in one (Case 13). The remaining patient (Case 6) showed no improvement in the first year and remained in grade 4, but after this she gradually improved to grade 3. In the other cases followed up for more than one year (Table I) there was no change in the clinical condition, but one patient (Case 5) developed hypertension and subsequently died three years later from a cerebral haemorrhage.

2. *Effect Upon the Renal Circulation.*—Accepting a change of at least 20% as being significant, valvotomy was followed by an increase in renal blood flow, renal plasma flow, and glomerular filtration rate in Case 4, and in renal blood and plasma flows unaccompanied by a change in glomerular filtration rate in Cases 7 and 13 (Table I). In Case 12 the renal blood flow showed a slight increase, but because of a fall in the haematocrit reading after operation the renal plasma flow increased to a much greater extent, and this was accompanied by an increase in the glomerular filtration rate. In Case 2 the glomerular filtration rate increased and in Cases 10 and 14 it decreased, with little change in renal blood and plasma flows. In Case 11 valvotomy was followed by a decrease in renal blood flow, renal plasma flow, and glomerular filtration rate, and in Case 6 a slight fall in renal blood flow associated with a decrease in haematocrit caused a marked fall in renal plasma flow, the glomerular filtration rate showing little change. In the remaining cases (Nos. 1, 3, 5, 8, 9, and 15) the changes in renal blood flow, renal plasma flow, and glomerular filtration rate were much smaller (Table I). As a result of these changes in renal plasma flows and glomerular filtration rates the filtration fractions increased in three cases (Nos. 5, 6, and 12), decreased in three (Nos. 7, 13, and 14), and showed little or no change in the remainder (Table I).

3. *Effect Upon the Diuretic Response to Ingested Water.*—After operation the volume of urine excreted in the first two hours after the ingestion of 1 litre of water increased in three cases (Nos. 1, 8, and 10), decreased in one (No. 2), and showed little change in the other, Case 11. In Cases 1 and 8 the maximal rate of excretion increased, whereas in Cases 2, 10, and 11 it decreased. The time of maximal rate of urine flow was earlier after water ingestion in Cases 1, 2, and 10, and the same in Cases 8 and 11 (Table II).

Discussion

All patients in the present series showed abnormally low values for renal blood flow, renal plasma flow, and glomerular filtration rate compared with those found in normals by Davies and Kilpatrick (1951), using a similar clearance technique. These findings are similar to those reported by

Blegen and Aas (1950), Heller and Jacobson (1950), and Werkö *et al.* (1952), and in many of the cases confirm that changes in renal circulation in patients with valvular heart disease occur long before the onset of congestive heart failure. After operation the renal blood flow and renal plasma flow often increased, but did not return to the normal range in any of the patients, and only in Case 12 did the glomerular filtration rate reach normal levels.

The clinical state following valvotomy improved in all except two patients (Cases 6 and 7), but this improvement was not always associated with one in the renal circulation, nor was it consistently accompanied by a change in the diuretic response to water ingestion. In the group with congestive heart failure (patients in grade 4), one patient (Case 13) improved to such an extent—grade 4 to grade 1—that she was only slightly disabled after operation and her renal blood and plasma flows increased greatly. In Cases 5, 6, and 10 there was less improvement in the clinical state, and this was associated with much smaller changes in renal circulation (Table I). The fifth patient with congestive heart failure (Case 7) showed a dramatic increase in her renal blood and plasma flows after valvotomy, but despite this she improved only slightly at first and then relapsed into congestive heart failure. Although all 10 patients without heart failure improved clinically after operation, only two (Cases 4 and 12) showed an improvement in renal circulation, and in one (Case 11) the renal blood and plasma flows and glomerular filtration rate decreased. These results are in accordance with those of Werkö *et al.* (1955) and Judson *et al.* (1955), who reported variable changes in renal blood flow after valvotomy.

Before operation all five patients whose response to the ingestion of 1 litre of water was tested excreted less than 702 ml. of urine in two hours (Table II), which was the lowest value found in normal fasting subjects by Taylor (1955). In all but one patient the maximal rate of diuresis was also below normal, but the time of the maximal urine flow was not delayed beyond the normal range given by Taylor (1955), except in one patient (Table II). After operation there was an improvement in the diuretic response in three patients. The maximal rate of diuresis increased to within normal limits in two patients, and in one of these the two-hourly urine volume also reached normal limits. In all patients maximal diuresis occurred within the normal time range (Table II). There was no apparent correlation between the improvement in diuretic response and changes in the renal circulation, since the patients whose two-hourly urine volumes and maximal rates of diuresis increased showed no significant change in renal blood flow or glomerular filtration rate, and Case 2, whose glomerular filtration rate increased, had a diminished diuretic response after operation. These results are in keeping with those of Judson *et al.* (1955), who reported that post-operative increases in water excretion could not be consistently correlated with any specific change in renal function.

Although these results show that sometimes there is a marked improvement in the renal circulation following mitral valvotomy, the series is too small to allow these changes to be correlated with recovery from or persistence of congestive heart failure. It is obvious that further studies are required, especially in patients with congestive heart failure who recover completely after operation, before it is possible to decide whether improvement in the renal circulation as a result of the operation is directly related to an increase in the capacity to excrete salt and water and the disappearance of congestive heart failure.

Summary

The renal circulation was studied before and after mitral valvotomy in 15 patients, and in five of these the diuretic response to water ingestion was also tested.

Five patients had congestive heart failure prior to operation; six others were severely and four moderately disabled.

Before operation the renal circulation was impaired in all patients and the diuretic response was abnormal in the five patients in whom it was studied.

After operation one patient died with congestive heart failure, another was unchanged, and the remaining 13 showed improvement in their clinical state. The renal circulation improved in five patients, was further reduced in four, and showed little change in six. In three of the five patients studied the diuretic response improved, and in one it became more abnormal.

From this small series there was no obvious correlation between changes in the renal circulation, diuretic response, and the clinical state, although one patient with congestive heart failure who was greatly improved showed a considerable increase in renal blood and plasma flows after operation. The results indicated a need for further study, especially in patients with congestive heart failure prior to operation.

We wish to thank Dr. J. W. Brown, Dr. C. E. Davies, Professor C. H. Stuart-Harris, Mr. J. T. Chesterman, and Mr. A. W. Fawcett for permission to investigate patients under their care, and Mr. A. F. Nichols and Miss S. Exley for technical assistance.

SEA-SNAKE BITES

BY

H. A. REID, M.B., M.R.C.P.Ed., D.T.M.&H.
Specialist Physician, General Hospital, Penang, Malaya

Sea-snakes are the most abundant and venomous of the world's reptiles. They inhabit the shores of the Indian and Pacific Oceans, ranging from the Persian Gulf to south Japan, the coasts of tropical Australia, and the southern Pacific islands. In this vast triangle all fishermen know the sea-snake and its hall-mark, the flat rudder-like tail. Water-snakes, also common along these shores, have round tapering tails (see Fig. 1). They are harmless—a fact familiar to the fishermen.

The frequency of particular genera and species of the sea-snake family (Hydrophiidae) varies in different parts of the world, but, generally speaking, the commonest species is *Enhydra schistosa* (common sea-snake). The adult is 3–4 feet (0.9–1.2 metres) long, about 1–2 inches (2.5–5 cm.) thick, a uniform grey above and whitish below. It is easily recognized by the deep cleft in its chin (see Fig. 2). Young ones have dark-grey bars. Most other species are banded. Some species of *Hydrophis* grow to a length of 9 feet (2.7 metres), but are relatively slender, with small heads. The genus *Astrotia* are the most massive, being up to 4 inches (10 cm.) thick. *Pelamis platurus* has the widest distribution, and has been noted off the western coasts of tropical America and the

shores of south-east Africa (Smith, 1943). The genus *Laticauda* is amphibious, but the rest of the sea-snakes are purely marine.

Sea-Snake Venom

Rogers (1902-3) found the average yield per bite of the common sea-snake (*E. schistosa*) to be 9.4 mg. This was about one-twenty-fifth of the yield from a cobra, but it was much more potent. The fatal dose for a 70-kg.

FIG. 1.—A, The flat oar-like tail of a poisonous sea-snake. B, The rounded tapering tail of a harmless water-snake. Both inhabit coastal waters.

FIG. 2.—Head and tail of a young adult *Enhydrina schistosa*, the common sea-snake (3 feet—0.9 metre—long). Eyes are small and rounded; valvular nostrils on top of snout. Inset is a view of the chin showing the characteristic cleft.

man was estimated as 3.5 mg., or about one-third of an average bite. *P. platurus* was equally toxic, *Hydrophis* species less so. Fraser and Elliot (1905) confirmed the virulence of *Enhydrina*, and found *Lapemis curtus* toxicity similar to that of the cobra. Smith (1926) found *L. hardwickii* extremely toxic for guinea-pigs. Smith and Hindle (1931) reported the venom of *Laticauda colubrina* to be twice as toxic as cobra for mice, but thought the yield too small to kill healthy human adults. Rogers (1903-4) and Fraser and Elliot (1905) demonstrated a neurotoxic effect mainly on the respiratory centre but also on the motor nerve-ends. Unlike cobra venom, there was no direct action on the vasomotor centre or heart and no vasoconstriction, haemolysis, or effect on the coagulation (in concentrations likely to be present in human beings). After a latent period of half to several hours, depending on the dose, progressive paresis, dyspnoea, and ptosis ensued. Respiration finally ceased, although the heart continued to beat for two to three minutes. Thus the Hydrophiidae (true sea-snakes)

are almost purely neurotoxic, in contrast to the other two poisonous snake families, the Elapidae being chiefly neurotoxic but slightly haemotoxic, the Viperidae mainly haemotoxic. Cobra antivenene was ineffective against *Enhydrina* or *Lapemis* poisoning. Richards (1873) kept a dog alive for over 24 hours by tracheotomy and bellows. Prior to this it was moribund. Venom was probably excreted in the dog's urine. Further investigations on sea-snake venom will be reported in due course.

Sea-Snake Poisoning

Records are rare and usually inadequate. The literature describing seven fatal cases (Cantor, 1841; Richards, 1886; Fayrer, 1874; Forné, 1888; Buckland, 1879; Fossen, 1940; Bokma, 1941) and two recoveries (Peal, 1903; Bokma, 1942) will be reviewed in a paper published elsewhere, together with an account of a series of cases personally observed or investigated in a current survey. From these a clear clinical picture emerges.

Victims are mostly fishermen bitten through some accident such as handling nets, sorting fish, treading on a sea-snake, etc. They usually know that it was a sea-snake and are aware of the significance. People bitten whilst bathing, paddling, etc., often do not see the snake or, if they do, think it is a fish. After the initial prick there is no pain or reaction at the site of the bite, the appearance of which is described below under "Diagnosis." A delay of minutes to several hours, usually about one hour, then elapses before further symptoms ensue. Thus the victim continues activities promoting spread of the venom. He may not even connect the bite incident with his illness.

The symptoms are due to bulbar and motor paresis, which is usually generalized from the start but may begin in the legs and ascend, rapidly within an hour or two, to involve the trunk, arm, and neck muscles. During the first few hours the complaint may be "aching," "stiffness," or considerable pain on moving rather than actual weakness. The paresis is usually flaccid, with depressed or absent tendon reflexes, but may be spastic, with hyperreflexia initially. Bulbar palsy may precede, accompany, or follow the peripheral paresis. Jaw stiffness due to trismus is the outstanding feature and is easily overlooked. Ptosis is another early and important sign. It is often mistaken for drowsiness (the patient is usually mentally clear until respiratory failure is advanced). Thirst, burning or dryness of the throat, a general feeling of coldness, and increased sweating are common early symptoms, some of which may be due to fright, but more probably are bulbar manifestations. The pupils are usually dilated. Dysarthria and dysphagia, mainly due to the trismus, are also common although not invariable. Vomiting, nasal regurgitation, and ocular and facial palsy may occur.

The paresis progresses gradually or rapidly, the patient being unable to sit up unaided, then incapable of lifting the heels or head off the bed, and finally lies quite inert. This total paralysis, combined with ptosis, may give a deceptively peaceful appearance. Muscles are extremely tender, although objective sensory involvement is absent or minimal. As trismus increases, only the end of the tongue, eventually not even the tip, can be protruded beyond the teeth margin. There is no clinical evidence of cerebral, cerebellar, or extrapyramidal involvement, and sphincter disturbance is uncommon. In fatal cases respiratory paralysis with terminal hypertension and cyanosis usher in death, which may take place a few hours or several days after the bite. Occasionally, little or no peripheral paresis occurs and the patient dies from pure bulbar palsy, often with convulsions. Failing vision is a fatal sign to fishermen. Cerebrospinal fluid is normal, albuminuria usual, and haemoglobinuria common. The peripheral blood is normal apart from a leucocytosis and some haemoconcentration. Except for the urine findings, there is no clinical evidence of direct cardiovascular involvement by the venom.

A Fatal Case

This is a representative fatal case from my series. A preliminary report has already been made (Reid, 1956).

A 26-year-old Chinese man was bitten at 3 p.m. on October 24, 1954, whilst bathing off Penang Island. He was walking in mud about 20 feet from the shore, the water up to his chest, when he thought he had been bitten by a crab. He looked at his foot but saw nothing wrong with it. No pain or swelling was felt after the initial prick. He continued bathing. Half an hour after the bite he had difficulty in talking owing to a dry feeling in the throat. He returned home. One hour after the bite he had general aching pains in the proximal limbs, with some stiffness and pain across the lumbar region. Two hours later he was unable to sit up unaided or open his mouth properly. Three hours later he noticed difficulty in swallowing. He was unable to sleep, and 12 hours later felt numbness of the fingers though not of the toes.

He was admitted to hospital on October 25, and I first saw him at 10 a.m.—that is, 19 hours after the bite. Two pairs of fang marks, each 7 mm. apart, were seen below the right external malleolus. There was no swelling or discoloration of surrounding skin. He was mentally clear. There was well-marked ptosis and trismus (maximal jaw opening, 2 cm.). The masseters were tender, but spasm was not observed. The eye and facial movements were full and there was no nystagmus. He was able to talk, to cough quite forcibly, and to swallow water, the latter with some difficulty owing to the trismus. The pupils were dilated and reacted to light; abdominal and cremasteric reflexes were present but no plantar responses were obtained. All muscles were tender. There was generalized paresis, with increased tone and tendon reflexes. He was able to move the limbs in bed but unable to lift them or the head off the bed. There was no objective loss of light touch, pain, or vibration sense. The blood pressure was 130/85 and the remaining physical examination was negative. The urine was normal except for a trace of albumin. The Hess test, bleeding-time, coagulation time, platelet count, and prothrombin time were normal; Hb 100%, and W.B.C. 16,000. He had been given 10 ml. of polyvalent antivenene intravenously and 5 ml. into the bite area on admission. On the basis that the venom action was similar to that of curare, 1.5 mg. of neostigmine was given intravenously at 10.45 a.m. Abdominal pain and vomiting followed, but there was no change in the paresis. In the afternoon his temperature rose to 101° F. (38.3° C.) and the pulse rate to 120 (probably a serum reaction). Thereafter the temperature varied between 98 and 99° F. (36.7 and 37.2° C.) and the pulse rate between 95 and 110.

Early next morning (36 hours after the bite) haemoglobinuria was apparent and continued until his death. The paresis was now more marked, the tone was diminished, and tendon reflexes were absent. Trismus had increased (maximal jaw opening 1 cm.) and there was difficulty in looking upwards. Breathing and coughing were normal. In the afternoon a marked increase in sweating developed. The E.C.G. (14 leads) was normal; Hb 110%; W.B.C., 20,000; plasma bilirubin, 1.2 mg. per 100 ml.; Kahn test negative; and spectroscopy showed a mixture of pigments in the urine, chiefly methaemoglobin.

Early on October 27 (60 hours after the bite) difficulty with breathing first appeared. He could cough fairly well; B.P. 128/75, Hb 108%, W.B.C. 26,000. A Bragg-Paul pulsator was started and he was nursed in the prone position. At 11 a.m. the paresis was quite flaccid, with slight hand and foot movements only. Breathing became embarrassed within a minute of stopping the respirator. Sweating continued to be profuse; B.P. 130/80. At 2.45 p.m. the B.P. was 145/100; there was no cyanosis or evidence of respiratory obstruction. At 3.15 p.m. cyanosis was denoted. At 4.30 p.m. the B.P. was 159/90 and pulse rate 120. At 7.45 p.m. the pulse was imperceptible, heart sounds were faint, there was no response to questions, and the pupils were dilated but reacted to light. He died at 8.20 p.m., 77 hours after the bite.

In addition to polyvalent antivenene he had received cortisone, 100 mg. twice daily, penicillin, intravenous glucose-saline, and 100 mg. gastric tube. Although haemoglobinuria continued till the end, the plasma bilirubin just before death was 1 mg. per 100 ml. and the urinary output had remained satisfactory. The Schumm and the Coombs tests were both negative.

A Mild Case

Less severe cases will not develop respiratory insufficiency. Trismus, ptosis, and peripheral paresis resolve rapidly within a few days, occasionally taking a few weeks. The milder cases only develop "weakness" or "stiffness," often con-

fined to the lower limbs, for a few hours or days. Tendon reflexes are depressed or absent. Usually, there are minimal bulbar symptoms as well and albuminuria. The following is a representative mild case.

A Chinese girl aged 16 was sorting fish on the shore at Batu Muang, a small Penang fishing village, at 8 a.m. on March 25, 1955, when she accidentally trod on a sea-snake, which bit her left ankle. It was an *E. schistosa*, 2 feet (0.6 m.) long. She felt no pain after the bite. She was given herbal medicine and brought to hospital at 12 noon. Her only complaint was "stiffness" in both legs and back, which started half an hour after the bite. Below the left medial malleolus were fang marks 8 mm. apart. On admission the knee- and ankle-jerks were sluggish, but no other abnormality was observed; in particular no objective paresis or bulbar signs were present. The urine contained a trace of albumin. Cortisone, 250 mg. intramuscularly, and polyvalent antivenene, 20 ml. intravenously, were given. She had a brisk anaphylactic reaction requiring three injections of adrenaline.

At 3 p.m. the knee- and ankle-jerks were more sluggish, maximal jaw opening was 4 cm. (5 cm. at noon), the urine contained a heavy cloud of albumin; Hb 94%, and W.B.C. 15,000 (P. 80%, L. 16%, M. 1%, E. 3%). Next morning she was feeling well; the maximal jaw opening was again 5 cm., the tendon reflexes were brisker and the W.B.C. 16,000; there was no spectroscopic evidence of haemoglobinuria, and the urine deposit, Hb, blood urea, serum bilirubin, and plasma prothrombin time were all within normal limits. She was discharged on March 30, when the tendon reflexes were significantly brisker than on the 26th. Albuminuria subsequently diminished, and was absent by April 17.

If recovery takes place it is complete. No permanent after-effects such as occur in poliomyelitis were known to the many fishermen whom I have questioned.

Diagnosis

When there is a "sea-snake scare," as recently happened in Penang, the majority of cases coming to hospital thinking they may be sea-snake victims turn out to be something else. During the last 3½ years, 17 cases of fish sting, mostly by catfish, have been admitted to Penang General Hospital, compared with nine cases of sea-snake bite and one case of eel bite and jelly-fish sting (and 28 cases of land-snake bite). On the other hand, if the doctor is unacquainted with the features of sea-snake poisoning he may miss the diagnosis entirely, even though the patient claims to have been bitten in the sea.

The minimum criteria of sea-snake bites are that (1) the patient was in the sea or river-mouth, sorting fishing-nets, etc., (2) felt no pain after the initial prick, and (3) bears fang marks at the site of the bite. The bite may be felt as a slight "brush." Sometimes the patient is quite unaware of a bite until the fang marks are seen. They are usually around the ankle—one or more pairs of circular dots as though made by a hypodermic needle. The pattern varies according to the number of teeth penetrating as well as the fangs, which are small in sea-snakes, rarely exceeding 4 mm. long. Behind them is a maxillary row of teeth and two internal palatine rows—that is, four parallel rows in the upper jaw. Most of my cases have had four dots (see Fig. 3), although two is common and single or multiple

FIG. 3.—Sea-snake bite, typical marks: inconspicuous, no local reaction or tenderness. The dots represent two bites (fang marks A and B in the inset).

dots may occur. Fang marks are slightly bigger than the teeth marks, usually 5-10 mm. apart, and there is no swelling, bruising, or tenderness around them (unless, of course, local "treatment" has been given). Sometimes the fangs or teeth break off and remain embedded. Fishermen draw a hair over the site to extract them as a diagnostic measure. Pin-head oozing of blood stops within a minute or two. The bite marks are often inconspicuous, and a good light may be needed to see them.

These three points—the sea, absence of pain, and fang marks—justify a presumptive diagnosis of sea-snake bite, and treatment should be given. The diagnosis is certain if the snake has been seen to have a flat tail or there is evidence of sea-snake poisoning, such as leg paresis, trismus, or ptosis. The delay between the bite and the onset of poisoning symptoms may be deceptive. Although usually half to one hour, periods of up to six hours have been recorded. If, however, more than six hours have elapsed since the bite and there is no evidence of poisoning, either it is not a sea-snake bite or no venom has been injected. Fish stings are easily distinguished, as they are always extremely painful and tender (see Fig. 4).

Fig. 4.—Sting mark from a catfish (*Plotosus*; "ikan sembilang"). This is always very painful, and the mark is ragged, linear, and tender. It is not always as conspicuous as in this case.

Treatment

From evidence which will be reported elsewhere, it is improbable that first-aid and local treatment are of any benefit except from the psychological viewpoint. Mainly for this latter reason, the following first-aid measures are recommended: (1) avoid all exertion, especially with the limb bitten (the most important measure); (2) apply a tourniquet to the thigh (in leg bites) or arm above the elbow (in upper-limb bites), releasing it every 30 minutes; (3) leave the fang marks alone; and (4) if possible, kill the snake by one sharp blow on the neck (avoid the head) and, after wriggling has stopped, lift by the tail into a container and bring to the doctor.

Specific antivenene is not yet available for sea-snake poisoning. A polyvalent antiserum containing a krait fraction should be used, as, of the Elapidae, krait poisoning (Ahuja and Singe, 1954) bears the closest resemblance to that of sea-snakes. In the admission room 20 ml. is slowly injected intravenously, preceded by cortisone to prevent serum reactions, which are frequent and may be severe. Adrenaline is indicated if, as commonly happens, the reaction occurs immediately, before the cortisone is acting. I have not found parenteral antihistamines of help. The problem of antivenene dosage and therapy is discussed later.

Feeding by gastric tube, preferably "polythene," which is less irritating than rubber, will usually be necessary on account of the trismus and, if present, dysphagia. The fluid and electrolyte balance may need careful watching, note being made of vomit and increased sweating on the output chart. The posture should be frequently changed and antibiotics given to prevent or control infection. Mor-

phine derivatives, on account of their depressive effects on respiration, must not be given. If a sedative is required, a barbiturate or intramuscular paraldehyde is suitable.

If respiratory insufficiency develops it may be due to (1) damage to the respiratory centre by the venom; (2) peripheral paralysis of respiratory muscles; and (3) obstruction of the airway by secretions, food, or vomit. The management of such cases, similar to that of bulbospinal poliomyelitis, toxic polyneuritis (Russell, 1955), and tetanus (Shackleton, 1954), is difficult and complex (Astrup *et al.*, 1954). The patient should be nursed prone, with the foot of the bed raised to drain secretions. Intubation, tracheotomy, and artificial respiration by intermittent positive pressure may all be required, involving intensive team-work between the medical and nursing staff. Cuirass respirators are inefficient and tank respirators have too many disadvantages (Astrup *et al.*, 1954).

Discussion

A great many problems remain to be solved, including various biological features of the sea-snakes, many aspects of the venom (such as yield and toxicity of different species in varying circumstances, rate and route of absorption, rate of fixation, its nature, site, and mode of action, excretion, and fate in the body), the effectiveness of a tourniquet, other local measures, and prolonged artificial respiration; and, most important, the question of specific antivenene. The latter should be effective against all the common species of sea-snakes, and could be combined with hyaluronidase to enable injection at peripheral dispensaries. In some river-mouth villages, active immunization might be the best solution. Detailed discussion of these matters will be postponed until the results of current research are available. At this stage it would seem profitable to consider three problems—namely, the incidence of sea-snake bites, the safety of bathing, and the outcome when people are bitten.

What is the Frequency?

It is generally assumed that sea-snake bites are extremely rare. Certainly, records are scarce. The three main reasons for this are: (1) the timidity of the snake; (2) the victim is usually a fisherman in some remote village: he very rarely comes to responsible medical authorities (Smith, 1926); and (3) for fear of offending the sea-snakes and other reasons, fishermen are reluctant to talk about incidents, especially fatal ones. The casual inquirer would probably be told that none occurred. Although the seas around northern Australia abound with sea-snakes, there are no known instances there of poisoning (Gray, 1930; H. Flecker, 1953, personal communication). Smith (1926) quotes a pearl-fisher who told him divers were often bitten, although symptoms were slight or absent. P. D. G. Pugh (1953, personal communication) was unable to confirm this from the many divers he questioned. In Gato, a small islet of the Philippines, enough sea-snakes breed to maintain a supply of 10,000 skins, at least 1 metre long, a year indefinitely (Herre and Rabor, 1949). Before the war 30,000 were taken each year. Despite this abundance, no cases have been recorded from the vast forces in that area during the second world war (personal communications from the Departments of Navy, Army, Air Force, U.S.A., 1955). Bokma (1941), in Java, found only six fatal cases over 20 years. There is a conspicuous dearth of reports in the Indian medical literature. Reviewing world mortality of snake bite, Swaroop and Grab (1954) produced few facts about sea-snake victims except that fishermen were occasionally bitten.

However, Rogers (1902-3) said that deaths were not rare among oyster fishers along the Madras coast. Peal (1903) was told that three or four fishermen were bitten each year in a fishing village on the Orissa coast and 25% died. Hospital statistics give virtually no help in assessing incidence, because at present the victims rarely go to hospital. An exception is Kuala Perlis, a village of about 1,200 fishermen in northern Malaya, from which 30 cases of sea-snake bite

were admitted in 1953 and 29 in 1954 (A. A. Wahab, 1955, personal communication). Smith (1926), writing of the Gulf of Siam, says, "There is hardly a village that cannot tell you of its fatalities." The preliminary findings of the survey of fishing villages already mentioned fully confirm this statement. Kuala Muda, a river-mouth 60 miles south of Kuala Perlis, has 10-15 cases each year amongst 750 fishermen (two fatal cases in 1954 and 1955).

In eight small villages (averaging 200 fishermen each) around Penang island I have so far personally interviewed the victims or close witnesses in 43 cases (8 fatal) occurring during the last 10 years. For varying reasons this is a considerable underestimate. Villages vary, but sea-snake bite is certainly not rare, especially at river-mouths. I believe that with improved transport, diminishing prejudice against hospitals, etc., many more cases amongst fishermen will come to light, as has already happened in north-west Malaya. This area contains a minute fraction of Asian fishing villages. Unless it is exceptional in the incidence of sea-snake bite (and there seems to be no reason why this should be so), the yearly toll amongst Asian fishing folk must be considerable, the mortality far from negligible.

Is it Safe to Bathe?

Sea-snakes, though very poisonous, are inoffensive and bite only under considerable provocation (Wall, 1909; Smith, 1926; Herre, 1942; Tweedie, 1953). However, two bathers were fatally bitten on the same afternoon in 1954, both ironically enough near "Lover's Isle," a famous beauty spot of Penang and (formerly) a favourite bathing-place. This posed the question, is it safe to bathe along the vast coastline frequented by sea-snakes? Millions must have previously bathed or paddled without harm. The risk is obviously infinitesimal. However, this statistic would be of small solace to a victim and not very reassuring to anxious mothers who are aware of the existence of sea-snakes.

Of 68 cases recorded or personally investigated 15 were bitten (7 fatally) whilst bathing, wading, or paddling for pleasure. Of the remaining 53 victims, 36 (11 fatal cases) were fishermen bitten at work, in 13 the circumstances of the bite (5 fatal) were closely connected with the fishermen's occupation, and 4 non-fishermen were fatally bitten when they grabbed the snake. As the vast majority of victims are fishermen not observed by doctors, these figures mean a little except that a sea-snake bite whilst bathing is a possibility, albeit remote. For the fisherman it is an occupational hazard which many accept with apparent nonchalance, although fully conversant with the implications.

Are there any special factors that make bathing dangerous? Little is known about the breeding habits of sea-snakes, although at such times they are said to be more active and aggressive (Herre, 1942). Many fishermen believe that altered salinity makes them attack people. This theory is supported by the fact that certain villages at larger river-mouths have a much higher incidence of bites, especially among bathers (8 of the 15 cited above were bathing, etc., in a large river-mouth). However, the latter may merely be due to sea-snakes being commoner around river-mouths (Smith, 1926). In captivity there is no doubt about the reluctance of the sea-snake to bite. I have observed a number of different species in glass tanks and have repeatedly tried to goad them into biting a plastic doll, fish, etc., both in the water and on the floor, without any success, provided they are not held. My present opinion is that these bathing cases are unfortunate coincidences, and it is just as safe to bathe now as always. But it would be wise to avoid river-mouths.

The Outcome

The outcome of a bite depends essentially on the amount of venom injected. Only a minority of those bitten develop severe symptoms or die. I have been accidentally bitten twice by sea-snakes, and dogs have been experimentally bitten with little or no evidence of poisoning.

It would thus be difficult to assess the effectiveness of antivenene in human victims. So far it has not proved possible to make specific antivenene, although the problem is being pursued. The mortality in cases of krait-poisoning treated by polyvalent but not specific antivenene is 77.1% in India (Ahuja and Singh, 1954). Similarly, polyvalent antiserum is not likely to be effective in sea-snake poisoning except in large amounts (preliminary findings suggest that antivenene with a krait fraction has limited neutralizing power against sea-snake venom). Little progress seems to have been made during the last 30 years in refining and concentrating antivenenes. Discussing this problem in 1921, Acton and Knowles pointed out that, for a "large" bite, over 700 ml. of antivenene would be required within a quarter of an hour. Polyvalent antivenenes available to-day are feeble affairs, 1 ml. neutralizing less than 1 mg. of venom. Specific antivenenes are not much more potent.

Theoretically, to counteract a "large" bite from the commoner venomous snakes an enormous dose of antivenene would still be necessary. As with diphtheria, the sooner the antiserum is circulating the more effective it is likely to be. Dividing and delaying the dose, as is often done, is irrational; but a pint (570 ml.) of antivenene by rapid intravenous drip would probably kill the patient. Even with 10 ml., reactions have often been very severe despite cortisone, etc. One is therefore reluctant to "push" intravenous polyvalent antivenene dosage. Subcutaneous injection with hyaluronidase may solve this problem when a specific antiserum becomes available. It will then be more important to decide whether the victim has received a "large" bite or not. Points indicating this are: (1) the snake has been seen to be fat—for example, thicker than a man's thumb; (2) fang marks more than 10 mm. apart; (3) rapid involvement of poisoning symptoms—for example, several features within half an hour; and (4) haemoglobinuria and failing vision. With one or more of these criteria, admittedly far from infallible, a large dose of antivenene would be indicated.

Experimentally, Rogers (1902-3) noted a similarity to tetanus toxin, which Wright (1954) found to be rapidly fixed to cells of guinea-pig brain stems. More than half the dose injected was fixed within two hours. Presumably sea-snake neurotoxin reaches the brain stem much more quickly than tetanus toxin. If a lethal dose is injected and fixed like tetanus toxin the outlook would appear to be grim. However, Richards (1873) kept his dog alive for over 24 hours by artificial respiration. Using similar methods, Lassen (1953) reduced the mortality of bulbospinal poliomyelitis from 94% to less than 40%, and Shackleton (1954) showed that cases of tetanus hitherto deemed inevitably fatal could be saved. As permanent after-effects of sea-snake poisoning are unknown, severe effects are usually short-lived, and there is experimental evidence that venom is excreted in the urine, it is possible that modern methods of artificial respiration by intermittent positive pressure will save many severe cases. With a specific antivenene the mortality should be even further reduced.

Summary

The clinical picture, diagnosis, and treatment of sea-snake poisoning are outlined.

Further problems are mentioned. The incidence and outcome of sea-snake bites and the safety of bathing are discussed. Cases amongst bathers occur, but are extremely rare except in river-mouths. In contrast, the incidence in fishermen and their kin is much higher than the scanty literature would indicate. A specific antivenene, adequately concentrated and refined, is urgently needed for these cases.

I wish to thank Mr. M. W. F. Tweedie, Raffles Museum, Singapore, for his help and advice, especially on the classification of snakes; Dr. H. W. Parker, British Museum, and the Librarian; Royal Society of Medicine, for their help with the literature; Mr. C. J. Sundram for the photographs; Dr. K. J. Lim for help on numerous aspects; the Director of Fisheries, Federation

of Malaya, for information about fishing villages; and the Director of Medical Services, Federation of Malaya, for permission to publish.

OBSTETRIC INDICATIONS FOR THE USE OF PUDENDAL NERVE BLOCK ANALGESIA

BY

I. ROCKER, M.B., M.R.C.O.G.

Late Senior House Officer, United Cambridge Hospitals

The problem of anaesthesia during the second stage of labour is complicated by the fact that the safety of both mother and foetus has to be considered. Anaesthesia often has to be induced in an unprepared patient in whom the foetus is showing signs of distress.

The technique of pudendal nerve block is simple and safe, and it avoids many of the dangers and difficulties of inhalation, extradural, and spinal anaesthesia. It produces analgesia of the lower vagina, the vulva, a varying area of surrounding skin, and some relaxation of the pelvic floor. Excluding those patients who are mentally unsuited for local analgesic techniques, safe and reliable analgesia can be produced for a number of obstetric manoeuvres with a minimum risk to the mother and her yet unborn infant.

Anaesthetic Mortality and Morbidity

The present low maternal death rate due to anaesthesia should not lead to complacency, as there are fewer greater tragedies to a family than the loss of its mother. Inhalation anaesthesia is the most common form of anaesthesia used during the second stage of labour. Its complications are the inhalation of vomit or regurgitated stomach contents, depression of the foetal respiratory centre, and relaxation of the uterus leading to post-partum haemorrhage. Spinal and extradural techniques need even more specialized experience, and there is always the risk of infection and permanent spinal cord or nerve damage. Both of these techniques produce varying degrees of hypotension.

Inhalation of vomit has been reported as a cause of death by many workers, and consideration must be paid to the asthmatic type of aspiration pneumonia caused by

the inhalation of acid stomach contents. Mendelson (1946) described 60 cases giving rise to two fatalities; these occurred among 44,016 cases.

The following authors have also described deaths due to aspiration of stomach contents. The incidence is higher than in prepared surgical cases, but often anaesthesia in obstetric practice is administered as an emergency, and it is well known that the emptying time of the stomach in women in labour is delayed. Eastman (1941) reported 51 deaths; an incidence of 1 in 40,000 anaesthetics. Dieckmann (1945) reported 45 cases in 46,000 deliveries (2 deaths; an incidence of 1 in 23,000 anaesthetics). Gilliatt (1949), reviewing the causes of death among 55 patients, found that 3 were due to inhalation of vomit; an incidence of 1 in 11,382 anaesthetics. Merrill and Hingson (1951) reported 59 deaths; an incidence of 1 in 44,135 anaesthetics. Parker (1954) reported 5 deaths; an incidence of 1 in 3,708 anaesthetics. Hall (1940) and Willcox (1949) have also reported five and two deaths respectively.

The variation between the British and American figures is explained by the more frequent use of general anaesthesia during the second stage of labour in American hospitals.

Local analgesics rarely give rise to death, and when death does occur the following factors are usually involved: (1) large amounts of agent, (2) intravenous injection, and (3) idiosyncrasy. The first two factors are controllable and preventable; the third can be minimized by interrogation about previous idiosyncrasy, and the symptoms can be controlled by the administration of a rapidly acting barbiturate. Idiosyncrasy is very rare.

The toxic effects of lignocaine have been discussed in the correspondence columns of the *British Medical Journal* (1955). There is no doubt that lignocaine can be dangerous, but not if the maximum dosage is kept well below 1 g. in a single dose. Many of the cases mentioned as having had toxic reactions have one thing in common—namely, that 2% lignocaine had been used. Lock and Greiss (1955) report a death following the injection of 40 ml. of 2% lignocaine for pudendal nerve block in a secundipara with mitral stenosis. She died seven minutes after the injection. Dutton (1955) reports a case in which convulsions occurred after 80 ml. of 1% lignocaine had been used. Therefore safety lies in weak solutions of lignocaine, used in the minimum quantity necessary for effective analgesia.

The Pudendal Nerve and its Branches

The pudendal nerve arises from the second, third, and fourth anterior sacral trunks, which form a single trunk 0.5 to 1 cm. proximal to the ischial spine. The nerve trunk courses through the greater sciatic foramen inferior to the piriformis muscle, passing posterior to the ischial spine—between the sacrospinous ligament anteriorly and the sacrotuberous ligament posteriorly. As the nerve passes the inferior tip of the ischial spine it enters the pudendal canal. The nerve lies medial to the pudendal vessels. It divides into three main branches: the inferior haemorrhoidal nerve; the dorsal nerve of the clitoris, and the perineal nerve.

Inferior Haemorrhoidal Nerve.—Klink (1953) in a series of 85 dissections found that in 50% of cases this nerve did not arise from the pudendal nerve but as a separate branch from the fourth anterior sacral primary ramus. In these cases the nerve did not lie in the pudendal canal but passed through the sacrospinous ligament 0.5 to 1 cm. inferomedial to the pudendal nerve. This nerve supplies the mucosa of the lower part of the anal canal, the external anal sphincter, and the skin anterior and lateral to the anus.

The dorsal nerve of the clitoris runs between the layers of the urogenital diaphragm, terminating in the filaments supplying the clitoris.

The perineal nerve arises above the inferior border of the ischial tuberosity and divides into superficial and deep branches. The former constitutes the main nerve supply of the superficial structures of the vulva and perineum, and also anastomoses with the perineal branches of the posterior

femoral cutaneous nerve of the thigh. The latter are the source of supply to the deep muscles and fasciae of the perineum.

The ilio-inguinal nerve also send branches to the mons pubis and the labia majora.

Effect of Pudendal Nerve Block

Klink (1953) studied the effect of this nerve block on the sensation of touch, pin-prick, and haemostat pinch in the vagina. He found that whereas 10% of patients felt pin-prick and 50% felt haemostat pinch in the lower part of the vagina, a nerve block abolished response in this area and in the surrounding skin.

It is therefore possible by careful technique to obtain satisfactory skin anaesthesia and relaxation by blocking the main pudendal nerve and skin infiltration to exclude branches from the ilio-inguinal nerve and perineal branches from the posterior femoral cutaneous nerve. In those cases where the levator ani receives its main supply direct from S. 4 relaxation may be poor.

Technique

The skin infiltration is begun at a point midway between the anus and the ischial tuberosity, using a fine needle. The nerve block and skin infiltration is then performed, using a 5-in. (12.5-cm.) needle, though a 3-in. (7.5-cm.) needle is often long enough to reach the ischial spine.

The main procedure is the pudendal nerve block, and aspiration must be performed before injection of the analgesic solution in order to make certain that the point of the needle is not in the lumen of a pudendal vessel.

Skin infiltration of the vulva is performed to produce a terminal block of any nerve filament arising from the ilio-inguinal nerve. A further injection into the deep tissues of the perineum and the levatores ani ensures analgesia in those cases where the inferior haemorrhoidal nerve arises as a separate branch from S. 4. An alternative is to inject 5 ml. of analgesic solution just medial to the ischial spine. The greatest technical difficulties arise in obese patients and when the presenting part is at the outlet, making palpation of the ischial spine less easy.

The purpose of the nerve block is explained to the patient and she is warned that only pain will be relieved, but that she will still be able to appreciate the sensation of pressure. Inhalation of gas and air or trichlorethylene is continued if necessary to relieve the discomfort of uterine contractions. As with all local analgesic techniques, patience and gentleness are required to achieve the patient's co-operation. Usually the interest of the mother to see the birth of her baby makes eye-shielding unnecessary.

The Investigation

The present series consists of 57 patients (38 primigravidae and 19 multigravidae) in whom pudendal block was carried out. An analysis of the group is given in the accompanying Table.

Analysis of Series	
Total number of cases	57
Number of forceps deliveries	24
Stillbirths	2
Assisted breech delivery in multiple pregnancies	6
Forceps delivery in multiple pregnancies	5
Spontaneous vertex deliveries	7
Stillbirths	1
Number of infants delivered under pudendal block analgesia	51
Number of stillbirths	3

Of the three stillbirths one was a spontaneous delivery of the second twin, the second was a forceps delivery for foetal distress in a case of mitral stenosis, and the third was a forceps delivery of the leading twin because the foetal heart could suddenly not be heard.

Post-mortem examination in the last-mentioned case revealed no evidence of cerebral haemorrhage other than the petechial haemorrhages associated with foetal anoxia.

Drugs

A mixture containing 1% procaine or 1% lignocaine, 1 in 100,000 adrenaline, and 1,000 units of hyaluronidase was used. The first 19 cases had procaine blocks, and in the remainder lignocaine was employed. To 50 ml. of analgesic solution was added 0.5 ml. of 1 in 1,000 adrenaline. These volumes were chosen to eliminate the risk of a miscalculation of the adrenaline concentration. Then 1,000 units of hyaluronidase was added to the solution. It was found that by using freshly made solutions of procaine or lignocaine in saline which did not contain chlorocresol (usually added to maintain sterility) the sensation of stinging directly after the injection was relieved. A total of 30 to 40 ml. of solution was used. Many papers have been written on the use of hyaluronidase as an adjunct in nerve-block analgesia, and the use of adrenaline to prolong the duration of analgesia is well recognized.

Douglas and Vosburgh (1951) tested concentrations of 1% and 2% procaine with and without the addition of hyaluronidase and adrenaline. They got the best effect from using 60 ml. of 1% procaine with hyaluronidase and adrenaline. With procaine and hyaluronidase, the delay before the onset of analgesia was only one to two minutes, but the duration of analgesia averaged only 32 minutes. With the addition of adrenaline (1 in 240,000) the delay averaged five minutes and analgesia lasted about 80 minutes.

In the present series of cases the following points were observed: (1) A five-minute delay occurred before the onset of analgesia, using 1% procaine plus adrenaline. (2) With the use of lignocaine and adrenaline the average delay was only one to two minutes, and an episiotomy could be performed without distress to the patient within that time. (3) The duration of analgesia was not timed, but was at least an hour. On several occasions a few millilitres of solution had to be injected before the superficial skin sutures were inserted. (4) Supplementary inhalation anaesthesia was used in three cases.

Indications

Normal Labour

This group comprised five cases of spontaneous delivery, all in primigravidae. Pudendal nerve block was performed because the duration of the second stage had exceeded one hour and only slow progress was being made. This effectively abolished the discomfort caused by stretching of the soft parts, and spontaneous delivery was accomplished with the aid of an episiotomy. Abolition of the perineal reflex meant that the expulsive efforts of the mother had to be directed for about a quarter of an hour, after which time expulsive effort recurred spontaneously.

Foetal Distress

In this group there were 11 cases of forceps delivery (seven primigravidae) and one stillbirth. The advantages of this form of analgesia are mainly that it allows the administration of pure oxygen to the mother while delivery is in progress, and the foetal respiratory centre is not depressed.

A block can be performed in two minutes and the forceps applied within five minutes of beginning the injection. This is equally as quick as induction and stabilization of anaesthesia with nitrous oxide, oxygen, and ether. Another merit is that there is no delay until the arrival of an anaesthetist.

The one stillbirth was in a patient with mitral stenosis. Oxygen was given by a B.L.B. mask during delivery.

In one case a transverse position of the head was easily corrected.

Delay in the Second Stage of Labour

The 13 patients, including 10 primigravidae, in this group had low forceps extractions because of failure to make steady progress. They comprised two cases of previous caesarean section (one patient also had heart disease); two cases of pulmonary tuberculosis (one bilateral artificial pneumothorax, and one tuberculous pleural effusion in early

pregnancy); eight cases in which the main indication was a second stage of labour prolonged for two hours—there were five primigravidae over the age of 30 among them; and one case of deep transverse arrest: the position of the vertex in this case was thought to be anterior until more adequate examination, after the nerve block had been performed, showed the true position. Kielland's forceps were applied and a forceps rotation and extraction was performed without distress to the mother. Unless rotation can be done without difficulty pudendal nerve block analgesia is not suitable for manoeuvres such as forceps rotation and extraction. Traction was performed at the time of uterine contractions.

Previous Caesarean Section.—Routine forceps delivery is advocated only when there has been no previous vaginal delivery. In this type of patient the second stage of labour may be prolonged, and it is felt that once the cervix is fully dilated no further prolonged strain should be placed on the uterine scar. In the case of patients who have had previous vaginal deliveries forceps delivery is indicated if the second stage of labour has lasted over half an hour.

Maternal Disease.—In cases of chest disease, heart disease, protruded intervertebral disk, etc., especially in primigravidae, forceps extraction under pudendal nerve block analgesia is a safe method of reducing the strain of the second stage of labour.

Assisted Breech Delivery

The nine patients in this group included six primigravidae. In an assisted breech delivery anaesthesia or analgesia is required during delivery of the arms and the head. Induction of anaesthesia with thiopentone, nitrous oxide, oxygen, and divinyl ether (Law and Ransom, 1954) or "neothyl" (methyl-n-propyl ether) combines the dangers of general anaesthesia with delay before anaesthesia is stabilized. Pudendal nerve block can be performed when the breech is on the perineum, and analgesia is sufficient to allow the performance of an episiotomy, Løvset's manoeuvre, and controlled extraction of the foetal head.

In four cases forceps were applied for delivery of the after-coming head.

The time for induction of the nerve block is when delivery of the buttocks is anticipated. Otherwise loss of the perineal reflex produces a time-lag of about 15 minutes before spontaneous expulsive efforts become re-established.

This technique allows a gentle unhurried and controlled delivery of the head without any danger of maternal anoxia. Oxygen can also be administered to the mother, so allowing good oxygenation of the infant during delivery.

Multiple Pregnancy

This group comprised five cases of twins and one case of triplets. Four of the mothers were primigravidae. There were two stillbirths.

The indications for pudendal nerve block fall into two categories: (a) when the breech is presenting; and (b) when forceps delivery of the leading presenting vertex is indicated: in these cases the urgency for extraction of the second twin because of general anaesthesia is removed. One is always loath to have to reintroduce anaesthesia.

* Among the 13 infants in this group there were six assisted breech deliveries; two spontaneous vertex deliveries (one stillborn) and five forceps deliveries—the indication in four cases was foetal distress.

Repair of Severe Lacerations

Pudendal nerve block was carried out for third-degree tears in four cases; repair of recto-vaginal fistula in three cases, and secondary suture of perineum in three cases.

The advantage of this form of analgesia is that immediate repair of third-degree tears is possible, and the same applies to the repair of the recto-vaginal fistulae of small dimensions immediately after delivery.

Secondary suture can also be satisfactorily performed, but gross perineal infection is an absolute contraindication.

Failures

There were three failures in this series. Case 1: twin pregnancy; foetal distress. After nerve block the vertex was found to be in the occipito-posterior position and general anaesthesia was induced. Forceps rotation and extraction was carried out. Case 2: Bronchiectasis; cyanosis in labour relieved by oxygen therapy. Re-examination revealed an occipito-posterior position and posterior lip of cervix. Continuous caudal analgesia given, and manual rotation and forceps delivery performed at full dilatation of the cervix. Case 3: Breech presentation with extended legs. Breech extraction performed under deep ether anaesthesia because of delay in delivery of the buttocks.

Complications

Bruising.—In six patients vulval bruising occurred after infiltration with analgesic solution. Severe varicose veins of the vulva are a contraindication to the use of this type of analgesia.

Haematoma Formation.—In two patients an ischio-rectal haematoma was formed. This was found on vaginal examination because the patient complained of unilateral perineal pain. In neither case was there any rise in the temperature, and no special treatment was required.

Oedema of the Vulva and Perineum.—Three patients had severe oedema, arising about six hours after delivery. By raising the foot of the bed the oedema resolved in about 12 to 24 hours. An injection of hyaluronidase might be a useful adjunct to this treatment.

Perineal Sepsis.—There were no cases of infection of the perineum, and all the episiotomies performed under pudendal nerve block analgesia healed by first intention.

Advantages

(1) The fatality described is the only one I have found reported in the literature associated with pudendal nerve block. (2) There are no pulmonary complications directly attributable to the procedure. (3) The technique is relatively simple and may be used in a home as well as in a hospital. (4) There are no ill effects on such vital sites as the liver, lungs, cardiovascular system, or kidneys. (5) There is no interference with the action of the uterus, the anterior abdominal wall, or the respiratory system. (6) The risk of asphyxia of the child, such as may occur after the use of inhalation anaesthesia, is absent. (7) The tissues must be handled gently, and there is seldom need for brutal hurry. (8) There is a reduction of bleeding from the episiotomy.

Disadvantages

(1) A needle may break during an injection, but since a needle nearly always breaks near the hub a long needle is advised. (2) Intravenous injection. Aspiration should always be performed before injection, and injection should be carried out slowly. (3) Idiosyncrasy to procaine or lignocaine. Fortunately this is rare. (4) Local complications such as bruising and oedema.

Contraindications

(1) When intrauterine manipulations are required. (2) Vulval sepsis, oedema, or varicose veins. (3) For correction of malposition of the presenting part unless this is very easy to perform. (4) In highly strung nervous patients.

Summary

A series of 57 patients (38 primigravidae and 19 multi-gravidae) in whom pudendal nerve block was performed is reported.

Pudendal nerve block was found to give safe and effective analgesia for the performance of low forceps delivery, for assistance in breech delivery, for the repair of severe lacerations, for the management of certain types of multiple pregnancy, and as a method of anaesthesia

for cases of lung and heart disease. It is also a useful technique in the management of the second stage of labour in primigravidae.

The risk of aspiration pneumonia is obviated, and for this reason the technique can help to reduce mortality and morbidity.

There were no foetal deaths that could be attributed to the anaesthetic used.

It is suggested that this is a simpler form of analgesia than caudal and spinal analgesia, and one which allows for full oxygenation of the mother and the foetus.

The maternal complications were comparatively slight and the length of stay in hospital was not increased, though 9 out of the 57 patients had oedema, bruising, or haematoma formation.

In three cases another form of anaesthesia was given in order to accomplish a technically more difficult delivery.

My thanks are due to Miss Janet Bottomley and Mr. Oswald Lloyd for their permission to perform the pudendal nerve blocks and to report the results.

FLUID CONTENT OF THE NUCLEUS PULPOSUS AS A FACTOR IN THE DISK SYNDROME

FURTHER OBSERVATIONS

BY

H. D. BUSH, Ph.D., A.Inst.P.

W. G. HORTON, B.Sc., A.R.I.C.

D. L. SMARE, Ph.D., M.Sc.(Tech.), F.Inst.P.
Bradford Technical College

AND

A. NAYLOR, Ch.M., M.Sc., F.R.C.S.

Consultant in Orthopaedic Surgery, Bradford Hospitals

The possibility that the hydrophilic property of the nucleus pulposus of the intervertebral disk has some bearing upon the development and symptomatology of low back pain, sciatica, brachial neuritis, and disk prolapse was suggested by Charnley (1952) and by us (Naylor, 1951; Naylor and Smare, 1953). The swelling of the nucleus due to an increased fluid content is thought to cause increased internal pressure within the disk, thus stretching the annulus fibrosus and stimulating the nerve-endings contained therein. Whilst the adult intervertebral disk has a poor blood supply, a considerable fluid interchange can occur, as shown by the rapid absorption of 35% diodrast when used in disk nucleography (Cloward and Buzaid, 1952). Charnley further showed that the absorption of fluid by the isolated nucleus could result in considerable pressure being developed when the nucleus was contained in a plethysmograph.

These results were obtained with nuclear material which was (a) removed from the disk, the annulus being disregarded; and (b) was not maintained at constant volume.

A preliminary investigation was carried out by two of us (Naylor and Smare, 1953) to discover whether the nucleus contained within a lumbar disk could absorb enough fluid to develop a high intra-disk pressure that might account for the symptoms associated with disk lesions. Isolated cadaveric disks, from subjects of varying ages, were immersed in water or isotonic saline solution and the pressure developed within the disk was recorded by means of a mercury manometer. Pressures of between 8 and 300 cm. mercury (1.5–58.1 lb. per square inch) were obtained from young subjects, but no pressures were recorded in disks from aged subjects in whom advanced degeneration was found to be present. A more comprehensive survey has now been made on disks from subjects in the age range 19–87 years, using the apparatus described below.

Apparatus

A diagram of the apparatus is shown in Fig. 1. A standard Bourdon gauge type pressure indicator A, reading up to a maximum of 60 lb. per square inch (4.2 kg. per square cm.), was connected to a copper tube B, of $\frac{1}{2}$ in. (1.3 cm.) internal diameter. Tube E, a glass capillary about 8 in. (20 cm.) long and 1 mm. internal bore, was attached by pressure-tight joints to B and to a 20-gauge serum needle F. A metallic bellows, C, closed at one end, was connected to tube B and could be compressed by means of screw D. The whole apparatus above point X was filled with water, while below this point there was an unbroken column of mercury as far as the tip of the serum needle. The mercury-water interface was arranged to be about halfway along the glass capillary, and consequently was always visible.

When used the needle was inserted through the annulus fibrosus of the disk into the nucleus pulposus. On absorption of fluid by the nucleus, expansion of the latter forced mercury up the serum needle. The bellows, C, was compressed until the mercury meniscus returned to its original position. The pressure recorded by the gauge was thus the pressure developed in the nucleus. An indicator (not shown in Fig. 1) was used to enable the mercury meniscus to be adjusted with precision.

Experimental Procedure

Fresh lumbar disks, usually in sets of five (L1–2, L2–3, L3–4, L4–5, L5–S1), were obtained from necropsy subjects with a plate of bone on each side (about $\frac{1}{4}$ in. (6 mm.) thick, this being essential for maintaining the nucleus under conditions corresponding as far as possible with those *in vivo*). Forces generated by the increase in volume of the nucleus will consequently result in a slight increase in the circumference of the annulus fibrosus and not in a bulging of the bone end-plates. The annulus of the disk under test was pierced by a hollow needle of the same gauge as that used in the apparatus, and the needle attached to the apparatus inserted along the track made. This minimized the risk of blockage of the needle by tissue. Each disk was then totally immersed in distilled water contained in a Petri dish.

FIG. 1.—Diagram of apparatus (see text).

By means of this procedure, pressure readings were taken at intervals of about three hours over a period of up to 48 hours. The Petri dishes were immersed in a temperature-controlled water bath, enabling all experiments to be carried out with disks maintained at a temperature of 22° C.

Results

Some 137 disks from 29 subjects (both male and female) aged from 19 to 87 years were examined on the apparatus. The largest number was in the age group 41-60 years; unfortunately, fewer specimens below 41 years were available. Fig. 2 shows the results obtained. In 30 disks no

FIG. 2.—Scattergram of pressure recorded in 107 cases.

pressure was recorded, final pressures of between 0.5 and 42 lb. per square inch (0.04 and 3 kg. per square cm.) being recorded by the other 107. The numbers of disks (expressed as a percentage) developing a given pressure for the age groups considered—namely, 19-40 years (29 disks), 41-60 years (59 disks), 61-90 years (49 disks)—were plotted on histograms (Fig. 3).

The following features were noted: (1) The wide variation in pressure recorded not only with age but also by disks from any one subject. (2) The relatively large percentage of disks recording pressures of 30-45 lb. per square inch (2.1-3.16 kg. per square cm.) in the age group 41-60 years. This feature may also be characteristic of the age group 19-40 years, but lack of data precludes any certainty. (3) The relatively low pressures developed in subjects over 60 years of age. (The above features can also be inferred from Fig. 2.)

The rate of pressure increase varied considerably for each individual disk. No consistent correlation between age and rate of pressure increase was apparent.

At the end of each set of experiments the disks were removed and sectioned with a view to attempting to correlate the pressure developed with the conditions prevailing in each nucleus. As expected, degeneration (as measured by increased hardness and discoloration from white to brown or grey) and an increased number of cavities, usually filled with mercury, appeared frequently in aged subjects. On inserting a serum needle into a disk the mercury has been observed to fall, indicating cavities of up to 0.1 ml. in volume in the proximity of the needle-tip. This is consistent with the demonstration of cavities by means of nucleography (Lindblom, 1950; Erlacher, 1952).

Discussion

The hydrophilic properties of isolated nuclear material may be explained by a process regulated by two opposing factors—namely, (a) osmotic pressure differences between the protein gel and surrounding medium, this being duly influenced by the mucopolysaccharide content; and (b) the cohesive forces of the tissue. Equilibrium is established when these forces are equal and opposite.

Sylvén *et al.* (1952) have shown that more hydrophilic groups of mucopolysaccharide become attached to the collagen molecule with advancing age of the nucleus, and this may result in decreased water-binding capacity. The precipitation of large orientated collagen fibres and possibly of elastin (Happey, Horton, and Naylor, 1956) will decrease the gel concentration within the nucleus. Both the above-

FIG. 3.—Percentage of disks developing a given pressure, arranged according to age groups.

mentioned factors should lead to a decrease in the swelling and water uptake of the nucleus with advancing age. This is in agreement with the observations of Göcke (1932).

In our experiments concerning the increase in pressure in the nucleus pulposus, the nucleus has been confined within the annulus fibrosus. This represents a close approach to conditions appertaining *in vivo*.

It is suggested that the pressure developed in the nucleus pulposus in this state may be affected by the following factors: (1) the amount of hydrophilic mucopolysaccharide material; (2) the concentration of protein gel in the nucleus; (3) the presence of cavities of differing size in the nuclei pulposi, which occur more often in disks from aged subjects; and (4) variations in the elasticity of the annulus fibrosus. Experimental evidence (Happey, Horton, and Naylor, 1956)

has been obtained which indicates that the elasticity of the annulus fibrosus may vary with its position in the disk, and, furthermore, the elasticity may be different for each individual disk.

The differences in mucopolysaccharide content occurring in the nuclei of disks from any given subject are probably insufficient to account for the large differences in pressure encountered within such disks. It is suggested that the controlling factor may be the variations in the osmotic pressure due to differences in gel concentration within each nucleus pulposus. Any decrease in concentration resulting from increased precipitation of collagen would automatically reduce the water uptake and hence decrease the pressure developed. The implications are the development of a high pressure in one disk together with the action of body weight and muscle action, which may be sufficient to cause herniation in this disk but not in another. In this connexion it should be noted that local variations in the precipitation of protein within a nucleus occur in, and after, the fourth decade. On the basis of the above argument, this may lead to differences in pressure within the nucleus when immersed in aqueous solutions.

The observations of Göcke (1932) on isolated nuclei are in agreement with our observations on nuclei surrounded by an annulus—namely, that water uptake and therefore pressure decrease with advancing age. This may be readily explained, since the frequency of occurrence of cavities and decreased number of free polar mucopolysaccharide groups augmented by the increased gel concentration will tend to lower the pressure developed in aged subjects. Disks from subjects in the age group 20-55 years develop a high intradisk pressure, after which the pressure progressively decreases with age (Figs. 2 and 3). This observation may afford some explanation of the well-known fact that not only is disk prolapse more common before the age of 50 years than after and rare after 60, but that attacks in a patient become less frequent with advancing age, since the decreasing pressure developed should make excessive stress on the annulus less likely.

A considerable number of disks in all age groups failed to record a pressure. This may result from the appearance of cavities due to removal of the forces of compression from the disk (these cavities should be distinguished from those due to chemical changes). There is no apparent correlation between the presence of these cavities and the development of small or zero pressures, for disks with large cavities do occasionally record considerable pressures.

Summary

Further extended measurements on the intradisk pressure developed on immersion in distilled water have been made, using large numbers of disks. Though disks from the same subject were found to generate widely differing pressure, there is a general trend towards a lower pressure with increasing age. The possible causes of such behaviour are discussed.

One of us (W. G. H.) is indebted to the Bradford Education Authority and the Bradford "A" Group Hospital Management Committee for a joint scholarship to carry out this work.

NEPHROSIS TREATED WITH INTRAVENOUS T.A.B.

BY

DENNIS MENDEL, M.D., M.R.C.P.

and Lymington Hospital, Hants

In the search for effective treatment for nephrosis—Type II nephritis of Ellis (1942)—the observation that infection might be associated with remission (Aldrich, 1926; Ball and Evans, 1932) led to the use of measles by Janeway and Hutchings (1947) and of malaria by Gairdner (1952) and Byrne (1952), the last of whom related the success of this form of treatment with the irregular remissions produced by corticotrophin (A.C.T.H.) (Barnett *et al.*, 1950; Riley, 1950).

Intravenous T.A.B. vaccine, a simple and well-known means of producing pyrexia, was used in the case reported here, and it regularly brought about a diuresis. The better-controlled production of pyrexia so induced allowed study of the mechanism involved. Below we give our observations on the diuresis, albuminuria, plasma proteins, plasma cholesterol, and the 17-ketosteroid excretion.

Case Report

A woman aged 53 noticed ankle oedema in September, 1951, which rapidly extended. Treatment at another hospital in April, 1952, with mercurial diuretics (mersalyl), plasma transfusion, urea, and a high-protein/low-salt diet, had not been beneficial, and Southey's tubes had been used. Two weeks after her discharge oedema recurred, and this steadily progressed in spite of mersalyl and urea. She had been bedridden for some weeks before admission. There was no previous history of acute nephritis.

On admission in December, 1952, she had gross generalized oedema, with pleural effusions and ascites, and the knees could not be flexed to the slightest degree. The blood pressure was 140/70. The fundi were normal. The thyroid was firm, with slight generalized enlargement, but there was no clinical evidence of toxicity or myxoedema. No other abnormality was detected.

Her urine contained albumin (Esbach, 20 g. per litre), but there was no other significant abnormality. Blood urea was 30 mg. per 100 ml.; plasma albumin, 2 g. per 100 ml.; plasma globulin, 1.5 g. per 100 ml.; plasma cholesterol, 680 mg. per 100 ml.

A low-salt/high-protein diet and unrestricted fluids were given throughout the period of observation, and fluid balance and Esbach estimations were recorded daily. The patient was at rest in bed for the first 12 weeks.

After observation for several weeks, during which mersalyl failed to produce a diuresis, intravenous T.A.B. therapy was started. The 24-hour fluid intake varied between 0.9 and 1.2 litres, and the 24-hour urinary output between 0.3 and 0.7 litre during this control period.

T.A.B. vaccine, containing 2,000 million organisms per ml., was used. The dose required was diluted to 1 ml. with sterile normal saline. Doses of 200-300 million organisms produced moderate fever (maximum temperature 102° F.—38.9° C.) and a generalized reaction (vomiting, backache) lasting up to 24 hours. Smaller doses had no appreciable effect. Five out of six injections in this dose range produced a successful response.

Five individual periods of diuresis have been studied. Some of the features of the response during two of the periods (second and third) are shown in the Chart. The data for the whole group are described below.

Diuresis.—Relative oliguria occurred on the day of injection. Diuresis followed in 24–36 hours and became manifest by a sudden large nocturnal output. The duration of the response was from 7 to 10 days, but lasted 35 days on the solitary occasion when a second injection was given during a successful response. The termination of the

Chart showing part of day-to-day reactions to T.A.B.

response, recognized by a rise in urinary albumin to more than 10 g. per litre and by a fall in urinary output below 1.2 litres, was also a sudden event. The average daily urinary output for the five periods was 1.8, 1.5, 2.2, 1.8, and 1.3 litres. Fluid intake remained between 0.9 and 1.2 litres. The net fluid loss for the whole of the five periods was 29.9 litres. A weight loss of approximately 40 lb. (18 kg.) was recorded.

Albumin Loss.—At the onset of diuresis the total urinary loss of albumin increased (see Chart). This was followed after 48 hours by a decrease in total albumin loss. Compared with an initial average loss of 12 g./24 hours, the average 24-hour losses during the five periods of treatment were 1.5, 7.1, 8.0, 6.5, and 4.7.

Plasma Proteins.—Determinations of plasma albumin and globulin were made at the onset and termination of three of the periods of diuresis. At the onset of diuresis these values were albumin 1.4, 1.7, and 1.6 g. per 100 ml., and globulin 1.6, 1.8, and 2.6 g. per 100 ml.; and at the termination of diuresis, albumin 3.2, 2.4, and 1.4 g. per 100 ml., and globulin 1.3, 2.1, and 1.6 g. per 100 ml. On the solitary occasion when diuresis continued for 35 days the plasma proteins at the end of this period were albumin 1.6 g. and globulin 2.9 g. per 100 ml. It can be seen that the diuresis was independent of plasma protein concentration.

Plasma Cholesterol.—Estimations of plasma cholesterol were similarly made at the onset and termination of two periods of diuresis. These values were 474 and 642 mg. per

100 ml. at the onset, and 672 and 696 mg. per 100 ml. at the termination. During the diuresis lasting 35 days 920 and 938 mg. per 100 ml. were recorded on the 21st and 35th days respectively.

17-Ketosteroids.—The 24-hour urinary excretion of 17-ketosteroids was measured at random intervals during the periods of diuresis. Values of 1.3 and 2.9 mg. per 24 hours were obtained at the onset of diuresis, 2.2 mg. 48 hours after the onset of diuresis, and 1.9 and 3.1 mg. on the 14th and 35th days in the case of the long-continued diuresis.

Discussion

Intravenous T.A.B. vaccine had a definite diuretic action in this case of nephrosis. The previous unrelenting course of the disease and the fact that individual large diureses occurred within a constant interval after T.A.B. would eliminate the occurrence of spontaneous remission.

The mechanism of the diuresis has been shown to be independent of plasma protein concentration, although secondary conservation of albumin occurs and cannot easily be explained by the three known mechanisms of producing a diuresis in nephrosis—namely, increase in plasma osmotic pressure, osmotic diuresis, and increased renal loss of sodium.

The action of pyrogens upon renal blood flow (Smith, 1951) is to induce an initial short period of ischaemia, followed by hyperaemia lasting four hours or more and reaching values of 30–60% above normal. There is, however, no change in filtration rate, and these transitory changes cannot be held to be responsible for the continued diuresis.

It has been shown by Slessor (1951) that hormones of the cortisone type may be concerned with the inactivation of the antidiuretic hormone. In the light of this work it is here suggested that the diuresis occurring during fever therapy for nephrosis might be due to increased corticoid output inactivating antidiuretic hormone, thus causing a primary water diuresis. Although in the above case we have been unable to show that following T.A.B. therapy there is an increase in urinary corticoids associated with a lowering of blood cholesterol, the diuresis in response to corticotrophin (Riley, 1951) is also independent of plasma proteins, and is associated in most cases with a lowering of blood cholesterol.

Summary

A case of Type II nephritis treated with intravenous T.A.B. is recorded.

Intravenous T.A.B. regularly produced a diuresis and a decrease in albuminuria. The diuresis was independent of changes in plasma proteins or cholesterol. A possible mechanism is suggested.

We are indebted to Mr. G. H. Pitt for referring this case to us.

Medical Memorandum

Regional Ileitis in Mother and Son

A familial incidence of regional ileitis is recognized (Crohn, 1949). We have been able to find reports of 18 instances. Five of these were recorded by Crohn (1949) from his series of 298 cases of the disease. Armitage and Wilson (1950), in their series of 34 patients, noted a single familial case.

In nine of the descriptions brothers and/or sisters were affected (Lewisohn, 1938; Brown and Scheifley, 1939; Edwards, 1948; Riech, quoted by Kirsner *et al.*, 1948; Crohn, 1949; Armitage and Wilson, 1950). In a recent communication (Crohn and Janowitz, 1954) an additional six instances (making a total experience of 11) of familial incidence are recorded, but the relationships are not described. Of the remaining three, the patients were first cousins (Bockus, 1943); a child and her two aunts (Crohn, 1949); and a father and son (Kirsner *et al.*, 1948).

We present here an acute regional ileitis occurring in the son of a woman suffering from the chronic disease.

CASE REPORTS

The mother from the age of 15 years had had occasional attacks of right-sided abdominal pain, sickness, and constipation. In 1945 (aged 27) she became pregnant; her bowel dysfunction was much less marked during the pregnancy. The remission persisted for some six months after the son was born in September, 1945. Symptoms then returned. Attacks of abdominal pain became more and more frequent, and she lost weight. Sixteen months after delivery she was admitted to Selly Oak Hospital, Birmingham, with acute abdominal pain. After a period of observation, an operation was performed. Her appendix was removed and she was told that she had regional ileitis. She continued to get occasional attacks of sickness and pain, but these resolved promptly if she restricted her diet to fluids.

In March, 1949, her second child, a girl, was born. During the pregnancy she was perfectly well. About six months after delivery symptoms recurred and became increasingly severe.

In January, 1951, she was admitted to Selly Oak Hospital with acute abdominal pain and vomiting. An ileo-transverse colostomy was performed. In January, 1952, owing to persistent symptoms and the presence of a large palpable mass in the right lower abdomen, she was readmitted to Selly Oak Hospital under Mr. R. P. S. Kelman, who performed a right hemicolectomy with resection of the terminal ileum. The histological report (Dr. J. S. McKinnell) confirmed that "the whole picture is quite typical of a chronic stage of regional ileitis with sinus formation." Since the operation she has remained well.

The son, aged 7½ years, was admitted to Neath General Hospital in April, 1953. He had had severe abdominal pain for 24 hours. There had been vomiting, and two loose bowel actions following a mild aperient. During the preceding six months similar but milder attacks had occurred on three occasions. He had seemed generally unwell, and had lost weight.

The signs were indistinguishable from those of acute appendicitis. His temperature was 101° F. (38.3° C.) and there was marked tenderness and guarding in the right lower abdomen and acute tenderness on rectal examination. Other systems were normal.

At operation, using a gridiron incision, the last 2 ft. (60 cm.) of small intestine was found to be acutely inflamed and oedematous, thick and turgid, and typical of acute ileitis. A wide-necked Meckel's diverticulum was incorporated in the inflamed gut. There were numerous large glands in the mesentery. The appendix was congested, but secondarily so. Appendicectomy was performed and a mesenteric gland removed for histological examination.

The report on it (Dr. D. B. Richards) stated that the appearances, in conjunction with the clinical and operative findings, were consistent with the diagnosis of regional ileitis. Convalescence was uneventful.

X-ray examination of the chest showed no pulmonary lesion, and a Mantoux test was negative. Barium studies—the first one month and the most recent eleven months after the operation—did not demonstrate any narrowing or alteration in the mucosal pattern of the terminal ileum.

COMMENT

The clinical course, the operative findings, and the histology of the specimen in the mother's case leave no reasonable doubt that she was suffering from chronic regional ileitis. A feature of interest is the marked exacerbation which followed the amelioration of symptoms during pregnancy and lactation (both children were breast-fed for about six months). This is comparable to the behaviour of many other diseases, and has been previously noted in Crohn's disease (Raffensperger, 1948).

Doubt has been expressed of the similarity in nature of progressive Crohn's disease and the "acute terminal ileitis" that is periodically encountered during operations for supposed acute appendicitis in children (Bargen, 1945; Armitage and Wilson, 1950; Storrs and Hoekelman, 1953). This opinion is based upon the rarity of progression of these cases to the chronic disease.

However, in a condition of such relative rarity, in which the aetiology is uncertain, and in which opportunities for histological study in the initial phase are uncommon, the matter must remain one for conjecture. The pathology of the disease in its later stages is non-specific, and its occurrence is infrequent enough to permit the view that it follows a rare failure of resolution of the original acute specific disease. In Crohn's series 30.6% had presented initially with symptoms and laparotomy findings which prompted appendicectomy alone. It may be that in children the powers of resolution are greater.

When at operation an acute terminal ileitis is discovered, the only procedure to be considered is appendicectomy. Some writers, including Crohn, have discouraged appendicectomy on the ground that it favours fistula formation. However, most recorded series have shown that, although fistula in regional ileitis has often been preceded by appendicectomy, the incidence of fistula following the procedure in the early acute phase of the disease is small, and an uncomplicated resolution is the common experience, particularly in children. The advantages of appendicectomy are summarized by Storrs and Hoekelman, who point out that, if the appendix remains, later symptoms referable to the right iliac fossa may be difficult to interpret, and also that involvement of the appendix in the process may lead to appendicular obstruction and early perforation.

We are grateful to Mr. R. P. S. Kelman for information in the case of the mother, and to Dr. J. S. McKinnell and Dr. D. B. Richards for the histological reports.

Reviews

STATISTICAL APPROACH TO EXPERIMENTS

Experimental Design and its Statistical Basis. By D. J. Finney, M.A., Sc.D., F.R.S. (Pp. 169+xi. 30s.) London: Cambridge University Press. 1955.

It has been Dr. Finney's aim in this small book to discuss the theory and practice of experimental design as based upon the present-day statistical approach, and to do so with sufficient simplicity to meet the needs, and remove the fears, of research workers in most fields of biology. He regards as usually entirely false the idea, firmly held by many investigators, that experiments and other research investigations can be conducted statistically or non-statistically just as the worker wishes. The biologist concerned with any quantitative assessments must inevitably use statistical methods of some kind. His only choice lies between good methods and bad. One of the greatest assets, however, of the good experimental design is that it frequently makes the conclusion so clear that laborious statistical analyses and formal tests of significance become unnecessary. For instance, the analysis of variance may be required only to give objectivity to inferences that a good experimental plan has made obvious with the aid of merely a few averages.

The first-class experimentalist has, of course, always been aware of this—though more often, perhaps, through intuition and a sense of rightness than through an intimate knowledge of Graeco-Latin squares. Unfortunately all workers are not so genetically endowed. They need help in the principles of experimental design and in a form which calls for no special training in statistics or mathematics. Dr. Finney has done much to provide it, though he rightly makes no claim that his subject is easy. To get much from these compact 160-odd pages the reader new to the ideas will certainly need to ponder and study not a little. Within this short space Dr. Finney compresses not only the simpler problems of measurements and counting, of relative frequency and tests of significance, but also the main experimental designs of modern usage—randomized blocks and Latin squares, incomplete block designs, factorial experiments, the sequential approach, and biological assay. The embryo experimentalist who is unable to come to terms with all these will certainly be stimulated to reflect upon his own techniques by the good logic and shrewd comments that Dr. Finney interpolates throughout his text.

A. BRADFORD HILL.

INFANT NUTRITION IN THE TROPICS

Infant Nutrition in the Subtropics and Tropics. By D. B. Jelliffe, M.D., M.R.C.P., D.C.H., D.T.M.&H. (Pp. 237; illustrated. 25s., \$5, Sw. Fr. 15.) Geneva: World Health Organization. 1955.

Children are "feverish, sharp colics bring on convulsions, they are choked by fits of coughing and tormented by worms, evil humours corrupt the blood, germs of various kinds ferment in it, causing dangerous eruptions. Sickness and danger play the chief part in infancy. One half of the children who are born die before their eighth year." This is a quotation from *Emile*, by Jean-Jacques Rousseau, written two centuries ago (1757-60); it sums up the situation in many communities in the tropics and subtropics to-day. Rousseau recognized in his day that much ill-health in childhood could have been eliminated if mothers fed their babies at the breast; they or, if they couldn't or wouldn't feed their offspring, the wet-nurse should be given "food in larger quantities and better of its kind." This is essentially the conclusion reached in the book under review. May the author not have to say, with Rousseau, "How emphati-

cally would I speak if it were not so hopeless to keep struggling in vain on behalf of a real reform!"

The prevention of infant and young child morbidity and mortality in the tropics is partly, at least, a matter of eliminating "worms and germs," but proper feeding of the child and of the mother to enable her to sustain an ample lactation is of equal importance. In some communities, the more unsophisticated ones, the achievement of this objective—proper feeding—is not so much a matter of reform as retention of the best traditional practices. These have to be discovered and examined in the light of local conditions and resources and not in relation to what appears to be successful in Western countries.

Dr. Jelliffe has had experience at first hand of the problems of paediatrics in several parts of the world. His monograph is the first to deal with a subject so much needed, to use his own words, "to shorten the 'phase of bewilderment,' which at present appears to be inevitable before it becomes realized that methods used successfully in the countries of training are often absolutely unsuitable for less technically developed tropical regions, where a very different cultural and dietetic background may exist." The book includes a review of nutritional disease in tropical countries, and a chapter, written in collaboration with Dr. Anne Burgess, on nutrition education in the maternal and child health centre. It is a work with which everyone concerned with nutrition of the young in the tropics should be familiar; may I also recommend it to all who teach nutrition and hygiene to overseas students?

B. S. PLATT.

MESCALIN AND MYSTICISM

Heaven and Hell. By Aldous Huxley. (Pp. 87. 7s. 6d.) London: Chatto and Windus. 1956.

In a book entitled *The Doors of Perception*, published two years ago, Mr. Huxley described his subjective experiences after taking 0.4 g. of mescaline. His visual perceptions were heightened by the drug, and his old grey flannel trousers became a labyrinth of rich and sumptuous patterns, while the legs of a bamboo chair were supernatural in their polished smoothness. He accepts in consequence a theory that the brain and nervous system act as a reducing valve for the totality of impressions which come from the "Mind at Large." Drugs such as mescaline act as a by-pass which circumvents the reducing valve; they allow the ordinary man to see with the eye of an artist and to enter with the mystic into enjoyment of the Absolute. Mescaline, he concludes, is not the ideal drug to replace alcohol and tobacco, but he expects the pharmacologists to produce a better escape—a chemical vacation in our Brave New World—for mankind, whose existence is likely to be so painful, so monotonous, and so limited.

His new book, *Heaven and Hell*, does not affront so thoroughly the orthodox conclusions of scientists and philosophers. He sees, but does not answer, the obvious objection of both physiologist and mystic that chemical changes in the brain induced by drugs or malnutrition are unlikely to represent authentic spiritual experiences. Obesity and holiness may seldom be found together, but it is surely a *non sequitur* to maintain that the subjects of El Greco were saintly because they were ill-nourished. Nor will pharmacologists, more aware than he of the perils of addiction and the variation in individual response, hope that self-transcendence will be achieved by drugs. Occidental man, even if *Homo sapiens*, has more urge to self-expression than to self-transcendence, and he does not share the manifest desire of Huxley the intellectual (who would be Huxley the artist and the mystic) to be other than his best self. Even those who remain unconvinced by the argument of these two little books will take pleasure in Mr. Huxley's erudition, in his ingenious hypotheses, and in the fine clarity of his writing.

D. V. HUBBLE.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 14 1956

THE PRESIDENTIAL ADDRESS

Dr. Alexander Hall is the third general practitioner to be elected President of the Association in the past fifty years, and it is as a general practitioner that he surveys the present medical scene against a background of wide experience in that branch of medicine he has "always found interesting and satisfying, if at times a bit exacting." He does not attempt to assess the influence on practice of the great advances in medical science, except to note one important result of this—that new and more precise techniques of diagnosis and treatment increase the time the practitioner must give to his patient's care. Dr. Hall looks first at the conditions in which medical practice is conducted, and asks the pertinent question "whether present conditions can satisfy patient and doctor alike." From his own observation of changed conditions, and from the pronouncements of contemporary authorities, he concludes that "the general-practitioner service is not in good heart, that it needs resuscitation if it is to survive." This is a serious conclusion at which to arrive, and the reader of this year's Presidential address will realize that it has not been reached hastily or without much searching of mind. Dr. Hall, it would seem, sees the introduction of the National Health Service in 1948 as the principal cause behind what he believes to be a lessening of the status of the family doctor. The N.H.S. widened the gap between the family doctor and the consultant that had already appeared before 1948. Organizational expediency then brought in "a more complete cleavage" between the two. The possibility for the general practitioner to become a consultant is now almost non-existent. This is, of course, bound up with increasingly narrower specialization and the gradual disappearance of the general consultant, an effect, largely, of the great advances in medical knowledge. But the gravamen of Dr. Hall's criticism lies in his belief that the conditions of general practice in the N.H.S. do not permit it to "fulfil its proper function in the national service . . . with the result that much of the work which family doctors should normally undertake is passed on to hospital or to local government clinics." What the family doctor needs

¹ Supplement to the British Medical Journal, 1952, 2, 83.

is "time and facilities to use his knowledge and experience"; with these essential desiderata he will willingly "accept further responsibilities in the health services of the country, with satisfaction to both the patient and himself, and with relief to the hard-pressed and costly hospital services." It is good that these things should be said once again, because constant repetition will prevent people from conveniently disregarding the cracks in the structure of medicine to-day. Dr. E. A. Gregg, the Chairman of Council, said to the Representative Meeting last week that it was not the business of the B.M.A. to white-wash the N.H.S., and Dr. Hall certainly makes no attempt to do this.

After an appreciative glance at what has been done by the State and others to alleviate unmerited misfortune, to improve conditions of health, to raise the economic status of workers, Dr. Hall questions whether "the acceptance by the State of more and more of these responsibilities has not induced in the individual a diminished sense of his own personal responsibility to keep himself fit and eager to add his regular daily quota to the work-pool of the nation and to partake in the life of the community." This is an aspect of the Welfare State which causes concern among many thoughtful observers of the social scene. The provision of an apparently free medical service is one of the most important features of the Welfare State. That a State-provided medical service may induce in the beneficiary a diminished sense of personal responsibility is the considered opinion of doctors in other countries, expressed through a pronouncement on social security by the World Medical Association¹ in 1952. Dr. Hall aptly quotes a passage from this: "In what is called the Welfare State, social security schemes loom large, and in these schemes the provision of (apparently) free medical services is important. The more the State does for the individual in this direction, the less is the individual's sense of obligation and responsibility."

This is a social problem of the deepest significance and one which the politician who seeks votes and power will avoid looking at too closely. It is one which, it is interesting to note, the World Medical Association has examined with greater care than, it appears, have many if not most of its national member associations. It may well be linked to Dr. Hall's concluding observation that medicine "is losing its dynamic." Without examining all the possible remedies for a state of affairs which is serious enough if his conclusion is soundly based, Dr. Hall considers that one step should be taken to counter "conditions which encroach on the freedom of medicine"—and that is that the Association should "preserve and

foster the practice of medicine outside the National Health Service. . . . This proposal is, of course, in line with Association policy. "The greater the area of freedom provided by the private practice of medicine," Dr. Hall writes, "the greater will be the encouragement to maintain a general high standard and the stronger the deterrent to the introduction into the National Health Service of terms and conditions of service which we believe will make such standards unattainable." This proposition will be unpopular with those who see the all-powerful and paternal State as the provider of all good things. But it is one that will appeal to those who see the area of individual freedom and individual responsibility gradually being submerged in a collective mediocrity, in "a society harried, hag-ridden by regulations and financially penalized"—these last words taken by Dr. Hall from an article in the *Times Literary Supplement*. In addition to the reasons Dr. Hall gives for the desirability of encouraging private practice there is one that is easily lost sight of in this age of levelling down. Some patients and some doctors are temperamentally averse to "service conditions." The great risk to the public of the N.H.S. is that it will lead to a standardized medicine practised by a standardized doctor on what he may come to regard as a standardized patient. Of all professions medicine needs diversity of opportunity, and a wide margin of freedom to bring out to the full the doctor's sense of personal responsibility to the sick person. Dr. Hall's appeal for the encouragement of private practice must be looked at in this context, and will no doubt receive the practical support of the Association of which he is the President.

MEGAVOLTAGE RADIOTHERAPY

The term megavoltage radiotherapy comprises both supervoltage x-ray therapy—that is, therapy with x rays of a million volts and over—and telecurietherapy with radioactive gamma-ray sources of correspondingly high energies. X rays and gamma rays are identical in nature, but while the x rays are generated by elaborate electrical equipment the gamma rays are obtained from a massive source of radioactive material; at present this is most commonly cobalt-60 mounted in a heavily protected, more or less spherical head, whence the more familiar term "bomb" therapy. Owing to advances in the design of x-ray generators, x-ray beams can now be produced with energies of many millions of volts; the energy of the gamma-ray beam emitted by the cobalt bomb is equivalent to that emitted by an x-ray generator of approximately 3 million volts.

Certain advantages are gained by the use of these high-energy radiations. The rationale of the radiotherapy of cancer is that certain malignant cells are more sensitive to radiations than the cells of the normal tissues, so that a malignant growth may be destroyed by a dose of x rays from which the normal tissues can recover. It was at one time hoped that the margin of sensitivity between malignant and normal tissues might be increased with radiations of higher energy. So far as present experience goes this does not seem to be so. The advantages of megavoltage radiations in cancer therapy result not from any difference in biological response but from certain physical characteristics of the high-energy beam. The first of these is that the megavoltage beam develops its maximum dosage not on the skin surface, as with the ordinary deep therapy beam, but at a distance below it which becomes greater as the voltage of the beam increases. For this reason skin tolerance is no longer a limiting factor in dosage, and except where growth involves the skin itself the patient is spared the distress of serious skin reactions. Secondly, the absorption of megavoltage radiations in tissues of different densities tends to become equalized. For this reason the risk of bone necrosis from the relatively high absorption in bone at deep therapy voltages is minimized, as is also the resulting tendency of the bone to shield the growth from the radiation which is intended to reach it. Thirdly, the greater penetrating power of the megavoltage beam, especially at the greater depths, enables treatment to be planned with a smaller number of fields, with consequent simplification. For this reason accuracy is increased, and the total radiation energy which has to be absorbed by the patient to obtain a given dose on a deep growth is reduced.

The advantages of megavoltage radiotherapy over ordinary deep x-ray therapy (200–250 thousand volts) are well shown in a series of articles recently published.^{1–3} R. Morrison, G. R. Newbery, and T. J. Deeley,¹ working with the Medical Research Council's 8-million-volt x-ray machine at the Hammersmith Hospital, found that the maximum dosage was delivered at about 2 cm. below the skin surface while the skin dose was only about 25% of the maximum. D. Greene and D. E. A. Tranter,² working with the 4-million-volt x-ray machine at the Christie Hospital, Manchester, found that the maximum dose was delivered at from 0.8 to 1.2 cm. below the surface, again with a surface dose of about

⁵ Williams, I. G., *Brit. J. Surg.*, 1949, **36**, 376.

25% of the maximum. Morrison and his colleagues found that the absorption in bone was reduced by more than half at 8 million volts as compared with 250,000-volt deep x-ray therapy. The figures for the cobalt-60 telecurietherapy unit, equivalent to about 3 million volts, are not very different from those obtained at the Christie Hospital, while at a level as low as 2 million volts the advantages of supervoltage radiotherapy have recently been confirmed by G. W. Bloomfield⁴ by physical measurement and also by clinical observation of 1,500 patients treated during the past five years. "The ease of treatment, the greater comfort of the patient during treatment, and lack of troublesome complications are factors which are soon apparent." As to the comparison of results of supervoltage therapy with those of deep x-ray therapy the same author remarks: "After working with 2-million-volt x-ray therapy we soon found that comparisons are still more difficult, because many patients who would never stay the course of radiotherapy by orthodox methods can yet be treated by supervoltage therapy."

There are, nevertheless, indications that at least in two regions—namely, the bladder and cervix—results of treatment of carcinoma are improved by supervoltage therapy, in the one case by supervoltage therapy alone and in the other in combination with intracavitary radium. The fact that I. G. Williams⁵ was able to report improved response of carcinoma of the rectum to 1-million-volt radiations at St. Bartholomew's Hospital offers hope of further improvement with still higher voltages. Even if the results show no dramatic improvement from megavoltage therapy, the sparing of much discomfort and distress to patients in the course of treatment, and the reduced risks of bone necrosis and other complications, are sufficient to mark a real advance.

POST-PARTUM PSYCHOSIS

The successful treatment of post-partum psychoses with progesterone has recently been reported. H. W. Bower and M. D. Altschule¹ studied a total of 39 cases over six years. With two exceptions only patients who had become psychotic during the first few weeks after delivery were included. Thirty-four patients initially received shock therapy (insulin or electroplexy) and received progesterone with or without shock therapy. Seventeen improved, and the improvement was maintained. Seventeen cases relapsed; one of these committed suicide, and, of the remaining sixteen, five improved with further shock therapy. The other eleven of this group, together with five more patients, received progesterone alone and none relapsed. All these cases except one improved and none relapsed. Progesterone alone did not usually effect a remission but it appeared to do so alone after a relapse following

electric convulsion treatment. Follow-up over a number of years confirmed that remission was maintained. The relapse rate for cases not treated with progesterone was 43.6%, and for those treated with it 6.3%. Progesterone was given in large doses, 100 mg. daily intramuscularly for about ten days and then by mouth in doses of 150 mg. After discharge the hormone was given by mouth for periods varying from weeks to many months.

No hormone estimations on these patients are reported, but the rationale of the treatment, according to the authors, is that the adrenal cortex may be overactive in early but not acute schizophrenic, manic-depressive, and involuntal psychoses, though this is probably not of aetiological importance. Their aim is to depress pituitary-adrenocortical function. They say there are marked adrenal changes during normal pregnancy and the post-partum period; the blood and urinary steroid content are increased during pregnancy and much more immediately after delivery; normal values are found after the sixth day. The placenta may produce both A.C.T.H. and corticoids. Placental progesterone depresses adrenocortical hyperactivity. Placental A.C.T.H. counteracts this. Later the loss of this placental A.C.T.H. may be compensated by a rebound excessive stimulation of the adrenal cortex by the anterior pituitary, and "this might contribute to the development of post-partum psychosis." The large doses of progesterone are designed to depress adrenocortical function via the pituitary.

Other reports about the use of progesterone in cases of post-partum psychosis have come from A. Blumberg and O. Billig² and H. J. Schmidt.³ However, both are reports on single patients who relapsed when menstrual bleeding was resumed. Only very small doses of progesterone were administered, and they could hardly have depressed pituitary-adrenal function. Bower and Altschule do not mention any relation between relapses and reappearance of the menstrual cycle or bleeding. J. Delay and colleagues⁴ repeatedly took endometrial biopsies, and they found that the remission after shock therapy persisted only if the endometrium had resumed a normal appearance; otherwise the patient relapsed. Bleeding is often due to an abnormal condition and does not represent resumption of the normal cycle. Bower and Altschule suggest that the use of progesterone should be considered for patients who show a severe increase of neurotic symptoms in the first week after delivery and in other cases of early psychosis in women. It is worth recalling here that important biochemical and physiological changes in the premenstrual phase have been found in the premenstrual tension syndrome, and that they could be explained by lack of balance between oestrogen and progesterone⁵ and by autonomic disequilibrium.⁶ Improvement with the administration of progesterone has been observed. A greater incidence of deaths occurring in the luteal phase has been reported recently and

the possibility of adrenal participation suggested.⁷ Further, progesterone is known to play a part in the metabolism of adrenocorticoids.

It is only when more complete endocrine and biochemical studies become available that the problem will be clarified. In the meantime the results of Bower and Altschule deserve clinical attention, especially in relation to the different varieties of puerperal mental disorder.⁸

SMOKING AND THE CARDIOVASCULAR SYSTEM

Last year we referred in these columns¹ to statistical evidence from Britain and the United States which strongly suggested that cigarette smokers have a significantly higher mortality from coronary disease than do non-smokers or pipe and cigar smokers. Since then several papers have been published on the circulatory effects of smoking both in normal subjects and in patients with coronary disease. We have already drawn attention to deterioration in the ballistocardiographic pattern in some apparently normal subjects after smoking.² F. W. Davis and colleagues³ found this in 7.5% of 252 subjects, I. E. Buff⁴ in 10% of 400, O. Tannenbaum and colleagues⁵ in about 20% of 82 subjects, and H. I. Russek and colleagues⁶ in over 50% of 28 subjects. The percentage in which ballistocardiographic deterioration is found appears to be determined by the method of selection of the "normal" subjects, and the two most important factors which have emerged are age and the presence of cardiac, gastro-intestinal, or cerebral symptoms associated with smoking. Thus in the work of Davis and his colleagues cigarette smoking had no effect on the ballistocardiogram in normal subjects under 40, whereas about 15% of those over 50 showed deterioration. All Buff's subjects were under 40. In the studies of Tannenbaum and his co-workers ballistocardiographic changes occurred in 15% under age 40 and 23% over that age. The subjects selected by Russek and his colleagues all had symptoms of one kind or another after smoking, and this feature was associated with a very high incidence of ballistocardiographic changes. It seems likely that some normal subjects are unusually sensitive to the effects of cigarette smoking, and this sensitivity is not confined to the circulatory system. In coronary disease both Davis *et al.*³ and Russek *et al.*⁶ found that after smoking the ballistocardiogram deteriorated in about 50% of cases. In comparing these figures with those for normal subjects it is probably relevant that the patients fall in older age groups, and it may be important that the ballistocardiogram was abnormal before smoking in a high percentage of cases—56% in the 190 cases investigated by Davis *et al.*

The cigarette ballistocardiogram test is purely empiric, as Davis and his colleagues were careful to point out, and there is no direct evidence that the changes in the

ballistocardiogram are due to alterations in the coronary circulation or the myocardium. It is known that the form of the ballistocardiogram can be altered by changes in the peripheral circulation, and sometimes the changes due to smoking can be reversed or prevented by the administration of whisky.⁶ Many will agree with the conclusion of Russek *et al.* that "there is as little evidence that alcohol increases the coronary blood flow as there is that tobacco reduces it." So far, therefore, it has not been possible to identify physiological changes in the coronary circulation as a result of cigarette smoking which would account for the statistically higher incidence of coronary disease in smokers. But the immediate response to smoking a single cigarette may be little guide to the long-term effects of heavy cigarette smoking. Curiously, no one seems to have thought of trying the effect on the ballistocardiogram of smoking a pipe or a cigar.

TREATMENT OF MEASLES

Though measles must be one of the commonest diseases in the world that doctors are called upon to treat, the best way of preventing the onset of complications is still in some doubt. The main issue is whether to administer sulphonamides or antibiotics as a routine prophylactic measure or whether to await the onset of a complication before starting specific treatment of it. To the many published contributions to this discussion an unusual addition has now been made in the form of a report by a study group of the College of General Practitioners.¹ The group, consisting of 132 members and associates of the College, set out as their primary aim "to collect a series of cases of measles, treated at home, large enough to determine whether sulphonamides or penicillin, given as a routine, produced a beneficial or an adverse effect upon the subsequent course of the disease." Their main conclusion is that "the prophylactic use of antibacterial drugs can confer little benefit on a healthy child undergoing an attack of measles of ordinary severity, and indeed it may do harm. In mild cases it is likewise unnecessary, but severe cases can obtain some benefit." The group was assisted by Professor A. D. Gardner, of Oxford, and Dr. M. R. Sampford of the Agricultural Research Council's statistical unit at Aberdeen.

In the final analysis the number of cases used was 4,728, observed from the beginning of 1954 to May 31, 1955. They were spread over urban, rural, and mixed practices, and composed a series that does not seem to have had any particularly exceptional features. Among these a group of 1,767 patients who received no prophylactic treatment can be compared with two other groups; one of these received routine sulphonamide prophylaxis (1,619 cases) and the other routine antibiotic prophylaxis (255 cases). The cases were classified into mild, average, and severe. Among the mild cases there was no significant difference between the three treatment groups, but among the average and severe

cases those on antibiotic prophylaxis did significantly better. Unfortunately only nine patients with a severe attack of the disease were among those put on routine antibiotic prophylaxis, a small number from which to reach any conclusions. Among the patients with an average attack, 171 received antibiotic prophylaxis as against 871 who received none; 14.5% of the antibiotic group and 19.0% of the control group developed complications, a difference that is not very great. But, while some slight benefit may follow the giving of prophylactic antibiotics, the dangers of their widespread administration are too well known to make the final decision an obvious one.

If prophylactic penicillin is to be given at all, it would seem better not to give it as a routine but to selected cases. These would be children specially liable to complications or children on whom the effect of complications might be particularly harmful. An interesting feature of the report is an attempt to identify a group of children as "catarrhal." These were defined as children who seemed to their doctor to have more than their fair share of respiratory infection. They comprised about 22% of the series, and the figures show that they did indeed suffer more severely from measles than the remainder. The catarrhal group included 9.9% severe cases against 6.5% in the non-catarrhal group, and 22.7% of mild cases against 33.6%. Whether such children should receive prophylactic penicillin remains nevertheless questionable. Recently the dangers of upsetting the body's bacterial flora by antibiotics during the treatment of measles was the subject of comment in these columns,² for a report³ from the U.S.A. had drawn attention to this risk. Infections with *H. influenzae* were found to be unusually frequent, but are not reported in the series from the College of General Practitioners. If the routine use of antibiotics is, as the report says, "largely unnecessary," the routine use of sulphonamides is found to have nothing to recommend it; indeed, it "increases rather than reduces the total complications rate."

THE BABINSKI RESPONSE

The plantar reflex described by J. Babinski⁴ in 1896 is probably the most famous physical sign in clinical neurology, and there is justification for believing it to be one of the most reliable. It must be stressed that this sign, which is known as the "Babinski" or "extensor plantar" response, and which is evoked by stimulation of the outer side of the sole of the foot, does not only consist of dorsiflexion of the great toe; in addition there must be flexion and abduction or "fanning" of the remaining toes. Both features must be present for the reflex to be abnormal; either alone may be elicited in a small proportion of normal individuals. As P. W. Nathan and M. C. Smith point out in a recent review,⁵ Babinski's claim that the sign "appears" to indicate a disturbance of function of the pyramidal tract has been misconstrued and distorted by subsequent writers, so that many now believe an anatomical lesion of the

corticospinal tract to be present whenever the Babinski response is demonstrated. That this is far from the truth is shown by many reports in the literature. Several cases have been described in which there were clearly defined lesions of the corticospinal tracts and yet the sign was absent; nor could it sometimes be obtained even after total division of the spinal cord. Conversely, there are also reports of cases in which the sign was clearly demonstrated and yet the corticospinal tracts were normal histologically; and it is, of course, well recognized that the response may be elicited in normal subjects during sleep, hypoglycaemia, or anaesthesia.

Additional useful evidence is provided by Nathan and Smith from their personal observations in 38 cases of antero-lateral cordotomy. They found that the Babinski response was often evoked in patients who were later found to have histologically normal corticospinal tracts; that apparently identical lesions on the two sides of the spinal cord could be associated with a normal plantar response on one side and a Babinski response on the other; and, indeed, that there was no particular relation between the anatomical state of the corticospinal tracts and the form of the Babinski response. However, it must be remembered that profound disturbances in function of nervous pathways may occur without recognizable histological change; furthermore, many patients with demonstrable lesions of the corticospinal tract do show this sign, which clearly indicates a serious abnormality in functioning of the central nervous system. It would be unfortunate if this work were to arouse doubts concerning the clinical value of a sign of such great and established worth, but Nathan and Smith have done a service by warning us that it is a mistake to be too rigid in interpreting the significance of physical signs, particularly so far as the anatomical integrity of individual nervous pathways is concerned.

WORLD HEALTH

An impressive story of progress and achievement in the improvement of health all over the world is related in two recent publications.^{1,2} In three fundamentally important fields—communicable diseases, national public health services, and the education and training of doctors and medical auxiliaries—the results, as described by the World Health Organization,¹ are shown to be strikingly favourable. Malaria has been attacked by a new strategy, aiming at eradication rather than control and relying on rapid and complete spraying of a defined area to combat the development of insecticide-resistance. The outlook on tuberculosis is undergoing a revolutionary change owing to the introduction of effective chemotherapy, for there is now a possibility of replacing the hitherto expensive programme of maintaining special hospitals by one making the best use of relatively inexpensive domiciliary treatment. The introduction of a poliomyelitis vaccine has raised questions about when and how to give it, and in many parts of the world these problems are being investigated by

surveys, some already completed, others still in progress. The Central Office of Information is also able to record² impressive progress in the United Kingdom Dependencies, as a result of the vigorous attack on leprosy, yellow-fever, and tropical blindness. For example, the remarkable decline in the incidence of leprosy in Eastern Nigeria is well described elsewhere in this issue by Dr. T. F. Davey and his colleagues. Further, the proportion of patients with leprosy discharged free of symptoms has been on a scale inconceivable a decade ago; and, as a result of the measures taken to destroy the vector, yellow-fever is now virtually confined to sporadic cases among unvaccinated persons.

The public health services in many countries are still not fully developed and both W.H.O. and the medical services in colonial territories have collaborated with other organizations, including U.N.I.C.E.F., the Food and Agriculture Organization, and the Rockefeller Foundation, in plans for establishing health services and training schools in these areas. The World Health Organization takes a particular interest in the health education of the public, and over 70 participants took part in its seminar on nutrition education and health education held last October at Baguio in the Philippines. Undernutrition will become less of a problem as knowledge improves. Working parties have been carrying out nutritional and agricultural surveys in United Kingdom Dependencies, including the Gambia, Malaya, Northern Rhodesia, Nigeria, and other territories, and are helping to combat ignorance and prejudice about diet and to encourage the best use of the land. Often the diet can be improved by adding to it local products of high nutritive value, such as shark oil and red palm oil, formerly often wasted, and the prevalent deficiency of protein can sometimes be counteracted by encouraging a greater consumption of fish and of vegetable protein.

REMEDIES FOR SCURF

Scurf of scalp, dandruff, or pityriasis capitis is almost a universal complaint. Little more is known about it than Sabouraud contributed fifty years ago. It is a source of interest and anxiety to most of those who suffer severely from the complaint and has for long been a matter of profitable concern to manufacturing chemists and hairdressers. Much misdirected energy and enthusiasm have been applied to the treatment of scurf not only by the layman. The finding of a scurfy scalp has always coloured the diagnosis and influenced the treatment of skin diseases, though it may often be quite irrelevant. Vigorous treatment of scurf may sometimes be responsible for loss of hair which is wrongly attributed to the presence of dandruff. It is true that scurf and baldness sometimes go together, but it is doubtful if the one is often directly responsible for the other. Certain organisms normally resident on the skin, harmless and saprophytic, are believed to play some part in the aetiology of pityriasis capitis—a scaling of the epidermis of the scalp consequent upon a low-grade infective

dermatitis. To eradicate these organisms permanently from the skin is not possible, for they are normal—and probably purposeful—residents. It is some altered state of the soil, of the skin itself, that would seem to be the major aetiological factor, and most people are familiar with the exacerbations of scurf of scalp that follow an infective or toxic illness, especially of the upper respiratory tract, or accompany a state of debility or stress. Though simple local hygiene will usually control the tendency to scurf, it is well to remember these further aetiological possibilities when the trouble becomes worse or more persistent.

Fashions in the treatment of such a common and incurable affection naturally vary with time and circumstance. Some advocate daily washing with soap and water, as of the normal skin, and this may prove effective. On the other hand, infrequent washing of the scalp does not necessarily aggravate a tendency to scurf, for when the layer of sebum on the skin becomes thick enough it remains constant, and is only replaced if the surface film is washed off. Such a film of sebum is of itself to some extent a protection against dandruff. In the past some authorities have recommended the application of cholesterol in treatment, and it is incorporated in some proprietary remedies. Sulphur and salicylic acid, mercury, and tar all have their advocates, but perhaps the most valuable recent addition to therapy has been the introduction of detergents such as cetrimide, which may be used alone or be incorporated in shampoos, soaps, or lotions. For some time selenium sulphide has had a considerable vogue and is indeed a very effective application. It is the modern equivalent of a very old remedy, cinnabar or red mercuric sulphide, which was commonly used in a strength of 1% with sulphur (2%) in a pomade or ointment. Mercury so used is probably a safer drug than selenium for this purpose. Either may cause occasional irritation of the skin or the development of allergic sensitiveness. There has recently been a report¹ from the U.S.A. of diffuse loss of hair from the repeated use of selenium sulphide shampoos at short intervals. Six patients suffered in this way when the shampoo was used at weekly intervals, but recovered on stopping the shampoo or using it at longer intervals. The observation merits attention in view of the wide use of this chemical to-day: the absence of dermatitis suggests that the loss of hair was due to a direct toxic effect.

CHAIRMAN OF B.M.A. COUNCIL

At the first meeting of the new Council on Monday, July 9, Dr. S. Wand was elected Chairman for the ensuing three years. Dr. E. A. Gregg, Chairman of Council for the past seven years, had previously announced his decision to retire from this onerous and responsible position. At the Representative Meeting on Monday Dr. I. D. Grant, Chairman of the Representative Body, made a most felicitous speech on the outstanding services Dr. Gregg has rendered the Association both at home and in other countries, and at the conclusion the Representatives rose and gave Dr. Gregg an ovation.

British Medical Association

ANNUAL MEETING, BRIGHTON, 1956

SUMMARY OF PROCEEDINGS

THE SECTIONS

SECTION OF GENERAL PRACTICE

Monday, July 9

Education of the General Practitioner

With the president of the section, Dr. T. A. MORRISON (Brighton), in the chair, Dr. RAYMOND WHITEHEAD (Manchester) opened a discussion on the "Education of the General Practitioner." He stressed that medical education was a continual process, from entry into medical school to the end of professional life, but that successive stages make progressively greater demands on the student's initiative. The undergraduate has his full-time curriculum planned by his teachers. The intern registrar and trainee could choose their particular field and place of practice but pursue an apprenticeship under the guidance of their chiefs, learning all the time from their methods and experience. The final stage of postgraduate education and maintenance of efficiency, as it affects the principal in practice, was entirely his own private affair.

Dr. Whitehead then discussed the methods of undergraduate teaching in this country and abroad, and noted the value of giving students some insight into general practice so that they might obtain a more balanced view of medical care and needs.

Turning to postgraduate education, he said that this is increased by carrying out research and working for higher degrees. There was much scope for both of these projects in general practice. A problem common to all doctors was that of keeping up to date. The fundamental method of that of continuing self-education was reading, and doing so and of continuing self-education was reading, and here he stressed the importance of reading up one's own cases. To be able to do this the doctor must have a small and suitable private library of his own. In addition he should make a regular study of periodicals, extracting and filing articles and annotations of interest. Next to reading, social and professional contacts with colleagues at home and abroad were the best ways of keeping up to date.

Young Practitioner's View

Dr. C. P. D. GRANT (Glasgow), the next speaker, gave his personal experiences as a young general practitioner of some four years' standing, following valuable years as a hospital resident and in H.M. Forces. On starting in general practice he found that, while his academic knowledge was adequate for the "hospital diseases," he was quite unfamiliar with the common diseases of general practice, which were quite different from those that he had encountered in his medical school. In hospitals the patient was treated as a "case" rather than as an individual with his own personality and social background, and too much stress was laid on the necessity and value of investigations to discover and substantiate a diagnosis.

Teaching was carried out by specialists who had little knowledge of general practice, into which at least 50% of their students would eventually enter. More teaching was necessary on the common everyday diseases rather than the rarities. There was a need for students to obtain some insight into general practice, but it should be realized that general practice was an art that could not be taught but had to be lived to be learnt.

An introduction into general practice would be best carried out by a general practitioner attached to the teaching team who could give lectures, attend rounds, and arrange for

students to be taken in by practitioners for short periods. Turning to the curriculum, Dr. Grant said that drastic cuts were necessary in the detailed studies of preclinical subjects, and more time should be devoted to practical experience in the handling of patients in the wards and in out-patient departments—again with accentuation on the commonplace rather than in the worship of the rarity.

He was in favour of a compulsory period of attachment to a general practitioner for senior students and a post-graduate trainee period of one year followed by a two-year hospital internship.

Education in the U.S.A.

Dr. ROBERT A. DAVISON (Memphis, Tennessee, U.S.A.) described his experiences as a teacher in the General Practice Clinic at the University of Tennessee. This clinic had been started in 1951 in an attempt to give students some teaching in the wider aspects of disease, which was lacking in the normal curriculum of most medical schools.

In the past there had been insufficient stress on the patient as an individual living in his own social and family environment and too much stress on the patient as a hospital case member. Medical schools had tended to graduate medical scientists and medical biologists rather than doctors. The general practitioner was an important member of the medical team in the battle against disease and was able to manage, on his own, some 85% of the illnesses in the community.

The General Practice Clinic was staffed by two full-time and 35 part-time practitioners. Ancillary staff included a medical-social worker, a laboratory technician, and a secretary. There were 16 private examination rooms, a laboratory, an x-ray unit, a physiotherapy room, a minor surgery room, a waiting-room, and a nurses' duty room. Twelve final-year students attended the clinic on alternate days for a five-and-a-half week period, and examined and followed up their patients. The patients (30 a day) were selected daily by the medical director of the hospital from those referred to out-patients and from poor indigent patients.

To supplement this type of work a "family care programme" was introduced to enable students to come in contact with the family at home. In his scheme each final-year student was given a family to look after during this year, and he acted as the family's own doctor—answering all calls for home visits and seeing members of the family in consultation at the clinic. During this period the student presented cases from his family at an informal conference which was held weekly.

The success of this programme was largely due to the development of good student-patient relationships, and allowing certain degrees of responsibility in the students under the supervision of experienced general practitioners.

Undergraduate and Postgraduate Education in General Practice

Dr. G. O. BARBER (Great Dunmow, Essex) spoke as a general practitioner with many years' experience in teaching students. He felt that the problems of teaching general practice were twofold—first, some teaching was necessary to give all students some information on this important branch of medicine, and, second, a more specialized form of education was necessary for the postgraduate who was taking up general practice as his career.

All students needed to be taught, from the earliest days of their clinical training till graduation, that there was a unity of medicine and that medical care was best carried out by a team which must, of necessity, include the family doctor as well as the hospital consultant. The treatment which the patient received in hospital was but an episode in the course of disease and the general practitioner played an equally important role.

Three methods of teaching the rudiments of general practice were popular in Great Britain. Lectures could be given to students, at various periods of their curriculum, by an experienced practitioner. Students could be sent to spend

¹ Grover, R. W., *J. Amer. med. Ass.*, 1956, 160, 1397.

a period with a general practitioner to watch and assist him at his work. Some general practice units were attached to teaching hospitals, notably at Edinburgh, and in this form of teaching students can be given more responsibility in the care of the patient. The third method was to invite a family doctor to accompany the consultant on his teaching rounds so that his views might be presented to the students. It was essential for the practitioner to get back into the hospital if improvements in education were to be made.

Postgraduate teaching of the future general practitioner should be based on the twin self-disciplines of thought and action. Discipline of thought required an adaptation of basic medical methods to the special field of general practice. Discipline of action must train the doctor to cope with the presenting situation and not merely to refer all difficult cases to hospital. The whole system of trainee assistantships must be re-examined. A whole year spent with one practitioner was probably too long, and a system of group training to include a variety of practices was suggested.

The future must depend on team-work between practitioner and hospital for the good of the patient, and it was up to the practitioner to raise and maintain his standards of work and to pass on some of the fire of his ideals to the doctors of the future.

In the subsequent discussion Dr. J. K. PATERSON (Huntingdon), winner of the Claire Wand Prize for 1956, said that to be a good doctor one first had to be a man, and the period spent in H.M. Forces was an important one as a training in lifemanship.

Dr. R. F. L. LOGAN (Manchester) described the development of the Derbyshire Health Centre at the University of Manchester, where students were attached to one of four general practitioners working together in a group practice.

Dr. ANNIS GILLIE (London) supported the view that regular hospital contact was vital to postgraduate training.

ERADICATION OF TUBERCULOSIS

ANNUAL CONFERENCE OF THE BRITISH TUBERCULOSIS ASSOCIATION

Although only one of the papers read at the annual conference of the British Tuberculosis Association in Bristol last week mentioned eradication of the disease in its title, most of the contributions were concerned with how this might be done. On the clinical side collapse therapy and the results of resection were reviewed; on the preventive side the role of B.C.G. and vole bacillus vaccine was debated. The latter discussion was based on the M.R.C. report, published in this *Journal* last February,¹ describing a controlled trial of these vaccines in adolescents. We discussed this subject in a leading article two weeks ago.² The other major subject at the conference was the clinical and social rehabilitation of the tuberculous patient.

A Nation-wide Campaign

What it might involve were Britain to undertake an all-out drive to eradicate tuberculosis was the subject of a paper by Dr. A. L. COCHRANE, of the Medical Research Council's pneumoconiosis research unit. His views were based on evidence from two surveys the unit is making, one in an area which might be taken as typical of one of the worst in the country in its tuberculosis record (the Rhondda Fach), and the other in an area regarded as one of the best (the Vale of Glamorgan). He divided the campaign into three phases.

Many would agree, said Dr. Cochrane, that the first logical step was to radiograph the whole community. But on how this should be done opinions were divided. Personally he favoured compulsion, though he recognized there were objections. The only alternative to compulsion was expensive and tedious surveys with home-visiting carried out on a very large scale, and even then the results fell short of

100%. The surveys in the Rhondda Fach and the Vale of Glamorgan had shown a much higher prevalence of pulmonary tuberculosis in the urban than in the rural areas, so the first attack should be made on the towns. From the administrative point of view it was important to estimate the proportion of unknown to known cases such surveys would disclose. Curiously, the Vale of Glamorgan—the low-prevalence area—yielded the higher proportion: two unknown cases were uncovered for every known case. Possibly a low notification rate gave a false sense of security.

Prevention of Fresh Cases

Radiographing the whole community would not win the battle, however. Fresh cases would occur. Their pattern had been studied by repeating the x-ray survey in the Rhondda Fach two and a half years after the first survey, and the results agreed well with those obtained by Springett in 1951. The surprising thing was that it was not the elderly males who were most attacked. The vast majority of new cases were in the younger age groups. It was here that the search for cases in the second phase of the campaign would have to be concentrated.

After referring to the importance of B.C.G. in preventing these new infections in younger people, Dr. Cochrane said he thought it would be mistaken to rely on B.C.G. alone. Evidence from the Rhondda Fach made it virtually certain that the overwhelming factor in the new cases was still contact with an infectious case. It could be assumed that practically all the cases found in the x-ray surveys would be hospitalized, but what proportion of them would leave hospital still sputum-positive? In the Rhondda Fach they had not been able to make anything like all the cases sputum-negative on discharge. Admittedly there were special factors there, such as the association with progressive massive fibrosis, but there was a real need to discover how closely the number of sputum-positive patients living at home in a community was correlated with its notification rate for new cases; he thought the correlation would be fairly close.

If conditions in the Vale of Glamorgan could be regarded as representing a somewhat later stage of the tuberculosis epidemic than in the Rhondda Fach, it could be said that as the attack rate fell tuberculosis would disappear in women of all ages and in the young men but not in the elderly men. The explanation for this, which Dr. Cochrane thought must now be accepted as a fact, was that there was a greater tendency for the apparently healed lesion to break down in the elderly male than in the elderly female. In the last phase this group of elderly males would probably be very difficult to deal with.

Other Contributions

The first two papers were by workers from Bristol. Dr. R. C. WOFINDEN, the M.O.H., paid a tribute to William Budd, the great Bristol epidemiologist of the last century, and Dr. J. S. WESTWATER spoke on "Tuberculosis in the Fourth Dimension." The contributors to the symposium on collapse therapy on the second day of the meeting were Dr. A. T. M. ROBERTS (Bristol) on artificial pneumothorax, Dr. H. G. TRIMBLE (California, U.S.A.) on artificial pneumoperitoneum, Mr. R. H. R. BELSEY (Bristol) on surgical collapse, and Dr. F. H. YOUNG (London), who discussed the choice of method for the individual patient. In the afternoon Mr. F. R. EDWARDS (Liverpool) discussed the results of resection on the basis of a 5-9 year follow-up of 400 patients, Dr. BERYL CORNER (Bristol) spoke on congenital tuberculosis, and Dr. A. M. SUTHERLAND (Glasgow) on tuberculosis of the endometrium. The third day was occupied by discussion of the Medical Research Council report on B.C.G. and vole bacillus vaccine, presented by Dr. P. D'ARCY HART, Dr. T. M. POLLOCK, and Dr. I. SUTHERLAND, members of the M.R.C. committee which prepared the report. Afterwards Dr. MARY FARQUHARSON (Lewisham) gave a physician's view of it, and Professor W. GAISFORD (Manchester) did the same from the paediatric angle. Dr. KNUD TOLDERLUND, of the State Serum Institute, Copenhagen, then followed with a paper on the preparation

and control of B.C.G. vaccine. During the discussion on anti-tuberculous vaccines some hope was expressed that a non-living antigen might soon become a practicable alternative to the use of attenuated live bacilli.

The last morning was spent in discussing rehabilitation. Dr. A. F. FOSTER-CARTER (Frimley) discussed the clinical problem, Brigadier T. F. KENNEDY, P.M.O. of Remploy Ltd., spoke on "Remploy and the Employment of the Tuberculous," and Dr. L. MACPHERSON (New Brunswick, Canada) described the rehabilitation programme in Canada.

The conference was attended by over 150 clinicians, including guests from the United States, Canada, Scandinavia, India, Pakistan, and Nepal.

RESEARCH ON CANCER

BRITISH EMPIRE CANCER CAMPAIGN

At the 33rd annual meeting of the British Empire Cancer Campaign on July 10 at the House of Lords, under the presidency of the DUKE OF GLOUCESTER, Mr. H. J. B. ATKINS, director of the department of surgery at Guy's Hospital, proposed the acceptance of the Report and Balance Sheet. The Report gives a most comprehensive review of the researches carried out during 1955 in some thirty different centres—university, hospital, and other institutions at home and abroad—and by individuals supported by the Campaign. With the guidance of its scientific advisory committee, the Campaign made available during the year some £400,000 for research. Work has been done on fundamental questions of the nature of growth—both normal and abnormal—on the search for the causes of cancer, and also on the development of methods of therapy of immediate application. But it is noteworthy that in the fields of both chemotherapy and radiotherapy research has been designed to produce fundamental information as well as more effective methods of treatment.

Lung Cancer

A considerable amount of research has been devoted to the important problem of tobacco smoking and atmospheric pollution in relation to lung cancer. While attempts to produce tumours in experimental animals by the application of tar condensed from cigarettes have failed, work is reported from the Strangeways Research Laboratory, Cambridge, of the growth-promoting action of tobacco tars on bridge, of the growth-promoting action of tobacco tars on fragments of human foetal lung growing *in vitro*. A study of lung-cancer death rates in rural and urban areas is reported. The rural death rate from cancer of the lung increased in proportion to cigarettes smoked, but in the urban area studied—Liverpool—it is estimated that about half the deaths of men from lung cancer arose from cigarette smoking and about three-quarters of the remaining half were due to a factor which is only slightly present in the rural area. The death rates among non-smokers for urban and rural areas were reported to be in a ratio of about 9 : 1, which corresponded roughly to the ratio between the concentrations of 3:4-benzpyrene found in the city and country air.

Biochemical Changes in Cancer

Continued searching for specific biochemical differences between malignant and normal cells is producing an increasing harvest of information, but what these differences may mean is still obscure. Enzymes such as catalase are reported to be greatly diminished in the livers of animals bearing tumours. β -glucuronidase is reported to be of high activity in the livers and kidneys of a cancer-resistant strain of mice, and the activity of this enzyme has been observed to be considerably raised in the urine of the patients with cancer of the kidney, stomach, prostate, and testis and with cancer of the breast, thyroid, larynx, and oesophagus. Investigations are reported on the content of sulphatases in certain neoplasms.

Studies related to the fundamental biosynthesis of protein have revealed a high content of mucoprotein in the serum

and urine of cancer patients, and in certain cases of leukaemia a mucoprotein has been found capable of bringing about an increase in the number of total myeloid cells in guinea-pig bone marrow. Much work has been done on the investigation of nucleic acids, which seem to be so intimately involved in the organization and reproduction of the cell. All preparations of deoxyribonucleic acid (D.N.A.) from tumours so far examined contain ribonucleic acid (R.N.A.) which is not combined with the D.N.A. and is easily removed by the action of ribonuclease and by alkali. It appears that the presence of R.N.A. in the tumour is due to abnormalities in the behaviour of the ribonucleoproteins, analyses of which show marked variation from the expected ratios of guanine to adenine.

An interesting study using interference microscopy has revealed a difference in the adhesive nature of the cell surface of normal and malignant cells. Isolated tumour cells show no adhesion of a permanent nature when their pseudopodia touch another cell. This is thought to suggest a chemical change in the nature of the cell surface, associated with the malignant transformation.

Chemotherapy and Growth Inhibition

The report describes the preparation and testing of a wide range of cytotoxic growth-inhibiting drugs. As examples of studies with chemotherapeutic agents designed to produce fundamental information, those of comparisons of the mutagenic properties of the nitrogen mustards on the one hand and of the effect of the same type of drug against bacteriophage are good examples; another is the use of the nitrogen mustard HN₂ containing isotopically labelled ¹⁵N to study the changes in the plasma proteins. Triethylene melamine, which has been used clinically, has been used in the investigation of anaerobic glycolysis in tumour cells.

The long-term results of busulphan ("myleran") in the treatment of chronic leukaemia are reported, and a description is given of maintenance therapy over long periods. It is reported that increasing numbers of patients have now been treated continuously with busulphan for three or four years and for the most part have been leading normal lives throughout.

The preliminary reports of the powerful growth-inhibitory activity of 1-chloro-2-methanesulphonoxymethane are interesting, for this is a very simple compound and offers considerable scope for investigation of its mechanism of action.

Radiotherapy

The proposal to introduce a new unit for clinical dosimetry, the rad, is described. Since the biological effects of radiation stem from the energy absorbed by a cell and are independent of the energy passing through it, the new unit, the rad, is being specifically defined as the energy imparted per unit mass of irradiated tissue, and will meet the need arising from the inadequacy of the roentgen. Its introduction will require that all dose charts should be recomputed.

There are descriptions of pneumatic transfer apparatus for 1,000 Curie cobalt-60 units, and of new supervoltage installations including a 4 MeV machine. There is also a description of a 15 MeV machine which so far has been used only for experimental research. Some improvements of radiotherapy technique include convergent-beam therapy for the irradiation of small targets such as the pyriform fossa, the pituitary, or the middle ear, and the horizontal rotation method which has given satisfactory results in five cases in carcinoma of the oesophagus.

In the belief that many of the biological effects of radiation arise in part from the radicals H and OH which are produced when water is exposed to ionizing radiation, further effort has been directed to determining the number of these radicals primarily produced by different types of radiations and their rates of reaction with organic molecules. Aerobic solutions of aromatic amino-acids have been irradiated, and it is claimed that the sequence of changes is similar to the enzymatic oxidation of tyrosine.

Irradiation produces complex alterations in the physico-chemical properties of the D.N.A. molecule which result in

¹ *British Medical Journal*, 1956, 1, 413.

² *Ibid.*, 1956, 1, 1534.

When antigen and antibody react in the blood, the platelets are involved and liberate serotonin or 5-hydroxytryptamine, a pharmacologically active amine which is probably responsible for some of the basic symptoms of anaphylaxis. The importance attached to histamine is decreasing, but its presence in allergic lesions of the tuberculin-test type seems linked with invasion by mononuclear cells, which possibly

As Knights: Colonel J. P. Jenkins, O.B.E., T.D., M.R.C.S., L.R.C.P., and Drs. C. S. C. Prance, K. E. Dowd, K. C. McGibbon, and H. R. Mustard. *As Commanders (Brothers):* Surgeon Rear-Admiral R. L. G. Proctor, M.D., F.R.C.P.I., D.P.H., Q.H.P., Brigadier J. N. B. Crawford, M.B.E., M.D., Mr. R. A. Mustard, M.B.E., M.D., F.R.C.S., and Drs. C. A. Bence, T. H. Jenkins, C. G. Mackay, H. D. Hebb, and R. P. Myers. *As Associate Commander (Brother):* Dr. R. T. Paton. *As Officers (Brothers):* Surgeon Captains W. V. Beach, O.B.E., F.R.C.S., and J. L. S. Coulter, D.S.C., M.R.C.S., L.R.C.P., R.N., Major Generals A. Sachs, C.B., C.B.E., M.D., Q.H.P., and C. W. Greenway, C.B., C.B.E., M.R.C.S., L.R.C.P., Q.H.S., Colonel M. Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Sex Factor in Coronary Artery Disease

SIR,—The letter from Drs. A. R. P. Walker, M. Anderson, and I. Bersohn (*Journal*, May 26, p. 1234), "The Sex Factor in Coronary Artery Disease," gives further substance to the point I have indicated before^{1,2}—namely, that the sex ratio of the incidence is related to the total incidence of the disease in the population and, ultimately, to the diet of the population. Much more evidence to this effect is now at hand.

There can no longer be any doubt that coronary heart disease is excessively rare among the negro peoples in Africa, and all the evidence is that this is to be explained by the mode of life, particularly the diet, and not by a racial peculiarity.³ In our own work in Capetown last year⁴ it was clear that the frequency of coronary heart disease among the Bantu is only a small fraction of that among the local Europeans, with the Cape coloured people (racially unrelated to the Bantu) intermediate. These differences corresponded with a similar gradation in the average serum cholesterol and beta lipoprotein values in samples of these populations and with the fat content of the habitual diets. Within the racial groups the same relationship between diet and serum cholesterol was found. In spite of the belief of some racists, Bantu can apparently be transformed into Europeans, at least in regard to the blood lipids, by giving them European-type diets. Further, Bronte-Stewart and his colleagues⁵ have now shown in controlled experiments that the serum cholesterol in the Bantu responds like the white man to manipulations of the diet fat. Finally, we note that newborn Bantu babies do not differ from their local European counterparts in serum cholesterol concentration.⁶ Their mothers, however, differ greatly, as would be predicted on the grounds of their diets, irrespective of race.

It is not possible to dismiss the rarity of coronary heart disease in the African negro on the theory that it is genetically determined. I am informed that coronary heart disease is now appearing among the more prosperous negroes in the Gold Coast where economic and political conditions allow some of the population to change their diets towards the European pattern. Negroes in the United States are certainly not free from the disease. In a large charity hospital admitting both white patients and negroes in New Orleans, Burch and Voorhies⁷ reported the ratio between the races for the incidence of coronary heart disease to be around 4 to 1 for the period 1928 to 1937. However, over two-thirds of the cases among white patients were diagnosed from clinical and electrocardiographic evidence and less than one-third by necropsy, whereas all but four of the diagnoses among negroes were made by the pathologist. This reflects a bias in medical examination at that time when, in all respects, the negroes in the United States were far more under-privileged than now.

More recently, among 450 young U.S. soldiers with myocardial infarction, there were 63 negroes, or 7.4%. At that time negroes comprised about 10% of the entire U.S. Army.⁸ At present, Dr. Jeremiah Stamler finds that the age-specific death rate among negroes in Chicago is roughly equal to, or even exceeds, that for white people in the same community (statistical studies on the incidence of heart disease in Chicago; to be published).

Further information about the negro in the U.S. is provided by the study, just published,⁹ on 519 myocardial infarctions in a large hospital in Alabama where the negroes still do not fully approximate to the local whites in economic status, though their mode of life does not remotely resemble that of Dr. Walker's Bantu. The incidence of myocardial infarction among these negroes is estimated to be 52% of that among the white people served by this hospital. The sex ratio of infarctions among the white patients was 2.9 to 1 while among the negroes it was 1.2 to 1. However, it was observed that, whereas obesity was not unduly common among the negro men or among the white patients of either sex, all of the female negro patients were obese, which might explain the high frequency of infarction among the negro women.

Data on the Japanese in Hawaii and Japan add confirmation. Severe atherosclerosis and coronary heart disease are certainly rare in Japan. Dr. Noboru Kimura's analysis of 10,000 necropsies shows far less frequent severe atherosclerosis of the coronaries among Japanese in Kyushu than among Minnesotans of the same age, the ratio of incidence rates in middle age being of the order of 1 to 10.⁹ But, whereas in middle age the ratio of incidence among men to that in women is four or five to one among Minnesotans, in Kyushu it is scarcely two to one. Recently in Japan I found general agreement among Japanese cardiologists that Dr. Kimura's figures are comparable to their experience in other parts of Japan, and we ourselves had abundant opportunity to see that coronary heart disease is really not a common disease in that country (Drs. Paul Dudley White and B. Bronte-Stewart participated in the clinical studies). Dr. Kimura's data, as well as the analysis of a large morbidity survey by Dr. Akira Kusakawa,³ are in such good general agreement with the Japanese vital statistics on heart disease that the latter may serve as an indication of the true mortality situation in Japan.

The table gives data from the U.S. and Japanese vital statistics for 1949. The analysis of more recent data is in progress, but apparently the essential picture will be similar. For middle age, where the problem is perhaps more important, the mortality rates ascribed to coronary heart disease (including angina pectoris) are far higher in the U.S. than in Japan, and there is greater disparity between the men than between the women of the two countries.

Death Rates per 100,000 for 1949

Age	Population	Arteriosclerotic Heart Disease		Cerebrovascular Disease		Ratios Between Sexes	
		Men (1)	Women (2)	Men (3)	Women (4)	(1)/(2)	(1)+(3)/(2)+(4)
45-49	U.S. white	231.8	42.8	34.5	37.5	5.4	3.3
	Japan	24.1	13.5	89.8	98.6	1.8	1.0
55-59	U.S. white	637.9	176.7	123.4	109.2	3.8	2.7
	Japan	60.3	31.2	375.0	311.1	1.9	1.3
65-69	U.S. white	1,402.8	659.4	415.0	349.0	2.1	1.8
	Japan	125.1	77.5	1,216.2	934.1	1.6	1.3

From personal experience in Japan I believe their vital statistics may somewhat underestimate their incidence of coronary heart disease or, alternatively, our U.S. physicians may err in the opposite direction. In Japan some sudden deaths, where there was neither necropsy nor opportunity for adequate medical examination before death, are labelled "strokes" when in the U.S. or the U.K. they would be classed as coronary deaths. The physician is always influenced by his knowledge of the pattern of the disease frequency in his country, and there is no doubt that coronary occlusions are more prominent with us while cerebrovascular lesions are more common in Japan. In any case, such bias cannot explain the sex differential. The table gives the death rates ascribed to cerebrovascular lesions and the ratios of death rates between the sexes when both ascribed causes of death are combined.

As in the case of the negro, it is not possible to attribute the rarity of coronary heart disease in Japan to racial peculiarity. Coronary heart disease is not rare among Japanese long resident in the United States, where, for the most part, they live (and eat) as do other Americans. According to the U.S. vital statistics, 71% of all heart disease deaths among Japanese in this country were ascribed to coronary heart disease in 1953. The sex ratio of these coronary deaths was 4.6 to 1.

In Hawaii this spring Dr. Nils P. Larsen was able to convince us that the large population of Japanese there, who are moving far towards the American mode of life in regard to the diet, are also beginning to imitate Americans in regard to the frequency of severe atherosclerosis and coronary heart disease. For example, Dr. Larsen's necropsies on Japanese long resident in Hawaii disclosed severe atherosclerosis in 30% of the men aged 50 to 59. This is still only half the incidence observed in necropsies on white men of that age in Hawaii, but it is close to five times the corresponding incidence observed in necropsies in Kyushu. We ourselves saw a number of Japanese patients with coronary heart disease during a brief visit to Honolulu, and others were seen during a hasty trip to the sugar plantations. But during five weeks of work in Kyushu in the large university hospital and in various small hospitals and clinics we found no classical cases. The only recent specimen of a heart with a large fatal occlusion in the pathology department was from a doctor who had returned to Japan after 20 years of practice in Honolulu.

It is particularly significant that the diet in Japan is, and has been throughout history, extremely low in fats (less than 15% of calories from this source) but that the average diet of the Japanese in Hawaii is much closer to the U.S. pattern of 40+% fat

calories. Preliminary estimates suggest an average of about 30% fat calories for the Japanese men we studied in Hawaii. Further, the serum cholesterol averages of the population samples we studied corresponded to these dietary differences.

The most important conclusion from all of these comparisons is that masculinity itself is not a basic cause of coronary heart disease nor is immunity conferred by female sex hormones. Vital statistics, necropsy data, and clinical observations all agree that American females are more susceptible to coronary heart disease than are males of the same age in Japan or among the Bantu and other negroid peoples in Africa. We could also include on the one side the females of other countries where coronary heart disease is rife—e.g., some northern European countries—and, on the other, the males in some other populations—e.g., poor people in Spain and the general population of southern Italy. Should we conclude that men in Italy and Spain, as well as in Japan and among Bantu in Africa, are charged with female sex hormones and are lacking in masculinity?

None of this is to suggest that sex hormones have no importance. Sex hormones are always important, and that includes the problem of atherogenesis. But it appears that the female sex hormones offer their greatest protection—and that is limited—only in the face of such extraordinary atherogenic forces as are generated by the current mode of life of the most prosperous western society. Perhaps the female has a greater natural affinity for fat (in the diet as well as in her person) than does the male. At any rate they seem to be less affected by, or are more resistant to, a high-fat diet. But in the American and British contemporary scene it is clear that even female sex hormones are not enough to provide full protection. In the United States we are now recording some 5,000 coronary deaths a year among women under the age of 50 years. In Britain, too, I notice in the 1954 Registrar-General's report that some hundreds of relatively young women are dying each year with the diagnosis of "arteriosclerotic heart disease." If we take the sensible step of adding the figures for International List numbers 420 and 422, as the Registrar-General conveniently does for us for 1954, the sex ratio of death rates for such "degenerative" heart disease turns out to be 5.1 to 1 for the age range 45 to 49 in England and Wales.—I am, etc.,

SIR,—We have read the letter by Drs. Alexander R. P. Walker, Marianne Andersson, and I. Bersohn (*Journal*, May 26, p. 1234) regarding the lack of importance of the sex factor in coronary artery disease among South African natives. These authors pointed out that "in a population relatively free from coronary artery disease differences in the severity of atherosclerotic lesions and in mortality rates from the disease between the sexes are not in evidence," whereas "in populations where the death rate is very high from the disease the corresponding figures are far higher in males than in females until old age."

In regard to this subject, we would like to call attention to the report of a recent study of the ratio of the incidence of acute myocardial infarction among 8,183 adults (90% were white) who came to necropsy at Washington University in St. Louis between 1910 and 1954.¹ In this population which underwent necropsy and which had a high incidence of acute myocardial infarction we found that a change has occurred in the relative incidence of the disease in the two sexes. In the period 1910-39 the incidence of acute myocardial infarction among men was twice as great as among women. In the period 1940-54 the corresponding incidence

among men was not significantly greater than it was among women. In the oldest age-groups the corresponding incidence was actually considerably higher among women than among men. The overall incidence of acute myocardial infarction was considerably higher among both men and women in the period 1940-54 than it was in the period 1910-39. However, even in the period 1910-39 the incidence was higher than that reported among the Bantu in South Africa.

It does not seem to us that our figures or those of Drs. Walker, Andersson, and Bersohn provide enough basis for sound generalizations. However, if we may be allowed to speculate along the same lines with the above authors, it appears to us from the figures available now that the sex factor operates extensively only at an intermediate level of incidence. When the incidence of coronary artery disease and its complications is very low the sex factor is not evident; at intermediate levels it is prominent; but at high levels it diminishes. It must be emphasized that this is only speculation and that many other variable factors are probably operating to produce the final results.

It is of interest to add that in a study now in progress² we have found an exceedingly low incidence of acute myocardial infarction among American negroes. Among approximately 3,000 necropsies performed on negro adults at a St. Louis City hospital we have found only 25 (12 men and 13 women) with acute myocardial infarction. Thus it appears that the racial characteristics or habits responsible for the low incidence of coronary arterial disease among negroes in Africa have been transferred to their descendants in America.—We are, etc.,

Mortality from Coronary Disease

SIR,—I was very interested in Dr. W. J. Martin's figures showing the distribution in England and Wales of mortality from coronary disease (*Journal*, June 30, p. 1523). It would appear that the figures for rural districts were always lower than those for urban districts. Would it be fair to assume that more animal fat (butter, eggs, bacon, meat) is consumed in the former areas as compared with the latter? Do farmers and rural males smoke less than their counterparts in the cities? These are two important questions for which Dr. Martin may have the answers.—I am, etc.,

Hull.

L. I. HARDY.

Silicone Barrier Cream

SIR,—Your correspondent Mr. M. H. Payne (*Journal*, June 23, p. 1487) has referred to the high cost of silicone barrier creams, and gives a formula for such a product. Many such formulae have been published, most of which suffer the same disadvantage—that is, they are water washable emulsions. When applied to the skin the water content may evaporate, but because of the content of emulsifying agent the resultant film is readily dispersed in water. They are thus unable to give protection for very long against aqueous solutions. It seems to me to be fundamental that any film which is to protect the skin from aqueous solutions must be free from oil-in-water emulsifying agents. This entails the use of a transitory emulsifying agent—that is, one which breaks down on application to the skin. Such emulsifying agents are well known to the manufacturers of emulsion polishes.

The cost of 5s. per pound (0.45 kg.) is of course only the cost of the materials. It would be unfair to compare this cost with the total cost of manufactured silicone creams. This is especially true when one remembers that the labour cost for the manufacture of small quantities is very high.—I am, etc.,

Athlete's Foot

SIR,—I was interested to read the comments (*Journal*, June 23, p. 1486) on my previous letter on athlete's foot (*Journal*, May 26, p. 1239). However, I feel there is some misunderstanding.

The treatment described was for athlete's foot, a condition of hyperhidrosis and maceration of the feet, of which tinea is only one causative organism. Scrapings were not taken, as facilities were not available for examination, and as all cases improved on this treatment this factor seems quite irrelevant. I fear Dr. G. R. Addlestone has made the mistake of making half an investigation and basing his very conservative treatment on his findings. Did he assume that there was no causative organism in the 90% of cases in which he did not isolate filaments of tinea? Did he take swabs and make cultures in these cases? Surely it must follow that where there is maceration of the skin, with death and decay, some organism is usually implicated. Those who have smelt the feet of these cases would hardly disagree. In which case the use of a fungicidal and bactericidal agent such as formalin will logically accelerate the healing of such an infection. This method of treatment is not specific against tinea pedis; neither are most of the proprietary preparations.

An Army medical officer is a powerful agent on matters of health. He can and should "advise" commanding officers in matters like "kit layout," and ensure that all socks are shown in a fit state to be worn (not unworn), thus ensuring the soldier is equipped for foot hygiene. In fact, in no unit where the M.O. has his eye on the hygiene of the unit is such "bull" as unworn socks tolerated. I believe the standard scale of issue of socks is four pairs and not three, as stated by Dr. Addlestone.

Naturally, in all cases treated, whatever the application used, foot hygiene was instituted. I would again stress that drug treatment is useless without foot hygiene. I would agree with Dr. M. D. A. Heller that powder could be applied direct to the feet when the skin is unbroken, but surely where there is maceration there is broken skin. Also I can assure him that it is a fact of simple pathology—or was when I was a student—that insoluble foreign bodies do delay healing.—I am, etc.,

Poole, Dorset.

D. HOOKER.

SIR,—In vesicular tinea pedis and scaly or hyperkeratotic tinea the fungi, usually *Trichophyton mentagrophytes* and *T. rubrum* respectively, produce an inflammatory reaction in the skin as evidence of their activity, and fungicides cure the conditions. *T. interdigitale* is found in a proportion of cases of interdigital maceration due to hyperhidrosis. Dr. G. R. Addlestone (*Journal*, June 23, p. 1486) found "filaments, etc., of tinea pedis" in less than 10% of soldiers with "athlete's foot." The appearance of the interdigital skin is the same in those cases in which the fungus is found as in the others, and the signs of inflammation are absent.

Is there any evidence that *T. interdigitale* produces disease, and is not merely a harmless saprophyte growing in a favourable environment? The presence of fungi has been demonstrated on clinically normal feet by Baer *et al.*¹ and the workers they quote. It is possible that all cases of interdigital maceration will respond to adequate hygiene and attention to hyperhidrosis, and that the use of a fungicide is unnecessary even when *T. interdigitale* has been shown to be present. I would be interested to learn of any experimental evidence on this point.—I am, etc.,

Cardiff.

Antibody to Synovial Tissue

SIR,—In your report (*Journal*, June 16, p. 1421) of a recent meeting of the Heberden Society we were quoted as having said that an antibody prepared by immunization with synovial tissue reacted with reticulin, whereas an antibody to renal glomeruli did not. In fact we reported that antibody to glomeruli had been found to react with two groups

of tissue elements—basement membranes and material present in the media of vessels forming one group, and reticulin the second. Antibody to synovial tissue, on the other hand, reacted only with the second.—We are, etc.,

ALAN G. S. HILL.

Aylesbury.

Atypical Weil's Disease

SIR,—In your issue of June 9 (p. 1342) a typical case of leptospirosis is described, not without justification, as an atypical case of Weil's disease. The purpose of this letter is to urge the abandonment of the thoroughly unsatisfactory name "Weil's disease" and its replacement in scientific publications by the more accurate term leptospirosis, to indicate an infection with organisms of the genus *Leptospira*.

In 1886 Adolph Weil, Professor of Internal Medicine at Heidelberg University, described four cases of infectious jaundice.¹ The most prominent feature of the disease that bears his name was jaundice, a complication that is now known to occur in less than 10% of cases of leptospirosis. The name cannot, therefore, accurately describe more than a tenth of the cases of leptospirosis.

In 1915 Inada and Ido showed that the disease was due, in Japan, to infection with *L. icterohaemorrhagiae*,² and the term Weil's disease came to be used for such an infection. This was probably wrong. In Bavaria an analysis of 719 cases of leptospirosis occurring between 1937 and 1947 showed that 663 (92%) were due to infection with *L. grippityphosa* and only 29 (4%) to infection with *L. icterohaemorrhagiae*.³ The disease described by Weil was very probably due to *L. grippityphosa*, and as this infection has never been reported in the British Isles⁴ it follows that "Weil's disease" cannot occur in the British Isles, although, of course, leptospirosis can and does.

These considerations apart, many medical historians dispute the claims of Weil to be the first to describe this type of infectious jaundice, and the French believe Baron Larrey's description of jaundice occurring among Napoleon's troops during the siege of Cairo in 1800 to have anteceded Weil's by 86 years.⁵ Actually it is doubtful whether Larrey was describing the same condition, but the claims of others, including Landouzy (put forward by Martin and Pettit⁶), Marsden, and Dupres (put forward by Broom⁷) cannot be as lightly dismissed.

If we accept the name Weil's disease to denote infection with *L. icterohaemorrhagiae* we must also accept a host of confusing names which denote infection with other leptospires—e.g., mud fever, swamp fever, harvest fever, rice-field fever, sugar-cane fever, swineherd fever, etc. To refer to the leptospiroses by these synonyms in a scientific publication is, in my view, to be deprecated.

At the beginning of this letter I said this was a typical case of leptospirosis, and indeed so it is to anyone who is aware of the possibility of such a diagnosis. Any case of unexplained fever accompanied by prostration, severe pain in the limbs, injection of conjunctivae, or signs of meningeal irritation should be considered a possible case of leptospirosis until proved otherwise. Vomiting and diarrhoea are not uncommon. Nor is the confusional state which your correspondent considered so exceptional.

There is one outstanding omission from the case report. The patient's occupation is not stated. Leptospirosis is an occupational disease, and an association with rats or water contaminated with infected rat urine would have proved an invaluable clue to the early diagnosis of the disease.—I am, etc.,

London, S.W.1.

Tuberculosis and Mass Radiography

SIR,—Dr. C. Rubinstein (*Journal*, June 16, p. 1429) quotes several remarks in my letter (*Journal*, April 14, p. 858), which was a plea against Professor J. Crofton's, Dr. G. Lissant Cox's, and Dr. A. L. Cochrane's advocacy of legal compulsion in mass radiography (*Journal*, March 24, p. 684). Their original joint letter has evoked but desultory response in your columns, including my "still, small voice"—the only one, hitherto, raised in unequivocal opposition to compulsion. The necessary delay, to which Dr. Rubinstein refers, in receiving the *B.M.J.* in Australia is matched by delay in our importing its Australian counterpart. We are grateful to him for the brief statistical summary of results of compulsory mass radiography surveys in New South Wales since 1953, and for reference to his paper¹ which I look forward to studying carefully and without bias. The figures he quotes do little, however, to convert me to the idea of compulsion. Do the numerical results given in his letter answer any "question as to their value," or merely reinforce the axiom that if, anywhere, you take a mass radiography unit out among a lot of people, you will find a lot of tubercle?

New South Wales and Sydney must be congratulated on their relatively low incidence of pulmonary tuberculosis, as found by mass radiography. The rate (1.3 per 1,000 persons in the city, and 0.6 per 1,000 persons in rural districts) as calculated from Dr. Rubinstein's figures, is about half that which would be revealed in the U.K. It interests me that, despite legal sanction and an acceptance rate of nearly 90% in the first survey, a repeat survey in Sydney nevertheless yielded a rate of 0.7 per 1,000. Compulsion had evidently not emptied the "infecto-pool," which, reduced within three years by about half, is still a large reservoir. Incidentally, as each of our British units does well to x-ray 50,000 persons, on average, annually, it is surprising to learn, by analysis of Dr. Rubinstein's figures, that the annual "output" of an Australian unit is 113,300. We would welcome his advice on means of doubling or more our "output," as that would solve some of our immediate problems.

I agree that the older male age-groups now bear the brunt of pulmonary tuberculosis and constitute most of the infecto-pool, and that we must concentrate radiographically and in other ways on them. As I said in my first letter, most middle-aged men who are phthisical have symptoms; in many, one or a series of sputum tests suffice to confirm the disease, chest x-raying being done later. Dr. Rubinstein was, indeed, fortunate to be able to con- sider firm tuberculosis bacteriologically in all 1,170 new cases found in Sydney, a finding suggesting either that they were in the main not so-called "early" cases or that Sydney has an unsurpassable bacteriological service.

That Australia is a country "where compulsion of any kind is vigorously resented" seems to be contradicted by the acceptance by Sydney and New South Wales of one kind of compulsion—namely, chest x-raying. I am at a loss, too, to understand, now that legal powers exist, why there were no prosecutions of non-attenders. Surely the 10% to 12% of defaulters were not all people out of town on business or holiday, or ill at home or in hospital, or who had escaped the compulsive net for any other miscellaneous reason. Compulsion is abortive and mythical unless, where there are transgressors of the law, the legal punitive machinery is operated. Can Dr. Rubinstein (or anyone) tell us how, granted we get legal sanction, we can enforce John Smith, Hull docker or Barnsley collier, perhaps hundreds or thousands of his kind, to come before our x-ray camera if he is unwilling, or if, resistant he is carried there, how we may take an adequate x-ray picture of his chest? It seems to me that, once legal compulsion is invoked, these are some of the fundamental problems that we shall face.

At the Commonwealth Health and Tuberculosis Conference held in London in summer, 1955, sponsored by the National Association for the Prevention of Tuberculosis, a day was devoted to discussing mass radiography, its present and future policy.² Several references were made to use of compulsory powers, mainly by speakers in the debates following the reading of the principal papers. Dr. E. Eilertsen, of Bergen, told the Conference that Norway had done mass radiography on a compulsory basis for 7 years, the results "rather satisfactory but of course not ideal." Dr. P. Kerley, 10% to 15% of the population default. Dr. P. Kerley, chairman at a joint meeting, in summing up, said: "Com-

pulsion neither in Norway nor in Australia has got to the hard core; the 10% who will not come in so many instances are the carriers of infection." Only a few speakers at the Conference were explicitly on the side of compulsion, and, of those, two were industrial medical officers, whose work lay among well-organized, not very large, groups of people, one living and working in Borneo.—I am, etc.,

R. HARDY.

Unit for Alcoholics

SIR,—I read with interest Dr. M. M. Glatt's letter (*Journal*, June 23, p. 1483) relating to the establishment of a special unit for alcoholics. Such units are clearly very desirable. In no way would I wish to detract from the splendid pioneering work carried out on behalf of alcoholics at Warlingham Park Hospital, but, in my view, the alcoholic rightly resents being sent to a mental hospital. Dr. Glatt bravely amplifies this opinion in his letter. This does not apply of course to the psychotic alcoholic, who represents a comparatively small percentage of all alcoholics.

The essential preliminary to the establishment of a special alcoholic clinic is the attitude of our profession itself towards the full acceptance of the concept of alcoholism as a disease entity. How often has one encountered considerable apathy, pessimism, if not downright antagonism, to these unfortunate members of society. This mistaken approach to the alcoholic patient is mainly due to complete lack of knowledge of the problem, and the all-too-ready assumption that the condition is largely determined by moral failure. It seems to me that, unless there is a definite change of heart, it is pertinent to ask who might be considered eligible to undertake the great responsibility of organizing such a unit for alcoholics.

I heartily endorse Dr. Glatt's opinion as to the invaluable help which the group therapy of Alcoholics Anonymous provides, but surely this does not mean that we should lose sight of the fact that alcoholism is primarily a medical problem, and the first essential of good medical practice is diagnosis.—I am, etc.,

Harrow Weald, Middlesex.

LINCOLN WILLIAMS.

SIR,—I am impelled to comment on Dr. M. M. Glatt's letter on a unit for alcoholics (*Journal*, June 23, p. 1483) as a medical practitioner who is also an alcoholic—a member of both B.M.A. and A.A. I was a patient in Warlingham Park Hospital last year for a period of three months—incidentally one of five doctors amongst approximately 20 patients. Most of us had undergone periods of treatment in other hospitals previously and had sought admission to Warlingham as a last-ditch attempt to deal with our common problem. I am very happy to say that in rather more than 60% of us the results have, up to now, been successful.

Up to very recently the prognosis for the alcohol addict was often regarded as hopeless. To what can one attribute the spectacular success of Warlingham Park in this field during the past four years? In other hospitals the alcoholic felt "alone." At Warlingham Park Hospital the main emphasis of treatment is on group therapy and a very close association with the Alcoholics Anonymous fellowship. One finds oneself one of an integrated group of other alcoholics with the same problems and the same experiences and all speaking the same language. One attends an average of five meetings of Alcoholics Anonymous weekly—three of them outside the hospital. All this apart from almost daily group therapy meetings in the hospital. The monthly magazine of the alcoholic group and regular reunion meetings help to keep up the feeling of "belonging" also.

I know that during my period as a patient very frequent requests were made for admission. These could only be met by adding the patient's name to an ever-lengthening waiting list. Nowadays, perhaps because of my close association with A.A., I am constantly being asked to arrange hospital admissions for alcoholic patients.

98882

This is a big problem. It would appear that arrangements in the United States of America are far ahead of those in this country. Could not specialized regional units be established in the country, in close association with Alcoholics Anonymous?—I am, etc.,

"LYN."

Jig for Inserting Radon Seeds into Bladder

SIR,—In certain types of carcinoma of the urinary bladder the implantation of radon seeds is the treatment of choice, but sometimes it is not easy to maintain the desired pattern during the insertion. It was felt that a method to give greater accuracy was required, and for this some form of jig seemed indicated. As many bladder tumours are of roughly circular outline it was decided to use jigs of circular shape. These required to be transparent to ensure accurate positioning and be slightly concave to fit the bladder wall. A suitable pattern has now been evolved. In general it resembles the ladle type of sugar sifter, and is made in three sizes. The smallest is 3 cm. in diameter and is perforated

to permit insertion of 12 seeds; the middle size is 4 cm. across and perforated for 17 seeds; and the largest is a 5-cm. circle planned for the insertion of 23 seeds. The bowls are made of perspex, suitably curved and perforated by holes large enough to accept freely the standard type of radon seed introducer. The holes are drilled at right angles to the surface to give a suitable distribution of the radon seeds, generally 1 cm. apart. The type of seed which has been used

is 0.7 mc., 10 mm. long, filtration 0.5 Au. The number used gives a dose of 5,800–5,900 r at 0.5 cm. from the plane. The bowl is attached to a handle of suitable length by a clamp in the smallest size, but in the larger sizes the perspex is contained by a metal ring attached to the handle. On this ring are three eyes by which the jig may be temporarily stitched to the bladder wall to prevent sliding or rotation during the insertion. After removal of the projecting bulk of the tumour by diathermy knife the radon seeds are introduced by standard seed introducers, which require to be of adequate length. Sometimes a straight introducer can be used, but it is necessary that the termination of the introducer be at right angles to the plane of the jig. Frequently, therefore, a curved introducer is required, and this should have a sufficiently long and open curve to achieve this relationship.

Sterilization of these instruments has been effected by immersion for half an hour in a solution of "roccal" 1 in 40 with 2 g. sodium nitrate added to each pint. They have been immersed in this solution for a period of four hours without ill effect. Boiling or immersion in phenols or cresols, even for a short time, is quite unsuitable, as these methods all have a deleterious effect on the plastic material used. This apparatus has now been employed by more than one surgeon, and has proved simple and effective in use. The only criticism is that a fairly large incision in the bladder wall is required to introduce the 5-cm. circular jig.

The original set was made for us by Messrs. C. F. Thackray Ltd., Park Street, Leeds, to whom we are indebted for the care and interest they have shown and for the illustration.—We are, etc.,

A. IAN L. MAITLAND.
T. MARTIN YOUNG.

Glasgow, W.1.

Worrying Reports

SIR,—Dr. T. H. H. Green complains (*Journal*, June 30, p. 1547) that patients suffering from dangerous or incurable diseases are worried by reading of these diseases in the popular press. His remedy would be to muzzle the press, presumably requiring an Act of Parliament and yet another committee to compile a list of dangerous diseases. Even then there would be patients so inquisitive as to seek information from medical dictionaries and similar sources.

Surely, the simple remedy is for the practitioner, both in hospital and at home, to exercise discretion in labelling disease for the sufferer and to take care that such terms as subarachnoid haemorrhage and disseminated sclerosis are neither seen nor heard by the patient.—I am, etc.,

Redhill, Surrey

HENRY ATKINSON.

Cigarette Swallower

SIR,—So much has been written in the past few years about the hazards of smoking that I feel I should like to add a humble contribution to the literature by quoting the following personal experience.

A patient consulted me recently complaining of an extremely sore throat. The previous evening he was at home attentively watching a big fight on television. At the crucial moment of the fight one of the less interested members of his family spoke to him. He started to say, "Sh," took a deep breath, forgetting that a cigarette was hanging from the corner of his mouth, and inhaled it. The cigarette end, about 1½ in. (3.8 cm.) long, lodged in his throat and he immediately "gagged," thereby expelling it. Unfortunately the stub stuck to the uvula and required repeated retching before it, too, was coughed up. On examination, he had two ulcers of the uvula and small first-degree burns of the soft palate and right fauces. These lesions were extremely painful, but responded well to treatment (painting with pig. iod. co., thymol mouth washes, and antiseptic lozenges).

I would like to add that this patient has now given up smoking—perhaps he should have given up T.V.—I am, etc.,

London, E.7.

M. LUBEL.

Unconscious Mental Activity?

SIR,—Much has been written recently about Freud and psycho-analysis in view of the centenary of his birth. E. Stengel (*Journal*, May 5, p. 1000) states that "it [psycho-analysis] is superior to other psychological treatments," and that "psycho-analysis proper is unrivalled as a tool of investigation into the mental life of individuals."

One feels that these statements cannot be left unchallenged. In your own appraisal of Freud and his ideas (p. 1027) you state that "many scientists have maintained that psycho-analysis can never be studied by the method of scientific experiment. . . ." I think one can go further and say that most of Freud's "hypotheses" are not really hypotheses in the scientific meaning of the word, but they are statements with little meaning—as they cannot be translated into scientific language or thought. For example, in psycho-analytical language a boy is born with an innate "Oedipus complex" in which he desires his mother and wants to get rid of his father as a rival. The thought of castration, however, forces him to give up this attitude. This idea, however, is "unconscious," so the boy does not know about it. This type of logic is incomprehensible from a scientific point of view. It is against all known scientific knowledge that a child can be born with "ideas" that exist in an undefinable entity known as the "unconscious mind." You also state that "hitherto there have hardly been any attempts" to study psycho-analysis experimentally. But it is difficult to visualize what type of experiment one can perform to verify the existence of an "unconscious mind" or the "super-ego" and the "id," etc.

Cohen and Nagel¹ state that a hypothesis can only be of value if it is capable of verification and it "must be stated in terms of

determinable empirical operations." They continue, "Many theories which have a wide popular appeal fail to meet the conditions specified. Thus the theory that whatever happens is the work of . . . the will of the unconscious self is unsatisfactory from the point of view we are now considering. For that theory is not 'verified' if after the happening we can interpret the event as the work . . . of the unconscious self. In fact the theory is so poorly formulated that we cannot state what its logical consequences are, and therefore what should be the nature of some future event. The theory does not enable us to predict. It is not verifiable. It does not differentiate between itself and any apparent contrary theory, such as that whatever happens is fortuitous."

To expand further on this point: Shaffer² states that "(1) A first serious shortcoming of psycho-analysis is that it is based on unreliable data. In recent years psychologists have tended less and less to use introspection as a method of research. (2) Especially incredible to scientific thinkers are the psycho-analytical concepts of inherited ideas, 'the collective unconscious,' and of fixed symbols. There is no conceivable biological mechanism by which an idea, a thought or symbol can be inherited. (3) Factually psycho-analysis has hardly a leg to stand on."

In contrast to psycho-analysis, however, the study of psychology was first put on to a scientific basis by I. P. Pavlov, when he studied conditioned reflexes, and later expanded by Watson, Hull, and Shaffer in the U.S.A. They explain human behaviour in terms of "stimuli," "responses," "drive," "adaptation," etc. These terms—in contrast to psycho-analytical jargon—can be defined in terms of "empirical operations," and therefore form the basis of laboratory experiments. One very important difference between this objective psychology and psycho-analysis is that in the former an attempt is made to explain human behaviour in terms of what we know of biology and physiology; whereas psycho-analysis is entirely divorced from the biological sciences and has created for itself a "dream world" of its own. Objective psychology (some have called it "behaviourism") is dynamic and stresses the importance of the individual's environment. Psycho-analysis is largely introspective.

One of the great failures of psycho-analysis is to explain neuroses adequately. Neurotic symptoms are supposed to be "substitutes for the gratification of repressed urges" and related to the Oedipus and castration complexes. However, the objective psychologists have defined neurotic behaviour as "unadaptive learned behaviour which in spite of repeated evocations fails to become extinguished," and this definition is elaborated in a most illuminating way by Wolpe.⁴ A characteristic experiment to produce neurosis is the well-known one by Pavlov, as quoted by Wolpe. "A dog was given food when a luminous circle was projected on to a screen, but never given food at the projection of an ellipse. After positive and negative conditioned responses had been established the ellipse was made more and more closely to resemble a circle. Eventually the dog 'broke down,' showing intense fear and avoidance of the experimental situation."⁴ Neurotic behaviour has also been produced experimentally in children.⁵ In other words normal and neurotic behaviour can be explained in terms of conditioning and habit formation without involving such imaginary entities as the "unconscious" castration complex, etc.

In conclusion I feel that psycho-analysis has outlived its usefulness and will be replaced by the scientific study of psychology along the lines developed by Pavlov.—I am, etc.,

SIR,—I agree with Dr. F. A. Pickworth (*Journal*, June 9, p. 1364) that the expression "unconscious mental processes," in spite of long usage, still has the semblance of a contradiction in terms, and it is partly on account of the intellectual indigestion that this and other psychoanalytic phraseology causes that Freudian psychology in particular and dynamic psychology in general are still regarded even now by many educated people, including many medical men and professional psychologists, with disdainful scepticism, sometimes amounting to open rejection. As Dr. E. Stengel (*Journal*, June 30, p. 1544) points out, the problem is a semantic one and its resolution comparatively simple.

The following points would seem to be relevant: (1) In everyday speech the term "mind" is commonly used as being synonymous with "conscious thinking." My "consciousness" is my "mind"—that which is "conscious" is "mental." (2) It may reasonably be argued that "conscious" or "mental" processes are physiological processes occurring within the brain. In other words, it may be said that mental—i.e., "conscious"—events constitute a special class of brain events. (3) At the same time, in psycho-analytically orientated circles "the unconscious" is also thought of as being "mental" and forming part of the individual's "mind" or "psyche." However, "the unconscious," although it may influence and be influenced by consciousness, is not (it hardly need be said) itself conscious—that is, "mental" in the everyday sense. (4) "The unconscious" is therefore, in my view, best regarded as being a dynamic physiological system within the brain, whose structure and mode of functioning can nevertheless be conveniently described to a considerable extent in metaphorical terms derived from the language of consciousness (and it is presumably for this reason that it is thought of as being "mental" by the analytically orientated). (5) Finally, in view of the fact that both conscious thinking and the processes of the unconscious can reasonably be held to occur within the brain, many of the philosophical problems concerning the relationship between "the mind" and "the brain" can be shown to be problems relating to the use of words and be resolved without difficulty.

In the light of what has been said above, we may now offer to Dr. Pickworth the following, in lieu of an "unambiguous redefinition" of Freud's "insight into unconscious mental processes": An understanding, formulated and expressed in metaphorical (one might even say allegorical) language, of that dynamic physiological system of non-conscious brain processes which Freud designated "the unconscious" (whose content and mode of functioning resemble in many respects the content and mode of functioning of that ever-changing organization of brain processes known as "consciousness").—I am, etc.,

Radioactive Iron Studies

SIR,—Dr. G. Wetherley-Mein and others in their article on radioactive iron studies in routine haematological practice (*Journal*, June 23, p. 1445) have failed to mention the physiological basis of their investigations. The results that they have reported are those giving the rate of disappearance of measurable radioactivity from the circulation and its deposition in various organs. These findings depend upon the take-up of the radioactive iron-protein complex by cells of the macrophage system (reticulo-endothelial system of Aschoff¹). The ⁵⁹Fe, either combined with β-globulin or with the metal-binding protein of the recipient's plasma, is removed from the blood mainly by macrophage cells contained in the liver, spleen, and bone marrow. It can be shown microscopically that following intravenous introduction of iron saccharate or of "protein-complex" these substances are contained almost exclusively in the macrophage cells of those organs.

In similar experiments to those reported by the authors, Halpern,² in Paris, has shown that, by injecting a radioactive ⁵⁹iodine-albumin-complex into experimental animals, the rate of clearance is equivalent to that of injected particulate carbon, and that both forms of experiment show an exponential clearance of the substance from the plasma. This rate of clearance is termed by him "the phagocytic index" and is denoted by a straight line, as shown by Wetherley-Mein *et al.*, when the clearance rate and the time are related on semi-logarithmic graph paper. Halpern has also found that the radioactive ⁵⁹I begins to be slowly released from the macrophage cells after some hours and is reintroduced into the circulation, there to be redeposited or excreted, mainly in the urine. Miescher,³ in Basle, using red blood corpuscles labelled with ⁵¹Cr, shows similar

results, although he indicates that the bone-marrow is eventually responsible for a greater concentration of the radioactive combination.

There are various other important factors which must be taken into account when evaluating the results of the reported experiments—namely, the total and relative volume sizes of liver, spleen, and bone-marrow; the vascularity of these organs; and the total blood volume of the body and its velocity. By various photometric and radioactive methods it has been found that in the normal experimental animal, subjected to a standard intravenous injection of colloid or particulate substance, the speed of clearance by the macrophage cells is directly proportional to the sizes of the liver, spleen, etc., and altered by the physical conditions operating in the cardiovascular system. Furthermore, it has been found that this clearance activity by the macrophage system can be experimentally modified by operation (partial hepatectomy, splenectomy), hormones, and drugs,^{4,5} and the introduction of a disease or pathological condition.⁷ The graphs which have been shown in this article indicate that the radiation was recorded from surface measurement. Thus, it is not taken into account that a normal adult liver (1,500 g.) is over seven times the size of the spleen (200 g.) and that these organs are physically modified by the size of each individual patient and by the particular pathological condition—e.g., high radioactivity found in splenomegaly and in myelofibrosis where the authors admit the presence of an "enormous spleen." In addition, the liver takes up the initial amounts of the injected substance, and only after a point of macrophage saturation or local "blockage" does deposition occur to any appreciable extent in the spleen and other organs. Thus, where liver damage is present, the measurements of radioactivity will be decreased in that organ and relatively increased in other areas.

Wetherley-Mein *et al.* have thus indicated another method for the measurement of macrophage activity using radioactive iron-protein complex. They have shown that the activity of the macrophage system has been affected by various pathological conditions. However, from their method and results there is no valid claim that guidance has been given in assessing either normal or abnormal erythropoiesis. In its present form their clinical procedure has no direct bearing on the diagnosis or treatment of blood conditions, and it is not therefore warranted in routine haematological practice.—I am, etc.,

Treatment of the Cord in the Newborn

SIR,—I was interested in Dr. A. B. Murray's memorandum (*Journal*, June 30, p. 1530) on treatment of the cord. I have recently reviewed our routine care of the newborn, together with some of the results obtained over six years (1950-5 inclusive) in two maternity units, and the following points have some bearing on the problem.

In unit A, with about 1,300 deliveries a year, we have continued to treat the cord in the "traditional" way, using powder, sterile dressing, and crêpe bandage. Small premature babies who are nursed naked and certain cerebral and asphyxiated full-term infants form exceptions to this rule. In unit B, with some 950 deliveries, a clamp which occludes the free end of the cord was adopted three and a half years ago.

During the six years under review no case of liver infection or, except in infants with gross congenital abnormalities, of death due to either streptococcal or staphylococcal organisms has been found among some 13,101 babies nursed in the two units. There was no evidence to suggest that

three cases of neonatal meningitis in premature babies had been acquired through cord infection, although this route may have been responsible for two cases of osteomyelitis developing soon after discharge in infants who had appeared healthy in hospital. Both the methods of cord treatment therefore appear to have been reasonably satisfactory in preventing serious infection, although the clamp has certain disadvantages, since it cannot be used with safety on a thick cord, it occasionally causes chafing of the skin, and some infants need an additional dressing as the cord separates.

The presence of resistant staphylococci and the recrudescence of streptococcal infection reported from some centres¹ make Dr. Murray's work timely. It may well be that the traditional method of treating the cord and navel is sound provided the binder is loose enough to allow abdominal respiration. Should we not regard the cord and umbilicus as open surgical wounds until healing is complete? Before reading of Dr. Murray's investigation we had decided to look into the problem here, particularly with regard to the care of the cord in the smaller premature babies.—I am, etc.,

Obituary

Mr. R. R. KERR, honorary consulting surgeon to the Victoria Memorial Jewish Hospital, Manchester, died suddenly on May 31 at Cannes, where he was on holiday with his wife and daughter. Roy Russell Kerr was born at Winnipeg, Canada, in 1888 of parents of Scottish descent. Early in his life his father, Francis Ferguson Kerr, a schoolmaster, went to Edinburgh to study medicine, which he practised later in Horwich and Prestwich, Lancashire. In 1904 Roy Kerr took up the study of medicine at Edinburgh University, graduating M.B., Ch.B. in 1909. After a year as house-surgeon to Professor Alexis Thomson in Edinburgh, he entered general practice at Heaton Park, Prestwich, near his parents' home, but at the outbreak of war in 1914 he joined the R.A.M.C. He served in a hospital ship and also as a battalion medical officer on the Western Front. A year later he transferred to the Royal Navy and saw service in light cruisers in the South Atlantic. He used his spare time at sea to some purpose, and was given leave to sit his Primary Fellowship, which he passed successfully in 1917. He took the final Fellowship in 1920. After demobilization Mr. Kerr was elected honorary surgeon to the Victoria Memorial Jewish Hospital, Manchester, which he served well for some 28 years, watching it grow from a very minor to a first-class modern hospital. He resigned when the National Health Service came into being rather than serve under the new dispensation. His chief work, which he carried out to the end, was medico-legal. He was an excellent witness, clear, concise, and absolutely fair. He enjoyed the confidence of the judges, both in the county courts, where he was a constant attender, and in the assize courts, where he usually had several cases in each session. Essentially an individualist who held his opinions strongly and was always ready to state them dogmatically, he was at the same time a very kindly, lovable man who was trusted and revered by his patients. He had a very human tolerance for the failings of others and was generous with help to all who needed it. Roy Kerr's home life was a very happy one. He loved his home, his farm, his apple trees, and above all his family. Everything he tackled he did with zest. He died suddenly, as perhaps he would have wished, but he had recently appeared so full of life and energy that his death has come as a severe shock to his family and friends. To his widow, two daughters, and two sons, both doctors, his many friends will wish to extend their sympathy and express their sense of loss of a very true friend and a vivid and colourful personality.—E. S. B. H. and J. H. K.

Medico-Legal

TAXATION OF VALUE OF INSURANCE POLICIES GIVEN TO VOLUNTARY HOSPITAL STAFF

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In 1937 the board of management of the Hospital of St. Cross at Rugby adopted a scheme designed to give recognition to the services of its voluntary medical staff by taking out on their lives endowment policies in the name of the board with premiums paid by the board. The sum assured was to be paid to the insured members of the staff when they reached the age of 60, and the scheme provided that if the hospital ceased to be voluntary and the management was taken over by the State the policies were to become the sole property of those in whose favour the board had taken them out. After nationalization the policies were assigned by deed from the board to the individuals insured, who thereupon had the option of continuing to pay the premiums themselves or accepting the surrender value of the policies.

Dr. Ronald Edward Smith, who was one of the voluntary staff included under the scheme, elected to pay the premiums and keep his policy on foot. Thereafter the surrender value, by then amounting to £650, was included by the Inspector of Taxes in his assessment for income tax under Schedule D. Dr. Smith appealed against this assessment to the General Commissioners on the ground that the surrender value was not part of the annual profits or gains accruing to him from his profession of medical practitioner, and the Commissioners allowed his appeal against the assessment. The Crown thereupon appealed against the Commissioners' decision.

This appeal was heard by Mr. Justice Vaisey, who delivered his reserved judgment on July 4.¹ His Lordship observed that the problem was a familiar one, exemplified by the cases relating to cricketers' benefits and clergymen's Easter or Whitsuntide offerings. Even a voluntary payment of his office or employment, like a clergyman's Easter offering or a cricketer's benefit. If, however, it was in the nature of a personal gift, as in the case of a "testimonial" or a contribution for a specific purpose such as to provide a holiday, it was not taxable. The test was put by Lord Loreburn in *Cooper v. Blakiston*² thus: "Where a sum of money is given to an incumbent substantially in respect of his services as incumbent, it accrues to him by reason of his office. What you choose to call it matters little. The point is, what was it in reality?" Applying this test, he held that Dr. Smith's services at the hospital were not within the scope of his profession, and accordingly the surrender value accrued to him by reason of the exercise of his profession.

His Lordship therefore allowed the Crown's appeal and remitted the case to the Commissioners to decide what was the proper year of assessment.

NULLITY REFUSED IN SPIKE OF IMPOTENCE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

It is a fundamental principle in all civilized jurisprudence that you cannot have your cake and eat it. This principle was well illustrated in its application to the law of nullity in a case decided by Lord Strachan in the Court of Session on June 29, 1956.³

In 1952 a nurse married a man who was, as they both knew, impotent as a result of war wounds, and whose impotence was incurable. She was largely influenced in her decision to marry him by sympathy arising from her

¹ *The Times*, July 5, 1956.

² [1909] A.C. 104.

³ *Scotsman*, June 30, 1956.

knowledge of his condition, and to some extent by the sense of dedication to duty instilled by her profession. She knew that by marrying him she would be giving up the chance of having children of her own, but she had a certain amount of affection for him and thought she could have quite a happy life with him. As she wanted children she intended to adopt a baby. The marriage was against the advice of her mother and of the surgeon who had performed a series of operations on the husband.

After the marriage came disillusion. The husband turned out to be unstable in character, a gambler, and unable to keep a job for any time. When they got a house of their own the wife tried to adopt a child, but apparently the husband was regarded as unsuitable as an adopter. She became subject to fits of depression which she could not explain, and after four years of marriage became so unhappy that she finally left him in July, 1955. She then instituted an action for declarator of nullity on the ground of her husband's impotence.

Lord Strachan, in dismissing the action, said that he was willing to assume that the wife married with the highest motives. Her position now was that she had changed her mind because the marriage proved to be unhappy. The absence of a sexual life had had an effect on her which she had not expected, and she had been mistaken about her husband's character. In the circumstances to free her from the rule of personal bar, which applied because of her knowledge of his impotence, would be to recognize that a woman in her position might solemnly enter a marriage with the option to annul it if it should not prove to be successful. This was not consistent with either public policy or equity. She had made her choice and accepted her husband with knowledge of his defect and must be held to her bargain.

Medical Notes in Parliament

B.C.G. Vaccination

Dr. A. D. D. BROUGHTON (Batley and Morley, Lab.) asked the Minister of Health if he would make British B.C.G. vaccine available for 5-year-old children, and also for newly born infants of tuberculous parents, now that there was evidence of this vaccine producing a high degree of immunity against tuberculosis without causing ill effects; and whether, in view of the recent favourable report¹ of the Medical Research Council on the efficiency of a British B.C.G. vaccine, he would extend the scheme for the vaccination of 14-year-old children to cover all children of that age. Mr. TURTON replied on July 4 that local health authorities were already able to offer B.C.G. vaccination to any person known to have been in contact with tuberculous infection and to all 13-year-old children. He was about to ask authorities to consider making fuller use of their powers in relation to 13-year-old children, but he did not consider it advisable to go further than this at the moment.

Days Lost Through Bronchitis

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Labour for the number of working days lost due to chronic bronchitis for each year since 1951. Mr. IAIN MACLEOD stated on July 2 that these figures were not available. He understood that statistics available for 1953-4, which did not distinguish chronic forms, showed that bronchitis generally was certified as the cause of incapacity for claimants under the national insurance scheme for rather more than 25½ million weekdays. This might be taken as an approximate measure of the number of working days lost through bronchitis in that year.

School Eyesight Tests

Mr. J. NIXON BROWNE, Under-Secretary, Scottish Office, told Miss MARGARET HERBISON (Lanarkshire, North, Lab.) on July 3 that the Secretary of State was seeking in con-

¹ *British Medical Journal*, February 25, 1956, p. 413.

sultation with the education authorities to assess the practicability and value of testing the eyesight of children at an earlier age than was at present adopted. Miss HERBISON urged him to consider carrying out the recommendations made by opticians in Scotland. Many people were never found by school testing to need spectacles, and yet did do so. Mr. Browne said these matters were under active consideration.

Building Cuts

The MINISTER OF HEALTH stated in answer to Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) on July 2 that since April 1 loan sanctions had been postponed on schemes for providing accommodation for elderly persons to the value of £900,000, including nine new buildings, and had been issued or promised on schemes to the value of £980,000, including 13 new buildings. Mr. BLENKINSOP described this as a shocking statement, and said it was hypocritical for the Minister to go about the country urging local authorities to go ahead with providing accommodation for the elderly and infirm when he was not providing the cash to enable it to be done. Mr. TURTON said that was not so. In view of the amount of current building work, in which the hospital programme played a not unimportant part, it had been necessary to restrict new loan sanctions to essential needs of the old people, and choose the most urgent projects. This would mean that the loan sanctions given before April, and the ones he had just mentioned, would constitute the present building programme for old people's hostels. In the autumn the matter would be reviewed again.

Mr. C. GIBSON (Clapham, Lab.) asked how many maternity and health centres had been refused consent, or a starting date denied, as a result of the cut of £340,000 in the capital estimates of local health authorities. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, said there were one health centre and ten maternity and child welfare clinics. Mr. GIBSON argued that it was bad economy to cut down on necessary health services. Miss HORNSBY-SMITH replied that all departments had had to make some contribution to the Government's policy. These schemes had not the highest priority, and they had not been able to sanction them.

Civil Defence Economies

The MINISTER OF HEALTH stated in reply to Mr. V. COLLINS (Shoreditch and Finsbury, Lab.) on July 6 that the detailed figures of the economy cut of £573,000 in the Health Service under the heading of Civil Defence were:

Expansion of Blood Transfusion Service ..	£ 5,000
Acquisition and initial repair of former hatted hospitals and camps for which there is no peacetime use ..	20,000
National Hospital Service Reserve (slowing down production and issue of uniforms) ..	140,000
Purchase of training equipment for the ambulance service ..	20,000
Grants to local authorities ..	10,000
Purchase and storage of materials for reserve ..	378,000
Total ..	573,000

Crash Helmets

Mr. E. W. SHORT (Newcastle-upon-Tyne, Central, Lab.) was informed by Mr. HUGH MOLSON, Parliamentary Secretary, Ministry of Transport, on July 4, that 1,146 motorcyclists were killed in road accidents in 1955. Of these 747 were reported not to have been wearing crash helmets. It was not known how many of these died from head injuries. He added that the Road Research Laboratory estimated that one in three motorcyclists used crash helmets. It was thought to be largely because of that that there had been a reduction in the proportion of deaths from accidents to motorcyclists.

Doctors' Pay Claims

Lieut.-Col. M. LIPTON (Brixton, Lab.) asked the Minister of Health on July 9 what claims for increased pay for

doctors he had received from the British Medical Association and other bodies, and what action he was taking. Mr. TURTON stated that a memorandum outlining a claim for increased remuneration for general practitioners and hospital staff had been submitted to the Secretary of State for Scotland and himself. He was not yet in a position to make any statement about it.

Parking Charges for Doctors' Cars

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister whether he was aware that medical practitioners in the course of their work would be subject to payment when parking meters were installed; and what allowances would be made to Health Service doctors to offset this charge. Mr. TURTON replied that the remuneration of doctors providing general medical services under the Health Service already took account of practice expenses generally, and he did not propose any special action in respect of this particular matter. Dr. STROSS urged that it would be unfair that men who had to visit frequently in these areas should have to pay these charges. Mr. TURTON pointed out that the regulations for parking meters had not yet been formulated. Mr. ERNEST DAVIES (Enfield, East, Lab.) asked him to make representations to the Minister of Transport that there should be some flexibility, so that general practitioners waiting on patients would not incur parking meter charges. Dr. STROSS said the Minister of Transport had already written to him stating that he could not make any relaxation—the charges would be made.

Atomic Radiation

Mr. LESLIE HALE (Oldham, West, Lab.) asked the Minister of Health what research the Medical Research Council were conducting into the effects of atomic rain which had recently fallen after the atomic explosions in the Far East. Mr. TURTON said that the Medical Research Council were conducting research on the biological effects of exposure to increased levels of radiation. This would cover any effects arising from radioactivity deposited in rain. Mr. HALE suggested that in view of the information now coming forward of the serious effects of strontium upon the bone structure, especially in children, and of the varied distribution, shown by its existence in animals, it was important that every possible method should be adopted for checking as soon as possible, and asked what were the possibilities. Mr. TURTON replied that the Medical Research Council were supporting a substantial and increasing programme of research on the biological effects of radiation from various sources, and would continue to do so. Dr. EDITH SUMMERSKILL (Warrington, Lab.): In view of the important report of the Medical Research Council of the effect of nuclear radiation on man, is the Minister going to treat this seriously and make a statement before the recess? Mr. TURTON: The researches are going on. I hope Dr. Summerskill will not exaggerate the report of the Medical Research Council, which said that the present and foreseeable hazards from the very small increase in the world-wide atmospheric radioactivity caused by test explosions were negligible, and would not be expected to produce any detectable ill effects. Dr. SUMMERSKILL: I would like the Minister to read that part of the report which says if bombs are dropped in the next 30 years at the same rate as they are being dropped now, the effect of strontium on the bone structure will be very serious. Mr. TURTON: I have given a summary, it is quite true that the report did mention the danger from radio strontium if the explosions went on during the lifetime of those living now, and that is being studied with other matters.

Mr. HALE also asked what research body was specifically charged with the study of the genetic effects of nuclear and thermo-nuclear explosions; and what material was collected during the allied occupation on the number of deformed and defective children born after the explosions at Nagasaki and Hiroshima. Mr. TURTON replied that research on the genetic effects of exposure to radiation from all sources was

being undertaken by the Medical Research Council, and studies were also in progress in various university and other research departments. The United States Atomic Bomb Casualty Commission had since 1947 been collecting information on the subsequent history of persons exposed to the atomic bombs in Hiroshima and Nagasaki, and a preliminary report had been published on the children born to such persons.

Fluoridation of Water Supplies

Mr. J. GRIMOND (Orkney and Shetland, Lib.) asked what was the present policy of the Government over the introduction of fluorine in water supplies. Mr. TURTON told him that it continued to be that recommended by the United Kingdom Mission to the United States of America and announced in the House in December, 1953—namely, that studies should be made in some selected communities of the various aspects of the fluoridation of water supplies before a decision was made whether it should be generally adopted in this country. Mr. GRIMOND said there seemed to be some doubt about the ultimate benefit, or otherwise, of this policy. When would the results of the investigations be known? Mr. TURTON said the experiment would have to continue for some time before any conclusions could be drawn.

Mental Deficients Review

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked how many people were detained under the Mental Deficiency Acts on December 31, 1955, in whose cases the circumstances rendering them subject to be dealt with were that they were found neglected, and how many of these cases had been reviewed by the Board of Control since the judgment in the case of *Regina v. Board of Control, ex parte Ruthy*. Mr. TURTON stated that the information was not available in the form requested. In response to inquiries made in February and March of this year by the Board of Control, 5,732 mentally defective patients were reported as having been found neglected by a judicial authority and dealt with under the Mental Deficiency Acts while in the care of public or charitable bodies. About 2,000 cases had been reviewed to date.

Board of Control

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister of Health if he was aware of the confusion in the public mind created by the fact that the Board of Control, previously located independently, had now an identical address with the Ministry of Health; and if he would arrange for adequate recognition of the separate existence of the Board as an independent body. Mr. TURTON said he thought the separate existence of the Board as an independent body was widely recognized. It was convenient for administration that the Ministry and the Board should be in the same building. Dr. JOHNSON asked if it could be made clear that the functions of the Board were to protect the liberty of the subject. Admirably intentioned though the Board might be, it had given the impression recently that it was both lethargic and inefficient in dealing with matters relating to the individual. Mr. TURTON: I can assure Dr. Johnson that proximity to me does not induce lethargy or inefficiency.

Hospital Consultants

Dame IRENE WARD (Tynemouth, Con.) asked the Minister of Health if he was satisfied with the machinery for reviewing the establishments of hospital consultants at each stage of the proceedings; what steps were taken to avoid unfairness and to pay regard to local conditions; and what action was taken by regional boards to find alternative employment for consultants declared redundant and to preserve their pension rights. Mr. TURTON replied that the hospital boards paid full regard to local conditions. In the rare case of redundancy a moral obligation rested on them to give the consultant the greatest possible assistance in finding another post. A consultant who considered that his appointment was being terminated unfairly had a right to have the board's decision reviewed by him.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 23 (No. 25) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

NUMBER OF CASES

WEEKS

Highest 1947-55

Lowest 1947-55

1956

**Week Ending June 30**

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 642, whooping-cough 2,372, diphtheria 8, measles 3,740, acute pneumonia 267, acute poliomyelitis 81, dysentery 1,466, paratyphoid fever 3, typhoid fever 5.

Scotland in First Quarter

The birth rate during the first quarter of 1956 was 19.2 per 1,000 of the population. This was 0.9 above the rate for the March quarter of 1955 and 0.8 above the average of the 5 preceding first quarters. The infant mortality rate was 31 per 1,000 registered live births, being 7 below the 5 years' average and the lowest rate recorded in any first quarter. The death rate was 15.0 per 1,000 population and was 0.1 below the average of the 5 preceding March quarters. Deaths ascribed to respiratory tuberculosis numbered 244 and 26 to other forms of tuberculosis; the death rates were 19 and 2 per 100,000 of the population, and these rates were 15 and 3, respectively, below the 5 years' average. There

Medical News

Scottish Antituberculosis Campaign.—On June 27 Dr. KENNETH COWAN, C.M.O. of the Department of Health for Scotland, discussed with medical officers of health his department's antituberculosis plans. The basis of the plan was that there should be a very large x-ray campaign in each city and in most populous areas throughout Scotland, he said. Each of these campaigns would be bigger than anything previously attempted, and the one in Glasgow would be the largest in Europe. It would be essential to success for voluntary organizations and the general public to co-operate to the full. Everyone over 14 should come for x-ray examination, including housewives and old people. The campaign, which will last for two years, will begin next March.

Ciba Foundation Report.—During 1955 the Ciba Foundation again lived up to its declared purpose—"the promotion of international co-operation in medical and chemical research." It provided free accommodation at its premises at 41, Portland Place, for nearly 800 visitors from some thirty countries, who were in London in connexion with their scientific work. Seven international congresses were held, the proceedings of four of which have been published as books. In addition there were discussion meetings, clinical forums, and scientific film sessions. Bursaries were granted to British medical graduates to allow them to work for short periods in France, and seven international awards were made for research on ageing. The new library was opened about half-way through the year, and access to it is granted to non-visitors, whenever possible, on application to either the director or the librarian of the Foundation (telephone: Museum 9456).

I.M.A. President.—Dr. J. C. McFEELEY, medical officer of health to No. 3 City Dispensary District, Dublin, was elected president of the Irish Medical Association at the annual meeting at Bundoran.

Dr. Scheele Resigns.—After being sworn in for his third 4-year term as surgeon-general of the U.S. Public Health Service only this April, Dr. LEONARD A. SCHEELER unexpectedly resigned his office on June 29. He leaves on August 1 to become president of the Warner-Chilcott Laboratories, the ethical drug division of the Warner-Lambert Pharmaceutical Company. Dr. Scheele, who is 48, became well known internationally last year in connexion with the U.S. anti-polio myelitis vaccination programme. It is understood that his new post carries a very much higher salary than the office of surgeon-general, and Dr. Scheele gives as his reason for resignation the need to provide "more properly for the future security of my family."

Abstracts on Demyelinating Diseases.—The U.S. National Multiple Sclerosis Society, a lay association dedicated to the advancement of research on disseminated sclerosis, announces a new monthly abstracting journal in English, covering world medical literature on demyelinating diseases. The society has made a grant of \$15,000 for this purpose to the Excerpta Medica Foundation, of Amsterdam, which is to produce the journal. Each issue will contain 100-150 abstracts. Dr. J. G. GREENFIELD, of the National Hospital, Queen Square, is named as one of the editorial board. The first issue is expected shortly.

Tropical Research Fellowship.—The Council of the Royal Society has awarded the Tropical Research Fellowship (Medical Sciences) to Dr. D. G. JAMISON, of Corpus Christi

College, Oxford, for his work on the histopathology of leprosy, with particular reference to the relationship of the mycobacteria to cutaneous nerve fibres.

Royal Society and Nuffield Foundation.—Nine Commonwealth Bursaries, announced this month, include awards to Dr. W. R. ADEY, lecturer in anatomy at Melbourne, for the study of temporal lobe epilepsy at neurosurgical centres in Britain; and to Mr. J. HARLEY-MASON, lecturer in chemistry at Cambridge, for the study of plants of potential chemical and medical interest in Jamaica.

COMING EVENTS

World Federation for Mental Health.—Ninth annual meeting will be held in Berlin, August 12-17. The subject will be "Mental Hygiene in Infirmary, Home, and School." Details from the general secretary, 19, Manchester Street, London, W.1.

British Veterinary Association.—Annual congress will be held at Leamington Spa, September 16-22. Details from the general secretary, 7, Mansfield Street, Portland Place, London, W.1.

Fourth International Conference on Instruments and Measurements.—Stockholm, September 17 to 19. There will be sections on nuclear instrumentation, automatic process control, computers, physical methods for chemical analysis, spectroscopy, optics, and general instrumentation. Details from Mr. S. Malmström, Association of Engineering Physicists, Stockholm.

Fourth International Congress of Internal Medicine.—The two main themes for the congress, which is to be held from September 19 to 23 in Madrid, will be: "The Role of the Adrenals in the Pathogenesis and Evolution of Internal Diseases" and "Bronchial Asthma and Emphysema." There will also be short contributions on miscellaneous medical subjects. Further details from the congress secretariat, Hortaleza, 90, Madrid.

Royal Statistical Society: Medical Section.—One-day conference, open to non-members, September 28 at County Hall, Westminster Bridge. Subjects include statistics in clinical obstetrics (Professor DUGALD BAIRD), genetical effects of radiation on human populations (Professor L. S. PENROSE, F.R.S.), cancer in relation to environment (Dr. P. STOCKS), and ionizing radiations in human leukaemia (Dr. W. M. COURT BROWN). Professor A. BRADFORD HILL, F.R.S., will give the opening address. Applications for tickets to the secretary, Royal Statistical Society, 21, Bentinck Street, London, W.1.

American Public Health Association.—The 84th annual meeting will be held at Atlantic City, N.J., U.S.A., November 12-16. Details from the association, 1790, Broadway, New York.

Chartered Society of Physiotherapy.—Annual congress will be held at St. Pancras Town Hall, London, N.W.1, October 4-6. Sir RUSSELL BRAIN, P.R.C.P., will deliver the Founders' Lecture. Registered medical practitioners will be welcome and can obtain tickets by application to the secretary of the Society, Tavistock House (South), Tavistock Square, London, W.C.1.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 40, No. 5) is now available. The contents include:

ANATOMICAL STUDIES OF THE TRABECULAR MESHWORK OF THE NORMAL HUMAN EYE. Norman Ashton, Alfred Brini, and Redmond Smith. CORRELATION OF THE SYSTEMIC AND INTRA-OCULAR EFFECTS OF DIAMOX. Dorothy A. Campbell, Eva L. Tonks, and Mary Jones. CONTACT LENSES IN TREATMENT OF KERATOCONUS. Frederick Ridley. ELECTRO-OCULOGRAPHY AS A FUNCTIONAL TEST IN PATHOLOGICAL CONDITIONS OF THE FUNDUS. II. BASE-VALUE AND DROP DURING DARK ADAPTATION. J. François, G. Verriest, and A. De Rouck.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—The new issue (Vol. 31, No. 157) is now available. The contents include:

SOCIAL FACTORS IN THE AETIOLOGY OF NEPHRITIS IN CHILDHOOD. Norman S. Clark. THE PROGNOSIS OF NEPHRITIS IN CHILDHOOD. Norman S. Clark. DEVELOPMENTAL APHASIA OBSERVED IN A DEPARTMENT OF CHILD PSYCHIATRY. T. T. S. Ingram and J. F. Reid. RESORCIN POISONING. A. A. Cunningham. CORTISONE THERAPY IN ERYTHROGENESIS IMPERFECTA. Rowland J. Calvert and Thomas Robson. AN UNUSUAL ILLNESS IN YOUNG CHILDREN ASSOCIATED WITH AN ENTERIC VIRUS. Mary Crawford, A. D. Macrae, and J. N. O'Reilly. CHROMATOGRAPHIC SEPARATION OF REDUCING SUGARS IN THE URINES OF NEWBORN BABIES. J. C. Haworth and David McCredie. OBSTRUCTIVE HYDROCEPHALUS IN CHILDHOOD. D. S. Gordon and A. R. Taylor. HYDRANENCEPHALY. Kenneth C. Watson. THE INCIDENCE OF INCOMPLETE DESCENT OF THE TESTICLE AT BIRTH. C. G. Scorer. THE SIGNIFICANCE OF HYPOGLYCAEMIA IN THE NEWBORN INFANT OF THE DIABETIC WOMAN. James W. Farquhar. THE EFFECT OF LARGE DOSES OF SYNKAVIT IN THE NEWBORN. Thomas C. Meyer and Joan Angus. CONGENITAL LOBAR EMPHYSEMA. A. Holzel, E. Bennett, and B. F. Vaughan. COR TRIANGULUM: CONGENITAL STENOSIS OF THE COMMON PULMONARY VEIN. Frank W. Nash and Donald MacKinnon. INFERIOR VENA CAVAL AND HEPATIC VEIN THROMBOSIS: THE CHIARI SYNDROME IN CHILDHOOD. M. A. Kibel and H. B. Marsden. HYPERVITAMINOSIS A. J. D. Pickup. SUCCESSFUL TREATMENT OF A PERFORATED ROKITANSKY-CUSHING ULCER. T. A. Sale. CONGENITAL ABSENCE OF THE ABDOMINAL MUSCLES WITH ASSOCIATED ABNORMALITIES OF THE GENITO-URINARY TRACT. Peter Roberts.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, July 17

● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—At Barnes Hall, Royal Society of Medicine, 5 p.m., William Meredith Fletcher Shaw Memorial Lecture for 1956 by Mr. Naguib Mahfouz: Urinary Fistulae in Women.

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., annual general meeting.

Wednesday, July 18

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. W. Riddell: special lecture on mycology.

Thursday, July 19

INSTITUTE OF PSYCHIATRY.—5 p.m., Professor K. A. C. Elliott (McGill University): Metabolism of Human Cerebral Tissues.

ROYAL SOCIETY OF HEALTH.—At St. Mary's Hall, Bayley Lane, Coventry, 10.30 a.m., Dr. J. Ardley: Topical Aspects of Poliomyelitis; Mr. D. C. Norcliffe: Role of the Public Health Inspector in the Campaign for Clean Air.

Friday, July 20

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. Sidney Farber (Boston, U.S.A.): Progress in the Chemotherapy of Disseminated Cancer in Children.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At 11, Chandos Street, W., 6.45 for 7.30 p.m., annual general meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Charles Tomes Lecture by Mr. B. W. Fickling: Oral Surgery Involving the Maxillary Sinus.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Fallon.—On June 29, 1956, to Valerie (formerly Kirkham), M.P.S., and Ronald J. Fallon, M.D., of 4, Dousland House, Dousland, near Yelverton, Devon, a daughter—Stephanie Anne.

Wilson.—On June 29, 1956, at the Christopher Nursing Home, Wigan, Lancs, to Dr. Ruth Audrey (Jane), wife of Bill Weatherston Wilson, F.R.C.S., a son.

MARRIAGES

Byth—Hunter.—On June 20, 1956, at Middle Church, Perth, Dr. George Lawrence Byth, to Kathleen Margaret Hunter, M.A., Dip.Ed., R.G.N.

DEATHS

Bremner.—On June 27, 1956, at his home, 89, St. John's Way, London, N., Walter Charles Palmer Bremner, M.D., aged 89.

Bruce.—On June 26, 1956, at Woodlee, Carstairs, Lanarks, Charles David Bruce, M.B., Ch.B., D.Psych.

Clouston.—On June 25, 1956, at Ipswich and East Suffolk Hospital, Eric Crosby Townsend Clouston, M.R.C.S., L.R.C.P., of "Swanslea," Westerfield, near Ipswich, Suffolk, formerly of Lavenham, Suffolk.

Courtauld.—On June 27, 1956, at Perceps, Greenstead Green, Halstead, Essex, Richard Minton Courtauld, M.D., D.P.H., aged 78.

Dobbin.—On June 25, 1956, at the London Clinic, Clarence John Valentine Dobbin, M.R.C.S., L.R.C.P.

Douglas.—On June 26, 1956, at Midhurst, Sussex, Kenneth Mackinnon Douglas, M.D., F.R.C.S.Ed., formerly of 19, Chester Street, Edinburgh, aged 93.

Fox.—On June 24, 1956, in Freedom Fields Hospital, Plymouth, Devon, George Raymond Fox, F.R.C.S., J.P., of Rockrose, Downderry, Cornwall, aged 86.

Jenkins.—On June 18, 1956, Naunton Reginald Jenkins, M.R.C.S., L.R.C.P., D.P.H., of Brentwood, Park Street, Bridgend, Glam.

Riches.—On June 26, 1956, at his home, 7, Lansdowne Road, Worthing, Sussex, Reginald George Riches, M.R.C.S., L.R.C.P., D.P.M., aged 70.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Hay Fever

Q.—Each succeeding year the hay fever from which one of my patients suffers appears to get more severe. What prophylaxis and treatment are advised?

A.—For mild hay fever, troublesome but not incapacitating, antihistamines, nasal drops, eye drops, the wearing of dark glasses, and whenever possible the avoidance of exposure to heavy concentrations of pollen are advised.

For incapacitating hay fever which has failed to respond to the above treatment or which is accompanied by pollen asthma, pre-seasonal hyposensitization is advised. Introduced in 1911 by the late Dr. Noon and by Dr. John Freeman, of St. Mary's Hospital, London, this treatment has for very many years been internationally accepted as the most satisfactory treatment for troublesome hay fever. It is not completely without risk, and untoward reactions are not uncommon. Expert advice is necessary, and very careful attention to the details of treatment and dosage is essential. It should be begun not later than March. The results are excellent or good in approximately 80%, and moderate or poor in some 20%.

Experience with hormonal therapy is as yet too short to enable the exact role of cortisone and corticotrophin in the treatment of hay fever to be defined. It would appear that these hormones give better symptomatic relief than antihistamines. Their use is justified when all other measures have failed in cases where a complete examination (including a radiograph of the chest) has excluded those illnesses which are known to contraindicate the use of cortisone and corticotrophin.

Man's Teeth

Q.—From a study of human dentition alone, on what kind of raw food would man be expected to exist?

A.—The teeth of many types of mammal have conspicuous anatomical features which can be interpreted as having arisen, during evolution, as a result of selection and isolation acting to produce a mechanism adapted to cutting and grinding a particular type of food. For instance, the last upper premolar and first lower molar of carnivores form a shear for cutting bones. In addition, their long and sharp canines are suitable for tearing flesh. On the other hand, herbivores lack canine teeth and their molars have a complex pattern of ridges which interlock with those of the corresponding teeth in the other jaw to make an efficient arrangement for chopping and grinding herbage.

Although in such cases there may be an obvious correlation between the anatomical features of the teeth and the particular type of food eaten, it does not necessarily follow that the diet of other animals can be inferred from a few apparently adaptive dental features. For example, big canines, *per se*, do not necessarily indicate a carnivore. Such teeth are also found, for instance, in many monkeys and apes, in which they engage with the lower first premolar to form a shear that is used for cutting leaves and fruits.

In man, the teeth are uncomplicated organs for biting and grinding, and their anatomical features would seem to give little information about the type of food to which early man was accustomed.

On the other hand, the degree to which the tooth crown is worn down enables some inferences to be drawn about the texture of the food that is normally eaten. The diet

of many monkeys and apes contains much abrasive material, which wears away the enamel to expose the underlying dentine. In some aged animals the cusp pattern disappears and is replaced by a single pool of exposed dentine which covers most of the crown. The teeth of many types of man, extending from prehistoric times and still including some primitive groups, wear down in much the same way as do those of monkeys and apes. Wear is not pronounced in the teeth of modern civilized man, and it seems reasonable therefore to infer that the diet of primitive man contained far more abrasive material than is customary in modern civilized races.

Corneal Ulceration in Virus Diseases

Q.—What are the aetiology, treatment, and prognosis in corneal ulceration complicating an influenzal laryngitis? The ocular symptoms developed during the first week.

A.—Corneal ulceration is not recognized as a complication of influenzal laryngitis. It is more likely that the same underlying general condition produced both laryngitis and corneal ulceration. Corneal ulceration is a recognized complication of a number of virus diseases, such as measles, herpes ophthalmicus, and the more recently recognized congeries of virus conjunctivitis, which include such affections as epidemic keratoconjunctivitis and pharyngoconjunctival fever. It may well be that the laryngitis in this case was part of this latter condition.

Hypotensive Drugs in Symptomatic Hypertension

Q.—Should patients with symptomatic hypertension be given hypotensive drugs? If so, what kind of regime is advised and to what extent is the prognosis improved?

A.—Since the average life of a hypertensive subject after recognition of the condition is about 15 years, with a considerable scatter on either side of this mean, it is unjustifiable to add difficulties and anxieties by starting drug treatment. The best policy is to wait until there is an indication that complications are developing—retinal, cardiac, cerebral, or renal—before beginning treatment. If the patient is anxious about himself in the asymptomatic phase a little phenobarbitone helps him to accept reassurance.

With the long life-expectation of most hypertensives, it will require a very prolonged period of observation before it is known whether hypotensive drugs really improve prognosis, and particularly whether they reduce the incidence of complicating atherosclerosis. The most widely used hypotensive drugs—methonium and its allies, reserpine, and hydralazine—are all unpleasant in their side-effects. A new, safe, and less troublesome drug will be needed before asymptomatic patients can be subjected to a therapeutic trial which may last a decade or two.

Head-banging

Q.—In order to go to sleep some small children resort to head-banging. How should this habit be managed when it persists into later childhood?

A.—Some regard head-banging as a disturbance of behaviour of the same type as a nervous tic or bed-wetting, especially if it persists after the age of 4 years.

Sooner or later the habit will cease, and usually it does so by the age of 3 or 4. It may, however, be associated with other emotional disturbances, and its management must depend largely on the child's character and general behaviour. Sedatives are useless in the treatment of head-banging. Firm handling, for instance at a boarding school, may produce a quick symptomatic cure, but it may also have a serious effect on the child's development and be frankly dangerous if there is other evidence of emotional instability. Psychotherapy may be advisable on account of this, but is not very effective in the cure of simple head-banging. Hypnosis is not considered a wise form of treatment in childhood. In fact it is generally best to try to pay no attention to the head-banging itself if the

child is not hurting himself, and to do what is possible to minimize the disturbance to the rest of the household. There may also be, within the home, reasons for the head-banging which a little extra sympathy and understanding may help to elicit.

Wart Charming

Q.—What is the technique of wart charming?

A.—The process whereby warts, the result of a virus infection, can be affected by psychogenic influences, as occurs in wart charming, is not understood. It would seem that nervous impulses from the cerebrum must affect the skin, in some way producing conditions unsuitable for the growth of warts. Perhaps there is an alteration in the blood supply or in the moisture of the skin. Certainly sweating predisposes to warts.

The technique of wart charming is as varied as it is ancient. It is often based on a form of magic, the intention being to transfer the warts to some other person or animal or object. Thus the warts may be touched by a lump of raw beefsteak, which is then buried at midnight at a cross-roads in the light of a full moon. The warts disappear, having been transferred to the meat. The moon was thought to have considerable influence on warts. Sir Kenelm Digby in the seventeenth century had an infallible cure. The hands were washed by the light of moonbeams in a polished silver basin in which was no water.

Alternatively, warts might be transferred to an animal such as a black slug or a toad. If someone who has no warts kills the toad, then he will get as many warts as the toad has spots.

Sir James Frazer, in *The Golden Bough*, mentions a fourth-century cure for warts. You touch your warts with as many little stones as you have warts. Then wrap the stones in an ivy leaf and throw them away. Whoever picks them up will get the warts and you will be rid of them. The wart charmer in Ireland would visit a village, make a careful note in his hat of the number of your warts, and take them with him on his departure. The buying of warts by a friend is still, at times, found efficacious. X-radiation in small doses and hypnotism are other techniques now practised in wart charming.

Side-effects of Rauwolfia Alkaloids

Q.—What are the recognized side-effects of rauwolfia alkaloids? One of my hypertensive patients suffers severely from rhinitis during treatment with them. Is symptomatic treatment advised for the rhinitis or a switch to some other hypotensive drug—preferably not hexamethonium?

A.—The important side-effects of rauwolfia alkaloids are: mental depression (occasionally leading to frank psychosis and suicide), Parkinsonism, looseness of the bowels, and nasal congestion. It is assumed that the rhinitis in this question refers to nasal congestion. As a first step dosage should be reduced below 0.5 mg. daily. If this does not suffice a nasal inhaler may be used: 2-amino-heptane sulphate in 1½% solution is one of the most useful inhalants.

Ganglion-blocking agents are the most effective blood-pressure-reducing substances and other recommended drugs are unreliable. Hydralazine is being frequently used at present in an attempt to reduce pressure, but it also is not without its dangers and side-effects. With a small background dosage of a rauwolfia alkaloid patients often tolerate a blood-pressure-reducing dose of methonium or pentolinium with much less difficulty than was the case in the days when methonium was used alone.

Threatened Abortion and Vaginal Examination

Q.—Is vaginal examination contraindicated in threatened abortion, even if the diagnosis is uncertain?

A.—The objection to vaginal examination in threatened abortion is that it may excite uterine contractions and aggravate the condition. A more cogent argument is that if

after the digital examination the miscarriage becomes inevitable the patient is likely to believe that the doctor's action was responsible. Nevertheless there is much to be said for vaginal inspection and gentle digital examination after reassuring the patient that these procedures are innocuous. Use of the speculum may show that the bleeding is not coming from within the uterus but is due to some cause unrelated to the pregnancy, such as a cervical polyp. The products of conception may be seen protruding through the os, indicating that the abortion is already inevitable. The cervix may be seen to be pointing forwards, suggesting that the uterus may be retroverted, a point which can be confirmed by palpation. Further, in many cases it is only by vaginal examination that the presumptive diagnosis of threatened abortion can be confirmed and other conditions such as ectopic gestation or metropathia excluded.

NOTES AND COMMENTS

Rupture of Tympanic Membrane during Syringing.—Dr. G. YOUNG (Glasgow) writes: It is worth while directing attention to a condition which comes under the above heading ("Any Questions?" June 9, p. 1377). On a number of occasions I have been asked to see patients whose drumhead is said to have been ruptured during syringing. The complaint had been hardness-of-hearing, usually without pain, and the meatus was found to be obstructed by a collection of wax. During the process of syringing, probably without previous softening of the meatal content, when the mass has emerged the patient has complained of severe pain, possibly of vertigo, and there may have been some bleeding. The inference is that the drumhead has been ruptured. On careful drying-out of the meatus, however, it is found that there is a small perforation in the attic region, with possibly a small granulation protruding, and that the process of syringing has uncapped the first visible evidence of attic cholesteatosis. It is to be noted that the patient will deny, probably rightly, that there has ever been any aural discharge previously.

Hazards of Dental Fillings under Local Analgesia.—Dr. T. T. SCHOFIELD, F.D.S. R.C.S. (London), writes: It is to be hoped that the person replying to the question on the hazards of dental fillings under local analgesia ("Any Questions?" June 16, p. 1440) is not a practising dentist. To suggest that the patient's response to pain should replace the operator's knowledge of the minute anatomy of a tooth is deplorable. Most local anaesthetics in dental use incorporate a vasoconstrictor which offsets to a large degree any hyperaemia due to the heat of normal cutting. Our clear duty, as in all branches of medicine, is to relieve, and not inflict, pain.

OUR EXPERT replies: My answer does not suggest that local analgesia should not be used for cavity preparation, only that the dangers which may result from its use should be recognized and avoided. Local analgesia should in fact be used whenever the discomfort which it causes is less than the pain caused by the preparation of the cavity.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Aitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: Medisecra, Westcent, London. B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

THE PURPOSE OF MEDICAL EDUCATION*

BY

G. W. PICKERING, M.D., F.R.C.P.

Professor of Medicine, University of London; Director, Medical Unit, St. Mary's Hospital, London, W.2

It has been remarked by an intelligent observer from across the seas that no country has produced so many excellent analyses of the present defects of medical education as has Britain, and no country has done less to implement them. It seems to me that this arises partly from our national conservatism, but chiefly because we have devoted too little thought to the true purpose of medical education, and thus omitted to select a yardstick against which to measure the virtues and defects of our system. My object here is to outline what I conceive to be the purpose of medical education and to discuss in general terms why this purpose has not been achieved. I can best introduce my subject by quoting from the Report of the Royal Commission on the University of London (1913) which, under the chairmanship of Lord Haldane, produced one of the most penetrating documents in the history of medical education.

"We must, in the case of the Faculty of Medicine, as in the case of other Faculties, consider what steps it is necessary to take in order to place the best teaching upon a real university basis. . . . We cannot, however, deal with the Faculty of Medicine on exactly the same lines we have followed in the case of other Faculties, such as those of Arts and Science. In those Faculties, the provision for teaching and the highest university standard may be deficient, but the standard itself is not questioned. In the case of the Faculty of Medicine, we have no test to apply. Except as regards pathology and hygiene the University has not attempted to determine which of the teachers of the subjects classed as Advanced Medical Studies are entitled to the status of Professors or Readers. . . . The question is therefore denied that they ought to do so. . . . The question is therefore forced upon us, whether the standard we have accepted for the teachers in other Faculties ought to be abandoned in the case of the teachers of the most important professional subjects in this Faculty. . . ."

That was 43 years ago. The University of London has changed much since then, and, in fact, led the country in the development of clinical studies along true university lines. Nevertheless, as I hope to show, the chief issue facing us to-day is whether the objects of medical education are the same or different from those of other faculties of the university. Should medicine, in fact, be taught within the university or in a technical college?

Proper Training

The proposition that the purpose of medical education is to turn out properly trained doctors would probably receive general assent. There is, however, dissent about what constitutes a proper training and yet more about

*An address which had to be postponed.

what kind of doctor should be trained. Are we trying to train physicians, surgeons, psychiatrists, and medical scientists in all their special branches as well as general practitioners? Clearly, to do all these things in the scope of one single curriculum is impossible. A man would either spend the major part of his lifetime as a student, and render service to the community only in his dotage, or else be improperly trained. The recognition that this is so is one of the major achievements in the post-war period. It is now agreed that the training of a doctor does not stop at his final professional examination, that postgraduate experience is necessary for all doctors who are to be licensed to practise medicine; and that experience and training should differ according to the career ultimately to be followed. The organization of postgraduate education, and particularly the institution of a compulsory year of hospital practice under supervision, has in fact liberated the undergraduate curriculum to serve its proper purpose. It remains to agree what that proper purpose is.

Postgraduate education is perhaps in its infancy. Since, however, it is chiefly concerned with the acquisition of detailed factual knowledge and of special techniques, it provides a fairly well defined problem about which there is fairly general agreement. While acknowledging the great importance of postgraduate education, I would like to say no more about it and devote the rest of my remarks to the medical curriculum proper, the course leading to the degree of Bachelor of Medicine.

While few would now maintain that the function of the undergraduate curriculum is to train specialists, there are many teachers and administrators who hold that its purpose is to train general practitioners. This, however, seems an inadequate definition. Thus there is an increasing body of opinion which believes that at least part of the special training necessary for a general practitioner should be postgraduate. Again, much of what is included in the present curriculum is quite unnecessary for general practice, and it would be very difficult to justify the vast public expenditure on preclinical departments merely to train general practitioners. In fact, if this were the sole function of medical education, some might doubt whether it was desirable to include medicine within the faculties of universities. It would be cheaper and more efficient to carry out the small amount of pre-clinical training necessary at technical colleges and to revert to the system of apprenticeships. The fallacy of so defining the purpose of medical education would be

clearly demonstrated were we to fashion our educational system on such a definition. Not only would those who intend to specialize have an inadequate background, but the advance of medical science would come to a standstill.

Basic and Special Requirements

The conflict between the needs of future general practitioners on the one hand, and of specialists and research workers on the other, led Lewis to suggest that there should be two medical curricula, a shorter and a longer designed for the two groups. This suggestion has never found much favour and probably never will. As all experienced teachers and examiners know, much may happen to a man during the five years or so of the medical curriculum. A boy may enter loaded with examination honours, and at the end be in the bottom part of the class, qualifying with the greatest difficulty. I also know of one man who had difficulty in matriculating but whose scientific work was so distinguished that he became a Fellow of the Royal Society at 35. It would thus be a thankless task to try to select men at the outset for those two types of education, and I for one would not care to do so. However, an even greater objection would be the creation of two separate grades of doctor with detrimental effects on the unity and the morale of the profession. And here let me venture an aside and remark that in these days of the Welfare State matters affecting morale are of much greater importance than is generally realized. There is an increasing tendency for men to be concerned more with what they can get out of life than what they put into it.

The idea that the medical curriculum should be primarily designed for any particular kind of doctor proves thus unacceptable. It would seem rather that it should be regarded as a basic foundation on which may be built the special requirements of the various specialties. We might say that the function of the medical curriculum is to train the basic doctor, provided that we recognize that the concept of the basic doctor is a mere abstraction.

It would seem, then, that the problem of defining the purpose of medical education resolves itself into two questions: What are the basic requirements that all doctors need, and what are the special requirements severally needed by general practitioners, scientists, and specialists?

Function of University Education

Medical education has grown up within the framework of the universities. No one would dispute that this is the proper place for medicine. The study of man in both health and disease is part of biological science. Scientific knowledge is indivisible, and advance on one front makes possible advances on others. Were medicine to leave the universities, both medicine and science would be immeasurably the poorer. It may be accepted as axiomatic that medical education is part of university education. We may therefore approach our subject by inquiring what is the purpose of university education and whether this purpose needs modification or amplification in the case of medicine.

I would suggest that the function of university education is to train the student's mind so that he can gather data accurately and so that he can learn to form a balanced judgment on those data. Some disciplines use for the training of judgment data that bear little relevance to those with which the student will later deal. Such, for example, are the classics, and there is no doubt that in our ancient universities the quality of teaching and refinement of methods over the ages has made this discipline an excellent introduction to handling the affairs of men both in the civil

services and outside them. In fact, it was once the fashion at the ancient universities to regard all other disciplines as inferior. To my mind this attitude has been of great disservice to our country, for such is specialization at school and in the universities that these future leaders completed their formal education with no more than a smattering of scientific knowledge. In our age, when scientific knowledge and its applications seem likely to determine the future of mankind, it seems at least odd that such ignorance should be tolerated, much less encouraged, amongst our leaders. Nevertheless, whatever its shortcomings, it is to be acknowledged that the discipline of the classical studies fulfils much of the purpose of university education, and that, at best, it is highly successful in sharpening the wits so that the student emerges with a mind that is a much finer instrument than when he started. Most of the other major disciplines of the university—mathematics, law, theology, natural science, and medicine—have a more vocational aspect—that is to say, they use for educational purposes data of the same kind as those with which the student will deal in later life. There is much to be said for this. To quote the report of the Cambridge University Committee on University Education and Business (1945):

"The view that a university course should not be closely related to a man's ultimate career, but should be a general education in non-vocational subjects, is open to various interpretations. If it is meant that a university course should not consist merely of specific instruction designed for earning one's living then no objection can be taken to it. If, on the other hand, the statement is interpreted to mean that a man is best prepared for life by reading subjects wholly unconnected with his career, then a good many objections can be taken to it. Such an interpretation depends ultimately on the assumption that habits of thought are transferable from one subject to another, but there is nothing in experimental psychology to suggest that such transfer will take place automatically. Any subject can be used as a means of training and developing the intelligence, and when intelligence has been developed by exercise, it will be a better instrument for studying other subjects. This, however, is not the same as saying that the clarity in thought attained in one subject is directly transferable to another. In order to secure clarity the ideas involved must be easily manipulated, and an early acquaintance with these ideas is a great aid to proficiency. Further, if the subject is one for which the student has special interest, he will more readily advance by using his innate ability unchecked by lack of interest in the subject-matter."

I would suggest, then, that the primary purpose of the undergraduate medical course within the university is to train the student's mind so that he can collect and verify facts concerning health and disease in man, and so that he can form a balanced judgment on issues that affect both individuals and groups. If this has been achieved in the undergraduate curriculum, then the special requirements of scientific and vocational medicine can be erected, in the postgraduate period, on a firm foundation. Moreover, the student is equipped to learn, so that in his future professional life he will have little difficulty in keeping abreast of advances in thought or knowledge. It is not the function of the undergraduate curriculum to turn out fully fledged general practitioners or specialists, nor to turn out men who have detailed knowledge of aspects of the basic sciences. These are the proper responsibility of the postgraduate period.

Does the Undergraduate Medical Course Fulfil its Purpose?

If this be the purpose of the undergraduate course, it is now proper to inquire whether this purpose is fulfilled. We may look at the content and methods of teaching of the course, the examination system, and the effect on the student, and we may compare these with the discipline of classical studies at our older universities.

The conduct of the two courses could not provide a greater contrast. The student reading classics attends a few lectures in the course of the day; the rest of his time is spent in reading and performing individual exercises which he presents for comment or correction to his tutor. The medical student spends nearly all his time in the lecture theatre and laboratories; in the medical curriculum proper

in the four schools with which I have been associated as student or teacher the student is not, except in rare instances, encouraged to read original papers or to prepare material for his teachers to correct. In every medical school library which I have visited (and I have visited them all in this country), with one single exception, nearly every student is either reading textbooks or his lecture notes.

We find a similar contrast in the examinations. In classics, the examination papers are designed to test the capacity of the student to discriminate; he is given a wide choice of questions so that he can show his mental capacity, using data with which he has become familiar. How different in medicine! The examination papers allow no choice of question, and they seem designed not to test a student's capacity to discriminate but his capacity to reproduce material learned from the pages of textbooks or the notes of lectures. The kind of question which is still current in the final examinations for university degrees in medicine is a question such as, "Describe the symptoms, signs, complications, and treatment of ulcerative colitis." What a comment on six years of university education! And the earlier examinations are no better. When we set examination papers like this it is not surprising that arts teachers regard us as uneducated.

These facts can leave us in no doubt that, as at present conducted, medical education in the universities is not directed to training the student's mind as a discriminating instrument but merely as a temporary storehouse for miscellaneous information collected from textbooks and lecture notes and retained for long enough to be reproduced at the moment of the examination. Nor is there much doubt (though the assessment is, of course, highly subjective and in the nature of a clinical impression) that the effects of the medical curriculum on the student's mind bear this out. Thus the Planning Committee of the Royal College of Physicians made the following comment:

"We are agreed that, quite apart from lack of character and ability that may be avoided by improved recruitment and selection, the average medical graduate has defects which are to be attributed chiefly to the manner of his training. He tends to lack curiosity and initiative; his powers of observation are relatively undeveloped; his ability to arrange and interpret facts is poor; he lacks precision in the use of words. In short, his training, however satisfactory it may have been in the technical sense, has been unsatisfactory as an education. This is a matter of very great importance. The average student leaves his medical school at about the age of 25; during the subsequent thirty or so years of professional life, his ability to learn from his own experience and that of others, and to keep abreast of the stream of advancing medical knowledge, depends entirely on those qualities in which his training has left him defective."

It would seem to me that all the numerous criticisms of the medical curriculum are embraced in the general criticism that it does not fulfil what should be its central purpose of training the student's mind. And I suspect that so little has been done to remedy the worst defects because there has been no yardstick, no clear concept of purpose, by which questions of detail could be subordinated to questions of principle.

Can this Purpose be Achieved?

If the primary purpose of the medical curriculum is to train the student's powers of observation and of critical judgment in the field relevant to medicine, then the achievement of this purpose will require a drastic reorganization of the medical course and a revolution in the attitude of most of the teachers to it. So far as content is concerned, the three great obstacles to education are its enormous content of so-called "facts," its rigidity, and its disorder. Nearly all committees that have considered the curriculum have recognized these three defects, but it is an interesting fact that most of the proposals for reform would actually have accentuated some, at least, of these defects. It is well recognized

*I put "facts" in inverted commas deliberately. As the Dean of Harvard (Dr. Sydney Burwell) put it at a Harvard dinner which I was privileged to attend, "My students are dismayed when I say to them, 'Half of what you are taught as medical students will in 10 years have been shown to be wrong.' And the trouble is, none of your teachers knows which half."

that the growth of scientific knowledge has been accompanied by a corresponding growth in the content of the curriculum: much has been added, little taken away. As a one-time teacher of elementary biology to medical students, I maintain, with some right to an opinion, that compulsory botany for medical students is quite unjustified, though of course a knowledge of it may give, as it has given to me, untold pleasure for a lifetime. Again, there is no justification for the amount of anatomy that is taught in some schools. These are old issues, but there are new dangers.

I have heard extremely intelligent scientists maintain that all doctors need a knowledge of nuclear physics and of electronics. I, personally, can think of few things more useless to the average practitioner, though of course they are essential to certain lines of scientific research. I need hardly remark that neither of the eminent gentlemen who presented these views had a medical degree. These examples illustrate the kind of difficulty that an attempt to reduce the content of the curriculum is likely to meet—the obstinate conservatism of old subjects, the predatory enthusiasm of the new. Each represents powerful vested interests; for the amount of time allocated to a subject in the curriculum is, in a sense, a measure of its prestige; and the more time the larger the staff required and the greater the power and security of the departmental head. I have no doubt that these are very strong motivating forces, though, of course, most teachers are unconscious of them. Hitherto, the student has been sacrificed to these vested interests because there has been no good weapon with which to defend him. A good weapon would be provided by agreement on the purpose of medical education. It would seem to me that the main problem of medical education is this: Will the medical course be arranged primarily in the interests of educating the student, or primarily in the interests of the prestige of the teachers? I say this as a teacher and with a full appreciation of the meaning of the words I use.

Collaboration in Teaching

The chief difficulty in integrating the course so that the field of biological science relating to health and disease in man is presented and treated as a whole, and not in discrete and apparently unrelated parts, has been the insularity of so many teachers and departments. Schemes of research requiring the collaboration of different departments are probably the most important means by which men of different disciplines learn what is new elsewhere and how to talk a common language. Notable attempts at collaboration in teaching have also been made, for example, in pre-clinical science at Birmingham. Clinico-pathological discussions and combined ward rounds are other important methods.

Finally, I would like to make a plea for elasticity. Any attempt at defining a medical undergraduate course is necessarily a compromise, and a purely arbitrary one. There are many ways to Rome. We shall never find out the best way so long as all pilgrims are forced to take the same path.

The measures which we have considered affecting the content of the curriculum are all concerned with reducing the time which is now required for memorization, so that enough time can be found for the student to develop his own mind. This time will not be properly used unless there is a revolutionary change of attitude on the part of his teachers. There must be more seminars and tutorials (in the old sense of tutorial and not in the sense of a cram-class) and fewer lectures; more reading of original papers and less of textbooks; more kindling of the flame of curiosity, and a greater readiness by teachers and taught to admit and remedy ignorance. This will not be easy, since most teachers mould themselves on those who taught them. Nevertheless, I can think of one or two universities where the professors are so enlightened that a change of the kind I have contemplated would not be difficult. There is a generation of young men who have experienced such teaching in the final honour school at Oxford, in Part II of the Tripos at Cambridge, and in B.Sc. classes at other univer-

sities and in other ways. They are aware of what such teaching did for them, and I have no doubt that with a little encouragement they could open a new era in medical education in this country. They have a right to expect, and I hope would receive, support from other faculties in achieving this, the common purpose of university education.

Conclusion

The development of postgraduate education, and, in particular, the institution of the compulsory year of hospital practice under supervision before licence is granted to practise independently, have at last freed the undergraduate course to serve its essential purpose, that of training the student's mind to collect and assess data and to form a judgment on them. The fulfilment of this purpose requires, first and foremost, a change in the attitude of teachers, and, second, a reduction in content and an attempt to integrate the subject matter on which the teaching is based. To quote Karl Pearson: "The true aim of the teacher should be to impart an appreciation of method rather than a knowledge of facts," for method is remembered when facts have been forgotten.

TWO NEW GANGLION-BLOCKING AGENTS IN TREATMENT OF HYPERTENSION

BY

S. LOCKET, M.B., B.S., M.R.C.P.

Senior Physician, Oldchurch Hospital, Romford, Essex

This clinical communication is based on results obtained in using, since January, 1955, the drug 356c54 and since October, 1955, the drug 139c55, two active members of a recently described group of ganglion-blocking agents (Adamson, Billingham, Green, and Locket, 1956). Chemically, 356c54 is $N^1:N^1:N^2$ -trimethyl- N^1 -(6-cyano-6:6-diphenylhexyl) ethylene-1-ammonium-2-morpholinium dichloride, and 139c55 is the 5-cyano-5:5-diphenylpentyl homologue (also called "presidal").

One very important property possessed by this new group of compounds, seen particularly when they were used in man, was the apparent dissociation between their activity as hypotensive agents and their ability to produce ocular changes and gastro-intestinal disturbances (dry mouth and delay in gastric emptying), a dissociation shown well by 139c55.

For both intravenous and subcutaneous injection we used a solution containing 20 mg. of the dichloride of either drug per ml. After discharge from hospital injections were continued by the patients at home.

Pattern of Activity in Patients after Intravenous or Subcutaneous Injections

In our hypertensive patients, using as our criterion of effectiveness a fall to or below 100 mm. Hg diastolic (measured in the sitting position), the minimal effective single intravenous dose of 356c54 was 2 mg. and the maximum dose necessary (used by us) was 12 mg., whereas the minimal effective single therapeutic dose given subcutaneously was 10 mg. and the maximum dose found necessary was 40 mg. With 139c55 the comparable doses were approximately half these, and the maximal subcutaneous dose used in treatment has been 27.5 mg. (Comparative blood-pressure readings were also always taken in the reclining and erect positions.)

The first detectable pharmacological response occurred after a delay of from 5 to 25 minutes. No immediate response occurred after an intravenous injection, irrespective of the dose given. Usually after an interval of about six minutes blurring of vision occurred. At this stage clinical examination revealed this subjective effect to be accompanied by objective changes in the eyes. Also it was often accompanied or immediately followed by a variable degree of bradycardia. A definite fall in blood pressure occurred within another 10 minutes, but the maximum fall occurred 45 to 60 minutes later. The bradycardia began about 10 to 20 minutes before the onset of any hypotensive effect. When the action of the drug was wearing off, the hypotensive effect gradually disappeared some time before the bradycardia subsided.

When the drugs were given by subcutaneous injection there was a somewhat longer delay, ranging from 10 to 60 minutes but on an average 12 to 15 minutes, before the first signs of pharmacological activity appeared. The pattern of activity was identical with that already described for the intravenous injection, but the duration of the desirable hypotensive action was much longer. With identical hypotension-producing doses the duration of hypotension given by 139c55 was longer than with 356c54—in many cases at least 50% longer and in a few even twice as long. With suitably chosen dosage—that is, that dosage which produces the longest period of hypotension below any desired maximum pressure, with the minimum of side-effects—using 139c55, this hypotension often exceeded 12 hours and on occasion 24 hours, and rarely was less than nine hours, and with 356c54 it was rarely less than seven hours and might even exceed 24 hours, though this latter duration occurred much less often with this drug than with 139c55. The maximum fall in blood pressure was reached some 60 to 120 minutes after the onset, and this level of hypotension persisted for some time before it slowly returned to its pre-treatment height.

Activity After Oral Administration

When an effective dose was given by mouth there could be a considerable delay before a fall in blood pressure began. A dose which was about 12 to 15 times the therapeutically effective subcutaneous dose was the usual effective oral dose, but it has, in an occasional patient, been as low as five times the effective subcutaneous dose and as high as 20 times this dose. The predictability of hypotension after oral administration, though certainly as good as was found in this group of patients using the other commercially available ganglion-blocking agents which could be given orally, in our opinion was not good enough, except in a very occasional case, to justify their use by mouth alone in the treatment of the severest cases. When the single oral dose

is increased to 15 to 20 times the effective subcutaneous dose there is still the same delay before the fall in blood pressure occurs. As with all other ganglion-blocking agents when given by mouth, even with this much larger dose, the degree of hypotensive response could not be accurately predicted, and might be very severe, though in some patients the response remained reasonably constant from day to day. Of the two drugs, 139c55 was far less likely to give any prolonged delay before the onset of hypotension, and it gave a higher frequency of successful responses with a more consistent oral dosage.

Ocular changes preceded the hypotension, but dry mouth was less pronounced than occurred with comparable periods of hypotension produced by subcutaneous injection. At all doses and for all comparable periods of hypotension, dry mouth occurred less often and in much less degree and less persistently with 139c55 than with 356c54. In fact, on many occasions dry mouth did not occur with 139c55 (given either by mouth or by subcutaneous injection) even though an effective degree and duration of hypotension was achieved.

Using special techniques, and with radio-opaque meals and repeated observations, we arrived at certain conclusions concerning the propulsion of intestinal contents in relation to these drugs. It was found that gastric emptying, small-intestine propulsion, and large-intestine propulsion behaved as three almost independent variables, and that all ganglion-blocking agents commonly used in the treatment of hypertension did not affect them all in the same degree. Whereas pentolinium and hexamethonium in therapeutic dosage caused a delay in gastric emptying and marked impairment of propulsion in both the small and the large intestine, 356c54 and 139c55 did not appreciably affect small-intestine propulsion. What was of still greater significance, however, was the observation that with identical hypotensive effects 139c55 produced much less delay in gastric emptying than did 356c54.

We suspected that gastric absorption of the drug did not occur, and this was confirmed experimentally (A. F. Green, 1955, personal communication). Here, then, was the explanation for the delay in the onset of hypotension after oral dosage and also the explanation for the greater success and more constant dosage response when 139c55 was used. By giving the drug on an empty stomach and following it immediately by a meal we obtained the greatest success, in that it enabled most of the ingested drug to enter the small intestine *en masse* and hence provide an effective hypotensive tissue-level of drug after absorption. Delay in gastric emptying was produced by initial small-intestine in gastric emptying was produced by initial small-intestine in that absorption of a minute dose of drug inadequate in that dosage to cause hypotension. Specially coated preparations that prevented gastric solution of the drug were also more successful but were not essential with 139c55. The fall in blood pressure—that is, to below 100 mm. Hg diastolic—lasted at least eight hours on every occasion that oral dosage was effective, and has lasted as long as 30 hours. The usual duration of hypotensive action of 356c54 and 139c55 when given orally was from 12 to 14 hours.

Ocular Effects

The effect on the eyes was usually (not invariably) the first clinical evidence of the action of the drug, appearing within a few minutes of intravenous or subcutaneous injections. The patient complained of blurring of near vision and an inability to read, though distance vision was not affected to any great degree (cycloplegic effect). This visual effect becomes less pronounced in many cases after the drugs have been in continuous use for a few weeks, though initial blurring of the vision within a few minutes of each injection was always noticed. Many patients, particularly older patients, showed a rapid adjustment to this ocular effect and regained their ability to read small type within 30 minutes of the injection. This recovery of vision was particularly marked in the case of 139c55. Visual disturbances could be corrected in considerable degree by

the use of 0.25% to 0.5% pilocarpine or eserine eye-drops. Most patients preferred to use pilocarpine.

Examination of the pupil usually revealed a fixed pupil in the mid-position—that is, neither grossly dilated nor constricted. Measurement has shown that both the drugs produced moderate dilatation of the pupil. Thus a pupil which was 3 to 4 mm. in diameter before the injection dilated to 5 to 6 mm. and was fixed at this diameter, not altering for light or accommodation. Neither fixation of the pupil nor any other demonstrable ocular change implied the absorption of an effective hypotensive dose. Pilocarpine and eserine eye-drops caused marked constriction of this pupil, and homatropine and atropine eye-drops caused further pupillary dilatation.

The most common order of appearance of the changes described was pupillary fixation, bradycardia, and hypotension, and the usual order of disappearance was hypotension, bradycardia, and pupillary fixation.

Effect on Gastro-intestinal Tract

With 356c54 dryness of the mouth was usually present, but varied greatly in degree. With 139c55 dryness of the mouth was often absent and for all grades of hypotension was always less pronounced than with 356c54.

The oral administration of a 15-mg. tablet of neostigmine bromide would occasionally relieve this xerostomia, but in many cases only at the expense of the production of abdominal colic.

Nausea and vomiting did not occur, nor severe constipation. Mild constipation was occasionally present. The absence of appreciable effect upon the small-intestine propulsion, even when using large oral and subcutaneous doses, has been one of the most interesting and useful features of these drugs.

Constipation, when it occurred, was easily remedied by the administration of liquid paraffin or the use of a saline—for example, magnesium oxide emulsion. It appeared to be due to a combination in varying degree of delayed gastric emptying and delayed passage along the large bowel. Oral neostigmine bromide produced more discomfort than purgation.

Fractional test meals have shown an effective cessation of free hydrochloric acid. Histamine injection during this phase of achlorhydria always elicited a free acid response lasting about 30 minutes.

Action on Cardiovascular System

Large doses of both drugs could produce postural syncope. If, one and a half hours after receiving a subcutaneous injection, standing erect and motionless caused dizziness, it was regarded by us as an indication that an effective therapeutic dose had been administered. Blood-pressure readings as usually taken—that is, sitting in a chair or lying reclining in bed—could be used as an indication of the absorption of an effective dose of drug. Standing erect always produced an additional fall of blood pressure, rarely promptly, but usually after a few minutes' delay. The return of this low blood pressure to its previous higher level on readopting the supine or sitting position also occurred only after some minutes' delay. We were always able to lower the blood pressure to below 150/100, and all the patients (except Case 6) in our series of trials had a diastolic pressure before treatment of at least 130 mm. Hg most of the time, and in several it was constantly in the range of 160–190 mm. Hg when not in receipt of treatment.

Bradycardia was present in some degree in most cases, occurring before the fall in blood pressure, and usually outlasting the hypotension. It was directly related to the heart rate before the injection of the drug. An initial rate of 90–100 a minute might fall to 70–80, and an initial rate of 70–80 might drop to 60–65. This rate never fell below 60 a minute.

Angina of effort ceased to occur during effective hypotensive treatment. In one patient severe angina of effort

and constant decubitus angina following two previous coronary thromboses ceased to occur whilst the patient was in receipt of this drug alone and without restriction of activity. In another, angina of effort which had been present for a year ceased to occur for the entire period of treatment (seven months) with these ganglion-blocking agents.

Episodes of severe paroxysmal nocturnal dyspnoea (in one patient these had occurred almost every night for two months with two severe episodes of pulmonary oedema) invariably ceased to occur after the use of daily injections of these drugs.

The electrocardiogram (using as a routine 12 leads—1, 2, 3, aVR, aVL, aVF, and V_1 to V_6) did not reveal any acute changes during the hypotensive phase—that is, it remained identical both before and during the hypotension. Several patients who had been receiving treatment (Cases 3, 5, 10, and 11) showed a reversion to a more normal electrocardiogram: inverted T waves in V leads became biphasic or upright, whereas previously they had been completely and persistently inverted. In one patient the duration of the QRS complex was reduced from 0.14 to 0.09–0.1 second. Three patients showed a gross reduction in the maximum transverse diameter of the heart over this trial period. In one case it was reduced by more than 2.5 cm. and in the others by at least 1.5 cm.

Action of Other Drugs

Subcutaneous injection of atropine (0.5 mg.) diminished the bradycardia, made the vision worse by dilating the pupil, and increased the dryness of the mouth, but it had no effect on the level of the hypotension. Conversely, tachycardia caused by an initial injection of atropine was always slowed within half an hour by injection of an effective dose of 356c54.

Intramuscular injection of 50 mg. of promethazine either before or during the action of 356c54 had no effect on the hypotension, merely making the patients sleepy. Occasional alcoholic drinks (sherry) did not seem to affect the hypotension. Injection of neostigmine had little effect on the bradycardia and none on the hypotension, but possibly made the mouth less dry, though abdominal colic almost invariably occurred.

Renal Function

Measurements of the para-aminohippurate and endogenous creatinine clearances before and during the fall in blood pressure, and also when the hypotension was present, revealed no gross change in any of these values. At the height of the hypotension antidiuresis was pronounced, the urine-minute volume in one case falling from 4 ml. to as low as 0.5 ml. This antidiuretic effect ceased to be noticeable clinically when twice-daily injections were persisted with. Advanced renal insufficiency did not cease to progress in spite of prolonged control of the hypertension and relief of all hypertensive phenomena—that is, incapacitating headache, vomiting, and visual deterioration (see Case 10). With increasing renal deterioration we found increasing resistance to all hypotension-inducing agents.

Tolerance

During the initial few weeks of treatment by subcutaneous injections some adjustment of the dose was necessary in most cases. Once this effective dose was achieved it did not become necessary to increase the dose by more than one-third in any patient, even with progressive renal failure (Case 10). Usually the increase was necessary in severe cases of hypertension stabilized initially on a small daily dose. In some severe cases which at first appeared to require a large daily dose it was possible, and desirable, to reduce the dose after the initial period of treatment, since we could, using this small dose, nevertheless maintain the same degree of hypotension as was initially obtained.

Case 1

A man aged 38 first attended in November, 1953, complaining of headaches and recent poor vision, and more

recently of recurrent attacks of paroxysmal dyspnoea. Examination revealed bilateral papilloedema with retinal haemorrhages. His blood pressure at the time was 220–240/140–160. Urine contained a small quantity of albumin. Blood urea was 30 mg. per 100 ml.; urea clearance 70% of average normal. Treatment consisted of injections of pentolinium tartrate, a salt-free diet, and digitalization. Nevertheless, left ventricular failure and paroxysmal nocturnal dyspnoea repeatedly occurred. The addition of *Veratrum viride* extract caused vomiting, with no improvement. The addition of rauwolfia alkaloids in September, 1954, did not improve the clinical picture. Early in November swelling of the ankles appeared and he also complained of recurrent episodes of light-headedness. His blood pressure was 240/130–160. In mid-November 3 mg. daily of the rauwolfia alkaloid rescinnamine was added. Morning sickness developed and bowel frequency increased to three times daily. All other treatment was stopped at this stage. After two weeks the dose of rescinnamine was reduced to 2.5 mg. daily because he complained of feeling unwell generally and restless, without being able to be more specific about the symptoms. He was sleeping poorly, his bowels were open three or four times daily, and he had severe occipital headaches. Nevertheless, the episodes of left ventricular failure and nocturnal dyspnoea had ceased and his blood pressure was now in the range of 190–205/120–125. Fundus oculi remained unchanged. His general mental and physical condition remained unsatisfactory.

On January 6, 1955, the rescinnamine was stopped and pentolinium injections were recommenced. After two weeks he was transferred to 288c53 (a ganglion-blocking agent). On March 11 he was transferred to 356c54, receiving a single daily injection of 20 mg. Treatment was accompanied by rapid improvement in his physical condition and sense of well-being. In April this injection was reduced to 17.5 mg. daily. This dose remained effective and kept his blood pressure down to 125–160/75–100 for at least eight hours daily. Early in August a recurrence of severe "bursting headaches" and increase in diastolic pressure to 140 necessitated an increase to 22.5 mg. and later to 25 mg. He remained well on this dose. In November he was changed to 15 mg. of 139c55; this was increased to 20 mg. by January, 1956, and in February was reduced to 18.5 mg. daily. This has kept his diastolic pressure below 100 for at least nine hours daily and below 85 for at least seven hours daily.

Since March, 1955, he has continued to work actively in his business, and this has necessitated constant journeying between Oldham and London. His papilloedema has now apparently faded. Since his transfer to 139c55 he has been able to read newspapers and books with little disability.

Case 2

A woman aged 52 was admitted to hospital with recent cerebral thrombosis. On examination gross bilateral papilloedema with exudates and haemorrhages was found. Her blood pressure on admission was more than 260/180, and remained in this region even with bed rest.

After trying various oral preparations for her hypertension without any effect, in January, 1955, she was put on to a regime necessitating the injection of ganglion-blocking agents, and on March 18 was transferred to 356c54. The initial controlling dose of 40 mg. once daily was reduced later to 30 mg. She remained fit and well on this and attended regularly as an out-patient. Owing to lack of personal cleanliness she, in August, developed infection at the sites of injection. This responded to treatment, but she then ceased to attend and received no drug for three weeks. She was readmitted in stupor due to a further cerebral catastrophe. Immediate recommencement of the drug resulted in a rapid recovery of function and she remained well until October, when she defaulted again.

In this patient 30 to 40 mg. of 356c54 produced a fall in diastolic pressure to below 100 which endured for more than 10 hours.

Early in November she was readmitted after a further acute cerebral episode and was rapidly controlled with 20 mg. of 139c55 daily. On this dose her diastolic pressure remained below 100 for at least 11 hours. She defaulted again in February, 1956, but was persuaded to attend again by her doctor, and on this occasion after two weeks without treatment her blood pressure range was 290–300+/170–190. As expected she had gross papilloedema and was physically and mentally extensively disabled. Further treatment by injection was not considered suitable.

Case 3

This patient, a woman aged 23, when first seen on January 18, 1955, was four months pregnant, and was complaining of breathlessness on effort. Her blood pressure was over 260/160. Ocular fundi, however, did not show papilloedema, nor were there exudates or haemorrhages, but thin almost invisible arteries and engorged veins. Heart examination revealed a presystolic gallop. There was an enlarged left ventricle in the skiagram. Electrocardiograms showed a "left ventricular strain" pattern, and the urine contained a small quantity of albumin. Blood urea was 43 mg. per 100 ml.

This patient, who admitted to some breathlessness on effort, was very reluctant to submit to any treatment. She was, however, persuaded to enter hospital for a rest. At rest in bed her systolic pressure varied between 220 and 300 and her diastolic between 140 and 165 but was never below 140. At this stage various ganglion-blocking agents were tried, and with these we could obtain a fall in blood pressure which lasted for five and a half hours. Routine and specialized investigation, including an aortogram, revealed a small ischaemic right kidney, and nephrectomy was undertaken at the end of February. No fall in blood pressure occurred after this nephrectomy, and histological examination revealed extensive malignant hypertensive changes in the kidneys. At the patient's request no further treatment for her hypertension was given, and she was discharged after this operation.

When seen again as an out-patient at the end of March she had not received any treatment for her hypertension since leaving hospital. She was now 26 weeks pregnant. Her blood pressure was 260/130 on this occasion.

At the end of April she was admitted urgently because of recurrent attacks of left ventricular failure, and a week of recurrent attacks of left ventricular failure, and a week later she produced a macerated foetus. Her blood pressure later she produced a macerated foetus. In May treatment (at rest in bed) was 260–300/130–170. In May treatment with 356c54 was begun. The daily dose was 35 mg. On this dose she was discharged home. She remained well, and after three months her electrocardiogram was more normal and skiagrams revealed a considerable reduction in heart size. In August the dose of drug was reduced and she felt well—so well, in fact, that in September she decided to discontinue all our treatment and receive treatment from a naturopath. We are awaiting the result of the herbalist's regime with interest. Her blood pressure without treatment when last seen by us was 270/140. The consequences of lack of any effective treatment had been fully explained to the husband on several occasions, as well as to the patient. In February, 1956, she still had the same blood pressure and felt quite well.

Case 4

This patient, a woman aged 56, was an unstable hypertensive. Her diastolic pressure varied from 110 to 150, irrespective of rest in bed. She was an emotional person. Electrocardiograms showed left axis deviation only. Because of breathlessness and recent occasional attacks of paroxysmal nocturnal dyspnoea and recurrent occipital headaches, she was admitted for treatment. Early in April she was discharged home receiving 20 mg. of 356c54 daily. On this dose her blood pressure fell from 200–260/110–150 to 120–170/70–95.

When seen on April 29 as an out-patient her blood pressure was 135/90 (sitting) and 120/70 (standing) when taken

four and a half hours after the injection. On May 6 her daughter informed us that she was not desirous of continuing injections. On May 20 her blood pressure was 210/120. She said she felt well. No treatment had been received for two weeks. She continued to attend regularly. On October 7 her blood pressure was 230/130. She was still feeling well and had received no treatment since the last visit. She was now getting occasional episodes of paroxysmal nocturnal dyspnoea, and by the end of November these were occurring every night in spite of the use of mercurials and digitalization. In March, 1956, this patient was receiving treatment from her own doctor for congestive heart failure.

Case 5

A man aged 57 was known to have had a high blood pressure and left ventricular enlargement for many years. At the time of admission he was regularly attending as an out-patient the hypertension clinic of a London teaching hospital.

On April 10, 1955, he was admitted almost *in extremis* with acute left ventricular failure and pulmonary oedema. His blood pressure range was 210–260/170. His blood urea was 53 mg. per 100 ml. He gave a history of having had several acute episodes of paroxysmal nocturnal dyspnoea during the weeks before the present very severe episode. He had not worked for two months. He was taking hydralazine and reserpine at the time of admission. By April 12 he had had several further attacks of left ventricular failure whilst in hospital in spite of a low-salt diet and the use of mercurials. His teloradiogram showed much enlargement of the heart, mainly of the left ventricle. His lungs were considerably engorged. At the cardiac apex in the mid-axilla a presystolic gallop was easily audible. His blood pressure was 210–220/160–170. His retinae showed gross arteriosclerotic changes but without papilloedema.

On April 15 356c54 was begun, and on May 4 he was discharged home to receive 20 mg. twice daily. He has had no further attacks of nocturnal dyspnoea since April 15 in spite of cessation of a salt-free diet and mercurials, and treatment with ganglion-blocking agent only. On May 11 the doses were reduced to 17.5 mg. in the morning and 20 mg. at night, and on July 13 this was reduced to one dose daily of 20 mg.

On August 3 he felt well and was advised to return to work. On this day his blood pressure was 160–170/110–115 some four hours after one injection of 20 mg. In November he was transferred to 139c55, with a much better control of the blood pressure.

When last seen (March, 1956) he remained well, though he still complained of shortness of breath on effort. He was receiving 21 mg. of 139c55 daily subcutaneously but omitting the Sunday dose. His blood pressure four hours after the injection was 160/105 sitting and 120/40 after standing four minutes. His electrocardiogram had now reverted to a more normal appearance and his heart was much reduced in size. No further attacks of paroxysmal nocturnal dyspnoea had occurred since April 15.

Case 6

A woman aged 55, first seen on January 25, 1955, was admitted to hospital on April 25 with a long-standing history of hypertension, two past attacks of coronary thrombosis (with electrocardiographic confirmation of severe coronary damage), and angina of effort since June, 1953. The angina had steadily worsened, and now even the most moderate of efforts caused pain. Decubitus angina occurred every night and on some nights attacks of left ventricular failure. Her blood pressure was 200–220/120–130. She had a presystolic apical gallop and a resting pulse rate of 110 a minute. No improvement occurred with reserpine (1.5 mg. daily) or rauwolfia alkaloids (8 mg. daily) combined with methimazole and nitroglycerin. On May 13 356c54 was begun with 10 mg. injected night and morning. No further attacks of left ventricular failure or decubitus angina occurred. Her resting pulse rate was 76 a minute.

On May 16 the dose was increased to 12.5 mg. night and morning. She felt well and was up and about. No further attacks of angina of effort occurred during either the day or the night, nor any attacks of paroxysmal nocturnal dyspnoea. Her blood pressure was 120/60 and her pulse rate 70 a minute for most of the day.

When seen on June 16 and 23 she was well, her blood pressure remained fairly steady at 120/70, and her pulse at 64 a minute for most of the day.

On June 30 she died suddenly. Necropsy revealed a fresh and recent coronary thrombosis and myocardial infarction.

Case 7

A woman aged 58 was first admitted to the eye department in 1954 because of severe frontal headaches. Her blood pressure was 230-250/150-160. She was admitted to medical wards in January, 1955, with an acute confusional episode due either to hypertensive encephalopathy or to cerebral thrombosis. Her retinae showed numerous ecchymoses and gross arteriosclerotic retinopathy, but no papilloedema.

In May she complained of vertigo and occasional mild attacks of paroxysmal nocturnal dyspnoea. Her blood pressure range was 210-250/130-140. She had been receiving 10 mg. of rauwolfia total alkaloids daily for three and a half months, with a slight effect on her blood pressure and little on her symptoms.

On July 4 356c54 was commenced, with 15 mg. daily by subcutaneous injection. On July 25 the dose was cut to 12.5 mg. Her blood pressure on this date, taken two hours after the injection, was 140/100. This effective hypotension lasted for only four and a half hours, so the dose was increased to 15 mg. daily.

On August 8 her blood pressure was 140/90 and pulse rate 60 a minute, taken five hours after the 15-mg. injection. She continued to attend and remained well. She was transferred to 10 mg. of 139c55 in early December and remained well on this small daily dose with a more prolonged control of her blood pressure. In mid-February, at her request as she was so well, all treatment was stopped. Two weeks later she was fit and well, blood pressure 240/145. A week later she had an acute cerebral catastrophe, was admitted to hospital in coma, and died the following day, the cause being a large cerebral haemorrhage, proved at necropsy.

Case 8

This patient, a woman aged 28, was admitted on June 21, 1955. At her first pregnancy, seven years earlier, she had been told she had "blood pressure." The pregnancy went to term and she was delivered of a normal child of 8 lb. (3.6 kg.). She was kept in hospital for the last 12 weeks of this pregnancy. On May 30, 1955, she had a stillbirth at 28 weeks and was kept in hospital for 10 days. Since her discharge she had felt vaguely unwell, with no energy, weak legs, attacks of vomiting and dyspnoea, and paroxysmal nocturnal dyspnoea. Her vision was blurred and poor, and appeared to be steadily deteriorating.

On examination her blood pressure was 220-300/150-160. Her urine contained albumin, blood urea was 38 mg. per 100 ml., and her urea clearance was 110% of average normal. Her fundi showed bilateral papilloedema with numerous exudates, both "soft" and hard, and numerous haemorrhages. Her heart was enlarged and her electrocardiogram showed left axis deviation and a left ventricular strain pattern.

On July 7 treatment with 30 mg. of 356c54 was begun. This was later increased to 32.5 mg. Her blood pressure range of 220-260/140-160 fell, so that six hours after an injection the readings were 180/130 (measured sitting) and 120/90-100 (standing). The patient characteristically always showed a marked postural fall in blood pressure on standing and only a moderate fall in the reclining or sitting position, and practically none in the supine position.

On July 18, with a marked fall in blood pressure on standing that lasted more than eight hours, she was allowed

home. Occasional postural syncope occurred on standing upright and motionless for more than a few minutes.

A week later she was feeling well. No fainting attacks had occurred since her last visit, and she was doing her housework.

On August 9 her blood pressure was 230/170-180 (sitting) and 110/85 (standing) three hours after injection had been given. In December she was transferred to 139c55 and has remained on 20 mg. of this drug daily. When last seen (March, 1956) she was working; her vision was still poor, and her blood pressure four hours after the injection was 180/120-130 (sitting) and 160/<100 (standing).

Case 9

This patient, a woman aged 59, was admitted on July 26, 1955. We had known her as an old severe hypertensive for more than five years. Rauwolfia alkaloids caused a fall of 10 to 20 mm. in diastolic pressure only. She had gross cerebral damage (two past cerebral thromboses) and also was practically blind from recurrent vitreous and retinal haemorrhages. She showed a mild organic dementia.

On August 8 20 mg. of 356c54 was given subcutaneously. Her blood pressure range was 210-260/130-140 before injection, and one and a half hours after injection it was 150/110 and remained at the level of 150-170/100-105 for 18 hours. On August 9 a further 20 mg. was given subcutaneously. Her blood pressure fell to 120/80 in one and a half hours and remained—in bed—below 140/90 for seven and a half hours; it returned to pre-injection level at 11 hours. She was readmitted in November and was transferred to 139c55, 11 mg. This produced a fall in systolic pressure to below 120 for longer than 12 hours. In this patient 100 mg. of 139c55 by mouth produced hypotension for more than 14 hours with a systolic pressure below 140.

Case 10

A man aged 32 was admitted to hospital on August 9, 1955, with a three-months history of headaches. Two months before admission the headaches became intensely severe and would awaken him at night. For the two weeks before admission they were accompanied by episodes of vomiting. These attacks were particularly severe on awakening in the morning. For two weeks his vision had been poor.

He was admitted to the neurological service because of bilateral papilloedema, exudates, and haemorrhage. His blood pressure was in excess of 260/150-160. Blood urea was 65 mg. per 100 ml. and his urine showed albumin (6 parts of albumin per 1,000 parts of urine) and casts. He was transferred to the medical service on August 20 in view of increasing severity of symptoms. The diagnosis was "probably malignant hypertension, possibly secondary to chronic nephritis." Treatment with 356c54 was begun immediately, the dose being 27.5 mg. twice daily. There was an immediate amelioration of symptoms. Later the dose was reduced to 27.5 mg. a day, and on October 29 he was discharged home. The retinal changes were considerably improved and the electrocardiogram showed upright T waves in leads V₄, V₅, and V₆ (previously T inverted in these leads). However, the renal function has ceased to improve, and the blood urea has remained steadily between 90 and 110 mg. per 100 ml.; urea clearance, 9 ml.; creatinine clearance, 11 to 12 ml. (serum creatinine 6 to 6.4 mg. per 100 ml.); P.A.H. clearance, 40 to 50 ml.

During the next months his condition remained static. At the end of November haemoptysis, cough, and a small area of pulmonary consolidation necessitated his readmission. He was then transferred to 139c55. Originally controlled by 15 mg., the dose was steadily increased to 20 mg. daily by the end of December. At this time his blood urea had risen to 120-140 mg. per 100 ml. and his serum creatinine to 10 to 12 mg. per 100 ml. His hypertension was now not causing any symptoms and his papilloedema appeared to have subsided. At this time 200 to 250 mg. of 139c55 given by mouth produced 12 to 14 hours' hypotension one day in

three. He was discharged home on this dose, but steady deterioration of renal function and the onset of gross oedema of his lower limbs and abdomen (not due to congestive failure) necessitated his readmission in January, 1956. His blood urea was in the region of 200 to 230 mg. per 100 ml., his urea clearance below 5% of average normal, his serum creatinine 16 mg. per 100 ml., and his creatinine clearance about 8 ml. At this time he required 27.5 mg. of 139c55 subcutaneously to produce hypotension for six hours with a blood pressure below 150/100.

Incidentally, during this period 50 mg. of mecamlamine by mouth had no effect on his hypotension but caused vomiting and intractable constipation, and injections of up to 70 mg. of pentolinium had no hypotensive effect. In view of the intractability of his disease all hypotensive agents were stopped. Dietetic measures and treatment directed specifically for his oedema and less hopefully directed towards his heart were without any success, and his attacks of left ventricular failure necessitated liberal use of morphine. He died towards the end of March. Necropsy revealed evidence suggestive of chronic nephritis with superimposed changes of malignant hypertension.

Case 11

A man aged 51 was admitted to hospital on September 8, 1955, having collapsed at work. The left side of his body was flaccid, the left great toe upgoing, and he was cyanosed and frothing at the mouth. His blood pressure was in excess of 260/140. His fundi showed bilateral papilloedema and recent haemorrhages. Blood urea was 41 mg. per 100 ml.; urea clearance, 50-75% of standard clearance; creatinine clearance, 58 ml. a minute; trace only of albumin in urine. He gave a past history of increasing shortness of breath for 12 months and had been receiving treatment for angina of effort during this period. Treatment with 356c54 was begun and he was discharged home on October 29, receiving 20 mg. twice daily.

Towards the end of November he was transferred to 12.5 mg. of 139c55. His blood pressure was controlled all the waking day with this dose, and postural symptoms were usually present for the second and third hours after the injection. Dyspnoea had practically disappeared, and angina of effort did not occur. Urea clearance has remained normal. His fundi have improved considerably. Papilloedema has subsided and haemorrhages were rarely seen. ST depression and T-wave inversion in chest leads were less pronounced, the T wave being biphasic or upright. The heart size had been considerably reduced. In March, 1956, his blood pressure four hours after his injection was 105/55 (sitting).

Case 12

A man aged 57 was admitted to hospital on February 10, 1956, with a history of incapacitating headaches for 10 weeks, steadily increasing visual deterioration for eight weeks, and frequent vomiting, particularly on awakening in the morning, for three weeks.

On clinical examination his blood pressure was 210-270/135-160. His fundi showed gross bilateral papilloedema and numerous exudates and haemorrhages. Extensive macular haemorrhages appeared to be the main cause of his visual impairment. His urine contained albumin. His blood urea was 40 mg. per 100 ml.; urea clearance in excess of 80% average normal; and creatinine clearance 90-100 ml. a minute. Treatment with 139c55 was begun and he was stabilized on a daily dose of 12.5 mg. and discharged home. When last seen (April 4) his blood pressure, sitting in a chair seven hours after a subcutaneous injection of 12.5 mg. of 139c55, was 90-110/50-80, his papilloedema had subsided considerably, no retinal haemorrhages could be seen but numerous exudates, and his vision remained very poor. He was feeling quite well.

Case 13

A woman aged 55 was admitted to hospital on February 18, 1956, complaining of recurrent attacks of paroxysmal

nocturnal dyspnoea and severe shortness of breath. She had been attending as an out-patient regularly since 1950. Her blood pressure since that date has varied between 210 and 300 systolic and 140 and 180 diastolic during most of this period. On the occasion of this admission her diastolic pressure was 170 mm. Hg (± 15 mm. Hg). Her urine contained 1+ albumin, and renal-function tests were normal. Her fundi showed bilateral papilloedema with a few small haemorrhages and exudates. She was put on to 139c55, a daily injection of 15 mg. consistently producing a fall of blood pressure for more than 10 hours, during which period the diastolic pressure remained below 90. When last seen as an out-patient (March 29) her condition was excellent.

Case 14

This patient, a woman aged 49, was admitted on August 14, 1955, with a history of sudden onset of severe pain in her neck and behind her right eye. The onset of the pain was accompanied by vomiting.

Clinical examination confirmed the presence of a sub-arachnoid haemorrhage, but neurosurgical examination did not reveal the presence of an aneurysm. Her blood pressure was 200-240/130-145. Her condition improved quite satisfactorily and it was found that 200 mg. of 356c54 by mouth produced a considerable degree of hypotension, the systolic pressure being below 110 for more than 14 hours. During her stay in hospital she had several epileptiform fits which were associated with hypertensive episodes. Piperoxan and phentolamine tests were negative. She was treated with mixed rauwolfia alkaloids and was discharged.

Her condition as an out-patient remained most unsatisfactory. Her hypertension and epileptiform fits were not controlled. She was readmitted on December 12. Her hypertension was found to be adequately controlled by a single injection of 139c55, 10 mg. of which gave at least 12 hours of hypotension, and she was discharged. When last seen (April 4) her condition was very satisfactory, her blood pressure three and a half hours after the injection being 140/90.

Case 15

A woman aged 54 was referred for treatment of her hypertension from the ophthalmic department, which she attended because of visual deterioration, and where she was found to have numerous retinal and macular haemorrhages.

On admission her blood pressure range was 190-250/130-160. Renal-function tests were normal. Her retinae showed gross arteriosclerotic changes but no papilloedema. She was adequately controlled by 10 mg. of 139c55, which produced hypotension for more than 12 hours with a diastolic pressure below 100.

Discussion

This report is concerned with the clinical results of the trials of drugs 356c54 and 139c55 when used in the treatment of severe hypertension. These drugs differ in many of their detailed actions from those of the methonium group. I would emphasize here the gradual though reasonably quick appearance of activity, the easily demonstrable prolonged effect when given by the intravenous or subcutaneous routes, as well as the fall in blood pressure in the reclining and sitting positions, their relative lack of depression of small-intestine propulsion, their ability to slow the heart rate, and the slower appearance of postural symptoms on assuming the erect posture.

Experience with other members of this group of compounds has revealed that some members have a differential action on ganglia concerned with different activities though situated in the same autonomic group. Thus hypotensive ability does not appear to run parallel to ocular, oral, and gastro-intestinal activity. This is well shown in a comparison between 356c54 and 139c55. From results to date we think that there is a reasonable chance of evolving a compound showing considerable dissociation of hypotensive power from the other activities not required in dealing with hypertension.

The trial group of patients (5 male, 10 female) were selected only because of their severity, and were in fact consecutive admissions. They happen also to give a reasonable selection of the various disorders associated and often attributable to hypertension. Cases 1, 10, 11, and 12 (male), and 2, 3, 8, and 13 (female) were probably cases of malignant hypertension. Cases 2, 9, and 13 (female), and 11 (male) had cerebral thromboses, Cases 3, 4, 5, 6, 7, 8, 9, 10, 11, and 13 had recurrent attacks of left ventricular failure. Case 11 had angina of effort for at least a year, Case 6 had severe angina of effort and decubitus angina, and Cases 1, 2, 8, 9, 10, 11, 12, 13, and 14 had severe incapacitating occipital headaches often accompanied by vomiting and made worse by reclining. Gross vascular arteriosclerosis in peripheral vessels was easily demonstrable in Cases 2, 4, 5, 6, 7, 8, 9, 11, 13, and 15. The ages of the patients were 23, 28, 32, 38, 49, 51, 52, 54, 55 (two patients), 56, 57 (two patients), 58, and 59 years, and all except the 23-year-old woman and the 32-year-old man were known to have had severe hypertension for more than two years, and in some cases (Nos. 5, 6, 7, 8, 9, and 13) for more than seven years. Every patient in this series was fully investigated for pheochromocytoma (phenolamine and piperoxan in every case) and had full radiological investigation, including intravenous pyelography and often aortograms—for example, Case 3.

In no case were any of the hypertensive signs and symptoms made worse by treatment. In every case in which a change occurred it was for the better. In every case attacks of left ventricular failure stopped when treatment began, breathlessness was relieved, and angina of effort ceased to occur. When electrocardiographic changes occurred they were towards normal, and heart size was reduced. It was believed that the papilloedema in Cases 1, 2, 8, 10, 11, 12, and 13 was subsiding or has subsided. Only one patient (Case 10) in this group had grossly impaired renal function. There was no evidence to suggest an increased liability to thrombosis in arteriosclerotic vessels: in fact, the evidence in these patients and many others was to the contrary. Those headaches which were hypertensive in origin were immediately ameliorated, but they recurred when treatment was inadequate to maintain the lowered blood pressure.

In conclusion, there can be no doubt, from our experience with this group of patients, that the ability to maintain a sustained hypotension with the drug 356c54 and, better still, with 139c55 resulted in a rapid relief of symptoms and a reversion to normal of many of the changes known to be associated with persistent severe hypertension.

Summary

This paper is a report on the use during the past year and a half of two of a new group of ganglion-blocking agents (compounds 356c54 and 139c55) in the treatment of 15 severe cases of hypertension. These compounds were given subcutaneously, and the results so far have been most satisfactory. The advantages of the compounds, particularly 139c55, in the treatment of hypertension lie in the more gradual onset of activity, the greater duration of action, which makes treatment possible with a single or at most two daily injections, the slowing effect on the heart rate, and the relative lack of action on the small intestine.

I am indebted to a number of lay, technical, and medical helpers, too numerous to mention. I am grateful to my scientific collaborators, Dr. D. W. Adamson, Mr. J. W. Billingham, and Mr. A. F. Green, without whose close chemical and pharmacological association this work would never have been accomplished. I am indebted to Dr. F. Prescott, from whose original suggestion this entire investigation arose, and to the Wellcome Foundation for supplies of ganglion-blocking agents and for help in many other ways. I wish to acknowledge the careful and ungrudging work of Mr. H. Williams, Mr. A. Richardson, and the other staff of the Oldchurch Hospital pharmacy; and Mr. D. Stephenson, of the Wellcome Chemical Works. I am grateful to Dr. J. Stewart and the technical staff of the radiological department of

Oldchurch Hospital for undertaking a multitude of x-ray investigations, and to the sisters and doctors of my medical wards for the thousands of blood-pressure readings necessitated by this work; also to Sisters Turner and Fredway and my registrar, Dr. A. J. Gray. The biochemist, Dr. W. S. M. Grieve, and the laboratory technical staff have, as always, rendered yeoman service. Finally, I am also grateful to my secretary, Mrs. E. D. Price, for keeping my numerous records.

INFECTED SUBDURAL EFFUSIONS

BY

JOHN HANKINSON, M.B., F.R.C.S.

Senior Registrar, The National Hospital, Queen Square, London

AND

LUIS V. AMADOR, M.D.

From the Children's Memorial Hospital, Chicago, Ill.

The striking improvement in the results of treatment of purulent meningitis in recent years has led to the increasing recognition of the relative frequency with which subdural effusions complicate convalescence in such cases in childhood. Partly responsible also is the present awareness in paediatric circles of subdural collections of fluid of various kinds in infancy.

The condition has long been recognized and cases have been described; thus Schwartz (1916), in a paper on the aetiology of pachymeningitis haemorrhagica interna in infants, describes a fatal case of meningitis with bilateral subdural effusions. The pathological findings were described by Spitz, Pollak, and Angrist (1945). Only two cases were encountered in a series of post-mortem examinations of 95 consecutive deaths from meningitis in a total of almost 5,000 necropsies. One was an elderly man, the other a child of 3 years. Spitz *et al.* concluded that "subdural suppuration is a rare complication of purulent meningitis, although a higher incidence will undoubtedly be revealed as a result of more complete necropsy studies."

The contrast in recent American experience is expressed by McKay *et al.* (1953), who state that 60% of all infants under 1 year of age suffering from meningitis due to *H. influenzae*, pneumococci, and meningococci develop subdural effusions. Likewise Smith *et al.* (1951), in a period of 11 months, found 20 cases of subdural effusion in 43 infants under 2 years admitted with proved meningitis. The role of *H. influenzae* (Pfeiffer's bacillus) as the causative organism in meningitis associated with subdural effusion is impressive, appearing in at least 50% of the American cases, the pneumococcus and meningococcus accounting for the remainder. *H. influenzae* was the fourth commonest cause of meningitis; but in infants it was the most frequent, with the highest incidence in the second six months of life. It is possible, however, that subdural effusions may be peculiar to the age of the patients rather than to the causative organisms.

The case-fatality rate of *H. influenzae* meningitis was reported by Mutch (1941) as being between 90 and 100%. The very significant change in mortality which has occurred was recorded by Bloor, Grant, and Tabris (1950). Their 44 cases showed a mortality of 22.7%; but when divided into cases above or below 9 months of age the mortality was 8% and 42% respectively. These authors make no mention of the presence of sub-

dural effusions either in the fatal cases or in those surviving. However, about 50% of the survivors were considered to be retarded and 20% had severe neurological defects, including hydrocephalus, hemiparesis, bilateral pyramidal signs, and deafness. It appears probable, in view of the relatively high incidence of subdural effusions recorded in other series, that some of these defective children are suffering from the sequelae of subdural effusions as well as the primary cerebral damage attributable to the meningitis.

Of the five cases of infected subdural effusions presented here, four were associated with purulent meningitis and one was an unusual sequel to bilateral subdural haematomas treated four years previously, in which no organism was isolated. The organisms responsible for the meningitis were *H. influenzae* in two cases and meningococci in one case; no organism was grown in the fourth. All the cases were seen at hospitals in or near Chicago.

Case 1

A 12-months-old girl was admitted to hospital because of vomiting and a left hemiparesis. Seven weeks before admission she had a convulsion associated with a high fever. Subsequently she vomited frequently, and had respiratory difficulty with continued fever. At this time the parents noted that there was weakness of the left arm and leg and that the child was extremely irritable. She was admitted to another hospital and given sulphonamide, penicillin, chlortetracycline, and oxytetracycline, which had little effect on the fever, although the child vomited less and her general condition appeared to improve. She was discharged from hospital, but after two weeks was readmitted. Her temperature continued to be elevated and stiffness of the neck was noted. She was given streptomycin and serum. *H. influenzae* was cultured from the cerebrospinal fluid following lumbar puncture. During the week before admission vomiting had again increased considerably and the child developed a left hemiparesis. She had had no previous serious illness and had developed normally.

On admission to the Children's Memorial Hospital, Chicago, her temperature was 102° F. (38.9° C.), pulse 132, and respirations 26. She was irritable and appeared ill, but was fairly well nourished. The anterior fontanelle was bulging and the veins of the scalp were engorged. The fundi were normal, the pupils were equal in size and reacted normally to light. (The pharynx was not injected and the ears were normal. The heart, chest, and abdomen were normal.) The right arm and leg moved normally, the left leg moved not at all and the left arm only slightly. The deep tendon reflexes were increased on the left side, but both plantar responses were flexor.

The subdural spaces were tapped at the lateral angles of the anterior fontanelle (Fig. 1). No fluid was found on the right side, and on the left there were a few drops of clear cerebrospinal fluid only. Examination of the blood revealed a moderate anaemia with a white-cell count of 23,000, predominantly polymorphonuclear leucocytes. Streptomycin was given, but there was no real change in the child's con-

FIG. 1.—Case 1. Showing difficulty of needling this effusion from the anterior fontanelle.

dition. Accordingly on the sixth day in hospital bilateral posterior parietal burr-holes were made under general anaesthesia. The left subdural space was normal, but on the right side 30 ml. of pus was evacuated from a subdural empyema. A further burr-hole was then made in the right parietal region, but the dura mater and cortex were adherent and congested and nothing further was done. The subdural empyema was irrigated with warm saline and penicillin by a catheter through the posterior burr-hole and the wounds were closed. The child made a satisfactory recovery. Culture of the pus obtained from the subdural space resulted in no growth.

The child's subsequent progress was satisfactory. Her temperature was normal on the third post-operative day and remained so with continued clinical improvement. The hemiparesis improved slightly during her stay in hospital and she was discharged on the ninth post-operative day. She has since been followed up as an out-patient, and there has been a return of function of the left upper and lower extremities and she is developing normally. This child has been under observation for more than one year.

Case 2

A 5-weeks-old female infant developed fever and irritability 10 days before admission. On the fifth and third days before admission generalized convulsions occurred. At this time she was admitted to another hospital and received an unspecified amount of penicillin. Lumbar puncture there revealed a purulent meningitis, but no organism was isolated. She was immediately transferred to the Contagious Disease Hospital, where she was treated with intravenous oxytetracycline, 50 mg. every six hours. The temperature of 102° F. (38.9° C.) returned to normal in 24 hours.

The baby was transferred to the Children's Memorial Hospital because of diarrhoea and abdominal distension, which followed recommencement of oral feeding. The abdominal condition rapidly improved, but on the day following admission her temperature was again 102° F. (38.9° C.) and lumbar puncture yielded a cloudy fluid containing 110 and lymphocytes per c.mm., protein 92 mg. per 100 ml., and glucose 34 mg. per 100 ml. The white-cell count on admission was 26,000 per c.mm. Antibiotic therapy was continued and the temperature was again normal on the fifth day after admission.

On admission the anterior fontanelle was said to be flat, but on the third day it was described as "full," and three days later as "bulging but not tense." Bilateral subdural taps were then performed and 6 ml. of light yellow fluid was obtained from the left side and 4 ml. of a darker-coloured fluid from the right. The fluid from the right side contained protein, 2.8 g. per 100 ml., that from the left 0.9 g.

Subdural taps were repeated on four occasions during the next 10 days with decreasing amounts of fluid at each tap from the right side until no further fluid was obtained. The left side continued to yield 6 ml. on each occasion, containing protein about 0.6 g. per 100 ml.

The child was making good progress, was feeding well, and had a normal temperature. The white-cell count was now 10,000 per c.mm. She was accordingly discharged home and returned on two occasions subsequently, at intervals of one week, when the left subdural space was tapped. There was 2 ml. of yellow fluid at the first tap (protein 0.67 g. per 100 ml.; 52 W.B.C.). No fluid was obtained on the second occasion.

She subsequently made good progress. There were no neurological defects, and at 18 months of age she appeared to be normal. At no time were organisms seen on smear or grown by culture from either the C.S.F. or subdural fluid.

Case 3

The patient was a baby girl of 5 months. Her antenatal development and birth were normal. Post-natal development so far was normal and she was said to have been quite well until three weeks before admission to hospital, when she had an upper respiratory infection which progressed to

Subdural Effusions Complicating Meningitis

Although I can give only two examples of effusion complicating meningitis, I feel that in past years, before certain antibiotics were obtainable in England and before treatment of the meningitides had been accurately worked out, I must have had others.

Case 7.—A female neonate was treated at a maternity hospital for 16 days for what was undoubtedly a septicaemia with meningitis, organism undiscovered. She was transferred to a children's hospital because of convulsions. The urine contained pus and *E. coli* and the fontanelle was bulging. C.S.F.: 32 cells per c.mm., mostly lymphocytes; protein, 130 mg. per 100 ml.; globulin, slight excess; chlorides, 635 mg. per 100 ml.; sugar, 35 mg. per 100 ml. A bilateral subdural tap yielded an amber-coloured fluid containing a protein concentration of 1,000 mg. per 100 ml. Subdural taps were repeated on the following days, and antibiotics were continued. The infant was discharged a month after admission, and at 7½ months of age was sitting up unsupported, appearing normal in every way.

Case 8.—A male infant was transferred to my care at 3 months of age because of vomiting. He had been under treatment with various antibiotics for "acute pneumonitis." The head was retracted, neck stiff, fontanelle full, and the disks were normal. C.S.F.: 38 cells per c.mm.; 160 mg. protein, 710 mg. chloride, and 37 mg. sugar per 100 ml. From 10 to 40 ml. of yellow fluid was withdrawn from each side by subdural tap on 16 successive days—a total of 563 ml. of subdural fluid. Mr. Pennybacker subsequently operated and removed a membrane from the left hemisphere.

Treatment

Specific treatment is primarily the concern of the paediatrician, who should withdraw the subdural fluid on each side daily until it becomes difficult to obtain. This is really a method of producing gradual decompression, and may take anything from a few days to a few weeks. An antibiotic such as procaine penicillin 300,000 units or oxytetracycline 20 mg. per lb. (40 mg. per kg.) body weight should be given daily as a prophylactic or to clear up infection in the respiratory passages or elsewhere. A considerable amount of protein is lost in the subdural fluid, and this should be made good by one or more transfusions of citrated blood. Some infants show an increasing anaemia, so that transfusions of blood serve a double purpose. The nutrition is as often as not below average, sometimes much below, and good feeding during the pre-operative period enhances the prospects of successful operation.

When the infant is transferred to the care of the surgeon the presence of solid clot or membrane is determined by inspection after making burr-holes in the temporal region in the first place, and elsewhere if necessary. If clot and membranes are found, bone flaps are turned down and the tough outer membrane is attached to the dura, and the thin membrane and clot over the pia are removed on one side and, at a later date, on the other.

As has been seen, subdural haematomata that are discovered within a few days of birth can be successfully treated by subdural taps without resort to operation.

Subdural effusions as a complication of meningitis undoubtedly occur more often than has been realized, particularly after infection by *H. influenzae*—not only one of the most frequent infections in early infancy but also one of the most difficult to treat—and also after pneumococcal and meningococcal infections. Smith (1953) states that subdural taps alone seem to constitute adequate local therapy in these effusions, which generally clear up within three weeks. On the other hand, McKay and his colleagues (1953) achieved success by subdural tap in only 15 out of 50 cases, for the remaining 35 needed craniotomy as well.

One may conclude that small sterile effusions often arise in the course of treated meningitis and clear up spontaneously. Effusions which become clinically recognizable may be sterile or infected, and clear up in response to subdural taps and continued antibiotic therapy. If definite membrane formation has taken place and the contents of the sac are infected, subdural taps alone are unlikely to effect cure, and

craniotomy will be necessary. Subdural taps should be initiated when adequate antibiotic treatment of the infection does not bring down the fever, sterilize the spinal fluid, and abolish symptoms in three or four days.

Discussion

The detection of subdural effusions may fall to the lot of all who have to do with the medical care of young infants—the obstetrician, the paediatrician, and the general practitioner—whether in hospital or in the home. As has been seen, certain signs and symptoms found in such effusions are common to a number of unrelated conditions. Vomiting, anaemia, and wasting, and even convulsions in early infancy are so much more related to digestive disturbances and infection that the real nature of the trouble may escape recognition unless careful examination of the nervous system is a repeated routine. A simple and neglected procedure is the measurement of the circumference of the heads of young infants from time to time as a means of estimating normal and abnormal growth.

A history of a normal or non-instrumental labour should not put the physician off guard, for the real quality of the labour is often unknown unless good hospital records are kept; and, in any case, birth injuries occur in deliveries that have been apparently normal. It must be remembered that post-natal injuries, or a knock on the head, can cause subdural effusions of blood, though the history of such injury is always more forthcoming, and evidence of fracture in the skull x-ray film is more often associated with it, than with injuries incurred at birth.

Conclusion

Subdural haematomata and inflammatory effusions are best prevented by good obstetrics, and by early diagnosis and correct antibiotic therapy. When they do occur, early recognition and appropriate treatment should reduce to the minimum the incidence of sequelae such as paralysis, spasticity, mental defect, and death. Ingraham and Matson (1954) are able to state authoritatively after 14 years' follow-up that 70 to 80% of the children who had been surgically treated appear to be developing mentally for their age, and that residual neurological signs and post-operative convulsions are uncommon. The retarded and deficient children have been for the most part those with large chronic haematomas with marked atrophy of the hemispheres well established when the membranes were removed.

In 1955 there were 759,571 donations of blood, compared with 700,202 in 1954. This is the largest number recorded. 116,410 people gave their blood for the first time to the National Blood Transfusion Service last year, and at the end of December the total strength of the donors' panel was 591,204, compared with 540,389 a year before. The National Blood Transfusion Service needs at least 650,000 regular donors to make sure that adequate supplies of blood are available to meet the needs of the hospitals, to replace the older donors when they reach the age of 65, and to provide adequate reserves of blood plasma. Anyone who is in normal health and between the ages of 18 and 65 is welcomed at the donor sessions, which are held frequently in convenient places throughout England and Wales.

VIADRIL: A NEW STEROID ANAESTHETIC**PRELIMINARY COMMUNICATION**

BY

L. H. LERMAN, M.R.C.S., D.A.

Consultant Anaesthetist, Moorfields, Westminster and Central Eye Hospital

Ideal anaesthesia is seldom carried out to-day with only one agent. Like "all Gaul," such an anaesthetic consists of three parts: (1) a basal narcotic—for example, thiopentone sodium; (2) a muscle relaxant—D-tubocurarine chloride ("tubarine"), gallamine triethiodide, curarine chloride ("tubarine"), and (3) an analgesic—suxamethonium chloride, etc.; and (3) an analgesic mixture of nitrous oxide and oxygen with or without such adjuvants as trichlorethylene or pethidine.

"Viadril" (21-hydroxypregnane-3:20-dione sodium succinate) telescopes the narcotic and relaxant functions and requires only minimal nitrous oxide and oxygen to maintain anaesthesia. This substance is revolutionary in that it is a steroid. It bears no resemblance, therefore, to any group of drugs hitherto used or contemplated for the purpose. Viadril is a non-volatile crystalline solid, freely soluble in water, the solution having a pH of 7.8 to 10.2.

History

Selye (1941, 1942), investigating many different steroids in 1941, noted that some of these caused depression and the anaesthesia in laboratory animals. Further work on the anaesthesia in laboratory animals. Further work on the pharmacology of some of these compounds was carried out by Elliott and Gordan (1947). Laubach *et al.* (1955) investigated a large number of these compounds in animals and found 21-hydroxypregnane-3:20-dione sodium succinate to be the most satisfactory.

Viadril

It was found to have a wide margin of safety, the therapeutic index in mice being 11.1, as compared with 4.6 in thiopentone sodium. In anaesthetic doses it did not produce significant hormonal effects or cause salt retention. Gordan *et al.* (1955) studied its effects on cerebral metabolism in man, and reported changes identical with those of barbiturate anaesthesia. Thus emboldened, they used the drug together with nitrous oxide for a prefrontal leucotomy.

Murphy *et al.* (1955) described a series of 125 patients anaesthetized with viadril. The duration of anaesthesia varied from 1 to 10 hours.

The known disadvantages of viadril anaesthesia are the risk of venous thrombophlebitis and the slowness of induction.

Venous Thrombophlebitis.—This occurred in three of the cases described by Murphy *et al.* Their three patients, however, had severe pre-existing vascular disease. In an attempt to obviate this I injected the drug slowly into the giving-set tubing of a normal-saline drip, just below the inspection chamber. The drip was set to run at its fastest into a large vein of the arm. Two of the cases here

reported (Nos. 7 and 19) developed thrombophlebitis in spite of these precautions. In Case 7 on the day after operation the patient complained of a painful red swelling of the forearm and arm, which he did not regard as of major importance and which improved steadily day by day. A week later a cord-like thrombosis started at the site of injection in the cephalic vein at the wrist and extended by minor vessels on the volar aspect of the forearm to the basilic vein, which was thrombosed almost as far as the axilla. The veins were slightly tender throughout their length and there was some limitation of extension at the elbow due to tenderness.

Thrombophlebitis in the median basilic vein developed in Case 19. Five days later this could be felt as a solid cord from the elbow to the axilla, and was discoloured throughout its length. It was not, however, very painful or tender.

Slow Induction.—This is a marked feature of the drug and is something of a problem in the course of a busy operating session. Doubtless further chemical research on the compound will disclose a substance with a shorter time-lag. Gordan *et al.* (1955) suggest, in fact, that an intermediate metabolite of viadril is the cause of the anaesthesia. This would explain the delay in onset of unconsciousness. A search for this substance is being carried out.

Pharmacology

In many endocrine disorders disturbed mental or psychological function is seen. Myxoedema, hypoglycaemia, hypoparathyroidism, hypopituitarism, and Addison's and Cushing's diseases are examples which spring readily to mind. The use of cortisone and corticotrophin has familiarized many with the dramatic euphoria and psychoses which these agents provoke.

Merryman *et al.* (1954), whilst investigating progesterone in psychiatric practice, found that several of their patients fell asleep. Woodbury (1952) studied the effect of steroids on electric convulsion therapy. He showed that deoxycortone is a powerful anticonvulsive agent.

The steroids exert a regulatory influence upon cerebral metabolism, as shown by the high rate of oxygen uptake of the brain of the castrate immature male rat. By administering various steroids this increased oxygen uptake can be reduced. The steroids with the androstene nucleus (including testosterone and 21-C steroids) can restore this "braking" action, which is normally exerted upon cerebral metabolism by the sex hormones.

The intravenous injection of viadril causes loss of consciousness, analgesia, absent corneal reflex, and muscular relaxation, particularly of the larynx. It has no demonstrable hormone effects. No electrocardiographic changes have been observed. No haemolysis occurs with its use. There is no depression of respiration. Slight pain is sometimes noted in the recipient vein with dilutions higher than 2.5%. Hypotension commonly occurs, but small doses of pressor drugs soon restore the blood pressure. Nitrous oxide has a remarkable synergism with viadril. If necessary, relaxant drugs, pethidine, and the volatile anaesthetic agents can be given at the same time as viadril, though much smaller doses are needed.

Technique of Administration

Viadril was supplied for this clinical trial in bottles containing 500 mg. The addition of 19.8 ml. of normal saline results in a 2.5% solution. This is injected into the tubing of a giving-set, as already described. If the patient is engaged in conversation he will say he feels nothing. After a minute or two the creases in the face begin to smooth out. Blinking begins and finally the eyes close. Soft snoring supervenes a minute or two later. This process takes about five minutes. The observer cannot but be struck by its resemblance to the coming of ordinary sleep. The fact that viadril is a steroid promotes interesting speculation into the mechanism of normal sleep. Viadril induction is quite different from thiopentone induction. There is

no yawning or sighing. The patient has no feeling that "something is about to happen." There is no unpleasant smell or taste.

After the patient has fallen asleep, quite naturally as it were, he remains peacefully in that condition. There is no stertor. The colour remains pink and the pulse is unchanged. The patient is now allowed to breathe 20-30 breaths of a nitrous oxide and oxygen mixture in the proportion of 3 litres of the former to 1 litre of the latter. This dilute mixture can be given with the utmost confidence, owing to the remarkable synergistic effect of nitrous oxide and viadril.

At the end of this induction it will be found that the laryngeal reflex has been obtunded and intubation with a cuffed tube can now be carried out. The patient may "buck" slightly but soon settles down. With the doses that I have used breathing continues normally and hyperpnoea may occur, but in spite of this there is very little resistance to assisted respiration and the patient's breathing can be "taken over" almost at once. Relaxation is good, though not comparable to that of gallamine triethiodide or suxamethonium. Bleeding is usually much reduced. The blood pressure may fall, but it responds very quickly to small doses of vasopressors. Throughout, the colour of the skin is pink. At the end of operation the nitrous oxide is cut off and coughing begins, quickly followed by grimacing. On return to the ward the patient lies in an apparently normal sleep. After a short period he can be roused. At the end of an hour or so he is fully awake, and in reply to questions will say he feels well and is in no pain. Euphoria is a distinct feature of this agent. Vomiting occurred in only one of the cases here reported.

At all times my supplies were restricted, and it will be seen that only one patient received as large an amount as 1,250 mg. of viadril (Case 6).

American workers report the use of other adjuvants, pethidine, gallamine triethiodide, and suxamethonium being used. It must be remembered, however, that the duration of their operations much exceeds common British practice. Analysis of one American series (personal communication) of 57 cases in which viadril was given yields the following figures. Of the 28 cases in which the duration is mentioned

the average time was 3½ hours, the individual times ranging between half an hour (one case) to 8½ hours (one case). The average dose of viadril was 1,301 mg., ranging from 500 (one case) to 3,000 mg. (one case). Of these cases, 18 received pethidine, the average dose being 66.6 mg., ranging from 15 (one case) to 210 mg. (one case). The other adjuvants mentioned were thiopentone, 175 mg.; 2 ml. of D-tubocurarine chloride and suxamethonium chloride for the peritoneal closure; D-tubocurarine chloride, 5½ ml.; D-tubocurarine chloride, 4½ ml.; "small amounts of suxamethonium"; and "a suxamethonium drip" (no total mentioned).

In my series of 19 cases the average time was 26 minutes, ranging from 8 (one case) to 90 minutes (two cases). The average dose of viadril was 824 mg., ranging from 500 (two cases) to 1,250 mg. (one case). All except three were pre-medicated with "omnupon," ½ gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.). In Case 4 morphine, ½ gr. (22 mg.), and atropine, 1/100 gr. (0.65 mg.), and in Case 8 morphine, ½ gr. (11 mg.), and atropine, 1/100 gr. (0.65 mg.), were given; another had pethidine, 100 mg., and atropine, 1/100 gr. (0.65 mg.). None received pethidine during the operation. Case 6 (see below) required 80 mg. of gallamine triethiodide and Case 8 50 mg. of suxamethonium. Local infiltration of lignocaine and adrenaline to obviate bleeding was used as routine in three cases (two thyroidectomies and one dacryocystorhinostomy). Chlorpromazine was used in Case 1. No significant reaction was noted.

A précis of the anaesthetic case histories is given in the Table, and three fuller histories are given to bring out various points.

Illustrative Cases

Bad Risk: Case 8.—Man aged 76. General condition very poor, ears cyanosed, tongue very dry and furred. Emaciated. Ill for six weeks with "stomach trouble." Very deaf; extremely difficult to take history. Barium enema previous week showed "large filling defect" of stomach. Perforated eight hours previously. Premedication: morphine, ½ gr. (11 mg.), and atropine, 1/100 gr. (0.65 mg.). Temperature 102° F. (38.9° C.), pulse 112, B.P. 160/100. At 11.33 viadril, 400 mg., injected into drip. 11.38: patient

Summary of Anaesthetic Case Reports

Case No.	Sex and Age	Operation	Pre-operative Condition	Pre-medication	Viadril (mg.)	Conduct of Operation	Length of Op. (min.)	Post-operative Condition	Vomiting
1	M 73	Cystoscopy; extravesical prostatectomy; bilateral vasectomy	Very good; has large scrotal hernia. B.P. 140/80	Omnupon, ½ gr.; scopolamine 1/150 gr.	750	Excellent relaxation. Hypotension relieved by methylamphetamine 30 mg. Chlorpromazine 50 mg. intramuscularly*	60	After ½ hour could be roused; said, "I feel all right." Eight hours later was reading newspaper. Developed thrombophlebitis	No
2	M 55	Cystoscopy; extravesical prostatectomy, bilateral vasectomy	Excellent. B.P. 120/70	Omnupon ½ gr.; scopolamine 1/150 gr.	750	"Some fullness" in arm during induction. Relaxation excellent. Patient almost "apnoeic at will"—i.e., breathing can be easily taken over. B.P. fell to 155/90	62	1½ hours later: excellent condition, says he has no pain	"
3	M 73	Transvesical prostatectomy; bilateral vasectomy	Fair. Was admitted 4 days earlier for emergency supra-pubic cystostomy for retention. 84 fl. oz. urine evacuated from bladder. Haemoglobin 69%; blood urea, 105 mg./ml. B.P. 170/80	Omnupon ½ gr.; scopolamine 1/150 gr.	750	Patient coughed once or twice. When N ₂ O/O ₂ mixture was raised from 3/1 to 6/1 patient relaxed. B.P. fell from 170/80 to 95/50, but methylamphetamine 15 mg. restored this to 150/80	40	Patient answered to his name ½ hr. later. Four hours later was in excellent condition and free from pain	"
4	M 80	Partial thyroidectomy	Good. Deviation of trachea. B.P. 210/100	Morphine ½ gr.; atropine 1/100 gr.	500	Local infiltration of lignocaine and adrenaline. Excellent anaesthesia. B.P. fell to 120/70. Surgeon says, "practically no bleeding"	33	Twenty minutes later was rousable. One hour later: sitting up; says he is "dry"	"
5	M 47	L. Keller's operation	Good	Omnupon ½ gr.; scopolamine 1/150 gr.	750	Very satisfactory	30	75 minutes later patient dozing. On being roused says "feels fine"	"

* Routine: This surgeon uses adrenaline 0.1 mg. in 60 ml. water as a prostatic capsule haemostatic. The chlorpromazine is here used as a prophylactic against pressor effects. B.P. fell steadily until unreadable, though pulse good. Methylamphetamine 30 mg. restored B.P. to 120/70 immediately.

Summary of Anaesthetic Case Reports.—Contd.

Case No.	Sex and Age	Operation	Pre-operative Condition	Pre-medication	Viadril (mg.)	Conduct of Operation	Length of Op. (min.)	Post-operative Condition	Vomiting
6	M 75	See text							
7	M 53	Excision of hydrocele	Good	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Some hyperpnoea, but soon abolished by raising N ₂ O/O ₂ mixture from 3/1 to 5/1	18	Two hours and a half later: dozing—says "feels fine" Developed thrombophlebitis	No
8	M 76	Laparotomy	See text						
9	M 29	Trendelenburg. Stripping of veins of lower limb	Good. Is a eunuch (post-mumps)	Omnupon ½ gr.; scopolamine 1/150 gr.	750	Patient "bucked" on tube a good deal. Owing to shortage of supply only 750 mg. viadril given. Would have been better with 1,000 mg. B.P. pre-op. 100/60; during operation 120/60	30	Patient dozing in ward an hour later but easily roused	No
10	F 50	Local excision of tumour of breast	Good. B.P. 135/80	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Very relaxed throughout. Very satisfactory result. B.P. fell to 85/60	25	Two hours later patient sitting up in bed	"
11	M 20	Right inguinal herniotomy	Good. B.P. 145/75	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Good anaesthesia. Surgeon complained at beginning of operation that muscles were tonic, but assisted respiration obviated this	21	Two hours later patient sitting up in bed	"
12	F 32	See text							
13	F 17	Right lateral rectus resection and recession	Excellent. B.P. 130/65	Omnupon ½ gr.; scopolamine 1/150 gr.	750	Very quiet smooth anaesthesia. B.P. rose to 150/100 (? CO ₂ retention) then fell to 115/70	11	Quickly recovered	No
14	F 39	Rt. dacryocystorhinostomy	Good. Apprehensive. B.P. 110/70	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Asleep under five minutes. Nose packed with gauze soaked in 0.2 ml. cocaine hydrochloride 15% containing 0.5 ml. adrenaline (1:1,000). Local infiltration of eyelids with lignocaine containing 1:80,000 adrenaline. After intubation nasopharynx packed. B.P. rose to 135/80. Excellent anaesthesia. Colour pink, bleeding minimal, quiet respirations; B.P. 85/60. Pulse 80	70	Forty minutes later patient says she feels fine; "eve does not hurt"	Yes
15	M 50	(1) Right inguinal herniotomy. (2) Appendicectomy	Good. Fat man; looks old. Thyroidectomy 20 years previously (? myxoedema)	Omnupon ½ gr.	750	B.P. fell steadily from 100/80 to 60/50 at 42nd minute. Pulse 70. Methylamphetamine, 15 gr., had no effect. On repeating dose B.P. rose to 130/80. Two hours later in ward, sitting up, delighted to have had operation. Surgeon's comment: "Certainly does not look like man who had an operation two hours ago"			No
16	F 35	Local excision of tumour of breast	Excellent. B.P. 130/100	Omnupon ½ gr.; scopolamine 1/150 gr.	750	Asleep in five minutes. Easily intubated under N ₂ O/O ₂ 3/1	20	Seen by surgeon 3½ hours later. Patient sitting up in bed complaining of slight headache	"
17	M 53	Dilatation of urethra	Good	Omnupon ½ gr.; scopolamine 1/150 gr.	500	No nitrous oxide. Slept peacefully throughout procedure. Jaw not relaxed. Breathing quiet; B.P. fell from 195/100 to 130/80, with pulse 66	8	Excellent. Rapid recovery	"
18†	F 50	Radical mastectomy	"	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Very satisfactory anaesthesia. Bleeding very troublesome. This was due at first to slight respiratory obstruction due to kinking of endotracheal tube. Excessive bleeding persisted after this had been dealt with and in spite of fall in B.P. from 160/90 to 115/105 and very quiet respiration; transfused with 1 pint of blood during operation	90	Fair. Coughing at end of operation but appears shocked. P. 110. Contents of re-breathing-bag show CO ₂ content = 0.3%. Collapsed after return to ward and required further pint of blood to restore her condition	"
19	F 28	Partial thyroidectomy	Good, thin; was toxic 3 months previously but not now; has been treated medically	Omnupon ½ gr.; scopolamine 1/150 gr.	1,000	Local infiltration with lignocaine and adrenaline. Breathing quiet and shallow. Occasionally "bucked" slightly when trachea was disturbed, but assisted respiration overcame this within 3 or 4 breaths. Very satisfactory anaesthesia	90	Excellent. Coughed as soon as tube was removed and nodded head when spoken to. 80 minutes later patient conscious in ward; had slightly sore throat when swallowing. Developed thrombophlebitis	"

† This is the same patient as Case 10.

sleeping lightly; viadril, 250 mg. (total, 650 mg.); ears now pink. N_2O/O_2 (3/1) begun; patient intubated. 11.45: on table, almost apnoeic; B.P. 170/70, pulse 120. 11.50: abdomen opened; fluid in peritoneum (stomach contents); carcinoma of stomach found with many secondaries in liver; B.P. 150/80, pulse 150. 12.05: operation very difficult on account of secondary involvement of mesentery, peritoneum, colon, etc., and adhesions between all these organs. Blood transfusion begun. The perforation could not be found. Three pints (1.7 litres) of fluid were aspirated from the peritoneum and the heart began to fibrillate (B.P. 100/60, pulse 118, respirations 36). Methylamphetamine hydrochloride, 30 mg., restored the B.P. to 120/80. At 12.30, the perforation not having been found, the peritoneum was closed. One-half was sutured with ease. The patient now began to tighten up. Suxamethonium, 50 mg., relaxed him at once. The operation was completed at 12.40; the patient was then pale, but pink, with a dry skin. The pulse was of good volume but fibrillating. Death occurred on the fifth post-operative day.

Very Satisfactory Anaesthetic: Case 12.—Woman aged 32. Operation: medial rectus recession. Premedicated with omnopon, $\frac{1}{2}$ gr., and scopolamine, 1/150 gr. B.P. 110/70. At 9.59, viadril, 750 mg. (B.P. 130/65, pulse 120). 10.02, asleep. 10.04: N_2O/O_2 (3/1) begun. 10.06: intubated. 10.12: patient nearly apnoeic (B.P. 115/60). 10.20: breathing regular and of adequate volume. 10.25: operation completed, N_2O/O_2 stopped; coughed immediately. At 11.00 the patient was seen in the ward, sleeping. Easily aroused, she asked—although the conjunctival sac of the affected eye was filled with blood—“Have I been done?” and when reassured said, “Lovely; I’ve been asleep.”

Unsatisfactory Anaesthetic: Case 6.—Man aged 75. Operation: herniotomy and repair; orchidectomy. A very fit, well-built man who appeared younger than his years. B.P. 180/80. At 11.04, viadril, 750 mg. 11.12: patient was “just asleep,” N_2O/O_2 (5/1) begun. 11.17: not relaxing; viadril, 250 mg. 11.22: unable to intubate. 11.30: viadril, 250 mg. 11.35: intubated; still coughing. 11.40: relaxing (B.P. 100/60). 11.45: methylamphetamine hydrochloride, 20 mg. 11.48: patient still coughing (B.P. 110/70). 11.50, N_2O/O_2 still running at 5/1; patient resented cord being pulled. 11.53: orchidectomy complete; operation proceeding with difficulty. 12.10: gallamine triethiodide, 80 mg. 12.15: B.P. 120/80, pulse 100. 12.25: operation completed, neostigmine, 25 mg., atropine, 1/100 gr. (0.65 mg.), patient began to cough immediately. N_2O cut off.

On consideration of Case 6 it was thought that the viadril when being injected into the tubing of the drip was going up into the saline bottle. As a result the routine was instituted of closing off the tubing by means of a clamp whilst the injection was actually being given, a few millilitres at a time; stopping the injection; opening the clamp to dilute the viadril; then repeating the process as often as necessary until the full dose had been given.

Summary

A steroid, viadril (21-hydroxypregnane-3:20-dione sodium succinate), has been used as an anaesthetic in 19 cases. The pharmacology of the drug is discussed and the mode of administration described. Usually pre-medication was with omnopon and scopolamine, and maintenance by nitrous oxide and oxygen. In some cases relaxants were also given.

Viadril anaesthesia resembles normal sleep; relaxation is fairly good and bleeding usually much reduced. The patient is fully awake in an hour or so after operation, feeling well and without pain. Hormonal effects are absent and vomiting is rare.

Disadvantages are the slowness of induction and the risk of thrombophlebitis in the injected arm. Measures to combat these are suggested.

Details of the 19 cases are tabulated, and three case histories given to emphasize special points.

I am indebted to my surgical colleagues at the Moorfields, Westminster and Central Eye Hospital (Royal Westminster Branch and Highgate Annexe), the Connaught Hospital, Walthamstow, St. John's Hospital, Lewisham, and the Lewisham Hospital for their patience and interest in this clinical trial; to Dr. Gilbert S. Gordan, of the University of Medicine, San Francisco, for his great help; and to Messrs. Pfizer Ltd., and especially Dr. A. M. Brunton, their deputy director of medical services in the United Kingdom, for the supply of viadril and for much of the information contained in this report.

FAMILIAL TUBEROUS SCLEROSIS

BY

W. M. JORDAN, B.M., B.Ch., D.Obst.R.C.O.G.
Late Senior House Officer, Solihull Hospital; Lately
Captain, R.A.M.C.

Tuberous sclerosis was first diagnosed in 1880 by Bourneville, who described the case of an epileptic imbecile who died of the disease; and the disease was named after the discoverer. The fully developed disease is manifested classically by infantile epilepsy, mental defect, and the characteristic facial eruption of adenoma sebaceum. It is a rare hereditary disorder of tissue growth, in which many different tissues may be affected and many varying clinical syndromes found. It may be familial, and such an afflicted family is described.

Family History

The composition of the family is shown in Fig. 1. The family is mainly domiciled in Malta, and is compounded of mixed Anglo-Maltese racial stock. The heredity is com-

FIG. 1.—Family tree, showing four members affected with tuberous sclerosis. The ages of living members examined are shown. The grandfather married his first wife's sister.

plicated by the two marriages of the grandfather, who married his deceased wife's sister. The four patients affected by tuberous sclerosis are all alike, showing the typical facies, and anxious family inquiry is made whenever a child is born into the family. All other members of the family are of normal facial appearance and are reputedly healthy.

Case 1

This young girl died in convulsions at the age of 14 years in 1935. Zahra Neumann (personal communication) states

that the girl had suffered all her life from major epilepsy, and that the attacks increased in severity with the onset of puberty. She had a developmental asymmetry of the face, but did not show the lesions of adenoma sebaceum. She suffered also from congenital heart disease, and from retarded mental and physical development. No post-mortem examination was made, so the diagnosis of tuberous sclerosis as the cause for the congenital epilepsy is inferential.

Case 2

This patient, a woman of 39, is the mother of five children, including Cases 3 and 4. She is the half-sister of Case 1, having the same father, and their respective mothers being siblings. As a child she suffered from major epilepsy, and in early adult life from minor epilepsy. She was slow and late in development and was backward in her speech, and for many years she had a bad stammer. She was always shy and retiring when young on account of her peculiar skin condition and stammer. She has never suffered from any other illnesses.

FIG. 2.—Case 2. Photograph showing pronounced adenoma sebaceum.

When examined her face showed a pronounced degree of adenoma sebaceum (Fig. 2). The lesions covered the whole face and forehead and upper neck anteriorly. They were largest around the naso-labial folds, where some of them were of the size of a split-pea, and others protruded as pedunculated excrescences above the skin. They were discrete and pinkish in colour. They diminished progressively in size peripherally, until they could be picked out as small elevated pinheads above the skin, which contained telangiectatic capillaries.

The adenoma sebaceum had been present as long as she could remember, and the lesions had increased imperceptibly in size over the years. Some of the larger adenomata with well-developed pedicles had been treated by the constriction of horse hair around their bases.

Physically she is now a very healthy woman, with no other congenital signs. There are no associated congenital abnormalities, and radiographs of the skull and extremities and of the lung fields are all normal.

Mentally she presents as a woman of average intelligence, alert and lively, and quick in her responses to novel situations or to formal tests. She is stable and well balanced, runs her house and family affairs very capably, and can plan her future course of action ahead. She has a normal pleasant personality, and is an excellent mother to her five children.

Case 3

This patient, a schoolboy aged 13, is the second child of Case 2. He was a full-term infant of a normal and easy birth, but his mother could tell at birth that he was going to have “her kind of skin.” He developed well until he was 9 months old, when he began to have major epileptic fits. These fits were very violent for two years. He occurred about once a fortnight for these convulsions, frequently cut and bruised himself during these convulsions, and was admitted to hospital on several occasions for suture and scalp injuries. He never received any sedative or anti-convulsant therapy for his epilepsy, but gradually after he

was 3 years old his seizures became less intense and less violent, dying away completely at the age of 4. He has been completely free from all epileptic attacks for nine years.

After the onset of epilepsy he regressed mentally and developmentally and became grossly retarded. He was unable to walk until he was 5½ years old, and he could not frame a coherent sentence until he was 7. But since that age he has developed with increasing rapidity. He is now in the fourth form at school and participates keenly in normal school activities. He is bilingual and can read and write English and Maltese.

Physically he now presents as a healthy active schoolboy of slight build and pre-pubertal development. He has multiple small lesions of adenoma sebaceum covering the nose and cheek and beard areas. The lesions are slowly becoming more evident, and increase in size after any trauma. He has various traumatic scars on the forehead, and occipital alopecia where an infected dermoid cyst was excised at the age of 6 years. He also has an area of alopecia in the right parietal region, where the skin is thickened and lustrous. He has no other physical or congenital abnormalities.

Psychologically he is a quiet and shy boy, who speaks English with a pronounced Maltese intonation. As Maltese is his “natural” language, exact reliance cannot be placed upon intelligence testing, but his mental age is estimated to be in the region of 8½ years (chronological age 13½ years).

Case 4

This boy aged 8½ years is the youngest son of Case 2. His mother was well during the pregnancy and free from virus infections, and had a normal easy delivery. He weighed 7 lb. 4 oz. (3.3 kg.) at birth, and was breast-fed for six months. He was apparently normal at birth, and his mother thought his facial appearance was normal. All the early milestones of physical development were passed normally; he walked when he was 18 months old; he was talkative, and spoke many common words.

He developed petit mal at 3 years, and had two or three attacks daily for a period of nine months. In an attack he would suddenly stand quietly, run to a chair or bed, stare into emptiness, and then make repeated swallowing and shivering movements; if he was approached by his parents he would push them away. Each episode lasted about two minutes, and was followed by an unnaturally deep sleep for at least two hours. There was no tongue-biting or involuntary micturition. He was treated with sedation by phenobarbitone tablets for three years. Five years have elapsed since his last attack. He started to develop the early lesions of adenoma sebaceum when he was 3 years old, coincident with his attacks of petit mal.

At a recent examination he had a pink raised facial rash of butterfly pattern distribution, with discrete red pin-point spots especially prominent by the naso-labial folds. His physical development was normal, his vision and hearing were good, and there were no abnormal physical signs in any system. Radiological examinations of the skull, hands, and lung fields were normal.

His speech was normal until the onset of his epilepsy, but from then onwards he retrogressed steadily. He gradually spoke less and less, until he appeared to his mother to have forgotten how to speak. It was the inability to talk at the age of 8½ years that induced his mother to seek medical advice and led to the whole family coming under review. He then had a vocabulary of about 40 words, all of them common objects which he could recognize in life or in pictorial representation, and to which he could ascribe the correct name; and for these words his phonation and articulation were distinct. But for the rest of the time he made unnatural crowing noises and jabbered gibberish. He understood and obeyed simple commands, such as “clap your hands.”

In his habits he is cleanly and his sphincteric control is good. He always dresses himself and manages to use a

knife and fork capably. He is placid and good-natured in temperament, without any psychotic tendencies, nightmares, or tantrums. He has never been to school or undergone any special or institutional training. He lives at home, and each morning he performs much of the routine housework, the sweeping and dusting, and drying of dishes, and does the shopping and fetches the groceries. On occasion he exhibits a striking form of stereotyped movement, a compulsive obsession to moisten objects with saliva and polish them vigorously, and other forms of repetitive hand and finger play. In summary, his vocabulary and behaviour and responses to requests are similar to those of a mongol child, and probably correspond with a mental age of about 2 years.

The remaining three children in the family are all unaffected by tuberous sclerosis. The eldest son is lively and intelligent and well developed, and is the hope of the family. The twin girls are bright self-possessed young ladies of good average intelligence. They all speak English and Maltese with equal facility.

Discussion

Tuberous sclerosis is a rare disease, but with increasing recognition of its salient features and clinical manifestations it is being diagnosed more frequently. The incidence in America has been estimated at about 1 in 500,000 in the general population (Ross and Dickerson, 1943). In London the incidence of tuberous sclerosis with mental defect is about 1 in 300,000, and the milder forms without mental defect probably occur equally often (Dawson, 1954). All surveys show an approximately equal sex incidence. The family here reported contains the first cases diagnosed in Malta.

Tuberous sclerosis is a congenital disorder in which tumour-like masses are found in large numbers in many of the tissues of the body. These lesions are not confined to tissues of a single germinal layer, for the abnormalities of skin and brain are ectodermal and those of the kidneys, heart, and lungs are mesodermal in origin. The lesions are remarkably non-progressive and show little tendency to grow in size during life. The cutaneous lesions of adenoma sebaceum may not be apparent at birth, and often become prominent only when the normal adolescent development of the sebaceous glands takes place; but after puberty they remain static and may even regress slightly. There is no evidence that these multiple tumours could be caused by a placenta-passing virus or that there are any exogenous aetiological factors. Tuberous sclerosis is a true tissue dysplasia, beginning in the earliest months of foetal life.

Dickerson (1951) has published a complete review of the familial occurrence of tuberous sclerosis. When a family is affected cases may be found in different generations, and many members may be sufferers. In one family which he reported there were eight cases; and in a family subsequently reported by Dawson (1954) a mother and 9 of her 12 children were affected, most of them suffering from mental defect and epilepsy.

The precise pattern of inheritance has been investigated by Penrose (1938), who concluded that the disease was transmitted by a dominant gene. The great clinical variation in the heterozygous state he explained by the existence of modifying genes in the same zygote, which might lead to abortive forms or might even completely mask the dominant gene. The homozygous state has never yet been reported.

Half of the patients suffering from tuberous sclerosis have no relatives at all affected by the disease. These cases must have arisen by mutation, and if it were not for the high mutation rate the disease would have died out rapidly owing to its dysgenic effect.

One interesting factor in the heredity of such a pleomorphic disease is that in many families the pattern of the disease remains remarkably constant. Thus the prognosis for the younger children and infants may be assessed and evaluated by a careful examination of any affected relatives, and all members of the family should be sought out and

examined. In addition to this main hereditary pattern of the classic disease, the inconstant and rarer manifestations of tuberous sclerosis are also hereditary. Particular families have been described in which such features as nail-bed tumours, cystic phalanges, retinal tumours, shagreen skin patches, renal tumours, cystic lungs, and laryngeal polyps have all proved hereditary (Dickerson, 1951). In each family the pattern of transmission may be complicated by formes frustes in apparently unaffected members.

The diagnosis of tuberous sclerosis in a florid case of infantile epilepsy and mental defect should become obvious when the lesions of adenoma sebaceum appear. But it has now become apparent that tuberous sclerosis is a very pleomorphic disease, with lesions in many different structures and with diverse modes of presentation, which often render diagnosis difficult. Patients may present with epilepsy, with mental retardation in a child, with dyspnoea in an adult, with swellings in the loins, with facial lesions, or in many other different ways. Careful examination will almost always show other stigmata of tuberous sclerosis, although occasionally the diagnosis may be made only by finding relatives with adenoma sebaceum or other conclusive features of the disease. Thus when an adult presents with dyspnoea or spontaneous pneumothorax, and is found to have radiographic changes of honeycombing of the lungs, or when a child presents with haematuria and abdominal pain, and is found to have renal tumours or polycystic kidneys, then tuberous sclerosis must be considered in the differential diagnosis.

Confirmatory evidence is most likely to be found in the skin or the eyes, or by radiographic examination of the skull and extremities. In the skin the commonest and most obvious stigma is adenoma sebaceum. Other common diagnostic features are the patches of thickened shagreen skin, often 3-4 in. (7.5-10 cm.) in diameter, located usually in the lumbar region, and multiple subungual fibromas and haemangiomas. Ophthalmoscopic examination often discloses the retinal phakomas which are seen as several small round white plaques, about half the size of the optic disk. Plain x-ray examination of the skull reveals in 80% of cases multiple areas of low-density intracranial calcification, and scattered sclerotic plaques can be seen in the cranial vault in 40% of cases. Holt and Dickerson (1952) have demonstrated characteristic changes in x-ray films of the hands and feet in 66% of cases. These consist of localized cyst-like areas of bone destruction in the phalanges and irregular periosteal new bone formation along the shafts of the metacarpal and metatarsal bones. Careful examination of individual cases of tuberous sclerosis will often reveal other types of skin lesions, visceral tumours, or congenital abnormalities, but none of these are constant enough to confirm a clinical diagnosis.

The prognosis in tuberous sclerosis is poor, but is not as gloomy as is usually stated. Russell Brain (1951) declares that "most patients finally reach a mental state comparable with that of an advanced stage of schizophrenia. A few remain stationary at the mental level of a low-grade mentally defective patient. Death occurs early, usually before the age of 20, although some patients survive into the third and fourth decades." This is an accurate and succinct account of the course of the classical disease, and is especially true of those patients in mental deficiency institutions; but it is not a true picture of the disease as a whole, where increasing experience has shown that mild forms of the disease occur as often as the severe forms (Dawson, 1954). Mental defect probably occurs in only half of the cases, and some patients with retarded development improve surprisingly with adolescence. Although probably most tumours of tuberous sclerosis are present at birth, they often do not manifest themselves until later in life, while the pulmonary form of the disease always presents in adult life.

The prognosis in any afflicted patient may be assessed more accurately by a careful investigation and study of

other members of the family. This will often bring to light several undiagnosed cases, and, as the disease in any one family tends to breed true to type, the management of the individual is assisted by further knowledge of the family.

Summary

Tuberous sclerosis is a rare disorder of tissue growth, in which many different tissues may be involved. It is hereditary and may be familial: an Anglo-Maltese family is here described in which four members were affected. The classic descriptions of the disease, to which the name epiloia was given, concentrated on the symptom triad of infantile epilepsy, mental deficiency, and adenoma sebaceum of the face, and emphasized the bad prognosis. But only about half the sufferers exhibit the disease in this fully developed form, and milder forms with good prognosis occur just as often as the severe ones. The disease is very pleomorphic, and other common manifestations are renal or retinal tumours, and cystic lungs and phalanges. The disease is probably transmitted by an incompletely dominant gene, and in any affected family the pattern of the disease remains constant. Whenever tuberous sclerosis is suspected or diagnosed in a patient the remaining members of the family should be studied.

THE BLOOD GROUPS IN PEPTIC ULCERATION

BY

D. A. PEEBLES BROWN, M.B., Ch.B.
From the Peptic Ulcer Clinic, Western Infirmary, Glasgow

From the Southern General Hospital, Glasgow

AND

J. WALLACE, M.D., B.Sc.
From the Glasgow and West of Scotland Regional Blood
Transfusion Centre

Evidence continues to accumulate that there is a distinct relationship between the ABO blood groups and certain diseases. The incidence of Group A has been shown to be unduly high in subjects suffering from pernicious anaemia (Buchanan and Higley, 1921), carcinoma of the stomach (Aird *et al.*, 1953), and bronchopneumonia in infancy (Struthers, 1951). Group O has been found to occur with excessive frequency in persons suffering from peptic ulcer (Aird *et al.*, 1954). It has been pointed out (Clarke *et al.*, 1955) that in the latter disease the Group O excess is confined to duodenal ulcer subjects. The present communication was prompted by ABO blood groups to peptic ulcer in selected previous investigations relating to patients in English hospitals. In Scotland, important differences exist both in the prevalence of peptic ulcer in general and in the geographic distribution of the ABO blood

groups. Duodenal ulcers, as opposed to gastric ulcers, are between three and four times more frequent in Glasgow than in London (Doll, 1952); Group O is also present in a slightly greater proportion of the population than in England, Group A being correspondingly diminished.

This communication reports the results of a survey, carried out in Glasgow, into the ABO Rh(D) blood-group distribution in 2,059 patients suffering from peptic ulcer. In 276 of these subjects we have also investigated the maximum acid output of the stomach in relation to the above blood groups.

Collection of Data and Controls

The survey was carried out in two adjacent Glasgow Hospitals. The peptic ulcer clinic of the Western Infirmary supplied information relating to 1,588 cases, collected over the period 1946-55. Data concerning a further 471 subjects were obtained from the Southern General Hospital for the years 1952-5. Both in-patients and out-patients were included. The following items were recorded for each patient: site of ulcer, method of diagnosis, occurrence of previous acute complication, ABO group, sex, age, and place of residence. In 1,606 subjects the rhesus group was also noted.

It is obviously essential in a study of this type to ensure accuracy in diagnosis and in blood-grouping methods. Our criterion of diagnosis in 1,177 cases has been visualization of the ulcer at operation. In the remaining 882 patients the diagnosis has been accepted when a chronic peptic ulcer has been demonstrated by barium-meal examination and has confirmed a presumptive clinical diagnosis. These two groups of patients have been subsequently analysed separately, for we have been interested to discover whether any difference in blood-group frequency existed between patients diagnosed by x-ray examination and treated medically in the first instance, and those, presumably cases of a more severe nature, who required operation at some stage of the disease. The blood groups of the ulcer patients were determined at the Regional Blood Transfusion Centre in Glasgow for the Western Infirmary cases, and in the pathology department, Southern General Hospital, for patients from that hospital. The blood groups were specially determined for this investigation, freshly collected venous blood specimens being used. The ABO Rh(D) group was established, using two potent saline agglutinating sera. The control series was provided by 5,898 consecutive new registrations of blood donors at the Regional Blood Transfusion centre made over the period 1952-5. According to their location, the ulcers have been classified as duodenal, including juxta-pyloric; gastric; combined gastric and duodenal; and stomal.

An explanation of the excess of Group O in duodenal ulcer patients recorded by previous authors may be that there is an association between possession of blood Group O and excessive output of acid by the stomach (Koster *et al.*, 1955). We have investigated this possibility. The augmented histamine test (Kay, 1953) was carried out on 276 patients in whom the diagnosis of peptic ulcer and the ABO Rh(D) blood groups had previously been established.

Results

The basic data are recorded in Table I. The percentage increase of Group O over controls for each subgroup of cases is indicated in Table II. Although an increase is recorded in each instance, subsequent analysis reveals that only in some of the subgroups is this increase of statistical significance. Certain comparisons have been made within the material, subdividing it in a variety of ways. The primary subgrouping has been according to the site of the ulcer. In addition, our aim has been to ascertain whether clinical severity or site of the ulcer is mainly responsible

TABLE I.—Basic Data

Controls	5,898	" 83.10; " 16.90				

for the increase in Group O frequency. The duodenal and gastric ulcer groups have therefore been subdivided according to the method of diagnosis and presence of complications, on the assumption that a diagnosis based primarily on operative evidence or presentation with haemorrhage or perforation denoted a more severe type of ulcer. The diagnosis was confirmed surgically in all cases of stomal ulcer.

In analysing our figures we have compared Group O against Groups A, B, and AB individually, and not against these groups combined together. Table II shows that when Group O is increased it is not necessarily at the expense of Groups A, B, and AB to an equal extent. In certain cases when Group O is increased one of the other groups is also increased. Therefore, our χ^2 tests being in terms of all four groups, there are three degrees of freedom throughout.

Peptic Ulcer: All Cases.—The proportion of patients having Group O is considerably increased; this is statistically significant ($\chi^2=15.39$, $P<0.01$). The rhesus group distribution of 1,606 patients is recorded, and shows no significant difference from the control series ($\chi^2=0.8$): in this respect Aird *et al.* (1954) report similar findings.

Duodenal Ulcer.—A significant increase is present in the frequency of Group O in the duodenal ulcer patients compared with the controls ($\chi^2=13.15$, $P<0.01$). The results have been further analysed, depending on the occurrence of complications and the method of diagnosis. All the peptic ulcer patients who sustained haemorrhage or perforation show an excess of Group O, and this is statistically

significant ($\chi^2=11.99$, $P<0.01$). Among this group the duodenal ulcer patients are responsible for the increase in frequency of Group O ($\chi^2=10.88$, $P<0.01$), to which the gastric ulcer subjects do not contribute ($\chi^2=4.06$, $P>0.05$). In the duodenal ulcer patients whose disease was so severe as to warrant operation the increase in Group O is again significant ($\chi^2=9.21$, $0.02<P<0.05$); in contrast, among those in whom diagnosis has been confirmed by barium-meal examination it is observed that the increase in Group O, while still manifest, is no longer statistically significant ($\chi^2=6.6$, $P>0.05$). However, comparing those cases with haematemesis and perforation against the rest, there is no significant difference ($\chi^2=2.76$, $P>0.05$). Also comparing the duodenal ulcers submitted to surgery and those confirmed by x-ray examination only, there is again no significant difference ($\chi^2=1.911$, $P>0.05$). The results suggest that the more severe cases—those that required surgical treatment—make the greater contribution to the observed increase in frequency of Group O, although the difference is not statistically significant.

Gastric Ulcer.—In our series no significant difference was noted between the ABO group frequencies of patients with gastric ulcer and the controls ($\chi^2=2.24$, $P>0.05$). In actual fact, the percentage of Group O is higher in this group than in duodenal ulcer. The non-significance may be due to the smaller number of gastric ulcers (300) compared with those of duodenal ulcers (1,642). The total number of patients who had both gastric and duodenal ulcers was too small for separate analysis.

Stomal Ulcer.—The percentage increase of Group O compared with controls was greater in stomal ulcer than in any other subgroup. Although the number of stomal ulcer patients is comparatively small, statistically the excess of Group O is highly significant ($\chi^2=13.00$, $P<0.01$). Comparing the figures for stomal ulcer against all other sites of ulceration, the difference is significant ($\chi^2=7.815$, $P<0.05$). In 68 of our 79 patients the site of previous ulceration had been duodenal (Table III), and this would suggest a possible

TABLE III.—Site of Previous Peptic Ulcer in 79 Cases of Stomal Ulcer

Duodenal	68	Duodenal and gastric	1
Gastric	3	Not recorded	7

explanation of our findings. However, the possibility cannot be excluded that the greatly increased incidence of Group O in patients having stomal ulcers is a particular attribute of ulcers in this situation.

Age and Sex

Since Aird *et al.* (1954) have been unable to detect any significant difference in sex proportion or age between ulcer patients of the four ABO groups, we considered that further investigation along these lines was not justified at this time. Instead our object has been to detect whether our cases constitute a representative sample of the ulcer patients treated at the hospitals in this area. No information is available concerning patients at the Southern General Hospital, from which the smaller number of our cases were drawn.

TABLE IV.—Peptic Ulcer: Sex and Site Distribution. Comparison with Recent Series (Jamieson *et al.*, 1949)

Sex and Site Distribution			Male : Female Ratio		Gastric : Duodenal Ratio		
Site	Male	Female	Present Series	Jamieson <i>et al.</i> (1949)	Present Series	Jamieson <i>et al.</i> (1949)	
Duodenal	1,321	321	4.12 : 1	3.9 : 1	1 : 6.17	1 : 9.5	
Gastric	214	86	2.49 : 1	1.8 : 1			
"Double" ulcer, G.U. and D.U. ..	34	4	8.50 : 1	2.7 : 1	1 : 3.73 1 : 4.5		
Stomal	70	9	7.77 : 1	4.2 : 1			
Total	1,639	420	3.90 : 1	3.5 : 1			

However, at the Western Infirmary, a two-year survey of ulcer patients has been carried out (Jamieson *et al.*, 1949), in which information concerning a total of 3,258 patients was analysed. In Table IV we have recorded the site, distribution, and sex of our ulcer cases, and also the male:female ratio and the gastric:duodenal ulcer ratio, together with the results obtained by the previous authors. Excluding the cases of "double" and of "stomal" ulcers, in which the numbers are so small as to vitiate useful comparison, it will be observed that no gross dissimilarities are present. In our series a slightly elevated male:female ratio in gastric ulcer subjects with an associated depression of the gastric:duodenal ratio has been caused by a relative excess of gastric ulcers, predominantly in our male patients. While a real alteration in incidence of gastric ulcer cannot be excluded, this finding is probably due to the increasing percentage of this finding is probably due to the increasing percentage of gastric ulcers submitted to surgery, these patients having been drawn exclusively from a surgical unit.

Maximum Acid Output

In 276 patients in whom the ABO group and site of ulcer were known the maximum acid output of the stomach has been estimated. The results are presented in Tables V and VI. The maximum output in the duodenal and gastric ulcer subjects displayed the typical pattern of response to

TABLE V.—Duodenal and Gastric Ulcer: Results of Maximum Acid Output Tests

Blood Group	Duodenal		Gastric	
	No. of Cases	Acid Output. Mean Level	No. of Cases	Acid Output. Mean Level
O	136	671 mg./45 mins.	24	404 mg./45 mins.
A	73	653 " "	15	292 " "
B	17	621 " "	6	320 " "
AB	4	726 " "	1	460 " "
Total	230		46	

TABLE VI.—Duodenal and Gastric Ulcer: Statistical Relationship of ABO Blood Group and Maximum Acid Output

Duodenal			Gastric		
Difference in Acid Output	P	Remark	Difference in Acid Output	P	Remark
O-A = +18	>0.05	Not significant	O-A = +112	>0.05	Not significant
A-B = +32	>0.05	" "	A-B = -28	>0.05	" "
O-B = +50	>0.05	" "	O-B = -54	>0.05	" "

be expected in the presence of these lesions: in duodenal ulcer it was above, and in gastric ulcer within, the accepted normal range. No significant correlation could be demonstrated between acid output and blood group in either condition.

Discussion

The outstanding fact emerging from recent investigations into the relationship of ABO blood groups to disease is that the groups have a selective value, conferring a relative immunity or susceptibility to certain disorders. Further, in adult life, alterations in blood-group distribution occur most strikingly in association with pathological lesions of the stomach and duodenum. In this communication an excess of Group O is again recorded in duodenal ulcer patients. We have also been able to demonstrate a statistically significant Group O excess over the controls in duodenal ulcer when surgical treatment was required but not when the diagnosis was made by x-ray examination in the first instance, although these two groups do not differ significantly from each other. This difference may not be real, and would require a larger series to confirm or refute the possibility that an increased frequency in Group O is more marked in the more severe type of case. Further work would be required before the relationship, if any, between

Group O excess and severity in duodenal ulcer could be established. Similar considerations apply to stomal ulcer, which is recognized to be one of the most intractable forms of peptic ulceration. In this type the considerable Group O excess may be attributable either specifically to the site of the ulcer or to the duodenal ulcer which so often precedes it.

The selection of a control group presents a well-recognized difficulty (Allan, 1954). Hospital patients are unsuitable, because a proportion of them suffer from diseases which are known to have associations with certain blood groups. For example, at the Western Infirmary, Glasgow, in the period 1946-8, 4.3% of in-patients and 10% of out-patients were shown to be suffering from peptic ulcer (Jamieson *et al.*, 1949). We have therefore relied on data made available by the Regional Blood Transfusion Centre in Glasgow concerning consecutive donor registrations collected over a recent period.

Thomsen (1927) suggested that the distribution of the blood groups changed with increasing age. On theoretical grounds this is unlikely, as the human blood groups are widely accepted as being immutable inherited characteristics. Bryde Andersen (1955) has since failed to confirm the presence of a relationship between age and ABO group distribution, and Aird *et al.* (1954), with one possible exception, did not observe any significant difference in age between ulcer patients of the four blood groups.

The reason for the excessive frequency of Group O in peptic ulcer subjects remains obscure. Koster *et al.* (1955) have pointed out that there is an association between high acid output by the stomach, duodenal ulcer, and excess of Group O; by contrast, achlorhydria is associated with gastric cancer and excess of Group A. If, in fact, an unduly high output of acid occurred in duodenal ulcer patients of Group O, this would suggest an explanation of the observed difference in ABO group frequencies, but we have failed to establish any such correlation. Although the blood-group substances cannot be shown to influence the secretion of hydrochloric acid, clearly they have some important role in gastric physiology, and further investigations are proceeding in order to determine its nature.

Summary

The distribution of the ABO blood groups among 2,059 peptic ulcer patients in two Glasgow hospitals has been investigated. A total of 5,898 consecutive donor registrations at the Blood Transfusion Centre supplied a control series. An increased frequency of Group O was recorded in patients suffering from duodenal ulcer, but the blood-group distribution in cases of gastric ulcer did not differ significantly from that of the controls, probably because the number of cases with gastric ulcer was too small. Among the duodenal ulcer patients, those requiring operation made the greater contribution to the Group O excess. The frequency of Group O was greatly increased in patients having stomal ulcers. Compared with controls, no difference in frequency of rhesus-negative subjects was observed.

The maximum acid output has been estimated in 276 patients with duodenal or gastric ulcer. No correlation was noted between acid output and ABO group in ulcers at either site.

The results of a peptic ulcer survey at one of the hospitals involved enable us to submit evidence suggesting that the patients concerned in this investigation constitute a fairly representative sample of those attending or admitted to hospital in this area.

We wish to thank Professor C. F. W. Illingworth and Dr. L. D. W. Scott for valuable advice and criticism. Dr. E. G. Oastler and Mr. R. B. Wright kindly permitted one of us access

this country, May (1950) reported that in six out of eight cases "the most marked effect was in relief of the mental state."

Our experience has been rather different, since out of 52 patients treated with benzhexol hydrochloride no fewer than 10 have shown mental disturbances, severe enough to justify transfer to a mental hospital in three instances. These complications have arisen within a few days as a rule, but in Case 5 marked symptoms developed after three weeks' treatment on an "alternate day" regime, during which period it was believed that the patient had become tolerant of the drug.

Dosage throughout was relatively low, but intolerance occurred even on a daily total of only 5 mg., and we cannot agree that tolerance is soon established on reducing the dose slightly, although that is the view expressed in Martindale (1952).

In most cases cessation of this form of medication brought a rapid return to mental normality, and resumption of benzhexol hydrochloride therapy produced an equally rapid relapse.

In the treatment of Cases 1 and 5, benzhexol hydrochloride was replaced by ethopropazine and hyoscine respectively with no better results, and in fact the older patient with Parkinsonism is also apt to become confused under treatment with hyoscine or other solanaceous drugs. It is noteworthy that 9 of the patients were over 60, and probably were suffering from the arteriosclerotic type of Parkinsonism: the remaining patient, although aged 57, had had a typical post-encephalitic illness for 30 years.

By way of contrast, we have described one case (No. 11) which showed considerable mental improvement following benzhexol hydrochloride therapy. This patient was a younger man, of slightly subnormal intelligence, who was probably finding his increasing disability too much for him; his physical improvement on treatment encouraged a parallel mental improvement when he found himself able to cope more adequately.

Summary

In a study of 52 cases of Parkinsonism treated with benzhexol hydrochloride ("artane," "pipanol") during the past three years, we have found severe mental disturbance arising in 10—an incidence of about 19%.

This complication has arisen in spite of the use of the drug in small doses, and has been particularly common in the arteriosclerotic group. Mental change has been evident after a few days' treatment in most of our patients, but the onset may be more gradual, in which case there is a danger that its relation to treatment may be overlooked.

Recognition of the cause of the disturbance and prompt cessation of this form of medication usually result in the rapid disappearance of the symptoms of excitement, agitation, confusion, and possibly suicidal mania.

Tolerance does not become established, but recognition of the danger, and prompt withdrawal of the drug, usually lead to rapid return of the previous mental state.

Benzhexol hydrochloride was introduced to the Geriatric Unit of Newcastle General Hospital in 1950 by Dr. T. H. Bates, and we are indebted to him for access to his patients and records, and for his interest and encouragement.

Medical Memorandum

Blood Groups and the Age of the Menarche

It has recently become fashionable to investigate the frequency of occurrence of various diseases in relation to racial or genetic differences, as indicated by blood groups (Struthers, 1951; Discombe and Meyer, 1952; Aird et al., 1953, 1954; Pike and Dickins, 1954; Wallace, 1954; Westlund and Heistö, 1955). The present note describes a study of the age of the menarche in relation to the principal blood groups; the possibility of an association was first investigated by Vuori (1929).

All women blood donors aged under 25 years attending donor sessions in the Oxford Region from September, 1954, to March, 1955, inclusive, were asked the age in years at which they had first menstruated. Despite the deliberate restriction of the inquiry to young women, many could not say, with sufficient accuracy, when the menarche had occurred, and so could not be included in the inquiry. The relevant information was, however, forthcoming for a total of 516 donors, and their ABO and D(Rh) blood groups were determined by the standard techniques (D^u was regarded as D-positive for the purpose of this investigation). The results, which are summarized in the Table, show no evi-

Age of the Menarche in 516 Blood Donors

Blood Group	No. of Informants	Age of the Menarche (Years)	
		Mean	Standard Deviation
O	235	13.30	1.48
A	221	13.33	1.59
B	45	13.20	1.64
AB	15	13.67	1.62
D-positive	409	13.31	1.54
D-negative	107	13.34	1.50
Total	516	13.32	1.53

dence of any substantial differences between the various blood groups, either in the average age of the menarche or in its dispersion about the average.

Vuori (1929) collected his information from two groups of 104 and 140 schoolchildren, with mean ages at the menarche of 13.9 and 14.8 years respectively. In each school the mean age at the menarche was practically the same in Groups A and O; the slight departures from the general average, which he found in Groups B and AB, were to be expected in view of the small numbers of children in those groups. The present larger series confirms these findings and the investigation has therefore been discontinued. The explanation of the wide difference in the average age of the menarche in Vuori's two series is a matter for conjecture. The average of 13.32 years in the present study, although determined retrospectively, accords well with that of 13.49 years found for 2,590 schoolchildren in the South of England in 1948-9 by Wilson and Sutherland (1950).

Reviews

AN AMERICAN TEXTBOOK OF MEDICINE

Fundamentals of Internal Medicine. By Wallace Mason Yater, A.B., M.D., M.S. (in Med.), F.A.C.P. 4th edition. This edition was prepared with the assistance of William Francis Oliver, B.S., M.D., A.A.C.P. (Pp. 1,276+xxx; illustrated. 94s. 6d.) London: Staples Press Ltd. 1955.

The first publication in Britain of an established American textbook of medicine requires a critical comparison with its chief British rivals. There are still important differences between what is taught to medical students in this country and in the United States. An obvious example is the classification of nephritis according to Ellis, which is generally accepted here but is not taught in the United States and not referred to in this book. Here any student might expect to be taught that coeliac disease is caused by a specific gluten sensitivity; that there is a characteristic small-intestine pattern in steatorrhea; that cervical spondylosis and the anterior carpal ligament are more important than the scalenus anticus in the causation of pain in the arms: none of these will he find in this book. He should be surprised to read prescriptions for bronchitis which include ammonium carbonate and chloride, and he should be shocked to read that in the treatment of chronic myelogenous leukaemia "some men favour the use of Fowler's solution." He may be surprised to find, too, that hiatal hernia is included under respiratory diseases, that the chapter on "The Physician Himself" applies entirely to the American situation, and that the texts recommended are more than 90% American.

While this textbook has much of quality—the sections on the electrocardiogram and on endocrinology are particularly good, and there are useful chapters on diseases of the skin, the eye, and the ear—its virtues do not, for the British medical student, outweigh its defects. The editor, Dr. W. M. Yater, has written most of the book himself, and, though this is a fine accomplishment, complete success in such a task could not be achieved to-day by the great Osler himself.

D. V. HUBBLE.

TROPICAL HYGIENE

The Control of Disease in the Tropics. By T. H. Davey and W. P. H. Lightbody. (Pp. 408+x; illustrated. 47s. 6d.) London: H. K. Lewis and Co. Ltd. 1956.

One of the aims of every author and publisher of a textbook is to produce one to which the well-worn cliché of book is to produce one to which the well-worn cliché of supplying a much-needed want can be applied truthfully. A volume on hygiene in the Tropics is, however, a comparative rarity, and it is now seven years since one was produced in this country. Further, the authors rightly point out that standard textbooks on public health have not made good the lack of a work of this kind, because they "are largely urban in outlook and devote comparatively little attention to the problems of disease as they exist in under-developed rural areas which form the major part of the Tropics." This publication remedies the deficiency but, quite apart from the fact that it does so, its excellence makes it notable. It is written specifically with the needs in mind of the medical practitioner with public-health responsibilities in the Tropics, and in compiling it much information has been brought together from monographs not readily available. The authors state, however, that "no attempt has been made to produce a comprehensive volume dealing with every aspect of public health in the Tropics. . . due to considerations of space, much has had to be omitted which some may feel should have been included." Among these omissions is a consideration of milk supplies in the Tropics, and, although dietary and nutritional surveys are briefly commented upon, nutritional diseases are not discussed. Sections on diagnosis are, however, included in the chapters on each disease. It is questionable whether the space devoted to these sections might not have been better used for including material which the authors regret they

have had to omit, for most of those who seek information on diagnosis will no doubt prefer to look for it in one of the standard textbooks in which it is dealt with more fully. An important subject also not discussed is family planning. This must be taken up by hygienists if malnutrition is not to increase with increasing populations. Moreover, there are now grounds for optimism regarding the success of a family-planning programme in the Tropics. One is being tackled in India in spite of religious opposition and is meeting with success.

There is a tendency among hygienists at present to criticize expenditure on curative medicine and to press instead for funds to be diverted to more preventive services. Professor Davey and Dr. Lightbody subscribe to this viewpoint, but they are fair in the way in which they put it forward. The advocates of this view need, however, to be reminded that virtually all preventive medicine becomes possible only as a result of knowledge of disease arising from clinical research which begins at the bedside and can satisfactorily be carried on only in a hospital or other centre which has adequate laboratory backing and diagnostic facilities. Authorities might well bear this in mind when arranging their budgets—the need is for more hospitals with better equipment and research facilities than at present exist in the Tropics.

The subject-matter of this book is beautifully arranged, and divided into sections headed "Geographical Distribution," "The Parasite," "Epidemiology," "Diagnosis," and "Control." The clarity of presentation is admirable; the book is well written and up-to-date. It is one with which all studying hygiene in the Tropics should be familiar.

A. W. WOODRUFF.

NEUROCHEMISTRY

Neurochemistry: The Chemical Dynamics of Brain and Nerve. Edited by K. A. C. Elliott, Irvine H. Page, and J. H. Quastel. (Pp. 900+xii; illustrated. £7.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

This is a collection of 32 reviews or essays by different authors, mainly concerning chemical and metabolic processes which condition the functioning of the nervous system. Descriptions are given of the composition of brain and nerve, their respiration and glycolysis, and the main chemical exchange between brain, blood, and cerebrospinal fluid; of ion movements in the functioning of the nerve fibre; and of the metabolism, physiology, and pharmacology of acetylcholine. These accounts are well documented and of high standard, giving carefully assessed quantitative data specifically regarding the nervous system. On the other hand, accounts of oxidative and glycolytic mechanisms, of "neurotropic drugs," of nutritional disorders of the nervous system, and of the "thermodynamics of the message" are much below this standard. Several contributions miss the literature of the past five years. The subjects covered are commendably wide, including neuromuscular disorders, demyelination, bacterial neurotoxins, snake venoms affecting the nervous system, oxygen poisoning, the central nervous system of arthropods, and brief mention of blood analysis in behavioural disorders. The impression is given of a rapidly developing subject, basic to the study of the nervous system, but of which current neurophysiological texts give little inkling.

H. McILWAIN.

Perspective and Horizons in Microbiology, edited by Selman A. Waksman (Rutgers University Press, New Brunswick, 1955), contains papers read and addresses given at the dedication of the Institute of Microbiology, Rutgers University, in June, 1954. The thirteen scientific papers are loosely classified under three headings, but are really unconnected except that five deal with bacterial metabolism. Among the others, Lederberg writes on bacterial genetics, Heidelberger on unsolved problems in immunology, and Eagle on problems in antibiotic research. In these and other contributions leading authorities give fresh accounts of progress at some of the most active growing points in microbiology; these are naturally not exhaustive, but they afford interesting glimpses both of present knowledge and into the possible future.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 21 1956

ANNUAL REPRESENTATIVE MEETING

Two things this year struck an experienced observer of past Representative Meetings. The first was that the average age of the representatives seemed to be lower than usual. The second was that the representatives seemed to have studied the agenda closely, shown principally by the fact that their contributions to the debates were cogent and free of empty rhetoric. Whatever financial anxieties there may have been in the mind of the Treasurer about the vote in favour of subsistence allowance for representatives this will have the one wholesome effect of making it easier for young men to play an active part in determining the policy of the Association; as speakers did not hesitate to remind the platform from time to time, there is only one body which can determine the policy of the British Medical Association, and that is the Representative Body. There have been periods in the past when it seemed as though an extra dose of courage was needed to challenge the authority of the platform, but under the benevolent guidance of Dr. Ian Grant, the Chairman of the Representative Body, there seems to have been a more ready give-and-take in debate and a healthy reluctance on the part of the representatives to be influenced by anything other than the facts of the case and the justice of the cause. Certainly it looked as if the facts of the case against smoking made it impossible on each day of the meeting to secure the necessary majority in favour of the suspension of Standing Order 70. It was the facts of the case against governmental action in the proposed banning of heroin that were responsible for two successful motions expressing as a matter of principle "its determination to preserve the right of any individual doctor to prescribe what he thinks is in the best interests of his patient," modified in a second motion of protest against Government action interfering with this right "until and unless there was some overwhelming reason to the contrary which had been agreed between the profession as a whole and the Minister." And again it was the facts of the case, allied to a vigilant concern for principle, that led the Representative

Body decisively to reject a motion from Bournemouth and Winchester aimed at disturbing the traditional responsibility of the Editor of the *Journal*.

The proceedings of the meeting have been fully reported in this and last week's *Supplement*, and here it is possible to comment on only one or two of the matters brought before the R.B. As Dr. E. A. Gregg, Chairman of Council, said at the beginning of the meeting: "Quite naturally and rightly we are much occupied with medico-political affairs." Inevitably what doctors get paid for their work looms large in these affairs. Apart from the fact that many doctors are suffering hardship because what they are paid does not make it possible for them to meet their obligations and commitments with a mind free from financial worry, salary, where a salary is paid, is linked with prestige and status—a burning issue this with senior hospital medical officers and also with public health medical officers. But if less was said than usual about remuneration it was because the representatives knew of and endorsed the recent joint approach of the General Medical Services Committee and the Joint Consultants Committee for increased remuneration. Dr. A. Talbot Rogers, the Chairman of the G.M.S. Committee, said that the basis of the claim lay in the legal argument that general practitioners and those in the hospital service were not being paid what they should be paid according to the recommendations of the Spens Committee. He added subsequently that one of the things it was hoped to win from the claim was agreement by the Government that the profession was entitled to a periodic review and that if obtained this would be "of more value than the money the claim itself would bring." But the hard-pressed doctor to-day may nevertheless feel that a bird in the hand is worth two in the bush, and no doubt those negotiating on behalf of the profession will press their claim home with all the vigour and knowledge at their disposal. In presenting the report of the Remuneration Policy Committee its chairman, Dr. J. G. M. Hamilton, drew attention once more to the fact that the Association reaffirms its policy that the two Spens reports remain the basis of professional remuneration. From the inception of the Service in 1948 each successive Minister of Health has done his best to escape from the commitment entered into by both Government and profession; and, as we learnt late on Monday this week, the present Minister is keeping in line with his predecessors. The Representative Body was at least able to learn that the Minister had agreed with the principle that private patients had the right to free drugs under the N.H.S., and will now be waiting for this right to be put into effect. Concern was expressed during the

meeting over the inadequate pay of the medical officer of health and the neglect of his position in medicine to-day. Nevertheless some of the most interesting discussions were held after the presentation of the report under Public Health by Dr. J. B. Tilley, Chairman of the Public Health Committee, when representatives showed their concern about clean milk, clean air, and immunization against infections. A welcome newcomer to the Representative Meeting was Mr. T. Holmes Sellors, Chairman of the Central Consultants and Specialists Committee. The meeting much appreciated the succinct and clear way he dealt with many matters arising as a result of his report, during the course of which ordinary business was interrupted to allow Dr. J. G. M. Hamilton, as Chairman of the Journal Committee, to introduce to the Representative Body Mr. Harry Cooper, who has been reporting the Annual Meeting of the Association for the *Journal* for fifty years. The representatives then rose and gave Mr. Cooper a resounding ovation.

The topics discussed and the 350 motions before the Representative Meeting in Brighton touched upon almost every aspect of professional life. That the proceedings have once more been so faithfully reported with so few mistakes is but one example of the great services Mr. Cooper and his colleagues have rendered the *Journal* now for half a century.

THE BRIGHTON MEETING

So diverse and extensive are the requirements of the B.M.A. for its Annual Meeting that no town or city in the British Isles can provide ideal conditions. But last week and the week before Brighton showed that it can come closer to perfection than most, offering a gay seaside welcome to the hundreds of doctors and their wives who gathered for the A.R.M. and the Scientific Meeting. The last four Annual Meetings were in Dublin, Cardiff, Glasgow, and Toronto, and it was fitting that the meeting this year should be held in so characteristically English a town as Brighton, with its promenades and piers, its Regency squares and terraces, its pink shingle and pinker rock, its "Lanes" full of antique shops, its good-humoured crowds, and, above all, with its exuberant burst of eccentricity in the shape of the Royal Pavilion—surely one of the most unusual buildings ever to give house-room to scientific discussions. The Dome in the Royal Pavilion Gardens was a splendid assembly-point for the A.R.M. and the plenary sessions, and, with the scientific and trade exhibitions in the Corn Exchange alongside, everything was made as easy as possible for the visitor to see and hear all that was going on.

With these physical advantages Brighton could confidently expect the meeting to go with a swing, but there were other assets which helped to make it specially memorable. One of the major sources of the friendliness and cheerfulness which pervaded the meeting was the new President, Dr. Alexander Hall, who, with Mrs. Hall, was always at hand to see that members and their wives were obtaining all the pleasure and profit from their visit that he and his colleagues of the Brighton and Mid-Sussex Division had so enthusiastically planned for them. The smooth organization at Brighton could only have been a product of first-rate team-work. Inevitably much of the burden falls on the local general secretary, and Dr. John Beynon carried through his task to the end with admirable efficiency and unruffled composure. The science secretary, Dr. H. G. McGregor, must have been gratified by the interest shown in the subjects chosen for discussion. Once again the plenary sessions attracted large audiences, and at the sectional meetings there were many lively discussions after the opening speakers had read their papers. An innovation at this year's meeting were the round-table conferences, at which a panel of four or five experts, after some brief opening remarks intended to put the subject chosen for discussion into perspective, became a brains trust ready and willing to answer questions from the floor. This form of discussion can be lively and entertaining, as well as instructive. Much depends on the suitability of the subject and on the way in which the chairman handles his team and guides the talk into the most promising channels: in both these respects the three panels of experts who took the platform at the unpromising hour of 9 a.m. on July 10 were remarkably fortunate. It was perhaps indicative of things to come that the Section of Child Health also chose this form of meeting for some of their discussions.

The other local arrangements were in the charge of a group of eight local sub-secretaries, and all who visited Brighton can testify to the success of their work in looking after the arrangements for premises and hotels, for private hospitality, for entertainments and excursions, for dinners and catering, for transport, for golf, for overseas visitors, and for the scientific exhibition. This last was perhaps the best that has so far been held, though the space for it was a little cramped. Nevertheless the display as a whole was a striking one and there was more evidence of the expert hand in the way the exhibits were arranged. The enthusiasm of the exhibitors themselves was notable; it was nothing unusual for the visitor to be warmly thanked for allowing an alarming gap in his knowledge to be painlessly filled in by a fascinating

and instructive exposition of the work on display. The scientific exhibition is certainly a part of the Annual Meeting which more than repays the time and trouble spent on it.

In his speech at the Annual Dinner the President spoke gratefully of all the ladies who had helped in the arrangements, and who, as he said, "had acted with charm and efficiency"; and he singled out for particular mention the honorary secretary of the Ladies' Committee, Dr. C. Lamorna Hingston. As chairman of that committee Mrs. Hall herself made an outstanding contribution to the success of the meeting. The popularity of the Ladies' Club and the heavy bookings for the visits and excursions showed how well the ground had been prepared by the hard preparatory work of the Ladies' Committee and its five subcommittees. It was a particularly happy moment when at the supper dance last Thursday evening it fell to the President to present to his wife the prize for the annual golf competition, the Notts Ladies' Challenge Cup.

At Brighton of all places the civic authorities must be almost painfully familiar with the task of welcoming the organizations which use the town's admirable facilities for meetings and conventions. But there was no hint of a standard formula in the welcome of the Mayor, Alderman Lewis Cohen, to the B.M.A., a welcome which was particularly warm because, as the Mayor himself said, "Brighton also claimed a medical degree." Thus it was practically as a colleague that the Association was able to greet the Mayor when he came to the Annual Dinner. There were many others in Brighton who helped to oil the organizational wheels, but a special word of thanks is owing to the sisters and nurses of the local hospitals who so cheerfully and efficiently shepherded the straying members as they sought the meeting-place of the section they wished to attend: their help was specially necessary in the Royal Pavilion, for anyone glancing into, say, the Music Room or the Queen's Bedroom was tempted to linger there irrespective of the subject under discussion.

One of the greatest pleasures at the Annual Meeting is to meet colleagues and friends from abroad, and it would perhaps not be invidious to mention the names of three whose presence was particularly welcome—Dr. Clarence Routley, Immediate Past-President of the B.M.A. and C.M.A.; Sir Henry Newland, from Australia, whose speech at the Annual Dinner was that of a gay young veteran; and Professor L. A. Hulst, of Utrecht, who came as the representative of the World Medical Association. There is no greater stimulus to the work of the B.M.A. than the interest

and support of friends and colleagues from overseas, of whom this year there was a record number. Their lively interest in everything connected with the meeting must have given Dr. Hall and his colleagues especial pleasure, and we hope that next year they will return, this time to the colder but no less hospitable north.

THE MINISTERS' NO!

On Monday afternoon the Minister of Health, in reply to a question in the House of Commons, said he was not prepared to say what were the terms of the medical profession's claim for increased pay for general practitioners and hospital medical staff—a claim jointly signed by Dr. A. Talbot Rogers, chairman of the General Medical Services Committee, and Sir Russell Brain, chairman of the Joint Consultants Committee. The grounds for his refusal were that the claim had not been published by the profession. Although it looks like being wise after the event, we believe that the decision not to publish the claim as soon as it was submitted was a mistake. The claim was presented last month in a lengthy memorandum setting forth a case based on the original two Spens reports, and an argument on betterment based on expert analysis of recent economic changes and alterations in the earnings of others. This detailed memorandum will be published in next week's *Journal*.

A brief statement of the present position appears in this week's *Supplement*. The claim is that the remuneration of all members of the medical profession whose case is covered by the recommendations of the two Spens Committees should, as at April 1, 1956, be increased by 24%. Our negotiators stress that this claim does not run counter to the recent plea of the Chancellor for a halt in claims for increased pay, because all the profession is asking for is the fulfilment of contractual obligations accepted by the Government of the day in 1946 and 1948.

Like all his many predecessors, Mr. Turton has to listen to the Treasury, and, as usual, inflation or no inflation, crisis or no crisis, blue parties or red parties in power, the answer is No. Mr. Turton, as counsel for the defence, shows that he has not lost his barrister's skill of inserting a probe in the weak spot of his opponent's anatomy. He has been able to say No to a question in Parliament on the grounds that the claim had not been published. And it was to his great advantage that the terms of the claim had not been before the meeting of the Representative Body in Brighton. The Minister added that a reply had been sent refusing consideration of "any claim for a general

increase in medical remuneration." It is interesting to note that the reply from the Ministry of Health was dated July 13, the last day of this year's Annual Meeting. What a convenient time to choose!—the moment when the 400 or so representatives who determine B.M.A. policy were dispersed on their holidays.

The Representative Meeting once again this year, as it has done in previous years, reaffirmed its determination to stick to the recommendations of the two Spens reports on the remuneration of general practitioners and of consultants and specialists in the National Health Service—recommendations accepted by both Government and profession, recommendations, moreover, which were a turning-point in the profession's decision to enter the Health Service in the face of a majority vote against such a decision in 1948. The medical profession will not be content with a lawyer's answer from the Minister of Health, even though he is holding a brief for a Government department other than his own. The Minister should at least recognize the legal force of a contract. He should recognize more than this: that doctors, coming unwillingly into the N.H.S. in 1948 because Parliament, Press, and people bludgeoned them into it, nevertheless thought that the people through Parliament would keep their word, would honour their bond. The Minister and the Secretary of State for Scotland, through Sir John Hawton—or it may well be the other way round, because Ministers of Health change faces so quickly—say they do not accept the premises on which the memorandum is based. Does this mean that they repudiate the reports of the two Spens Committees? If they do, they had better say so in plain terms that are not misunderstood, so that the answer, too, may be completely free from ambiguity.

C-REACTIVE PROTEIN

In 1930 W. S. Tillett and T. Francis¹ reported the presence of a specific protein in the serum of patients suffering from pneumococcal pneumonia. It was originally considered to be specific for this condition, and was detected somewhat laboriously by a precipitation reaction using the somatic C polysaccharide of the pneumococcus; hence the name of the test. But it soon became apparent that the reaction was largely non-specific and belonged to the group of tests which have been labelled "acute phase" serological reactions. These are phenomena that occur in cases of generalized inflammation, but they also occur in the presence of tissue necrosis.

The abnormal protein was originally isolated and purified by C. M. MacLeod and O. T. Avery² in 1941 and crystallized in 1947 by M. McCarty.³ Salt frac-

tionation suggested that it was associated with the albumin fraction of the serum,⁴ but subsequent electrophoretic studies⁵ indicate that it is probably an alpha-globulin. After overcoming considerable technical difficulties, it was found possible to produce a specific antiserum to this protein by injecting it into rabbits, and this antiserum is now available commercially, though expensive. By using it the test becomes a simple and rapid procedure, and also considerably more sensitive than the original test.⁶

The applications of the test to clinical medicine are slowly becoming apparent. Since C-reactive protein is seldom, if ever, found in normal people, the incidence of false positive reactions is exceedingly low. It would seem, therefore, that the test might be usefully administered as a screening test, possibly as a supplement to the erythrocyte sedimentation rate, in which false positive results are common. A second point is that the test is only roughly quantitative as performed routinely, and the gradations in which the results are conventionally reported are merely a convenient code. They do not imply chemical accuracy.

The early clinical studies with this test were largely on cases of acute rheumatic fever, and G. H. Stollerman and colleagues,⁷ reviewing its use in sixty-two patients, found it to be a sensitive and reliable indication of rheumatic activity. In the absence of any other pathological condition they also found it a good method of assessing prognosis, and more rapid and reliable than the sedimentation rate in controlling therapy. Even more important, they provided evidence—albeit not yet conclusive—that the test is not influenced directly by cortisone and other antirheumatic drugs. In other words it does appear to be a true reflection of the disease activity in these circumstances, unlike the sedimentation rate.

Some doubt has now been cast on this rosy picture by a recent American study,⁸ in which it was found that thirty out of forty patients suffering from congestive heart failure from various causes gave positive results to the test in the course of serial studies. It is true that fifteen of these cases had a rheumatic aetiology, but in only four was there any question of rheumatic activity. The test was in general positive when the failure was most severe and became negative as the patient improved. The possible causes of this phenomenon are discussed in some detail. It is an especially curious finding, since it is well known that exactly the opposite occurs to the sedimentation rate in congestive heart failure, and C. McEwen and M. Ziff⁹ had claimed this to be a specific advantage of the newer test.

¹¹ Hedlund, P., *Acta med. scand.*, 1947, Suppl. 196, p. 579.

R. J. Roantree and L. A. Rantz have recently published the results they obtained in 443 general medical patients.¹⁰ They found C-reactive protein to be almost constantly present in patients with bacterial infections, myocardial infarctions, and widespread malignant disease. It was commonly but not consistently present in virus infections, active rheumatoid arthritis, and active tuberculosis (in which the erythrocyte sedimentation rate was acknowledged as a more reliable test of clinical activity). It was rarely positive in limited primary carcinomata, chronic leukaemia, and widespread superficial dermatoses. Two other curious discrepancies have been reported: in cases of nephrosis and multiple myelomatosis, despite raised globulin levels and sedimentation rates, the C-reactive protein test was persistently negative.¹¹

In short, therefore, we have a simple, highly sensitive but non-specific test of tissue inflammation and necrosis. Its uses in clinical medicine are only now beginning to be explored. Since it is a qualitative rather than a quantitative test it seems as though it may be used chiefly for screening purposes. Its principal disadvantage is that it is excessively sensitive and may therefore cause confusion by becoming positive for irrelevant reasons.

BLINDNESS

The bleak if familiar forecast of an ageing population, increasingly blind, deaf, halt, and impotent, is underlined by the further Ministry of Health report¹ on blindness in England that Professor Arnold Sorsby has just prepared. This is a carefully documented analysis of the figures of blind registration in England during the period 1951-4, along the lines of his previous study² for the years 1948-50, and it follows the evolutionary history of the various blinding diseases one further stage down their gloomy course.

As might be expected from an affection of which all the major causes are part of the degenerative changes of old age—cataract 26.2%, senile macular lesions 21.6%, and glaucoma 13.6%—the figures show a disproportionate increase of blindness in the whole population, from 86,389 on March 31, 1952, to 93,622 on December 31, 1954, but practically the whole of this is confined to the group over 70 years of age. Women greatly outnumber men among the aged blind. The largest single cause of blindness is still senile cataract, and this is *par excellence* a remediable condition; yet of those so registered 82% have received no treatment, though some 50% are considered to be amenable to surgical relief. Many factors probably contribute to this astonishing finding—the patient who seeks no advice because of ignorance, timidity, folly, or passivity; the unqualified practitioner who treats failing sight with repeated changes of glasses without referring the patient to an ophthalmic surgeon; and, finally, the oculist who for personal reasons always

hesitates to operate. At least we can be encouraged that this admirably clear report must lead, however indirectly, to the enlightenment of patient, optician, and oculist, so that this vast assembly of the remediable blind should surely decrease as the years pass.

In the younger adult age-group (21 to 59) there has been an encouraging decrease in those registered as blind, possibly attributable to the improved methods and coverage of ophthalmic treatment. The reduced incidence of sympathetic ophthalmitis is particularly noteworthy, perhaps a result of cortisone treatment.

A striking increase in blindness has been noted in the very young, primarily due to the spate of retrolental fibroplasia, which was responsible for over a half of those registered as blind when less than a year old and a quarter of those aged between 1 and 4. These blinded infants are expected to swell the population of blind schools from 1,400 to 2,200 in 1958-9. The report discusses retrolental fibroplasia with rather more concern than seems justified, for it does not mention how dramatically the situation has changed. Since oxygen administration to premature babies has been curtailed (with a maximum concentration of 45%), no further cases have been reported. A year ago a report came from the Medical Research Council which, after summarizing the work of N. H. Ashton and his associates at the Institute of Ophthalmology, concluded thus: "It seems clear that retrolental fibroplasia as a common and tragic disease has already virtually disappeared as dramatically as it appeared a little over a decade ago. Seldom has a disease, so apparently enigmatic in its causation, so intractable to treatment, and so tragic in its effects, been so rapidly brought under control."³

CHRONIC PROSTATITIS

Before the days of sulphonamides and penicillin gonorrhoea was nearly always followed by prostatitis, especially if it affected, as it usually did, the posterior urethra; indeed, prostatic abscess was not uncommon. Since the introduction of penicillin the disease, if treated early, is usually confined to the anterior urethra, and the posterior urethra and prostate escape. Nevertheless, chronic prostatitis is still diagnosed frequently, especially in venereal disease clinics, and it no doubt follows some form of genito-urinary infection. A recent article by three U.S.A. Army medical officers¹ suggests that the usual symptoms—low back pain and heaviness in the perineum—even if accompanied by a considerable number of pus cells in the prostatic secretion do not necessarily validate a diagnosis of chronic prostatitis. These investigators examined 411 "normal" males, 155 suffering from non-specific urethritis, and 449 who had been tentatively diagnosed as chronic prostatitis. 62% of the first group, 59% of the second, and 54% of the third were considered not to be suffering from prostatitis. The presence of 15 or more pus cells per high-power field in the prostatic secretion was considered to indicate prostatitis. These findings will be somewhat surprising

to many, the more so since it was found that 55% of what appeared to be normal prostates one week were abnormal a week later and 45% of abnormal ones became normal within three weeks, whereas symptoms were unchanged. Incidentally these authors were able to isolate a pathogenic organism in only one out of 68 patients of whom 29 showed pus in the prostatic secretion.

Prostatitis is synonymous with inflammation of the prostate, and where there is inflammation there will be pus cells. If, therefore, a specimen of prostatic secretion contains an abnormal number of pus cells (opinions will differ on what is abnormal) it may be assumed that prostatitis is present. It is necessary before making the diagnosis to be sure that the pus cells emanate from the glands of the prostate (or perhaps from the seminal vesicles); for this purpose it is wise to get the patient to pass urine and to wash out the whole urethra and bladder with bland fluid before massaging the prostate. If after this the fluid expressed is found to contain large numbers of pus cells it is difficult to avoid the conclusion that the prostate is the subject of inflammation. Symptoms are often a poor guide; the patient who reports with low back pain, heaviness in the perineum, disturbances of micturition, or impotency is usually one who has been exposed to or suffered from urethritis or who is mentally upset. Digital examination of the prostate may or may not confirm the diagnosis. If the organ is soft and boggy it is obviously abnormal, but in mild chronic cases little change can be detected and the reliance must be placed on history, symptoms, and the results of pathological examinations. Most cases will clear up after gentle massage of the organ repeated every 5-7 days for a few weeks, followed by irrigation with, say, oxycyanide of mercury 1/8,000. When the patient is nervous and over-anxious reassurance, a placebo, and perhaps a sedative will usually hasten recovery.

PRIMARY TUBERCULOSIS OF THE MOUTH

When primary tuberculosis appears in unfamiliar situations, it is apt to be missed or misdiagnosed. Tuberculous ulcers in the mouth are familiar as a complication of pulmonary tuberculosis, but reports of cases in which the mouth was the site of a primary infection are scanty in the British and American literature, and most of them have appeared since 1950. F. J. W. Miller¹ reported three cases in 1953, and careful examination of patients with submandibular adenitis has now resulted in the publication by J. Boyes, J. D. T. Jones, and Miller of a report of seven cases in children and adolescents.² This report of seven cases in children and adolescents suggests that the condition is not so rare as had been supposed, and that more cases would be found if they were more diligently sought.

As the primary ulcer in the mouth is usually small and painless, the patient may make no complaint, even

if he is aware of its presence. Attention is drawn to the existence of tuberculous disease by swelling of the related lymph nodes, most often those of the submandibular group. There is a tendency to attribute tuberculous cervical adenitis to a primary infection of the faucial tonsils, and the possibility of a focus in some other part of the wide drainage area of those nodes is often not considered. Injury to the oral mucous membrane is important in allowing the infection to become established. In a majority of the cases reported by Boyes and his colleagues there was a history of dental trauma by tooth extraction or alveolar abscess; but the injury may be trivial and unnoticed. A definite history pointing to a source of infection appears to be unusual. The tubercle bacilli may be of either human or bovine type.

The pathological features of these cases conform to the pattern of primary tuberculosis. The primary focus is an ulcer in a tooth socket, or on the gum or other part of the oral mucous membrane. The infection spreads rapidly to the regional lymph nodes, which enlarge and are at first firm but later tend to soften and break down. The primary ulcer may be very small and may heal without trace while disease in the lymph nodes is still active, but in some cases a scar remains at its site. As in any case of primary tuberculosis, haematogenous dissemination is a possibility. One of the patients in the series of Boyes and colleagues developed tuberculous meningitis. In all their cases the primary ulcer healed rapidly on chemotherapy and the lymph nodes diminished in size. There was, however, a high incidence of recrudescence of active disease in the lymph nodes within a few weeks or months, sometimes with formation of abscess. This led these authors to conclude that there is a case for excision of the enlarged nodes while they are still firm. However, most of the patients had only a short course of streptomycin, whereas J. W. Galloway and N. W. Horne³ recommend six months' combined chemotherapy. For the detection of cases of primary oral tuberculosis it is recommended that any chronic ulcer of the mouth that does not heal should be examined histologically; and that primary tuberculosis should be suspected and an oral ulcer looked for when the submandibular lymph nodes are found to be enlarged.

COLLEGE OF GENERAL PRACTITIONERS

The College of General Practitioners is to have a home of its own. The President of the College, Dr. William Pickles, announces this week (p. 174) that "generous financial support"—we understand from a donor who wishes to remain anonymous—has made it possible to construct, and in part to endow, a building which, it is hoped, will be completed by 1962. This munificent gift, and the ready help of the Royal College of Surgeons, which has agreed in principle to lease a site near by on the south side of Lincoln's Inn Fields, will be acclaimed by all those who have watched with admiration the mounting success of this, the youngest, college.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND

FIFTIETH ANNIVERSARY MEETING

The Pathological Society of Great Britain and Ireland celebrated its jubilee by a three-day meeting, from July 12 to 14, in Manchester, the city in which was held its inaugural meeting on July 14, 1906. That meeting was also reported in this *Journal*.¹

From its inception the Society has prided itself on its role as a learned society without political affiliations. It exists, in the words of its founders, "to advance pathology and to facilitate intercourse between pathologists." It has no permanent president, and the rule is that the chair shall be taken by the head of the laboratory (or his delegate) at which a meeting is being held. It was in accordance therefore with this strong scientific tradition that at the jubilee meeting this year pride of place should have been given to scientific papers, which ranged over the fields of bacteriology and virology, immunity, morbid anatomy, and experimental pathology and cancer research. There was, however, one exception to this scientific fare, the notable address by Professor J. H. DIBLE, secretary of the Society since 1934 and now its joint secretary, on the history of the Society, which in shortened form is reproduced below.

History of the Society

In June, 1906, said Professor Dible, many pathologists in Great Britain and Ireland received a notice suggesting the formation of a Pathological Society of Great Britain and Ireland. The signatories were amongst those most eminent in their subjects in these countries—professors of pathology, men eminent in the Services and in tropical medicine, distinguished physicians, professors of physiology, and veterinarians. The idea of such a society was doubtless forming in more minds than one, but those most active in establishing the new society were Lorrain Smith and Robert Muir, together with Ritchie and Boycott. To this little group of fathers of the Society the name of Sims Woodhead must be added on account of his connexion with the Society's journal.

Why did this movement take place at that particular time? It occurred at a climax in a period of great and expanding activity in pathology and medical science generally. In the preceding three-quarters of a century the science of pathology, if not founded, certainly came to recognition as a branch of science distinct from the clinical arts. The publication of great classics on morbid anatomy, such as the atlases of Cruveilhier and Carswell, and of Virchow's *Cellular Pathology*, Cohnheim's *Lectures*, Metchnikoff's *Lectures on the Comparative Pathology of Inflammation*, Villemin's experiments on tuberculosis, and Koch's work on the aetiology of tuberculosis, had evoked a wide response. And there was also a great burst of activity along the newer lines which were being opened up by the technical advances of the histologists, such as Weigert, the experimental pathologists, like Ehrlich, and by the great advances in bacteriological technique which in the last quarter of the nineteenth century had led to a spate of discoveries of causal organisms in infective disease. This upsurge of activity demanded more and more men for its service, possessed of more specialized knowledge than had been available to the great clinical investigators like Hunter, Bright, and Addison. The first chair of pathology had been established in Edinburgh in 1831. Fifty years later, in 1882, the second whole-time chair in Britain, that of Aberdeen, was founded, and by the end of the century, or within a few years of it, chairs had been established in all the Scottish and in many of the English provincial universities. In London the situation was different owing to the independent position of the London hospitals and their teaching schools. Their domestic arrangements did not favour the appointment of the whole-time pathologist and they had no real university affiliation. Further, in London there was the Pathological Society of London, which had been in existence since 1847

¹ *British Medical Journal*, 1906, 2, 149.

and remained a great force. It was partly for these reasons that the Pathological Society of Great Britain and Ireland found in its early days its greatest support in Scotland and the English provincial schools, and that tradition had to some extent endured.

At the first meeting in Manchester on July 14, 1906, on Professor Muir's motion Professor D. J. Hamilton took the chair, and it was moved that "the Pathological Society of Great Britain and Ireland be constituted": this was carried by acclamation and so the Society came into being.

Scientific Traditions

The *ad hoc* committee appointed at this first meeting drew up draft rules, based to some extent on those of the Physiological Society. Next it took steps to acquire an official publication. Negotiations were opened with Professor Sims Woodhead, of Cambridge, the owner and editor of the *Journal of Pathology and Bacteriology* which he had founded in 1892 with Mr. Pentland, the Edinburgh publisher. This journal was adopted as the official organ of the Society, and in March, 1907, an association was formed to acquire it from Sims Woodhead and to publish it under his editorship, with Ritchie and Boycott as assistant editors. In the editorial of October, 1907, announcing the new affiliation of the journal, the editor stated: "Records of personal research and not historical résumés are specially desired; and in all cases preference will be given to articles not overburdened with abstracts from literature. Illustrations must in all cases be confined to new features. . . . Although the editors reserve to themselves the right of editing articles submitted for the journal, they will not hold themselves responsible for any statement made in the articles published." These forthright pronouncements gave some warning of the editor's determination to be master in his own house; a decision from which he never departed and which had outlived him as a tradition.

From this point onwards the records of the Society were those of steady progress. There was the part played by the Society in the encouragement of the Pathological and Bacteriological Laboratory Assistants' Association, now the Institute of Medical Laboratory Technology. Within a year of the Society's foundation the committee was asked to consider the admission of laboratory attendants engaged in scientific work as members, and, as the minutes have it, found that "there was nothing in the rules which necessarily prevented the admission of these gentlemen"; at that same meeting Richard Muir, of Edinburgh, a man outstanding for his technical work, was nominated amongst other candidates. In 1911 a subcommittee was appointed to consider and report upon "the possibility of establishing some form of employment bureau for laboratory assistants." The matter, however, was already *en train* in another quarter. Six months later the Society learnt with pleasure that such an association was in process of formation amongst the assistants themselves, and expressed its willingness to assist and encourage its objects. As time went on certain tendencies began to emerge, and traditions became established. The Society refused to send delegates to conferences and the like; it also resolutely turned its back on any action which had any sort of political flavour, regarding itself as a scientific society and refusing to deviate from its purpose as laid down by its founders: "To advance pathology and to facilitate intercourse between pathologists." Thus the meetings had been almost wholly devoted to scientific matters, and attempts from time to time to get the Society to engage in medical politics or current administrative problems had met with little support.

Epitome

In a short life of 50 years, said Professor Dible in conclusion, it was not likely that there would be much that was stirring in a dramatic sense in the history of a scientific society devoted to the advance of one particular branch of medical science, however fundamental that might be. The true history of the Society was the work of its members,

and that was to be found recorded in the proceedings of its meetings and in the 58 volumes of the *Journal of Pathology and Bacteriology* published by the Society. Their Society, Professor Dible said, had had an honourable and honoured past, and they looked forward with confident expectation that the present and future generations would uphold the traditions which the first 50 years of the Society's existence had seen established.

HYPERCALCAEMIA IN INFANTS AND VITAMIN D

Because of reports in medical journals suggesting that cases of hypercalcaemia in infants might be due to an excessive intake of vitamin D, the Ministry of Health approached the British Paediatric Association on the subject. Lacking the adequate information on which to base a firm opinion, the association appointed a committee* to inquire into the prevalence of the condition in infants, and the kind of diet with which it was associated. The committee's report, now released and dated July, 1955, is summarized below. In reaching its conclusions, the committee states that it referred to an earlier report† to the British Paediatric Association, in which in 1943, when the fortification of infant foods with calciferol was not yet standard practice, had recommended that, under the Government scheme, the daily dose of cod-liver oil for all infants (except those born prematurely) should provide 700 i.u. of vitamin D.

COMMITTEE'S REPORT

A letter of inquiry was sent to 196 consultant paediatricians in the United Kingdom. By the end of June, 1955, 204 cases of hypercalcaemia had been reported as having been recognized since the beginning of 1953. The peak incidence of onset of symptoms was between four and eight months of age. Among the reports received there was no convincing instance that, at the onset of symptoms, the infant had been entirely breast-fed and had not received any vitamin D supplement.

Calciferol Added to Dried Milk and Cereal for Infants

When calciferol is added to infant foods there is during subsequent months a fall, at varying rates, of the calciferol content of the dried food. This fall is probably considerably less in the case of milks than in cereals.

Information was obtained from a manufacturer of National Dried Milk and proprietary infant foods.

(i) *National Dried Milk*.—In September, 1953, the Ministry of Food sent a letter to the manufacturers of National Dried Milk recommending that 500 i.u. of vitamin D, as calciferol, per dry oz. be added to allow for a maximum deterioration of 44%, thus giving a minimum concentration of 280 i.u. per dry oz. in the food as marketed.

(ii) *A Proprietary Milk*.—The following tables show the amounts of crystalline calciferol added to a proprietary brand of

Date	Crystalline Calciferol Added i.u./Dry oz.	Date	Sales Statement to Contain Not Less than i.u./Dry oz.
Up to August, 1942	70	1943	Increased to 280
From August, 1942	128	Late 1943	320
" October, 1943	403		
" November, 1944	460		
" October, 1954	690		
	(This is not yet on the market)		

Age of Milk Months	Year of Manufacture	Assays i.u./Dry oz.
7-12	1950	362
		463
13-18	1952	405
3-6	1952	560

The assays are by a biological method: error $\pm 30\%$

*Dr. Reginald Lightwood (chairman), Dr. Wilfrid Sheldon, Dr. Charles Harris, and Dr. Thomas Stapleton (secretary).
†*Arch. Dis. Child.*, 1943, 18, 58.
‡28 grammes.

full-cream dried milk, the sales statement as to the vitamin D content, and reports of assays of vitamin D in the milk.

It will be seen that the sales statement—that is, the statement on the label of the preparation—refers to the minimum level of vitamin D in the dried milk. If there is not much deterioration in a particular batch, or the milk powder be retailed soon after manufacture, the level would be higher than the minimum sales level.

A more dilute, or "half-cream" milk, was made by adding lactose to the calciferol-fortified full-cream dried milk, referred to in the above table. The concentration in the full-cream milk ensured that there was enough vitamin D in the more dilute milk.

(iii) *A Proprietary Cereal*.—The following table shows the amounts of calciferol added to a dried cereal, the sales statement, and reports of assays.

Date	Crystalline Calciferol Added i.u./Dry oz.	Sales Statement Approximate i.u./Dry oz.	Assays Age of Food Months	i.u./Dry oz.
Up to March, 1946	1,000	625	0-2	1,110-1,870
From March, 1946	2,000	1,000	13-18	758-1,200

Thus, in a fairly recently prepared batch of cereal, there may well be 1,500 i.u. vitamin D per dry oz. or even more.

The above figures permit an approximate estimate to be made of the likely intake of vitamin D of an infant fed on the full-cream dried milk, referred to above, fortified with crystalline calciferol 460 i.u. per dry oz., the calciferol-fortified cereal shown above, together with the generally recommended quantity of cod-liver oil compound:

For example, the vitamin-D intake of an infant who receives each day

	Approximate Figures
(a) $\frac{1}{4}$ pint of a full-cream dried milk containing 460 i.u. vitamin D per dry oz.	1,725 i.u.
(b) 1 oz. of a cereal containing 1,500 i.u. vitamin D per dry oz.	1,500 "
(c) 1 teaspoonful of national cod-liver oil compound (Welfare Food Service)	700-800 "

would be about 4,000 i.u.

Committee's Conclusions and Recommendations

Clearly it is important that agreement should be reached on what should be the optimum intake of vitamin-D from all sources in the infant's diet. The evidence whether or not vitamin D is responsible for "idiopathic hypercalcaemia" is not here considered. There is, however, a strong case for taking steps to safeguard infants against the possible risks of an unnecessarily high intake of vitamin D. The ways in which the intake of vitamin D could be reduced are as follows:

(1) By omitting calciferol from dried milks. There is, however, no doubt that dried milks fortified with calciferol have played a part in the abolition of rickets. In this connexion it may be noted that the intake of cod-liver oil compound in England and Wales (actual issues being expressed as a percentage of the potential demand) varies between 19 and 32%.

(2) By limiting the amount of calciferol incorporated in dried milks by a range of figures. This is understood to be technically feasible. A corresponding range of figures would also be required for fortified evaporated and condensed milks. Before the range is chosen the vitamin-D needs of healthy infants would require reconsideration.

(3) By omitting cod-liver oil supplements in the case of infants fed on a calciferol-fortified dried milk. Cod-liver oil, however, is given not only for the benefit of its vitamin-D content but also for its vitamin A, and it might therefore become necessary to make separate provisions to cover this. The committee believes that the intake of vitamin D given in any supplement should be individually adjusted according to the type of feeding.

(4) By omitting calciferol from cereals used for infants. By itself, this might not be enough to remove entirely the risk of too high an intake of calciferol.

\$0.9 litre.

British Medical Association

ANNUAL MEETING, BRIGHTON, 1956

SUMMARY OF PROCEEDINGS

FIRST PLENARY SESSION—RECENT ADVANCES
IN THE KNOWLEDGE OF CANCER

Wednesday, July 11

Under the chairmanship of Mr. A. DICKSON WRIGHT (London) a group of speakers reviewed the most recent advances in the treatment of cancer. Professor G. HADFIELD (London) discussed the latest physiological work on the development of the breast and showed how this would be of great importance in the future surgical management of cancer of the breast. Workers in America had shown that the maintenance of breast structure depended on a finely balanced mechanism. An oestrogen of ovarian or adrenal origin was insufficient to produce full development of the breast. Prolactin in relatively large quantities was essential for this. Experiments had shown that on weanling male mice, which had been castrated and hypophysectomized, full development of the breast, including lactation, could be produced if prolactin, oestrone, progesterone, and cortisone were given in suitable proportions. Approximately 50% of human breast cancer was of hormone-dependent origin. It was therefore of the utmost importance that a full study of the hormones that cause development of the breast should be undertaken in these patients. Work carried out in the clinico-pathological laboratories of the Imperial Cancer Research Fund proved that prolactin could easily be demonstrated and fairly accurately estimated in the urine of all pre-menopausal women and in 58% of post-menopausal women. It had been shown that, if prolactin was absent from the urine, hypophysectomy would not cause a remission in metastatic deposits. Further work on the hormones of the breast had shown that the secretion of prolactin by the pituitary was dependent on oestrogen thresholds, and it was believed that this mechanism was of fundamental importance in causing relapses that followed oophorectomy and adrenalectomy.

Mr. A. LAWRENCE ABEL (London) gave a general survey of the progress that had been made in cancer surgery over the last ten years. He stressed the importance of early diagnosis and the treatment of premalignant conditions in lowering the mortality from cancer. Among the premalignant diseases discussed were gastric ulcer, cholelithiasis, ulcerative colitis, polyposis coli, rectal polyps, thyroid adenomata, and skin tumours. New procedures played an important part in early diagnosis, especially exfoliative cytology and frozen-section techniques. Isotopes were coming into use in diagnostic measures; new methods for the diagnosis of carcinoma of the oesophagus and stomach dependent on ^{32}P were in the course of development. Over the last 20 years the techniques of operative surgery had been improved enormously, and the results of cancer surgery had improved in consequence. This was most marked in the surgery of the colon, where the resection rate had been doubled and the five-year survival rate had increased by 15%. The lecturer outlined the important work that had been done on the treatment of carcinoma of the breast. In patients with tumours affecting the inner quadrants of the breast, a dissection of anterior mediastinal lymph nodes was mandatory, in addition to clearance of the axillary nodes. In patients in whom the lymph nodes were involved x-ray therapy played an important part. The procedures of adrenal and pituitary ablation caused in many instances satisfactory regression of the metastatic deposits. In concluding he stressed that in the immediate future a considerable lowering in cancer mortality could be achieved by propaganda among the public and by routine medical examinations.

Radiotherapy

Dr. W. M. LEVITT (London) then spoke about radiation. He said that recent advances in the radiotherapy of cancer stemmed from two main sources—first, the introduction of artificial radioactive isotopes, and, secondly, the application of new principles to electrical apparatus for the production of very high energy x rays. Radium, until recently the only radioactive substance in general clinical use, suffered from severe limitations, apart from its scarcity and high cost. The long half-life amounted for practical purposes to permanence. It was never completely eliminated if introduced into the body. It produced its radiations through the medium of the gas radon, and not directly. These combined to make it an extremely dangerous substance. The precautions necessary to render its application safe necessitated the use of comparatively stout sealed containers and thus hampered its application to clinical work. Artificial radioactive isotopes with shorter half-lives, and radiating directly, overcame many of these difficulties. Radioactive tantalum wire, for example, could be introduced directly to the tissues for interstitial therapy, and was flexible. Some isotopes with very short half-lives, such as ^{131}I and ^{32}P , could be deliberately introduced into the blood stream so that they were selectively taken up by certain tissues, their radioactivity dying out after they had served their purpose.

The gamma rays of radioactive substances and electrically produced x rays were identical in nature, and the term "megavoltage radiotherapy" covered both telecurie therapy with such substances as cobalt-60 and radium, and super-voltage x rays. The introduction of megavoltage radiotherapy might well prove to be the most important recent advance in the radiotherapy of cancer. Telecurietherapy apparatus using massive quantities of ^{60}Co produced radiations approximately equivalent to those of a 3-million-volt x-ray machine, and there were a number of x-ray machines now in use producing x rays of from 2–4 million volts. Already considerable experience had been gained in the treatment of cancer with radiations of these high energies. It was as yet too soon to say what was the optimum range of megavoltage for treatment. It could, however, be said that megavoltage therapy at 2–4 million volts, which included the ^{60}Co apparatus, offered a good prospect of improvement in results on conventional deep x-ray therapy in suitable situations, if only because the distress and discomfort to the patient were so much less, owing to the reduced effect on the skin, and because the target dose to the growth could be more easily and consistently achieved. In particular, a ray of hope, though no more, had been introduced into some very dark places, such as the treatment of inoperable carcinoma of the bladder and rectum.

Chemotherapy

Professor A. HADDOW (London) spoke on the subject of chemotherapy. He said that the special difficulties confronting chemotherapy in cancer arose from the facts that the cancer cell was but a modification of the normal, that the biochemical differences between the two were quantitative rather than qualitative, and that there was little sign of any immunological specificity. Endocrine control (as of tumours of the prostate and breast) was rendered possible by the retention of a hormonal responsiveness already present in the corresponding normal cell, or by the development, by the cancer cell, of an active hormone-dependence, which might also be demonstrated through the procedures of oophorectomy, adrenalectomy, and hypophysectomy. Agents which acted more directly on the dividing cell included the nitrogen mustards and other biological alkylating agents such as various di-epoxides, ethyleneimines, and dimethylsulphonyloxybutane and the carboxylic nitrogen mustard "chlorambucil" ("lukeran"), had received clinical application in the past few years in cases of chronic myelogenous leukaemia, and in cases of chronic lymphatic leukaemia, other lymphomas, and Hodgkin's disease, respectively. The development of antimetabolite therapy was a great step

forward in the treatment of the acute leukaemias, and the principles governing the application of antifolic-acid and antipurine agents, whether alone or in combination with cortisone and A.C.T.H., continued to clarify. Other substances, possibly acting as antimetabolites, included urethane in the treatment of multiple myeloma.

None of the agents so far available was curative, yet all merited further study for the fundamental interest of their mechanism of action. Recently a new agent had been discovered which would cure cancer in the experimental animal. This substance, however, was not curative in man, but opened up wide future possibilities for research. Until more was known of the fundamental intimate biochemistry of cancer cells, chemotherapy would not achieve a curative nature. The future chemotherapy of cancer might depend on the development of antimetabolites, which might be used in a form of substitution therapy.

SECOND PLENARY SESSION—THE PRESENT
POSITION OF A.C.T.H., CORTISONE, AND
DERIVATIVES

Thursday, July 12

Sir CHARLES DODDS (London) opened the Plenary Session from the chair by saying that A.C.T.H. and cortisone were not alternatives. A.C.T.H. stimulated the suprarenal to produce all its products, some of which were characterized (such as hydrocortisone), some of which had only recently been discovered (such as aldosterone), and very possibly there were others as yet unknown. Cortisone, on the other hand, provides only one or a modification of one of the substances produced by the cortex.

Dr. HOWARD POLLEY (Mayo Clinic, U.S.A.) gave a paper on the present therapeutic status of cortisone and its derivatives. Apart from their metabolic and endocrine effects, which were extensively relied on therapeutically, these compounds were valuable for their antirheumatic, anti-inflammatory, and anti-allergic properties and for their inhibition of fibroblastic scar-tissue formation. Refinements in their use had resulted from modifications of methods of administration, and alterations in the chemical structure of the steroid molecules, with consequent change in metabolic effect. Examples of the last procedure were prednisone and prednisolone, which had four times the antirheumatic effect and less effect on electrolytes than cortisone; 9 α -fluoro-hydrocortisone, which had an antirheumatic potency ten times that of cortisone but a fifty-fold effect on electrolytes; and hydrocortisone, which had a more certain action than cortisone when administered locally. All the cortisone substitutes as well as cortisone were capable of causing hypertension if given for any length of time, and there was general agreement that long-term therapy with them was more satisfactory if this could be avoided. Symptoms included the cyclical occurrence of fatigability, emotional instability, and general muscular and articular aching, which improved with rest, got worse when the patient was tired, and varied directly with the time from the last dose of hormone. Other manifestations of hypercortisonism were mesenchymal reactions simulating disseminated lupus erythematosus or periarteritis nodosa. Transfusion reactions, light sensitivity, and false serological reactions during blood grouping could occur. Chronic hormonal excess could modify mesenchymal reactions in rheumatoid arthritis and might be fatal. Dosage of the hormone needed to be adjusted according to the age and sex of the patient, and in cases where prolonged treatment was going to be necessary the dose should be gradually reduced by small steps to the lowest dose which kept the patient free of symptoms.

Dr. W. S. C. COPEMAN (London) said that in rheumatoid arthritis cortisone and A.C.T.H. were of equal value, although cortisone was most commonly used. He now gave an initial dose of 50–75 mg. daily in divided doses. Women tolerated hormonal therapy less well than men. Hormone treatment for rheumatoid arthritis was indicated only when treatment

by rest, splinting, and gold injections had failed. Even then cortisone was contraindicated if there was a past history of tuberculosis, peptic ulcer, diabetes mellitus, hypertension, or psychosis. Cortisone therapy did not actually influence the underlying disease process; patients felt subjectively better and were able to return to work. Provided irreversible joint changes had not occurred, he had maintained selected cases with great relief from symptoms and impaired function for as long as five years. The frequency and dangers of side-effects were overrated. The most frequent complication of hormone therapy was peptic ulceration, and any digestive symptoms should be investigated, since an ulcer might bleed or perforate. Nevertheless peptic ulcers could heal without treatment being stopped. It was essential not to stop treatment with cortisone in patients who had been receiving it for a long time and who had to undergo operations, or they might die as the result of the stress of operation. Hydrocortisone had the same effect as cortisone, but prednisone and prednisolone caused less disturbance of water and electrolyte metabolism, though they were more ulcerogenic. Hydrocortisone was typically useful for intra-articular injection in cases of rheumatoid arthritis in which a number of joints had been left unaffected by systemic treatment with cortisone. There were no side-effects from local treatment with hydrocortisone. Although the position of cortisone treatment for acute rheumatism was not completely clear yet, it seemed that after three years there was little difference in the incidence of heart disease between treated and untreated cases. More cases of rheumatoid arthritis treated with A.C.T.H. went into natural remission than did cortisone-treated cases. Most cases of rheumatoid arthritis would respond to conventional treatment, which was not outmoded by therapy with steroids.

Mr. A. J. B. GOLDSMITH (London) said that cortisone and related steroids were valuable in ophthalmology because of their anti-inflammatory effects. When steroids were combined with appropriate antibiotic therapy, infections could be controlled both bacterially and anatomically. Hydrocortisone was slightly more effective by local application than cortisone. There were no side-effects, since such small quantities were used, and the drugs could be given for a long time without losing their potency. They did not cure ocular inflammation, but blocked the exudative phase and stopped the formation of fibrous tissue. The cause of the inflammation was in no way influenced, and bacteria could continue to proliferate if unchecked by antibiotics, with disastrous consequences. If cortisone treatment was stopped too soon the disease process would continue as though untreated and possibly might be exacerbated. Cortisone could not remove chronic fibrous tissue. Hormone treatment prevented the development of scar tissue in deep keratitis, iridocyclitis, and choroiditis, and limited the chances of corneal scarring in interstitial keratitis. Assessment of the aetiology was essential in ocular disease—for example, hormone therapy in tuberculous uveitis might light up systemic tuberculosis with disastrous results. Hormone treatment was dangerous in cases of dendritic ulcer of the cornea due to the herpes virus, since extension of the ulcer might occur, with perforation of the cornea. Cortisone therapy was helpful after corneal graft operations, when it prevented invasion of the graft by new blood vessels.

Dr. F. DUDLEY HART (London) said that A.C.T.H. was only of use in treating adrenal insufficiency in cases where the adrenals were hypoplastic, as in Simmonds's disease, or in covering operations on the pituitary or hypothalamus. In acute adrenal insufficiency cortisone could be given, but 100 mg. of hydrocortisone intravenously over six hours and repeated as necessary was the treatment of choice. 5 mg. of 9 α -fluorohydrocortisone or hydrocortisone succinate could be used in such cases, but intramuscular cortisone was too slow in its action. Cortisone, hydrocortisone, or hydrocortisone acetate were the best drugs for treatment of Addison's disease or totally adrenalectomized patients, though some required additional deoxycortone acetate and salt. Treatment with 20 mg. of cortisone and 0.125 mg. of 9 α -fluorohydrocortisone orally twice daily was effective,

Dr. W. M. DAVIDSON (London) said that 1% of all new patients attending King's College Hospital suffered from iron-deficiency anaemia with a haemoglobin value below 60%. The body normally contained about 5 g. of iron, divided between the red blood cells, other systems of the

body, and the iron stores in the reticulo-endothelial system. The body conserved iron carefully, but the reserves were not large, and were easily depleted if the intake of iron was low or if abnormal amounts were lost, as for example through menorrhagia. Once the iron stores were much reduced it took only a small additional drain for frank anaemia to occur. Most patients with iron-deficiency anaemia responded satisfactorily to iron preparations given orally, but some required to be treated with parenteral injections. In that case the amount of iron given should be that calculated to restore the haemoglobin to normal and to replenish the iron stores of the body.

Wednesday, July 11

Management of Asthma

With Dr. GLADYS M. WAUCHOPE (Brighton), a vice-president, in the chair, Dr. R. S. BRUCE PEARSON (London) opened a discussion on the management of asthma. He said that three main causes operated singly or in combination to produce an asthmatic attack in a predisposed person—namely, allergic factors, infection, and emotional disturbance. Allergens should be eliminated so far as possible and desensitization reserved for severe cases. Pulmonary infection should be treated early with the appropriate antibiotic. Infection of the nasal sinuses might also require treatment. Emotional factors were often present in chronic cases and should be sought.

Symptomatic remedies were used when the main precipitating factors had been dealt with. In mild cases, inhalations gave relief and were harmless. Breathing exercises were valuable. The use of adrenaline, aminophylline, and other bronchodilator drugs was well established. More recently, cortisone and corticotrophin had been used, and they represented the greatest advance in treatment since the introduction of adrenaline. However, their action was purely symptomatic, and side-effects were likely to occur if they were used for longer than very short periods. The main uses of corticoid therapy in asthma were to treat severe status asthmaticus, to prevent status asthmaticus when it threatened to occur, and as long-continued treatment in some severe, chronic cases. There were numerous contraindications to the use of corticoid therapy in asthma, such as the coexistence of tuberculosis, peptic ulcer, heart failure, diabetes mellitus, hypertension, and nephritis.

Treatment of Asthmatic Attack

Dr. D. A. WILLIAMS (Cardiff) said that an acute attack of asthma might vary in severity from a mild attack easily controlled by simple symptomatic therapy to the highly dangerous condition of status asthmaticus. For a mild attack one of the many inhalants such as adrenalin. et atropin. co. (N.F.) or isopren. sulph. co. (N.F.) was an effective and safe form of treatment. Ephedrine by mouth was also useful for treating mild attacks in younger people, but in the elderly oral aminophylline was better. Antihistamine drugs were of little use. For more severe attacks isoprenaline tablets or subcutaneous adrenaline were the drugs of first choice. In status asthmaticus, when ordinary doses of adrenaline failed, the practice of giving additional adrenaline at the rate of 1 minim (0.06 ml.) per minute was often successful. Intravenous aminophylline often succeeded when adrenaline failed. Cortisone, corticotrophin, and related compounds were a major advance in the symptomatic treatment of asthma, especially for the treatment of status asthmaticus and in severe chronic asthma resistant to other forms of therapy. The contraindications to corticoid therapy should not be forgotten. A suitable dose for status asthmaticus was 300 mg. in divided doses on the first day, 200 mg. on the second, and 100 mg. on the third and subsequent days for a period of 7-10 days. Corticotrophin was most conveniently given in the form of the long-acting A.C.T.H. gel by intramuscular injection, the usual dose being 80 units on each of the first four days, followed by gradual reduction over the next few days. Improved symptomatic therapy had reduced the importance of

sedatives. Paraldehyde was a safe and effective hypnotic for severe cases. Neither morphine nor pethidine should be used, both because they were drugs of addiction and because they might cause respiratory depression and death.

Psychological Approach to Asthma

Dr. D. O. NEIL (London) said that emotional excitement could provoke an asthmatic attack. The three types of emotional excitement most commonly concerned were anxiety, resentment, and feelings of guilt. Secondly, the illness often began when the patient's emotional atmosphere was highly charged. Thirdly, when the asthmatic attacks were linked to emotional tension, it might be possible to modify either the circumstances of the patient's life or his reaction to them, so that the attacks diminished or disappeared. It was easier to achieve this with children than with adults. One of the most satisfying things in medicine was to see asthmatic attacks in an only child subside as the child grew less anxious and the mother learnt to handle him (and her own reactions) differently.

Recent Advances in Therapeutics

Dr. A. H. DOUTHWAITE (London) discussed some therapeutic advances in three common conditions—barbiturate poisoning, hypertension, and duodenal ulceration. Addiction to barbiturates had become alarmingly common, and the rise of barbiturate poisoning proceeded *pari passu* for these drugs had now become the favourite agent for suicide. A new antidote was bemegride ("megimide"), whose molecular structure was similar to that of the barbiturates. It was given intravenously in doses of 50 mg. repeated every five minutes until the patient was only lightly comatose. Use of the drug to bring about full consciousness was likely to induce vomiting, twitching, and convulsions. There was now a reaction against routine gastric lavage in barbiturate poisoning, for most of the drug had left the stomach before coma ensued and many deaths had been caused by the inhalation of gastric washings by comatose patients.

The most important advances in the treatment of hypertension had been the discarding of surgical procedures such as sympathectomy and the development of various hypotensive drugs. The most powerful hypotensive drugs acted as ganglion-blocking agents. Hexamethonium salts had generally been superseded by pentolinium tartrate ("ansolysen"). The latest ganglion-blocking drug was "ecolid," which was more powerful and prolonged in its action than earlier agents. The ganglion-blocking agents were effective in smaller doses if they were combined with other hypotensive agents such as reserpine and hydralazine.

In connexion with the control of gastric acidity in duodenal ulcer, the speaker described the action of alkalis incorporated in tablets which were slowly sucked, such as "nulacin" tablets. More recently aluminium glycinate had been used as the basis of a tablet to be sucked ("rodexin"). The control of night secretion was a separate problem, and the speaker described the effect of oral mersalyl in suppressing gastric secretion, a method he had recently been using.

Analgesic Drugs

Professor STANLEY ALSTEAD (Glasgow) defined analgesics, and pointed out that their use represented merely one part of a much bigger subject, the relief of pain. He said that the cynic might classify analgesics into two groups: (a) drugs which were very effective but which should not be used; (b) drugs which might be used though they were not very effective. The critical practitioner's approach to the subject was naturally empirical but was none the less valuable, and was indeed complementary to the brilliant contribution of the chemist and the pharmacologist. The speaker then commented briefly on analgesics grouped on a clinical basis of potency—"the incomparable morphine" at one end of the scale and "the humble aspirin" at the other. In the intermediate group were several fairly powerful analgesics which had mostly fallen into disuse because of their

toxicity—acetanilide, phenacetin, phenazone, and amidopyrine. Special reference was made to N-acetyl *p*-aminophenol; under its trade name of "panadol" it was a fairly recent innovation, but it could claim ancient lineage because of its relationship to acetanilide and phenacetin.

Professor Alstead included pethidine in his intermediate group and discussed its merits and its limitations. Among special techniques for enhancing the potency of analgesics the speaker referred to the intravenous injection of small doses of morphine, and also to the combination of morphine and chlorpromazine when long-continued use was necessary.

Use of Drugs in Neurosis

Dr. DESMOND CURRAN (London) said that, while the treatment of the psychoses was a job for the psychiatrist, every practising doctor dealt with patients who suffered from insomnia, tension, anxiety, mild depression, or anorexia. Judicious use of the many drugs now available was a great aid in treating such complaints, although the physician might be confused by the plethora of drugs now being released on the market, often without adequate clinical trials. Three classes of drugs were involved—hypnotics, sedatives (or “tranquillizers” in modern jargon), and stimulants. With respect to hypnotics, the speaker's preference was for barbiturates, pentobarbitone for short action and amylobarbitone sodium for longer action. As a tranquillizer, amylobarbitone sodium was effective, safe, and cheap. Chlorpromazine and reserpine had achieved notoriety in recent years, but though of proved worth in psychotic illness their value in neurosis was not proved. Various new drugs were available. Stimulating drugs were chiefly used in mild depression, when the patient noticed exhaustion and fatigue. The physician must first distinguish between endogenous depression (best treated by electric convulsion therapy) and reactive depression following social or domestic stress, in which amphetamine and its derivatives were of great value. To counteract the insomnia and irritability which might occur with these compounds, they were often combined with a sedative drug.

Illness as a Hobby

Dr. RICHARD ASHER (London) entertained the section with a discourse at once wise and witty on "Illness as a Hobby." Most people had a hobby of some kind, he said, and some of them chose illness. The devotees of this hobby could be classified into three main groups. First came "the genuine student," who, without being neurotic, took a keen interest in his illness and developed an extensive knowledge of x rays, blood tests, etc. When the illness was going well it was a harmless enough hobby, but there was always a risk of the devotee becoming hypochondriacal in the process. Secondly, there was the chronic hypochondriac, who might be one of several varieties. The rich hypochondriac travelled about Europe, going from one consultant to the next, and thus could be regarded as the "grand tour" type. Such women were usually married to rich but inattentive husbands who supplied them with money for their hobby as a substitute for affection. They were fond of discussing with their friends the virtues and failings of the various consultants they had seen, much as they would argue over the merits of rival tailors or hairdressers. The poor hypochondriac, precluded from extensive travelling, became the "perpetual out-patient," of which every hospital had its quota. Discharged from one department, they lost no time in appearing at another, and thus acquired a collection of documents rivaling that of their rich sisters, though written on less luxurious paper. Another variety was the chronic convalescent, the man who had had a long-standing organic illness and could not bear to give it up and thus abandon the sympathetic inquiries of his friends and the security of his medical régime. The third main group included the sufferers from chronic autogenous disease, among which we might recognize anorexia nervosa and Munchausen's syndrome. The speaker concluded: "To make a hobby of one's own illness is always a mistake, whereas to make a

hobby of studying other people's illnesses is an enthralling pursuit and the purpose of this annual meeting."

Placebos

Professor E. J. WAYNE (Glasgow) contributed a valuable paper on placebos. He said that for a long time little interest had been taken in the action of placebos, but numerous clinical trials employing inert "dummy" preparations in order to make the trial a "blind" one had incidentally revealed that the placebo itself could exert powerful therapeutic effects. He gave several examples of how chemically inert substances had been shown to bring about both subjective and objective improvement in a considerable proportion of patients. For example, he had personally conducted a controlled trial of the treatment of asthma by a protein derivative which was compared with saline injections. There was no difference between the two forms of treatment, but, more important in the present context, a considerable proportion of the subjects were improved by the inert therapy. An even more striking example of the power of placebos was the finding by other workers in a blind controlled trial of mephenesin that, not only did the same number of patients show improvement in the treated and control groups, but three control cases developed complications in the form of dermatitis medicamentosa, urticaria, and severe diarrhoea.

The question arose whether it was wise to use placebos deliberately, with the physician realizing that he was making use of suggestion as the therapeutic agent proper. Some had condemned this practice, like the person who said that "the placebo is a form of deceit, initially of the patient, ultimately of the doctor." The speaker himself thought that placebos should be used. "When a physician is in doubt about whether a medicine is going to act through physical or psychological mechanisms, he should use a simple, cheap, and relatively inert preparation. If he does not achieve the desired effect he can then try the effect of more potent preparations."

Epidemic at Royal Free Hospital

Dr. N. D. COMPSTON (London) described an outbreak of an epidemic illness which affected more than 300 of the staff of the Royal Free Hospital group. The clinical features resembled those described in epidemics in Iceland and elsewhere since 1948 of an illness now named benign myalgic encephalomyelitis. The earliest symptoms were malaise and headache, with depression. Within a week there supervened severe pain in the neck, back, or limbs, and dizziness. In some cases the illness proceeded no further, but in the majority neurological symptoms appeared together with intensification of the earlier symptoms. The neurological manifestations were cerebral irritation, with photophobia and neck rigidity, hypersomnia, nightmares, panic states, and uncontrollable weeping. Blurred vision due to intrinsic ocular palsy was sometimes found. Pupils were often unequal and reacted poorly to light and accommodation. Various extrinsic ocular palsies were met with and lateral nystagmus was frequent. Other cranial nerve palsies were fairly frequent. Vertigo sometimes became severe and was at times associated with nerve deafness. The limbs and trunk were usually involved in the patients with central nervous signs. Both motor and sensory disorders occurred. The course varied. Without neurological involvement, recovery was complete in one month, although recrudescence might occur. The more severe cases required hospital treatment for some months, and a few patients were still disabled after nearly a year although recovery was proceeding. No specific treatment had been found of value. Premature activity should be avoided because of the danger that relapse might be provoked. The diagnosis had to be made on clinical evidence. The cerebrospinal fluid was uniformly normal and no other laboratory tests had been found helpful. Extensive virus studies in different laboratories had so far proved entirely negative, and it seemed as though the infection was not due to any known virus.

minal surgery done in three general hospitals in the Brighton area over a five-year period, and in 10,166 abdominal operations there were 140 bursts, or an incidence of 1.3%. When appendicectomies were excluded the figure was 2.1%, and this agreed with other reviews in the literature. Most bursts occurred about the fifth or sixth day, and upper abdominal incisions were more prone to rupture than lower ones. The mortality rate was 30%, and this, too, was similar to other workers' series.

He distinguished between two varieties of wound disruption. On the one hand there was the debilitated patient with a wound which never showed signs of healing and which gaped between the sutures. But it was more with the second type of case he was concerned, where a patient in good condition disrupted his wound after discharging sero-sanguineous fluid about the fifth or sixth day. Some of these were undoubtedly due to bad surgical technique, imperfect haemostasis, and poor closure of the peritoneum. Others appeared to be outside the surgeon's control. None occurred in cases operated upon in nursing-homes, and the records did not show any significant correlation between anaemia or low serum proteins and the incidence of wound disruption. The bursts occurred most commonly in the fifth, sixth, and seventh decades, and more than a third were in patients with malignant disease. The greatest incidence occurred in the winter months and might be linked to cough. 45% of those investigated showed wound infection. Catgut alone had been used in 72% of the bursts, and it was remarkable how no trace of catgut was found in many of the wounds at resuture. He questioned increased absorption of catgut or allergy to it. An exciting factor was always increased abdominal pressure, usually due to cough, vomiting, and ileus.

Mr. SELWYN TAYLOR (London) considered that a discussion concerned with mistakes was of much more value than one concerned with successes, and that this part of the programme should have started the day, not finished it. He had reviewed the figures at a teaching hospital and was surprised that there was an almost identical pattern of age, sex, day of disruption, and preponderance of bursts following elective rather than emergency surgery, as in Mr. Park's series. Rather more of the wound disruptions followed operations by members of the senior staff, but probably many of these were completed by junior ones. Too much reliance should not be put on a study of other people's records. He agreed with Mr. Park that the burst abdomen was of two quite distinct kinds, and confined his remarks to those whose wounds disrupted for no obvious reason. The sero-sanguineous fluid, which could appear as early as twenty-four hours after operation, had never been thoroughly investigated, and he made a plea for a study of its bacteriology both aerobically and anaerobically. It did not appear to matter what type of suture material was used, since bursts had occurred where catgut, thread, silk, and steel wire had been used. He quoted the experimental work of Professor Sandblom, who had shown that where repeated wounds were made subsequent ones healed more swiftly. This might explain why a burst abdomen when resutured usually healed. In experimental wounds the introduction of antibiotics had improved the tensile strength, which suggested that asepsis was important. Finally he stated that he could find no record of a burst following a transverse abdominal wound, so that placing an incision was important if this complication was to be avoided.

Mr. HOSFORD (London) stated that the nursing staff should be taught the importance of the appearance of sero-sanguineous fluid in a wound, and they should report it at first sight. Mr. HAROLD DODD (London) said that he always explored a wound as soon as such a discharge occurred. Mr. BERNARD WILLIAMS (Portsmouth) had never seen a burst following transverse incisions, but Mr. G. E. MOLONEY (Oxford) had seen two occurring in patients who were jaundiced. Many others took part in the discussion, and it was apparent that there was no unanimity among those present either in the choice of material or in the technique for closing wounds.

SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND CHILD HEALTH

Tuesday, July 10

Post-maturity

The president of the Section of Obstetrics and Gynaecology, Professor T. N. A. JEFFCOATE (Liverpool), took the chair for the opening of the joint session with the Section of Child Health. The first subject discussed was post-maturity. Mr. T. L. T. LEWIS (London) remarked that true post-maturity not only meant prolongation of pregnancy beyond 40 weeks but also implied consequent placental inadequacy. With the foetus progressively deprived of its oxygen supply, it was in danger of dying from anoxia. Death *in utero* before labour was uncommon, but the contractions of labour suddenly reduced the oxygen supply still more. Slowing of the foetal heart and the passage of meconium might then be a warning of foetal distress, but death might be too sudden to allow delivery of a live baby. A few babies survived labour only to die soon after from the inhalation of liquor amnii during labour in response to hypoxia. Mr. Lewis said there were two kinds of evidence for belief in post-maturity. First, there was a significantly higher perinatal mortality when pregnancy was much prolonged. Secondly, experimental work had shown that the percentage oxygen saturation of foetal blood decreased gradually up to term and rapidly thereafter. By the 43rd week of pregnancy there was only enough oxygen in the umbilical vein for the basal metabolic needs of the foetus and no reserve of oxygen for the foetus to use during the uterine contractions. There was also a greater proportion of long and difficult labours in post-mature cases, even after excluding disproportion and malpresentation. Mr. Lewis then discussed the diagnosis of post-maturity. Generally, the duration of pregnancy had to be estimated on the sum total of all clinical and radiological evidence. The greatest risk of post-maturity was in primigravidae over the age of 25 who were at least one week overdue.

Mr. JAMES WALKER (London) concerned himself with the management of prolonged pregnancy. He adduced figures to show that the perinatal mortality in deliveries after the 41st week could be greatly reduced by accepting three principles: that prolonged pregnancy plus another anoxia-producing factor (such as toxæmia) added to the foetal risk; that meconium staining in a long labour was an indication for caesarean section; and that difficult vaginal delivery was to be avoided in the post-mature baby. He advocated routine induction of normal primigravidae of over 35 at the end of the 41st week of pregnancy. It had been suggested that the induction of labour after term was attended by more risks than profits. About 100 inductions would be required to save 5 babies, but he himself thought it was worth it. If induction produced scanty liquor, especially if it was thick meconium, there was much to be said for immediate elective section. If labour did not follow amniotomy an intravenous oxytocin drip might be started on the third or fourth day, and in the uncommon case in which this was also ineffective section should be seriously considered.

Dr. T. E. OPPÉ (London) said that most post-mature babies showed no ill effects and were not readily distinguishable from infants born at term. From the point of view of the paediatrician, however, the baby might show signs of past or present anoxia, with difficulty in breathing, asphyxia, and signs of pulmonary aspiration. It might be dehydrated and wasted, but its alert expression, long nails, and absence of vernix distinguished it from the premature baby. Neonatal death in the post-mature baby was usually due to asphyxia or aspiration and less often to trauma or infection. Except for the prolongation of pregnancy seen sometimes in anencephaly, congenital malformations were not more common in post-mature infants. The paediatrician's concern was limited to resuscitation, drainage of

bronchial aspirate, and care of the dry cracked skin. The baby was usually hungry and required full feeds for optimal growth.

Mr. G. H. BANCROFT-LIVINGSTON (Belfast) described experimental work on the level of oxygen in umbilical-vein blood of the infants of primigravidae delivered vaginally, with no evidence of foetal distress. This had failed to show any relationship between oxygen level and either maternal age or apparent maturity of the foetus. When foetal distress had been present it was nearly always in prolonged pregnancy, but again it had been impossible to correlate foetal distress with oxygen levels in umbilical-vein blood. He did not think that prolongation of pregnancy constituted such an important problem, and it seemed unlikely that anoxia played the major part in post-maturity. The care of the individual patient was to be preferred to any method of mass induction at any given date. The passage of meconium, although not closely correlated with foetal anoxia, might indicate foetal embarrassment of a transient nature, but it was a neonatal rather than an obstetric problem.

Dr. O. D. FISHER (Belfast) said that a study of the haemoglobin level in cord blood of babies of normal primigravidae had not shown any significant correlation between haemoglobin level and foetal age or maternal age. The lowering of the intrauterine oxygen level was not reflected in a rise in foetal haemoglobin level. Post-maturity of itself in a rise in foetal haemoglobin level. Post-maturity of itself did not constitute a major paediatric problem, but the inhalation of meconium might produce a paediatric emergency.

Others who participated in the discussion were: Mr. A. PERRY (Dunedin, New Zealand), Dr. BERYL D. CORNER (Bristol), Dr. MARK S. FRASER (Aberdeen), Mr. R. M. CORBET (Preston), Miss MARY K. LAWLOR (Brighton), and Dr. A. BARKER (Whitstable).

Haemolytic Disease of the Newborn

Mr. J. B. BLAKLEY (London), a vice-president of the Section of Obstetrics and Gynaecology, took the chair when Dr. D. C. A. BEVIS (Manchester) opened the discussion on the rhesus factor and the management of haemolytic disease of the newborn. He said that the sensitized Rh-negative pregnant woman presented a difficult problem to the obstetrician. There were no clinical signs in the antenatal period which enabled one to assess the foetal condition, yet it was the obstetrician's duty to present to the paediatrician an infant as undamaged and yet as mature as possible. Dr. Bevis then reviewed the attempts that had been made to limit the effects of rhesus iso-immunization during the antenatal period. The transfusion of the mother with Rh-negative blood, the injection of stronger antigens or of negative blood, the injection of methionine, and ethylene disulphonate, the administration of methionine, and the injection of extracts of Rh-positive blood (haptens) were all ineffective, while the use of cortisone might only increase the hazards to both mother and baby. As regards the prognosis for the individual baby, the previous obstetric history of the mother was only sometimes helpful. Studies of changes in the titre of antibodies during the pregnancy were of doubtful prognostic value. He himself had thought that, as the affected baby was being subjected to haemolysis *in utero*, it was logical to look for evidence of the degree of this haemolysis antenatally by chemical analysis of liquor of this haemolysis antenatally by chemical analysis of liquor removed by abdominal paracentesis. Investigations in 41 affected babies showed that the maximum amount of free iron in the liquor during pregnancy was proportionate to the cord haemoglobin concentration at birth. This method was useful, but did not forewarn of the possibility of kernicterus in the individual case. The more anaemic the baby at birth the more likely it was to develop kernicterus, but kernicterus could occur even with a normal cord haemoglobin level. However, he had found that the concentrations of bilirubin and oxyhaemoglobin in the liquor gave a fairly accurate index of prognosis for the baby. The bilirubin concentration was high and the oxyhaemoglobin concentration low in the case of babies which were anaemic or hydropic at birth. The babies that were potentially kern-

icteric had high concentrations of both. In the absence of estimations of the liquor pigments a shrewd idea of the outlook could be obtained by similar examination of the cord blood. The maximum death rate for kernicterus, continued Dr. Bevis, was on the fourth day of life, and a replacement transfusion in the first 24 hours after birth could therefore be life-saving. He believed that these examinations of liquor and cord blood would eliminate unnecessary replacement transfusions. Moreover, they might indicate in which individual cases it was advisable to induce premature labour.

Exchange Transfusion

Dr. P. L. MOLLISON (London) discussed the indications and results of treatment of haemolytic disease by exchange transfusion. While anti-Rh immunization was about as common as ABO incompatibility, 60% of the infants born to immunized Rh-negative mothers required treatment, whereas treatment was only rarely required in ABO incompatibility. Only 1% of Rh-negative mothers with Rh-positive husbands became immunized in the first pregnancy and about 10% in the second. Previously many women had been sensitized by blood transfusion or intramuscular injection, but this was becoming much less common as blood typing improved. He was strongly of the opinion that estimation of cord haemoglobin and bilirubin concentration provided the most reliable indication of severity of the disease or the chance of developing kernicterus. Prematurity significantly reduced the chance of survival. It was very doubtful if spectroscopic examination of liquor was yet accurate enough to be used to decide severity or predict treatment. Two antibody tests—one early in pregnancy and one at 32–34 weeks—were required as a routine, and Dr. Mollison said he was shocked to discover, only a year ago, that only 50% of all women were so tested. The mother with Rh antibodies in her serum should be delivered in a hospital staffed and equipped to care for the infant. At delivery cord blood should be taken from all Rh-negative mothers. In his hospital, if the Coombs test was positive, all premature infants received exchange transfusion. The bilirubin level was recorded, and the aim was to prevent a rise to more than 20 mg. per 100 ml. Repeated exchange transfusion was done if necessary. The technique of exchange transfusion had always required skill and care. In particular infants became ill if a greater volume of blood were injected into the circulation than was removed from it. Packed cells should be used rather than stored citrated blood.

Kernicterus of Prematurity

Dr. BERNARD M. LAURANCE (Derby) described the kernicterus of prematurity. The premature infant was usually under 4½ lb. (2 kg.) and on the fourth to fifth day became deeply jaundiced, went off his feeds, developed head retraction, and sometimes had cyanotic attacks. At Derby two years ago six premature infants had died of kernicterus of prematurity soon after the dose of vitamin K analogue had been increased to 10 mg. three times a day for three days by intramuscular injection; thereafter the dose was reduced to 2 mg. as a single dose (and later to 1 mg.), and since then 250 premature infants had been admitted and there had not been a single death from kernicterus. There seemed no doubt that in the premature infant the injection of vitamin K was associated with a rise of serum bilirubin.

The next speaker was Dr. A. C. ALLISON (Oxford), who described work which showed that vitamin K analogues produced haemolysis in experimental animals deficient in vitamin E. Not all vitamin K analogues produced the same degree of haemolysis, but only small quantities of vitamin K substances were required to prevent or treat haemolytic disease—1 to 2 mg. as a single dose was sufficient.

Dr. BERYL D. CORNER (Bristol) supported the previous speakers, and said the changes in the kernicterus of prematurity and of haemolytic disease were identical. In the mature infant the bilirubin was maximal on the second day,

but in the premature not until the sixth day. Exchange transfusion was usually required when the circulating bilirubin rose higher than 25 mg. per 100 ml. of blood. In Bristol for 2½ years menaphthone dipotassium bisulphate vitamin K analogue had been used, and in 308 premature infants no significant difference in bilirubin levels could be detected between those who had received this vitamin K analogue and those who had no vitamin K. In that series there were no deaths from kernicterus.

In the following discussion Dr. O. D. FISHER (Belfast) presented figures which he claimed suggested that premature induction of labour resulted in a smaller foetal loss than in the series allowed to proceed to spontaneous labour. In reply, Dr. MOLLISON pointed out the many difficulties of investigations of that type, and stated that in his view the only method of pursuing clinical trials was one in which the cases were divided by true random selection.

SECTION OF OBSTETRICS AND GYNAECOLOGY

Wednesday, July 11

Management of Hypertension in Pregnancy

Mr. J. R. NICHOLSON-LAILEY (Taunton), a vice-president of the Section, occupied the chair when Professor R. J. KELLAR (Edinburgh) opened the discussion on the management of hypertension in pregnancy. Professor Kellar said that about 10% of all pregnant women developed a degree of hypertension during pregnancy—that is, a blood pressure of more than 140/90 mm. Hg. The pregnancy toxæmias still caused an appreciable number of maternal deaths and a high proportion of the perinatal foetal mortality. Control of the hypertension was more effective in improving the prognosis for the mother than for the baby.

The most important discovery in recent years had been that pre-eclampsia was associated with a diminution of the blood supply to the placenta. This caused impaired transfer of nutrients and oxygen to the foetus and diminished the steroid function of the placenta. The first object of treatment was to prevent the mother developing eclampsia, and this could nearly always be done. Secondly, it was desirable to improve the placental blood flow in the interests of the foetus, but this was less easily achieved because the changes in the placental vessels might be irreversible, especially if the toxæmia was of long standing. Even the milder cases of toxæmia were best admitted to hospital for rest, sedation, and observation, because the course of the disease was unpredictable. Reserpine was a useful drug if the hypertension continued despite these measures, but had to be employed with caution. It was more apposite to cases of essential hypertension than to simple pre-eclamptics. The patient with severe or imminent pre-eclampsia constituted an obstetric emergency. Termination of the pregnancy was generally required within a few days no matter what treatment was given, but hypotensive drugs could be used to control the blood pressure and thus prevent the onset of convulsions.

Mr. E. W. L. THOMPSON (Dublin) said it was important to establish early in pregnancy the individual patient's basic blood pressure. If it were high it did not necessarily portend a complicated pregnancy or labour, but it did call for special care and supervision by the obstetrician. There were four types of hypertension in pregnancy—pure pre-eclampsia (foetal loss 5%), essential hypertension (foetal loss 10%), essential hypertension with pre-eclampsia superadded (foetal loss 18%), and chronic nephritis. The first was commonest, the last was rarely seen, the middle two constituted about 15% of cases of hypertension in pregnancy, and the third was most dangerous clinically. Mr. Thompson then described the management of these patients, stressing the traditional measures of rest, adjustment of diet, and limitation of salt intake. Hypotensive drugs were valuable for the temporary protection of the patient with a dangerously high blood

pressure. One tried to prolong the pregnancy until at least the 35th week, and induction of labour was commonly planned for the 37th week if the cervix was ripe. Caesarean section had been performed in 11% of his cases, the indications being uncontrollable toxæmia or the presence of additional adverse factors.

Mr. VINCENT O'SULLIVAN (London), Dr. KATHARINA D. DALTON (London), Mr. JOHN SOPHIAN (London), and Mr. S. BENDER (Chester) contributed to the ensuing discussion.

Diagnosis of Ectopic Pregnancy

Mr. J. R. Nicholson-Lailey vacated the chair in favour of his vice-presidential colleague, Mrs. CONSTANCE L. BEYNON (Brighton), before Miss MARY K. LAWLOR (Brighton) read a paper on the diagnosis of ectopic pregnancy. After detailing the classical symptoms and signs, Miss Lawlor emphasized the atypical picture presented by the subacute or chronic case. She then reviewed the diagnostic value of certain ancillary investigations. Curettage, aspiration of the pouch of Douglas, colpotomy, culdoscopy, salpingography, and arteriography had all been advocated with varying enthusiasm, but none afforded an infallible guide. In particular, the absence of any evidence of pregnancy decidua or placental tissue either in the uterine curettings or even in the original site of the ectopic gestation did not necessarily invalidate the diagnosis. Dr. E. E. RAWLINGS (Salford) contributed to the discussion a note on the value of aspiration of the pouch of Douglas.

Retroversion of the Uterus

Mr. K. F. MACKENZIE (Brighton), a vice-president, took the chair when Mr. K. V. BAILEY (Manchester) read a paper on the importance of retroversion. Mr. Bailey described three varieties of retroversion—the so-called congenital, the puerperal, and the pathological. Congenital retroversion probably represented a pubescent manifestation of minor endocrinal dysfunction. There were usually no related symptoms, but if the uterus were also acutely retroflexed, dysmenorrhoea, menorrhagia, and relative infertility were likely to occur. Puerperal retroversion was important only if the bulky subinvolved uterus occupied the pouch of Douglas; if so, backache, pelvic dragging pain, and menorrhagia might follow. Fertility was lowered, and if pregnancy occurred the gravid uterus might become impacted in the pelvis. In pathological retroversion the uterus was pulled backwards and was limited in mobility by adhesions either of inflammation or of endometriosis. The symptoms here were of the underlying condition, and it was at this that treatment must be directed. A spirited discussion followed in which the president, Professor T. N. A. JEFFCOATE (Liverpool), Mr. J. R. NICHOLSON-LAILEY (Taunton), Dr. E. E. RAWLINGS (Salford), Dr. C. J. FARR (Cuckfield, Sussex), Mr. JOHN SOPHIAN (London), Dr. BADEN R. COOKE (New South Wales), Mr. J. B. BLAILEY (London), Mrs. CONSTANCE BEYNON (Brighton), Dr. C. D. COE (Brighton), Mr. JOHN MACPHERSON (Torquay), and Dr. MARGARET I. NEAL-EDWARDS (Hove) took part.

SECTION OF ANAESTHETICS

Tuesday, July 10

Management of Respiratory Paralysis

With the president, Dr. H. E. K. ECCLES (Brighton), in the chair, Professor E. A. PASK (Durham) presented the opening paper on the management of respiratory paralysis. He outlined the many conditions in which respiratory paralysis occurred as a symptom of disease and those conditions in which it was induced, as in anaesthesia or during the treatment of tetanus. Though paralysis of respiration was often the most dramatic feature of the disease, he emphasized that the needs of other bodily systems should also be considered in treatment. The method of performing artificial respiration should be chosen to fit the particular circumstances. It

should be efficient but should not interfere either with physiological function or with the general treatment of the patient. Although various methods would always exist, immediate use of any available method was vital in emergencies. When paralysis was maintained for a longer period the efficiency of lung ventilation was important.

The use of intermittent positive pressure through a tracheostomy was becoming increasingly common, for this method also facilitated the separation of the new airway from the pharynx.

Professor Pask then gave some criteria for assessing the effectiveness of methods of artificial respiration and illustrated a device for sampling end-expiratory air developed at Newcastle. Finally he emphasized that when a patient with a tracheostomy was paralysed for any length of time communication with him was assisted if a controlled leak permitted whispering.

Dr. R. BRYCE-SMITH (Oxford) considered the respiratory problems of comatose patients, especially those with head injuries. Anaesthetists could give help in such circumstances, for anaesthesia gave practical experience in the problems involved. Patients with head injuries could easily die from complications such as the inhalation of regurgitated gastric contents. First-aid workers should be encouraged to transport all such patients in the semi-prone position, which would prevent this complication and at the same time help to maintain a patent airway. When the airway could not be maintained unaided, an endotracheal tube might be used, but only temporarily. If unconsciousness was thought likely to persist longer than 48 hours a tracheotomy should always be performed.

Dr. A. CRAMPTON SMITH (Oxford) spoke on the respiratory problems of poliomyelitis, emphasizing the importance of treating these cases in a unit with experience in handling the special problems which arose. The method of treating these cases depended on the type of paralysis present, and here some classification was of assistance. The patients could be grouped according to symptoms into three main categories—those with dysphagia, those with respiratory paralysis, and those with dysphagia and paralysis. The treatment of patients in the dysphagic group was in the first place posture. For patients in the other groups treatment was by tracheostomy and artificial respiration by intermittent positive pressure. It was important to realize how the patient's symptoms could quickly change and thus necessitate changes in treatment.

Dr. H. B. WILSON (Aberdeen) then spoke on the treatment of tetanus. Cases with a short incubation period admitted with classical signs of the disease would probably require the use of muscle relaxants. It was vital to have control of the airway by a high temporary tracheostomy through which artificial respiration could be carried out. The general anaesthetic for this also allowed the initial wound to be excised. The cuffed endotracheal tube prevented contamination of the lung by pharyngeal secretions and permitted aspiration of the trachea. Dr. Wilson discussed some aspects of the various machines used for performing artificial respiration and their effectiveness in patients being treated for tetanus. He believed that d-tubocurarine was the most suitable agent to produce muscle relaxation; the results of treating cases in this way were so hopeful that it should be considered the method of choice.

Those taking part in the subsequent discussion included Dr. H. B. C. SANDIFORD (Portsmouth), Dr. J. F. GALPINE (Coventry), Dr. H. H. PINKERTON (Glasgow), and Dr. R. P. HARBORD (Leeds).

Anaesthesia for Aortic Graft

The second half of the meeting was devoted to four occasional papers, and Dr. J. H. CRAWFORD (Brighton), a vice-president, took the chair.

Dr. H. L. THORNTON (London) gave details of the very careful pre-operative investigations and treatment carried out on patients requiring an aortic graft. The site of operation determined the method of anaesthesia. If the site was above

the origin of the renal artery, he used his standard anaesthetic technique and hypothermia was induced in addition. Dr. Thornton then described the method used at St. Mary's Hospital, giving details of the drugs used, the measurement and control of cooling, and the value of blood-pressure control and E.C.G. observations. During the post-operative period special attention was devoted to producing a slow rise in temperature and to maintaining the blood pressure and electrolyte balance. With this careful technique he found that the operative risk in these cases could be reduced to that of other thoraco-abdominal operations.

Anaesthesia for Fenestration

Dr. R. A. BINNING (Brighton) described the method of anaesthesia for the fenestration operation which he had found to be the most successful and which he had put into current practice at the Royal Sussex County Hospital. He gave chlorpromazine and promethazine hydrochloride together with "omnupon" and scopolamine as premedication, and thiopentone, nitrous oxide, and oxygen as the basic anaesthetic, using a large-bore cuffed tube. Effective topical anaesthesia was essential, and 4% lignocaine was used for this. Local infiltration, irrigation with adrenaline in saline, and a steep anti-Trendelenburg position minimized bleeding.

Recovery Rooms

Dr. RUSSELL M. DAVIES (East Grinstead) outlined the development of post-operative recovery rooms at East Grinstead, giving details of early American and Canadian experience in this field. The statistics available of operative mortality throughout the country confirmed the belief that the widespread practice of special post-operative care in recovery rooms would be of the greatest value. Dr. Davies concluded by stating that, although recovery rooms might now be thought a luxury, they would be considered essential at all hospitals in a few years—a belief supported by all the members of the Section.

Neurological Complications of Anaesthesia

Mr. G. BONNEY (London) described the neurological complications of anaesthesia as seen by an orthopaedic surgeon, and discussed the pathology of nerve injuries, differentiating between the degenerative and non-degenerative lesions of peripheral nerves and their mode of recovery. He then described the causation of nerve injuries occurring in patients under anaesthesia. Post-operative examination and diagnosis gave some fair idea of prognosis. If degenerative changes occurred the only method of treatment was operative. The probability of success depended largely on the site and nature of the injury.

SECTION OF CHILD HEALTH

Wednesday, July 11

Accidents in Children

The president, Dr. WILFRID SHELDON (London), introduced the members of the panel for the round-table conference as Dr. C. A. BOUCHER (Ministry of Health), Mr. PATRICK CLARKSON (London), Dr. RONALD MAC KEITH (London), and Dr. KEITH SIMPSON (London). The questions had been grouped to represent different aspects of the problems of accidents.

Question 1: It has been said that in Canada and America accidents in pre-school children (1-5 years) were responsible for more than twice the number of deaths caused by the common infectious diseases of early childhood. Were there any comparable figures for England and Wales? In reply, Dr. BOUCHER said the number of deaths from accidents was more than three times the number of deaths from the common infections mentioned. They were the third most important cause of death in that age group, and at school age the second most important cause. Dr. SIMPSON

said that to compare the accidents which caused death with the infectious fevers which formerly caused death did not give a true picture of the present position.

Question 2: What was the importance of accidents relative to the other causes of death? Dr. SIMPSON replied that in England and Wales there were 20,000 deaths a year of children at all ages under 5 years. Only 1,000 were caused by accidents. The real killers were congenital malformations, birth injuries, and pneumonia. Most deaths occurred in the first year. But deaths from accidents must not be set against deaths from uncommon diseases. Street accidents accounted for half the deaths from accidents under 5, and the other 500 were caused largely by choking (270), suffocation (185), almost all of which were in the first year, drowning (88), and then a miscellaneous group of poisonous fluids, burns, poisons, etc.

Question 3: What were the particular types of accidents from which infants and toddlers suffered? At the President's invitation Dr. BOUCHER replied. He said that this question linked with the previous one. For infants choking, scalds, and burns were important, for toddlers scalds, burns, and poisoning. In particular he would wish to mention drowning in shallow water. At school ages scalds diminished and burns increased, especially to girls, owing to the burning of clothes. Road accidents increased, and the worst age for accidents with bicycles was the ninth year. The PRESIDENT then asked if drowning in shallow water was associated with epilepsy, but Dr. BOUCHER thought not. Dr. SIMPSON at this point explained that drowning was common at school age, and he was surprised that all schoolchildren did not learn to swim, and that girls did not wear pyjamas rather than nightdresses. Dr. BOUCHER said that one large multiple store had now stopped selling girls' nightdresses, and he regarded this as an enlightened action.

Question 4: Were the facilities for treatment at hospitals adequate? Mr. CLARKSON took this question, and replied that there were some 11½ million attendances at casualty departments in England and Wales each year. In general he considered the provision in casualty departments to be the biggest single deficiency in the hospital services. They were deficient both in staff and in facilities, especially in theatre accommodation, and this deficiency often resulted in unnecessary disability and distress to patients.

Question 5: Were fireworks a cause of serious accidents and were there any limitations on their sale or power? Dr. BOUCHER said he was not well informed about the limitation of sale, but, of course, they could not be sold to unaccompanied children. The major effects were seen in hospital wards in late November. Mr. CLARKSON described the two major forms of accident—explosion of fireworks which the child was carrying in his pockets, and the explosion of a firework held in the hand. In the PRESIDENT's view education of parents in firework techniques was as necessary as the education of children.

Question 6: What part could the mother play in the care of the burnt child, and should children with serious burns go to special hospitals? Every member of the panel agreed that the mother had a major part to play and should come into hospital as much as possible; it did both mother and child great good. Mr. CLARKSON deprecated new wards being planned which did not provide accommodation for mothers. In general, children with serious burns should enter a special unit and go there as quickly as possible.

Question 7: Should clothing be treated to make it non-inflammable? Dr. MAC KEITH gave a practical demonstration of a treated non-inflammable material. He admitted it was not yet widely available and would cost more than the non-treated fabric. Dr. SIMPSON then asked the cost of treating a child with burns and was told that a first admission might cost £150, and several admissions were necessary for every child with severe burns. Mr. CLARKSON thought that when such materials became available some indication of their inflammability should be shown when sold. The question of cost was left to the next question.

Question 8: What was the cost of a road accident? Dr. BOUCHER stated that the average cost was £800, but a fatal

accident cost £3,000. The 200,000 accidents each year cost the community £172m.—more than £3 per head of population.

Question 9: What means could be taken to reduce road accidents in children under 5 and at school age? Dr. MAC KEITH thought the under-fives needed protection and the over-fives education, and in that respect the services of the police were most valuable. He was supported in this by Dr. BOUCHER, who added that the most powerful influence on the children came from the example of the parents, who should also make sure that bicycles and other vehicles were kept in good working order.

Question 10: Was mechanical suffocation common, and was the American practice of "prone" nursing to be advocated? Dr. SIMPSON repeated that almost all deaths from suffocation occurred in the first year of life, and most in the first 6 months; most of these children were found lying on the face. He had no doubt it was more dangerous to allow the infant to sleep on his face than on his back or side. He emphasized that pillows should be porous, but added that many infants found dead had actually died from natural causes, usually infectious. When he met such cases he always examined the child most carefully for marks of pressure indicating that the child might have been held down into the pillow.

Question 11: Had the panel any experience in barbiturate poisoning of the use of specific antidotes? The panel all had such experience and agreed that sometimes the use of bemegride ("megimide") was quite immediate and almost magical.

Question 12: Were the drug firms aware of the dangers of attractive pills which resembled sweets? All the panel felt very strongly on this point. Dr. SIMPSON produced and distributed samples of sweets indistinguishable from pills and pills from sweets. He thought it little short of scandalous that such a state was possible. Manufacturers should put up pills in paper "cellophane" packing or in "kiddiproof" tins. To this Dr. BOUCHER added that nowadays when every home was like a chemist's shop the medicines should be kept locked away and inaccessible to children.

Question 13: Had there been any suggestion that doctors, nurses, and health visitors could help to reduce the toll from accidents? Here again in this final question unity was evident. The panel were sure that everyone visiting the home had a most important part to play. Parents would listen to those in authority, and by slow, patient teaching standards of care would improve. Dr. MAC KEITH thought there was also a place for group teaching in, for example, antenatal clinics and youth clubs.

At the end of this final question the PRESIDENT said that all doctors had an important part to play in this respect, and thanked the panel for a most stimulating and informative session.

Abnormalities Which Cure Themselves

With one of the vice-presidents, Dr. CHARLES F. HARRIS (London), in the chair, the first paper was read by Mr. DILLWYN EVANS (Cardiff), who spoke from the orthopaedic point of view and restricted his remarks to abnormalities of shape, structure, and function. He grouped the deformities under three headings. In the first group he placed deformities which cured themselves once the deforming force had ceased to act—for example, postural deformities resulting from simple malposition *in utero*, some cases of wry-neck, club-foot, or idiopathic scoliosis. Some fractures tended to spontaneous correction of mal-union, but the result depended upon the age of the child, the site of the fracture, and the type of deformity. In the second group he would place deformities which were variations of the normal and now known to be phases in the development of physical types; in the feet pes planus or calcaneus, at the knees genu valgum, were examples. In group three he placed disturbances of function resulting from structural faults which might cure themselves, such as trigger-thumb, clicking knee, popliteal bursitis.

Dr. DERMOT MACCARTHY (Aylesbury) then continued with a paper on non-orthopaedic deformities, describing abnormalities mainly in the newborn and in children up to 3 years of age. Sometimes the natural cure was incomplete and sometimes it could be accelerated by treatment. He then described the various positions of the testes which might simulate true non-descent, and emphasized that the foreskin often adhered to the glans until 3 or 4 years of age. He said 93% of all umbilical hernias would disappear by the end of the first year; afterwards the rate was slow, but the ultimately cure was complete. He then showed slides of the various types of vascular naevi in stages of spontaneous healing, and finished with an account, illustrated by research into the secrets of the latter, of the natural history of the asymmetrical head so commonly seen in infancy. The child refused to lie on the other side. The deformity diminished after the child sat up, but sometimes some degree of asymmetry persisted throughout life.

SECTION OF GENERAL PRACTICE

Tuesday, July 10

Infectious Diseases in General Practice

Under the chairmanship of the president of the Section, Dr. T. A. MORRISON (Brighton), Dr. G. I. WATSON (Peaslake, Surrey) opened the discussion, speaking as a family doctor. In his own practice infectious diseases accounted for 50% of all new visits. After discussing the history of some common infections he continued by pointing out that even at the present time, in spite of all the recent advances in bacteriology and virology, and even with the introduction of antibiotics, a careful clinical examination was of prime importance. Many clinical questions required answers which could easily be given only in general practice. Thus, what was the significance of painless palpable enlargement of the cervical glands? How long before the rash appeared were cases of measles and chicken-pox infectious? What was the incubation period of glandular fever? Was it short—5–12 days—as was usually stated? It was high time that we clarified the whole matter of quarantine. Surely its value was grossly exaggerated. There was much in favour of encouraging German measles in the young. A further aspect that required study was the characteristic seasonal prevalence of diseases.

Dr. Watson described the clinical features of some recent epidemics in his own practice caused by A.P.C. and Cox-sackie viruses, and also mentioned the investigation into the epidemiology of epidemic winter vomiting by the College of General Practitioners. Discussing treatment, he advocated liberal use of oral penicillin and sulphonamides in bacterial infections. He wondered whether there was any danger in using aspirin in fevers, because of its cortisone-like effect. A report was given of the recent investigation carried out by the College of General Practitioners on the value of sulphonamides and antibiotics in the prevention of complications in measles. The results showed that there were no benefits in using these drugs in healthy children; indeed, they might do harm. In unhealthy, catarrhal children they might be useful, but even there it was better to wait for clear indications of the need for such treatment rather than to embark on an expensive and possibly harmful routine.

Dr. LISELOTTE LENNHOF (Brighton) spoke as a hospital clinician. Over the 13 years that she had been at her hospital there had been a change in the incidence of diseases. There had during this time been only one case of diphtheria admitted into the old diphtheria ward. Patients were admitted to hospital because of the severity or high degree of infectivity of the illness. Over the past five-year period the most common diseases admitted to her hospital were intestinal infections, poliomyelitis (proved and suspected), and measles. The greatest clinical problems were experienced with the diagnosis and management of the poliomyelitis group.

Enteric Infections

Dr. J. E. JAMESON (Brighton) spoke as one in charge of a local public health laboratory. Bacteriologists were of help to practitioners in detecting carriers and sources of infections, but even if these were found the mere isolation of organisms was not a proof of their virulence. Haemolytic streptococci were versatile organisms which produced infections of the throat and skin, puerperal infections, and septicaemias. The value of typing different strains was noted, and in impetigo and acute nephritis certain strains were almost specially responsible. In the control of epidemics removal of the carrier from the community was important; this could be done by physical removal of the patient or by producing temporary control of the organisms with parenteral penicillin.

Turning to bacterial infections of the bowels, Dr. Jameson discussed typhoid, paratyphoid, and salmonella infections. Typhoid and paratyphoid infections had similar epidemiological features. Water was a direct source of infection, and indirect sources were shellfish and water-cress. In paratyphoid infections cream cakes were a common source of infection. For infection to occur there had to be a group of circumstances present: the food must be infected, usually by a carrier, it must act as a suitable culture medium with sufficient moisture and at the correct temperature, and it must be eaten when the organisms were still virulent. Investigations to discover the source of infection were often disappointing. Salmonella infections had their reservoirs in animals, and food might be contaminated by dogs, cats, mice, rats, and tortoises, and organisms were often found in duck eggs. Since duck and hen eggs were often pooled as dried bulk or as fluid eggs this was a possible source of infection. The carrier state persisted a long time in typhoid and paratyphoid infections, a moderate time in salmonella infections, and a short time in *Sonne dysenteriae*.

Dr. H. PAUL (Smethwick), a retired medical officer of health, commented on the changing patterns of the common infectious diseases. Tuberculosis deaths had declined, but they were still very considerable—7,000 in 1954. Notifications were not reduced very much, however. It was still the most dangerous infectious disease in our community. New drugs were keeping the "chronics" alive and were increasing the risks of spread. Prevention must above all be based on social measures. Diphtheria had been virtually eradicated but could easily recur if the present apathy in our immunization programme continued. We must develop realistic policies and schemes of immunization for our children. Measles was universal but had greatly diminished in virulence. There was little value in preventing it, except in young and weakly children, since, if we produced too low a level of incidence, in a couple of generations a more serious and more virulent form of disease would emerge.

Among those who took part in the ensuing discussion were Dr. H. W. SALTER (Cleveland, Ohio, U.S.A.), Dr. RALPH GREEN (Hurstpierpoint), Dr. F. M. ROSE (Preston), Dr. R. M. S. MCCONAGHEY (Dartmouth), and Dr. W. J. H. SAYERS (Brighton).

Wednesday, July 11

Neurological Diagnosis in General Practice

Under the chairmanship of the president, Dr. T. A. MORRISON (Brighton), four short papers were read by general practitioners.

Dr. S. L. KAYE (Brighton) spoke on various aspects of neurological diagnosis in general practice. Characteristic patterns of symptoms were of more importance than the elicitation of physical signs, which often were not present till late stages of disease. Ancillary neurological investigations were now rarely carried out in general practice, but they must be interpreted and their significance appreciated. Headaches, personality changes, and fits required elucidation in accurate diagnosis. Physical signs were much more crude than symptoms, and the two must always be carefully

advocated crushing of the obturator nerve for spastic contracture of the adductor muscles of the hip-joint, and said that the paralysis would last about six months. The correction of deformity by arthrodesis might improve muscle function. He suggested that slight dorsiflexion and ulnar deviation was the optimum position for arthrodesis of the wrist-joint. This operation might be followed by a tendon transference. Before lengthening a tendon a careful assessment of the amount of correction should be made. This should be done before the patient was under the anaesthetic, and it was better to shorten too little rather than too much.

The Painful Shoulder

Mr. F. A. SIMMONDS (London) opened a discussion on the painful shoulder, but confined his remarks to the syndrome of frozen shoulder. He described the clinical cycle, emphasizing its length, and the points important in differential diagnosis. He had followed up 63 frozen shoulders, none for less than two years. Thirty were normal and fourteen almost normal; fifteen caused slight and four severe disability. He had found that the results were unaffected by age or sex, and that they were not so good after trauma or deep x-ray therapy. He thought it too early to give an opinion on the value of hydrocortisone in treatment.

In this series of cases he had found that any painful area in the arm or neck might have initiated the syndrome, but only in the right age group. There had been an association with pulmonary and cardiovascular disease. While the lesion had been bilateral in 8% of patients, the same shoulder had never been affected twice. It had never been associated with a complete tear of the supraspinatus tendon. Explorations of the frozen shoulder had shown the whole rotator cuff to be involved in a vascular inflammatory reaction and the biceps tendon to be adherent to the groove in the humerus. The pathological lesion had appeared to be a degeneration accompanied by a painful repair reaction. The primary painful area was probably in the supraspinatus tendon. In his opinion active treatment was related to the clinical cycle. It aggravated the condition in the early stages and appeared to give benefit in the later stages. He had found physiotherapy and manipulations to be useless. While deep x-ray therapy had relieved pain in 50% of patients, the end-results had not been good. His best results had been obtained by repeated explanation to the patient of the cycle of events, by encouraging movement in the pain-free range, and encouraging full use of the arm in the late phase of recovery.

Mr. G. BLUNDELL JONES (Exeter) said that he was in agreement with the previous speaker. He had studied a series of 366 cases of which 242 were frozen shoulders. He described the painful arc syndrome, which he attributed to a local inflammatory change. There had been 91 cases; 30 had recovered completely, 28 had a minor ache in the shoulder, and 8 had persistent pain. The average period of recovery had been about 7 months. He had tried a variety of treatments, but had a slight bias in favour of the use of hydrocortisone. He advised acromiectomy for resistant cases in the absence of stiffness or a rent in the supraspinatus tendon. He thought that when the tendon was ruptured the acromion process, by impinging on the head of the humerus, helped the deltoid muscle to abduct the arm. He described bicipital tendinitis, which he did not consider to be a precursor of frozen shoulder. The results of conservative treatment had been satisfactory in 22 cases. He differentiated three types of calcification of the supraspinatus: (a) an acute type which caused great pain but underwent spontaneous resolution and recovered in a period which varied from two weeks to three months; (b) a chronic type which responded to injection, aspiration, or excision, but occasionally merged into a painful arc syndrome; (c) a symptomless form. He spoke of the methods of diagnosis of tears of the supraspinatus tendon and advocated suture of large rents.

In a general discussion there was a sharp difference of opinion on the value of manipulation. A majority of

speakers considered it to be a valuable method of treatment for certain types of shoulder, but emphasized the need to choose the right time.

Structural Effects of Stress

Mr. J. C. SCOTT (Oxford) spoke of the structural effects of stress. He recalled the definition of physical stress as the interaction of a force and the resistance applied to it. This might serve as a definition of stress as applied to humans and animals, but the forces, resistances, and methods of interaction also had to be defined. While the word had been applied to humans for many years, Hans Selye was responsible for much of the attention paid in the last twenty years. He had pointed out, while defining stress, that there was a superficial reaction of the body which was common to a variety of widely different factors, such as injury, infection, or strain. The common factor was non-specific stress. Selye had divided the reaction into three stages—the alarm reaction, the stage of resistance, and the stage of exhaustion. The syndrome was not initiated in the absence of the pituitary or its A.C.T.H. and was not carried out in the absence of the adrenal.

There might be a clear-cut process as in a single injury, or there might be a complicated situation where there had been many minor stimuli, both mental and physical. In the present stage of our knowledge none of the three elements (force, resistance, reaction) could be assessed. It was important, however, to accept these three factors and the departure from the simple cause-and-effect concept of disease.

The increasing frequency of the disk problem and the increasing emphasis on the psychological aspects of it could not be explained on the basis of injury or other simple physical grounds. It was well known that there was a physiological variation in the disk size. It was suggested that a disturbance of fluid balance within the annulus led to an increase in pressure beyond the normal level, at times causing acute back pain and, if repeated, rupture of the disk. An attempt had been made to determine experimentally if stress produced alteration in the size of the disk nucleus in mice. Eventually 131 disks in experimental and control animals had been submitted for statistical analysis. The principal finding had been an increase in the size of the nucleus directly proportional to the amount of stress as determined by measurements of the adrenal and thymus. Later a pilot experiment had been undertaken to try to see if there were any morphological change. Various stains were used to demonstrate the morphology and the quantity of sulphated and non-sulphated mucopolysaccharide. Dr. A. H. T. Robb-Smith (Oxford) had reported definite morphological differences. Further experiments were in progress.

Shoes for the Young

Mr. W. H. GERVIS (Tunbridge Wells) opened a discussion on foot form, function, and footwear in the young, saying that in his opinion the arch of the foot in the condition known as flat foot did not collapse but merely rocked over to the medial side. He attributed the rocking over to a medial rotation of the talus, which might result from medial torsion of the tibia or from a postural internal-rotation defect of the leg. He said that elevation of the first metatarsal was secondary to the rocking over of the foot. He illustrated a special stool which he used to examine the footprints of children. This stool had a glass top; there was an oblique mirror below through which the foot was observed. He did not believe that the muscles of the forefoot were weak in postural exercises directed towards a correction of the rotational defect. He advised that children's shoes should be as light as possible without any form of arch support.

Mr. W. SAYLE-CREER (Manchester) said that it would be difficult to describe a normal foot in words even if it were known what it should be. He believed that a prolonged survey of

a large number of children was needed to determine what was a normal shape and the real significance of variations. The important part of the forefoot was the inner metatarsals, which, if weak, allowed the foot to fall over into pronation. He compared the action of the weak inner metatarsals to that of a wobbly leg on a three-legged stool. He described the three types of incompetent first metatarsal—the atavistic, the hypermobile, and the permanently elevated. The hypermobile first metatarsal was the precursor of hallux valgus, mobile first metatarsal was the precursor of hallux rigidus. He said that badly proportioned shoes were common in schoolchildren, where the incidence of hallux valgus increased with age. Female shoes were worse than male, and this was consistent with the much greater and increasing incidence of hallux valgus in girls.

Mr. T. T. STAMM (London) spoke of the mild congenital calcaneo-varus deformity, which might be more common than had been recognized, and a cause of elevation of the first metatarsal. The PRESIDENT said that he remained convinced of the value of a simple wedge on the inner side of the heel for a flat foot.

Management of Common Knee Injuries

Mr. A. T. FRIPP (London) said that in the treatment of injuries of the knee the aims were to obtain full movement, stability, a sense of security, and freedom from pain. Since a derangement of the knee might result from damage to any of its constituents it was essential to make an accurate diagnosis. A sprain of the knee, a partial tear of the collateral ligament, or damage to the synovial membrane was followed by effusion, pain, and loss of movement. This loss of movement came on gradually and was not locking. Treatment was by aspiration, support, and exercises. He emphasized the importance of using a back splint which fitted the leg closely and was of sufficient length.

He described lesions of the articular cartilage: (1) Osteochondritis dissecans, which occurred mainly in children and could be diagnosed only by radiography. It was often necessary to explore the knee-joint and to remove the fragment of bone and cartilage. (2) Chondromalacia patellae, which usually started in adolescence and was more common than had been appreciated. The diagnosis was not always straightforward, because the condition caused indefinite symptoms of derangement. Surgical treatment was by trimming the articular cartilage or removing the patella.

Complete tears of the internal collateral ligament were to be treated by repair, early cases by suture, late cases by grafting. Torn cruciate ligaments were often masked by grafting. Torn cruciate ligaments were often masked by haemarthrosis and muscle spasm. While the treatment of a torn cruciate ligament was conservative, its presence was a contraindication to the surgical treatment of a torn cartilage or ruptured collateral ligament. Most fractures of the tibia or tibia spines were to be treated conservatively, but occasionally the fragment had to be removed. He emphasized the importance of developing the extensor mechanism of the knee after all injuries, and said that even to-day it might be overlooked. He discussed the diagnosis of torn meniscus and stressed a number of points. The diagnosis was not to be made after the first injury, and the response to conservative treatment should be watched. The finding of a cartilage click was not a reliable test. The history was of more importance than the clinical examination, but the symptom of locking had to be differentiated with care from transient stiffening. The adolescent girl who had a derangement of the knee rarely had a torn cartilage. Both cartilages might be torn in the same knee-joint. The presence of a torn cruciate ligament or arthritis in the knee was not a contraindication to the removal of a torn cartilage.

Mr. K. H. PRIDIE (Bristol) described chondromalacia patellae complicating dislocation of the patella in an adolescent girl. He advocated the repair by grafting of large defects in the weight-bearing surfaces of the joint resulting from osteochondritis.

SECTION OF OTO-RHINO-LARYNGOLOGY

Tuesday, July 10

Nasal Obstruction

With the president, Mr. T. S. ALLEN, in the chair Mr. T. O. GRAHAM (Dublin) read a paper on nasal obstruction written by Mr. T. G. WILSON (Dublin), who was unable to be present owing to illness. He stated that nasal obstruction in the adult did not constitute a threat to health, but in the newborn child complete obstruction was a serious threat and might cause death from asphyxia. Nasal obstruction might be due to congenital atresia or other uncommon causes, but, although the condition was rare, it probably occurred more frequently without being recognized. In the child nasal sinusitis seemed to be accompanied less often than formerly by violently acute symptoms. This was probably mainly due to a cyclical diminution in the virulence of the pyogenic organisms rather than to the undoubted efficiency of antibiotic treatment.

In a follow-up of about 50 children operated on for enlarged tonsils and adenoids, the majority were found to be still mouth-breathers seven years later, although the peridental health of the children was strikingly better than that of the controls. From this it was argued that heredity was an important factor in causing nasal insufficiency.

In adults with chronic nasal sinusitis the tissue changes were more often irreversible than in children. The majority of proprietary drops and sprays probably did more harm than good, particularly if persisted in too long. Of the surgical means of treatment of nasal obstruction, submucous resection of the septum and of the inferior turbinate were advocated, although there was an increasing tendency to conservatism in the case of the former operation.

Mouth Breathing in Children

Mr. F. C. W. CAPPS (London) considered that pure mouth breathing, after adeno-tonsillectomy in children was probably very rare, but dual breathing, part nasal, part oral, was common, largely due to loss of facial tone with or without orthodontic deformity. It was therefore necessary after operation to rehabilitate the persistent "gaper" by appropriate exercises and orthodontic attention. Nevertheless there was often an inborn tendency to mouth breathing which was only overcome when the child grew up and realized the social implications of the habit. The speaker repeated the danger of over-medication with nasal drops and sprays, and warned patients and doctors against their use except with proper indications. Furthermore, their use was valueless unless properly administered in the head-down or Proetz position.

Trauma in children and adults was a common cause of nasal obstruction from fracture-dislocation of the bridge of the nose and springing of the nasal septum. Unless there was soft-tissue injury he advocated immediate manipulation with the thumbs in suitable cases. If instrumental manipulation was required this could be carried out with success up to two weeks after the injury under general anaesthesia, but the importance of deep general anaesthesia to avoid shock was stressed. Mr. Capps recollected seeing a death on the table when the manipulation was carried out under very light anaesthesia.

Obstruction due to malignant disease was a rare possibility. Early symptoms were often absent, and the disease was often quite advanced before obstruction, pain, bleeding, or offensive discharge became evident. Atrophic rhinitis, now or offensive disease in this country, might give rise to nasal obstruction from the formation of offensive crusts. In the absence of a curative medical treatment the speaker advocated the insertion of polythene plastic inserts under the floor of the nasal fossae to reduce the lumen. Although the plastic insert was occasionally extruded the results in many cases were excellent in preventing crust formation.

A. panel, presided over by Professor T. POMFRET KILNER (Oxford) and consisting of Sir ARCHIBALD MCINDOE (London), Sir WILLIAM KELSEY FRY (London), Mr. MICHAEL W. C. OLDFIELD (Leeds), Mr. RAINSFORD MOWLEM (London), and Mr. P. H. JAYES (London), answered many questions. When asked whether he thought that the modern usage of x rays was not better than the old, Sir ARCHIBALD MCINDOE reaffirmed his dislike of x-ray therapy and thought that the effects of smaller modern dosage could only be known in 20 years' time. Asked the indications for injection of sclerosant into cavernous haemangiomas, the panel agreed in disliking boiling water injections because of technical difficulty in injection. Mr. OLDFIELD would use other sclerosants, but others believed in leaving them all alone because a better scar resulted. The panel disagreed on immediate or late plastic repair after hemimandibulectomy for oral cancer. General considerations of age were

important, and if the growth was histologically less malignant early repair might be done, but the danger of recurrence was high, and therefore repair should be delayed. The plastic surgeons believed early repair of cleft palate necessary so that good speech could be achieved. Sir WILLIAM KELSEY FRY believed that repair should be performed at 3 years after the orthodontist had applied a splint to the teeth, thus preventing the surgeon from contracting the dental arch. Panel members doubted the possibility of treatment of wide areas of skin tattooing after gunpowder explosions, except by the use of cosmetics. It was difficult to get patients to use it, and isolation in hospital for a period of experiment and persuasion might be necessary. Mr. OLDFIELD said he would treat hypertrophic keloid scars by x rays. Sir ARCHIBALD MCINDOE said he would not, and would either do nothing, since they improved with time, or would try to rearrange the scar to lie along Lange's lines. Mr. JAYES suggested that, if the hypertrophy had followed infection, excision might produce an improved scar. Mr. MOWLEM said he had injected keloid scars weekly with hyaluronidase and cortisone for six months without lasting benefit. The panel did not know why erotic sensation in the nipple was sometimes impaired after plastic operations on the breast. All members agreed that to decide whether a "cosmetic" operation should be performed by the National Health Service it was necessary to see the individual patients. They found difficulty in defining the term "cosmetic." The final question concerned the state of research into skin homografting. Mr. MOWLEM said that the problems of homografting were similar, whatever the organ concerned. So far as he knew no advances had been made recently. Mr. OLDFIELD thought that a lead to research was that homografting on to people with agammaglobulinaemia was possible.

THE SCIENTIFIC EXHIBITION

Those who attend Annual Meetings have come to appreciate that a tour of the Scientific Exhibition is a small, palatable course in postgraduate education. The exhibition, housed this year in the Corn Exchange, Brighton, attracted a steady stream of visitors whose interest amply repaid the hard work put in by the organizers of the individual stalls. The total space available for the exhibition was somewhat confined, so that the stalls were rather uncomfortably close together, but what the demonstrators lacked in "lebensraum" was more than compensated for by their enthusiasm.

Cancer

A relatively large amount of space was devoted to neoplasia, and cancer of the breast formed the subject of display at four stands. The Royal Marsden Hospital and the Institute of Cancer have elaborated their exhibit, an outstanding success at Glasgow in 1954 and at Toronto in 1955, on the natural history, early diagnosis, and radical and palliative treatment of mammary carcinoma. Particularly useful was the depiction of the use of hormones and pain-relieving drugs in late cases by the family doctor. The Royal Sussex County Hospital displayed the results of a policy of treating operable cases of breast cancer by radiotherapy alone, mastectomy being resorted to only when a mass was still present in the breast six weeks after completion of radiotherapy. The Royal Marsden Hospital and the University of Glasgow separately presented demonstrations of the techniques for and results of destroying the pituitary gland in the treatment of advanced breast cancer. The Royal Marsden Hospital also offered information about the new telecaesium unit for radiotherapy and the special gun used for the implantation of radioactive gold grains to irradiate localized lesions. Finally, in the sphere of oncology the Royal Marsden, St. Peter's, St. Paul's, and St. Philip's Hospitals illustrated the aetiology, symptoms, types, and treatment of bladder tumours. Graphs showed that 65% of patients reported to their doctor within a month of their first attack

(G.B.S. Photopress, Brighton)

Facts about tumours of the bladder.

of haematuria, and the great majority of general practitioners referred the patient to hospital within a month of the first consultation. It was in hospital that the greatest delays occurred before the treatment of bladder tumours was begun. This was mainly due to incorrect diagnosis, inadequate investigation, and administrative delays. More rapid diagnosis would lead to improved results in the treatment of bladder tumours.

Diagnosis

Diagnostic techniques were displayed by several hospitals. The Royal Free Hospital and the Medical Research Council's V.D. Reference Laboratory marked the 50th anniversary of the discovery of the Wassermann reaction by exhibiting recent experimental tests for syphilis which use the *Treponema pallidum* itself as antigen. Leeds University and Leeds General Infirmary demonstrated laboratory aids in the diagnosis of mycotic infections, both superficial and systemic, occurring in Britain. The Glasgow Royal Infirmary portrayed the scope of arteriography in general and its value in urology in particular, while the United Cardiff Hospitals exhibited the use of radiology in the systematic investigation of the biliary tract.

Surgery

A special welcome among the surgical stands was extended to the sole exhibit from Canada. This display of the methods, complications, and results of radical herniorrhaphy was from the Shouldice Clinic, Toronto. The effects of prostatic obstruction were graphically set forth by St. Peter's, St. Paul's, and St. Philip's Hospitals and the Institute of Urology. The exhibit of ulcerative colitis from the Gordon Hospital for Gastro-Intestinal Disease was centred round surgical treatment, but the natural history, diagnosis, and medical treatment were also illustrated. From the Churchill Hospital, Oxford, came a fine pictorial representation of congenital deformities in infants and children, and their correction. Four telling exhibits came from the Manchester Royal Infirmary, depicting the management of patients with haemorrhage from oesophageal varices (well illustrated by a film of a patient with "flapping tremor"), supracondylar fractures in children, ocular injuries, and occlusive arterial disease.

Of ophthalmological interest were the displays from the Sussex Eye Hospital of transparent acrylic implants and trephines and of contact lenses, and from the Royal Eye Unit, Lambeth Hospital, of the advantages of sedation with pethidine and chlorpromazine for ophthalmic surgery under local analgesia. Also from Lambeth (the Annie McCall Hospital) came an assessment of the value of this type of sedation in labour. Obstetrics was also concerned in a panel demonstration of the various tests carried out on antenatal

(G.B.S. Photopress, Brighton)

Aids for the disabled.

blood specimens (Southern Blood Transfusion Service); and a comprehensive and clear account of hyaline membrane in the neonatal lung (Queen Charlotte Hospital and the Institute of Obstetrics and Gynaecology).

Some aspects of rehabilitation were demonstrated at the stands set up by St. Dunstan's (showing how the blind may be helped), and by the Royal Sussex County Hospital and Cirencester, Pewsey, and Swindon Hospitals, which showed many ingenious mechanical and household aids for the disabled. In the orthopaedic field there was a display of medical apparatus from the Norfolk and Norwich Hospital for use in the traction-manipulation of disk lesions.

General Practice

Another welcome feature of this year's exhibition were three displays of work in general practice. One of these demonstrated limb-holding apparatus for plaster-of-Paris splinting: it may be used in the patient's home or at the surgery by the practitioner working alone. The South-east England Faculty of the College of General Practitioners put on a striking demonstration of epidemiological research in general practice, with particular reference to the investigation of the spread of winter vomiting disease in England during the autumn of 1954. Another exhibit demonstrated two common gluten-induced syndromes.

Medicine

Exhibits coming within the physician's province were those depicting the control of blood pressure (Charing Cross Hospital), the modern treatment of genito-urinary tuberculosis (Harefield Hospital and Institute of Urology), and spirochaetal dysentery (Eastbourne Hospital Group). St. Mary's Hospital used man's sensitivity to insects to illustrate different allergic responses, and the Canadian Red Cross Memorial Hospital, Taplow, demonstrated recent work on experimental allergic encephalomyelitis (induced by mixtures of tubercle bacillus residues and extracts of brain tissue) and its possible application to human neurological diseases.

Pathology was represented by the illustrations of the variations in the peripheral pattern in bronchography (Charing Cross and Brompton Hospitals), and by photomicrographs supporting the view that the plaques in coronary occlusion were not lipid infiltration but organized mural thrombi (Westminster Medical School).

Services and Public Health

The Royal Naval Physiological Laboratory gave an interesting survey of the development of methods of submarine escape. The Royal Air Force Medical Branch exhibited flying equipment of medical interest and apparatus used in otological work. There was also a demonstration of audio-

metric methods from the Sussex Throat and Ear Hospital. The Princess Beatrice and Birmingham Accident Hospitals combined to indicate in forthright fashion the strong case for the compulsory use of crash-helmets by motor-cyclists. It was fitting that in the centenary year of the Society of Medical Officers of Health the London School of Hygiene should put on an excellent and entertaining survey of the history of the medical officer of health during the last 100 years. Also of historical interest was the exhibition by St. Albans City Hospital of a skull about 1,600 years old found near that city. Finally, *Family Doctor* was responsible for a series of admirable tableaux demonstrating the golden rules of health.

Special Pharmaceutical Exhibitions

The Pharmaceutical Society of Great Britain had a most topical exhibition of the pharmacy of some hypotensive drugs, while the Association of the British Pharmaceutical Industry presented 20 large panels featuring a representative selection of significant recent advances in drug therapy.

Each year the Scientific Exhibition increases in size and range. Each year also sees improvements in techniques of display, for although the tendency to crowd too much into too little space still lingers it is much less in evidence this year than formerly. It might be helpful to the visitor if the stands dealing with related subjects could be grouped together. The organizers of the exhibition in Brighton can certainly be complimented on producing a display from which every visitor could learn something of value to him in his own sphere of medicine.

B.M.A. FILM SHOWS

An innovation at this year's Annual Meeting was the exhibition of films from the B.M.A. Film Library. Nine films were shown in all—"Tuberculin Techniques," "Senile Obliterative Arteritis of the Legs," "Sigmoid Rectum and Anal Canal Endoscopic Views," "Some Aspects of Accessible Cancers—Breast," "Prosthesis," "Microscopic Changes Observed in the Wings of a Bat," "My First Baby," "Gait," and "Breast Self-Examination." The Annual Meeting has such a full programme that the arrangement of suitable times for film shows presents considerable difficulties. Perhaps more viewers would be attracted if a short précis of each film was printed in the official programme together with a note stating the type of audience, medical or lay, at which it is directed. There might also be some common theme to the three or four films constituting each programme.

"My First Baby" explains to the expectant primigravida, in exemplary fashion, the details of antenatal care and of the course of labour. It is an excellent film for showing to antenatal patients, but only such as have been booked for hospital delivery. The general practitioner enters the picture only to pen a note for the patient to take to hospital, and the scope of domiciliary midwifery, if any, receives no mention. Many obstetricians will envy the facilities and the furnishings of the hospital at which this film was made. Nevertheless the film succeeds admirably in its specific purpose of educating and reassuring the primigravida.

"Gait," another film made in Britain, is concerned with the effect of certain skeletal and muscular lesions on gait, and is designed for a medical, presumably undergraduate, audience. The colour is restful and the commentary a model of unhurried lucidity.

"Breast Self-Examination," which was filmed in the U.S.A. for the American Cancer Society, explains why all women should palpate their breasts once a month and demonstrates the technique of breast self-examination. Those who believe that education of the lay public is a powerful weapon in the fight against cancer will find this film eminently suitable for exhibition to women's clubs and similar organizations.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

College of General Practitioners

SIR.—The College of General Practitioners is developing so rapidly that it now needs a building of its own. Generous financial support, not only for construction but also in part for maintenance, is making this possible.

Agreement in principle has been reached with the President and Council of the Royal College of Surgeons for the long-term lease of a site on the south side of Lincoln's Inn Fields. Sir Edward Maufe, R.A., has kindly agreed to act as consulting architect, and Messrs. Trehearne and Norman, Preston and Partners have been appointed architects. An approach is being made to the London County Council, prior to application for planning permission, and it is hoped to erect a fine building on this site by 1962.—I am, etc.,

W. N. PICKLES,
President.

London, E.C.4.

Vaccination Against Tuberculosis in Childhood

SIR.—Your leading article on vaccination against tuberculosis in childhood (*Journal*, June 30, p. 1534) is encouraging reading for those of us who have advocated that B.C.G. vaccination should be given much more widely than has been the practice hitherto in this country. The M.R.C. investigation¹ which showed that as many as 40% of adolescents may be tuberculin-positive must make us realize that there is considerably more infection in the population than is revealed by the state of the tuberculosis registers and the official notification rates. Surely if B.C.G. vaccination is offered to school leavers there are no grounds in refusing it to the school entrants at the age of 5 and also to neonates. Any step that can reduce not only the death rate but the attack rate at any age is important if we are to get rid of tuberculosis in this country in the next few decades. It has been possible to reduce diphtheria and smallpox to the level of rare diseases. This state of affairs was brought about by a suitable propaganda drive and the development of adequate immunization techniques, in one case, and vaccination in the other. I believe that a similar state could be brought about with regard to tuberculosis, certainly among young people, by a suitable propaganda drive and the use of B.C.G. vaccination. I do not believe parents are prejudiced against B.C.G. vaccination because of the slightly longer persistence of the lesion in neonates. It has been my experience that in many instances mothers bring their other children to the chest clinic after the elder child, a school leaver, has received B.C.G. vaccination; but if we interpret the instructions from the Ministry quite literally B.C.G. vaccination cannot be given to these children.

Although the figure, 650,000 annual births, may seem large when considering vaccination of neonates, it is really a challenge to the clinical and preventive side of the Health Service. Surely vaccination could be given to all babies born in hospital and to those born at home when they attend the baby and infant welfare clinics. The district nurse and the midwife would be valuable in spreading the propaganda. The school medical officers could visit crèches. General practitioners would be only too happy to co-operate in giving the vaccination, especially if the new British freeze-dried preparation is made available. Admittedly this effort will not embrace all the babies born, but in the course of time other infants would be brought to the chest clinics, and by the age of 5, when children go to school, I believe about only 20% at the maximum would be in need of vaccination.

If the children, once they had been vaccinated, had routine tuberculin tests, preferably annually but certainly at their school medical examinations, it would be possible

to find how many had reverted to the Mantoux-negative state, and it would also be possible to find children who had acquired exogenous infection.

The opponents in this country of B.C.G. vaccination have said that there has never been a suitably controlled trial. The M.R.C. work is the answer. Now let us act upon it and give B.C.G. vaccination to all suitable children under the age of 14 and also to any over this age who are discovered to be Mantoux-negative.—I am, etc.,

London, S.E.5.

KENNETH MARSH.

REFERENCE

¹ *British Medical Journal*, 1956, 1, 413.

SIR.—I was interested in your leading article on vaccination against tuberculosis (*Journal*, June 30, p. 1534). You mention: "One of the main disadvantages of mass vaccination in adolescence is the substantial proportion of children—as many as 40% in the Medical Research Council's investigation—who are found to be positive reactors to tuberculin and who form a large group in which tuberculosis cannot be prevented by prophylactic vaccination."

The figure of 40% concerns tuberculin tests carried out from 1950-2. It is probable that the present percentage of tuberculin-positives in this 14-year age group is considerably less. Figures for Cornwall, given in the table below, show a marked decrease in tuberculin sensitivity for the past four years.

Year	Area Concerned	Tuberculin Tested	Percentage Positive	B.C.G. Vaccinated
1953	West Cornwall	2,075	39%	1,243
1954	Cornwall	2,597	20%	2,005
1955	"	3,197	17%	2,518
1956	"	3,110	14.9%	2,526

Though much is to be said for B.C.G. vaccination of the tuberculin-negatives at the age of 5, I would hesitate to introduce anything which might prejudice the present scheme, for which there is an acceptance rate of a little over 90% and which ensures protection for the most important years.—I am, etc.,

Truro.

E. R. HARGREAVES.

SIR.—In your leading article (June 30, p. 1534) the writer makes a case for vaccinating tuberculin-negative school-children at school entry. In the same article he quotes the total of notifications of tuberculosis (all types) as follows: ages 0 to 4, 1,916; 5 to 14, 4,085; 15 to 24, 10,752. If B.C.G. is to offer a 50% protection rate for ten years, then it would seem that the obvious time to vaccinate is at 15. If the vaccine is to give protection for far longer, why begin at 5? Why not vaccinate at birth?

We can see that as far as our present knowledge goes there is a good case for confining vaccination to the contacts, special-risk groups, and school leavers, while using the tuberculin test on younger schoolchildren as an indication of infection rates and as a pointer to infectious cases. In fact, if vaccination at school leaving is to be the policy, we consider the tuberculin testing of younger schoolchildren and subsequent case finding obligatory. Alternatively, we can see that there is a case for vaccinating all children at birth in order to get maximum protection in the community.

Except the argument of administrative convenience, we can see no good case for vaccinating children on entry to school.

Since rates of infection vary from area to area, it is likely that there are some areas where the rates of infection are very low. How low must infection rates become before B.C.G. vaccination is considered unnecessary? We believe that where infection rates are less than 1% per annum it is better to use recurrent tuberculin testing than mass B.C.G. vaccination.—We are, etc.,

Ipswich.

CHARLES J. STEWART.
DAVID VAN ZWANENBERG.

Diarrhoea and Vomiting

SIR.—The epidemics of "D. and V.," such as we used to have towards the end of every summer when I first went to Guy's Hospital as a student in 1924, are now fairly rare; and when outbreaks or odd cases do arise, despite the vastly improved hygiene and relative opulence of to-day, the patients' chances of recovery are no longer hopeless, as they were nine times out of ten in those days—far from it, for there is often a choice of several treatments nowadays, all nearly equally effective.

That was a disease of older infants—6 to 18 months or so—a true "cholera infantum," though the cholera vibrio was thrown in its hand when its watery hiding-place was revealed in the "Broad Street pump" outbreak of 1854. To-day it is older children and adults who suffer most from intestinal infections and other disorders, among which ulceration ranks increasingly high. And though non-cancerous, the deaths are falling, with some disappointing exceptions, are functional disorders, many of them seriously disabling, are getting an upper hand. Nor are the infectious, or infective, catarrhs—those that attack the alimentary tract's mucous membranes—by any means overcome. We in Tonbridge, a country town of 20,000 inhabitants, with a famous boarding-plus-day public school for boys, have only lately been passing through a short but unpleasant example of (?) infective gastro-enteritis, and its cause remains unknown at the time of writing. Nevertheless, it illustrated well the snags of management—i.e., of keeping the symptoms under control till nature had worked a cure, with whichever chemical and physical aids the medical attendants favoured. For this was an ailment where recovery was as certain as anything can be in this uncertain world; and the doctors' main problem circled round that of, "Which drug firm shall we back? That famous and familiar one? Or one of the comparatively tiny but often deserving newer names, which sometimes make us think for ourselves?"

Having a colostomy myself, I can speak with feeling, if not with authority, about diarrhoea cures. And a resident household of three others, one a schoolboy, taught me much about sickness, in both senses, and about other aspects of diarrhoea. I came to a few solid conclusions, though statisticians may question their bases. For the sickness, it seemed, only a hot bottle or electric pad, or blankets heated before the fire, and a few sips of some fizzy sweetened drink, were worth their trouble (we'd have felt differently if faced with real dehydration, no doubt). But for the diarrhoea there are now some genuine and unobjectionable—even non-poisonous—medicaments; about four, if I may classify a bit. They are:

(1) *Opiates*.—Morphine $\frac{1}{4}$ gr. (16 mg.), perhaps repeated once but once only, may check the diarrhoea while vomiting is still being troublesome; nothing (or hardly anything) else will, so this may be justifiable in the early stages; later on, a few minims of tinct. opii by mouth is surprisingly effective and leaves no boggy of addiction (a much overrated spook, I know). Make it tinct. opii 3-5 min. (0.2-0.3 ml.), kaolin 60 gr. (4 g.); aqua chlor. to the ounce (28 ml.); for that may save the patient trouble with the poisons rulers. Otherwise I would not include kaolin among *medicamenta vera*.

(2) *Sulphaguanidine*.—Old-fashioned? If so, incidentally so; for I am certain that this has a pharmacological binding action that "sulfasuxidine" and "sulfathalidine" have not got. It begins to bind, in fact, before it can have started killing off the pathogenic bacteria. Of this I have satisfied myself.

(3) *Methyl cellulose*, or "celevac," in granules, please; for the tablet form does not work so well in most people. I am medical adviser to the English makers of this cellulose derivative, but I got the job because I had found the granules worked so well on me, and not the other way round. So, though I am biased, my opinion still holds water. These are taken with as little liquid as is practicable (one

or two tablespoonfuls), and the dose is a drachm (4 g.) or two night and morning or more often if necessary.

(4) *Aspirin*.—Few people seem to remember the slight but definite constipating action of aspirin. It irritates the mouth and stomach, etc., yes; but very slightly, and it does more good than harm, always provided you have no gastric or duodenal ulcer liable to bleed. If you have, try more celevac and keep far away from aspirin and all the salicylates, or it will bleed forthwith and for certain.—I am, etc.,

Tonbridge, Kent.

E. CLAYTON-JONES.

Early Management of Poliomyelitis

SIR.—Dr. E. G. Brewis in his article, "Early Management of Poliomyelitis" (*Journal*, June 30, p. 1539), makes a number of statements with which few, I imagine, of his colleagues engaged in the treatment of this disease would agree. In particular he writes that when the diagnosis of poliomyelitis becomes probable "there may be a natural desire on the part of the family doctor, aided by pressure from the relatives, to send the patient to hospital. *This course must be firmly resisted* . . . hospital admission has nothing to offer the patient which cannot be done in the ordinary decent home. This should be emphasized because so often the parents . . . and occasionally the doctor himself, believe that something can be done in hospital which may make all the difference to the patient's chances. *In many instances the reverse is true*" (the italics are mine).

Your contributor may be trailing his coat, or perhaps doffing his bonnet to give a bee an airing, but, if he is serious, may I say that I regard this as most dangerous and irresponsible advice? Polio is one of the most insidious and unpredictable of all diseases, and nobody can possibly foretell what will happen in any given case. In one, paralysis may spread from head to foot—or from foot to head—in 24 hours; in another, paralysis may appear in one limb and then come to a halt for a day or two, only to return with a devastating rush when all danger appears to be past. In a third it may spread steadily but slowly for a week. No two cases are alike, and the only confident prediction one can make is that as soon as the process has begun anything may happen.

In these circumstances it seems incredible that anyone should counsel delay in bringing the patient under skilled and continuous observation as soon as possible. Such delay is undoubtedly responsible for so many of the lamentable results in the treatment of bulbar and bulbo-spinal cases reported by your contributor and others. Far too many of these patients arrive in hospital already hopelessly compromised—half-drowned in their own secretions, or having vomited and inhaled the vomit. Even in hospital, unless constant supervision is exercised, bulbar paralysis in particular may elude detection until serious damage has occurred.

There is a further consideration. The gravest disability from which the recovered case can suffer is paralysis of respiration in whole or part. Many believe that this can be minimized by giving assistance to the threatened neurones at the earliest possible moment. As soon therefore as any detectable weakness of respiration or significant fall in vital capacity appears, the patient is put in a respirator in the hope that by taking the load off the intercostals and diaphragm more of their capacity may be retained than if the relevant neurones are allowed to reach the point of exhaustion before relief is afforded. Results would appear to justify this approach.

There are other statements which one receives with some surprise, as, for example, that "the physical stress of ambulance journeys . . . may be a deciding factor in initiating paralysis." What evidence exists—or can possibly be adduced—to warrant such an assertion? But in any event, in direct contrast to Dr. Brewis, I would say to the family doctor: "As soon as you have made the diagnosis of poliomyelitis, and especially if paralysis has appeared, get him into hospital as soon as possible, for he is launched on a

branch during the last 30 or 40 years and the region of the human mind has been explored, the laws of mental healing are known, and dramatic cures are no longer looked upon as "miracles." But the "lay" mind would still think a "miracle" of healing had been performed if, for example, a girl with hysterical paralysis were suddenly cured by mind therapy.

The need for this kind of therapy is surely evident; for I understand that 50% of the beds in this country are occupied by mental cases. The strain and stress of modern life (hurry and worry, domestic, social, economic, and business anxieties) seem to be having a serious influence on the nervous system via ductless glands, upsetting function and possibly leading to organic disease. One thinks of toxic goitre, hyperpiesis, coronary disease, and afflictions of the nose, bronchi, oesophagus, colon, bladder, and stomach. Duodenal ulcer is commonly associated with nervous tension, and this must be considered in treatment. These considerations seem to indicate the great importance of mind treatment, which is in the second dimension. We have been very slow to appreciate the fact that thinking can be damaging even to the physical body. "As a man thinketh in his heart, so is he." Compare our quite recent recognition of the importance of the blood—the circulation being discovered by Harvey in 1615. Yet 4,000 years ago it was written: "The life of the flesh is in the blood"; "The blood is the life."

So it is that few medical men understand the things of the third dimension—the spirit, which again is superior to the mind and exerts a profound influence on a man's thoughts. If the B.M.A. called for evidence of revolution and reconstruction of character through faith in Jesus Christ, there would be tens of thousands of indisputable testimonies. Those who have experienced this "miracle" might be excused for expecting "miracles" in the lower dimensions of mind and body—that is, healings of the mind and body outside scientific psychological and physical experience—such as occurred in the days of our Lord and His apostles. This is what we mean by divine healing.

I would not deny the occurrence of such miracles, but most will agree that they are very rare. And why? I can think of two reasons. One is, as I have indicated already, that it is divine guidance that has led us to the wonderful discoveries which enable us to enjoy to-day such health and healing, which we attribute to "nature." The other is that a study of the scriptures indicates that in this world of sin and death the righteous suffer with the wicked until such times as the "curse" is removed from mankind and all nature is redeemed and restored to life incorruptible. In dealing with the supernatural, one must consider divine revelation: for until we understand what is already well known in experience in the spiritual realm we shall never be able to discuss these things intelligently or make further progress. The atheist, agnostic, and sceptic have neither part nor lot in this matter.—I am, etc.,

Chigwell

N. BEATTIE.

SIR,—I can assure Dr. M. Curran (*Journal*, June 30, p. 1545) that by no means all his co-religionists, whether priests or doctors, adopt his own attitude of intransigence in the matter of co-operation with clergy of other Christian denominations and with non-Roman doctors. He may not be aware that in quite a number of districts where doctors, clergy, and ministers are established as a group and meet regularly for discussions, etc., the local Roman Catholic priest is also to be found taking his part in the giving of lectures and contributing to the discussions. In many cases Roman Catholic doctors are participants in such group meetings.

It is significant also that in *The Doctor's Profession* (S.C.M. Press), first published in 1949, the editor should have occasion to remark in his preface that "this book is the fruit of the work of a group which was almost equally composed of Roman Catholics and non-Roman Catholics, with a slight preponderance of the latter. It is worth recording that this was not planned from the outset. It merely

happened that people who were deeply concerned about these questions were to be found both among Roman Catholics and other Christians. The members of the group found also that they were able to discuss many controversial questions without either suppressing their own point of view or exaggeratedly emphasizing it." In neither of the circumstances cited above did the Roman Catholics who participated feel that they would "be giving recognition to the beliefs of the English Church as a spiritual body and would be denying our own faith."

The Roman Catholic doctors invited to submit evidence before the (Anglican) Archbishops' Commission were in no danger of being led astray by "heretics": they were merely being asked to express their opinions on certain facts, and it would be natural for them to do this in the light of their knowledge of the spiritual ministrations given to the sick in their own Church.

One would have thought that this, so far from compromising their faith, would have given them an excellent opportunity to witness for it.—I am, etc.,

Leamington Spa.

F. S. SINKER.

SIR,—It is surely fortunate that the B.M.A. committee which prepared the report on divine healing did not attempt to define miracle. It kept to its appointed task of providing evidence (*Supplement*, May 12, p. 269).

The correspondence which has appeared in the *Journal* in the past weeks confuses two different issues. First, the question is asked, Do miracles of healing occur to-day? Secondly, many believe that there are spiritual laws which, if understood and applied, would result in unusual healing of disease. The B.M.A. committee could obtain no convincing evidence that unusual healing has occurred: "The cases claimed as cures of a miraculous nature present no features of a unique and unexpected character outside the knowledge of any experienced physician or psychiatrist." This view falls into line with that expressed in the leading article of the *Journal* of June 18, 1910 (p. 1483), when the whole subject was fully reviewed in the light of the experience of those days and excellently written up by leaders of the profession.

To the Christian these findings offer no particular problem. He believes that God as creator and sustainer of this world can do a miracle when and where He chooses. However, the evidence of the Bible suggests that His miracles have been mainly limited to certain periods of history. They were supremely shown in the life and work of Jesus Christ.

Of the so-called "spiritual laws" which influence healing there is much that we do not understand, and those who speak of them often use phrases the meaning of which is hard to ascertain. What, for instance, does Dr. J. Burnett Rae (*Journal*, June 30, p. 1544) mean when he speaks of "lifting them [our therapeutic means] to a higher power and a finer end"? There are two important principles by which we may be guided. If a claim be made that the physical state of a patient's diseased tissues can be affected, then we, as doctors, believe that such changes can be observed and possibly measured by independent witnesses. They are subject to the "proof" of our senses. As Professor Alstead succinctly expressed it in an excellent article which appeared in the *Manchester Guardian* on August 29, 1955, "It may be objected that spiritual healing belongs to the realm of the spirit and that it cannot be measured with the yardstick of the clinical laboratory. To this I would say that if the spiritual healer enters the field of clinical medicine and makes claims in terms such as I have tried to explain then he must submit to the discipline of clinical science."

On the other hand, if such claims of physical change be not made and the benefit which the healer offers is purely spiritual, this too is subject to a yardstick which we should do well to use. The New Testament makes clear to us that the work of the Holy Spirit is concerned primarily with a man's relationship to God and with the quality of life which he leads. There is very little to lead us to suppose that special gifts of healing are imparted in the course of His normal activity to-day.—I am, etc.,

Gerrards Cross, Bucks.

C. GORDON SCORER.

Haemophilus Infection in Bronchiectasis

SIR,—I was interested to read the article on haemophilus infection in bronchiectasis by Dr. E. C. Allibone, Mr. P. R. Allison, and Dr. K. Zinnemann (*Journal*, June 23, p. 1457). I drew attention to the prevalence of haemophilus in chronic non-tuberculous lung conditions in childhood in 1927.¹ I cannot, however, endorse their confidence in the effects of treatment with antibiotics, which seem to me to be ineffective in eliminating the organism in such cases. Whereas in 1927 I regarded it as rather probable that the haemophilus was the actual cause of the persistent illness in these children, I would now rather take the view that the disease is bacteriologically non-specific and the result of bronchial obstruction with partial collapse and secondary infection in the collapsed areas. In fact, I would now rather regard the haemophilus as a secondary invader. It is a very common organism to find in the respiratory tract. The authors describe "relapse" as occurring in their cases. I am not clear what meaning they attach to this word. I think it clear that what they mean is reinfection occurs. The odds against this happening would be enormous; besides, they describe relapse as occurring on the average every six weeks. Their observations would therefore indicate that the haemophilus is not eradicated but only temporarily suppressed.

I am also not very happy about the use of the term "purulent bronchiectasis" in children. We rarely see the disease which used to go by this name—that is, a persisting bronchial dilatation with fetid sputum. No doubt workers in the northern cities see more cases of the type described in my M.D. thesis of 1927, but the number of cases in this area requiring bronchoscopy and bronchography has steadily diminished. We see very few cases of whooping-cough with collapse, and in most of our cases of whooping-cough or non-specific respiratory infection collapse is very transient and bronchiectasis distinctly rare.—I am, etc.,

Farnborough, Kent.

Apartheid in Blood Transfusions

SIR,—Might not Dr. David J. Adderley (*Journal*, June 30, p. 1546) be mistaken, and himself the victim of an emotionally charged concept? To assert that there is no essential difference between blood from different sources involves a large assumption, and, so far as I am aware, not sufficient work has been done to substantiate it.

It is known that there is a gradient of increasing proportion of group O blood from east to west across Europe. Thus, at a time when the ABO groups were unknown, it would have been safer to transfuse, say, an Irish person with blood from an Irish source rather than with blood from, say, Poland. No one will imagine that the last work has been done on the constituents of blood or its various groupings. With such a difference as between populations within Europe, there is at least a prima facie case for postulating differences between bloods from different continents. Before Dr. Adderley suggests offering gratuitous advice to the profession in South Africa, let him reflect that its ideas may not be altogether wrong. Let us not confuse scientific integrity with support for a political theory of racial equality.—I am, etc.,

Wednesbury.

J. TORLEY.

Post-menopausal Oestrogen Production

SIR,—Might we make a plea for the use of a standard method of estimating oestrogenic activity from vaginal smears? Dr. R. A. Struthers in a recent interesting article (*Journal*, June 9, p. 1331) employs a method of grading which makes it difficult to compare his findings with those of many other workers in this field. Authorities such as Shorr,¹ De Allende workers in this field. Authorities such as Shorr,¹ De Allende and Orías,² and Horwith³ all use a cornification index which is calculated as the percentage of cornified squames in

several unselected fields of superficial, intermediate, and basal cells. On the other hand, Dr. Wachtel,⁴ in her recent article entitled "Suggestion for a Cytological Test of Cancer Cure," calculates the cornification index "by counting the percentage of cells with pyknotic nuclei among 200 unselected superficial and intermediate squames. The basal cells are omitted from this count."

It seems logical to assume that a cornification index provides a better yardstick and is less liable to personal interpretation than any other forms of grading, but it would be of greater value if it was always calculated in the same way. Working at Dr. P. M. F. Bishop's endocrine clinic, we have found that a count of all the vaginal epithelial cells—that is, including the basal cells—gives a more accurate clinical picture.

We would also like to know if Dr. Struthers had any particular reason for obtaining smears by scraping the anterior wall of the upper vagina as opposed to aspiration from the pool of secretion in the posterior fornix. We find the latter method gives a much more representative slide and avoids contamination from the lower third of the vagina.—We are, etc.,

MOIRA MURRAY.

Maladjusted Children

SIR,—Dr. M. Park (*Journal*, June 23, p. 1487) is disappointed at the poor response to his appeal for action based on the report of the Committee on Maladjusted Children,¹ set up with commendable initiative by the Ministry of Education. This lack of response, I fear, reflects the disappointment of many in the medical field at the nature of the main recommendations of this informative report. There is a marked difference of emphasis from the evidence submitted to the committee by the British Medical Association² and from the recent memorandum of the Royal Medical Psychological Association.

An adequate service must meet the needs of the school child, the pre-school child, the post-school child, the child at the non-maintained school, and the emotionally handicapped parent. The most important categories, the pre-school child and the emotionally handicapped parent, can be least effectively dealt with on these recommendations. To deal with the child from the non-maintained school a call is made for new legislation. The proposed administrative structure is a complex of three local authority departments (education, school health, public health), grafted on to which is the regional board concerned. To the perils and difficulties of divided authority is added a contortion of the educational system to supply a community family mental health service. This proposed service would needlessly duplicate the service already supplied freely to all categories of patients by the regional hospital boards under the terms of the National Health Service Act, 1946; this family-orientated service has grown apace in the last five years and is based on the collaboration of the general practitioner and the school medical officer, one responsible for initiating referral direct from the home and the other from the school.

Much attention has properly been given by the Ministry of Health to the mental health problems presented by the psychotic patient; the obviousness of the problem and the number of occupied hospital beds have compelled attention. Affecting as it does approximately 0.5% of the population, psychosis is, relatively, a minor problem in mental health when due regard is given to the problem of emotionally handicapped individuals, who amount to an unquestioned 6%, perhaps 30%, and possibly a higher percentage of the population. The Ministry of Health has certainly not ignored this greater problem, but we are still awaiting a

process of which nobody can foresee the end. If you wait, and above all if you wait until *early* signs, for example, of respiratory paralysis as detailed by Dr. Brewis appear—i.e., 'restlessness, rapid, shallow respirations, increasing cyanosis and distress'—then you can be sure that you have waited too long.—I am, etc.,

Isleworth, Middlesex.

G. E. BREEN.

High-grade Defectives

SIR,—Dr. J. Newcombe (*Journal*, June 23, p. 1487) has raised a matter of great importance to all oligophrenicists—if I may be permitted to start a hare for the linguistic purists. The solutions he offers for this problem are at first attractive, but a few points seem to need closer scrutiny.

I suggest that it is misleading to speak of the period of detention in relation to the severity of the crime—this has merely served to bring the case to light much later than should have been. Surely the length of detention must depend entirely on the time needed for treatment. Dr. Newcombe says these patients are not admitted primarily because of their mental deficiency but because of superimposed behaviour disorder and instability. While this is certainly true in many cases, are not the behaviour disorder and instability part of the deficiency, rather than superimposed upon it, in many others? And is it not true that these cases, which usually have an abnormal E.E.G. record, do not respond quickly to treatment?

Some aspects of this problem bring to mind the old controversy about neurosis centres and mental hospitals, the problem of sheep and goats. While we must admit that our low-grade patients will always fall into the latter category, can we be sure that all those of high grade will not? What is to happen to the high-grade patients who do not respond to treatment as quickly as we hope? Will they not either block admissions to the special hospital or approved school set aside for them, or suffer a therapeutic set-back when transferred to an ordinary mental deficiency hospital?

It is not easy to find a solution to this problem, but on the whole I feel it lies in the correct planning and administration of the mental deficiency hospital rather as a group of small special hospitals within its precincts, in the discarding of diagnostic labels, and in the more energetic use of hostels and licence.—I am, etc.,

Morpeth.

C. GUY MILLMAN.

SIR,—Following the recent discussion in your correspondence columns (Dr. J. Newcombe, *Journal*, June 23, p. 1487, and Dr. Z. P. Fernandez, June 30, p. 1546) it may be of interest to consider the special problems of the mentally defective juvenile. Frequently the high-grade mental defective comes into conflict with the law during adolescence. As an educationally subnormal pupil he adapts fairly well at either a special school or, with special considerations, at the ordinary school. Social adaptation breaks down frequently when the juvenile is faced with the responsibility of earning and spending money, with decisions regarding personal relationships outside the family. The discrepancy between the retarded emotional and intellectual maturation and the needs of normal physical development creates tensions which often seek outlets in socially harmful activities. Stealing and sexual misdemeanour are the usual charges which bring the mental defective juvenile before the court. The inability to compete at work and to withstand the desire for pleasure and possessions leads to a situation of drifting about, following momentary impulses.

These adolescents need permission to mature slowly in an environment that provides training and guidance according to their individual need and capacity. Self-reliance may not be reached until the twenties, and sometimes sheltering conditions may be required much longer. Detention in an institution rarely meets their need. Their failure of social adaptation is largely related to the complexity of modern urban life and would be less disturbing in a small family-like or village community. In strictly supervised institutional care incentives for responsibility and self-reliance are few and maturation may be further delayed. Treatment of

the juvenile high-grade mental defective implies education and training rather than care and detention. This need may be met by a special Order, such as recommended by Dr. Newcombe. The Order would need to remain in force until education and training have reached the stage when the young person is considered fit to live independently. Hostels rather than hospitals are required for such training.

Special consideration of the position of unmarried mentally defective mothers seems necessary. Because of the girl's inability to fulfil the role of mother unaided, separation from the child is most frequently advocated. One may question whether this is the right step for mother and child. Mentally defective girls are often very affectionate and quite prepared to give their infants loving attention. The care for the child may have a beneficial effect, increasing steadiness of moods and aiding emotional maturation. The girl cannot, however, take on maternal responsibilities without provision for material security and guidance. It may be considered useful—and ultimately a means of saving public expenses—if hostels were provided for these young mothers and their children where they could receive training in mothercraft and become dependable. The child would thus receive its mother's care and perhaps a number of misfits in fostering and adoption could be avoided.—I am, etc.,

Winchester.

L. ROSENBERG.

Gases Administered in Artificial Respiration

SIR,—I have read with the utmost interest the abundant correspondence issued from the publication of "Gases Administered in Artificial Respiration" by Dr. K. W. Donald and Professor W. D. M. Paton (*Journal*, February 5, 1955, p. 313). In order to convey additional information in the controversy, may I inform you of an extract of an article, summing up my own experimental researches? In January, 1945, the U.S.A. War Department diffused a bulletin entitled: "Treatment of Respiratory Depression and Asphyxia." It stated in particular:

"For many years carbon dioxide or carbon dioxide-oxygen mixtures have been employed in the treatment of asphyxia neonatorum, asphyxia from carbon monoxide inhalation, asphyxia from drowning, and other conditions in which the patient is not breathing or in which respiration is severely depressed. Evidence is now available to show that such a procedure is not rational and is associated with certain dangers.

"It has long been known that carbon dioxide will produce narcosis, and recent investigations have emphasized the dangers associated with the use of this agent when the respiratory centre is depressed. When administered for a short time in weak concentrations, it does increase the depth of respiration. This same effect is not exhibited when the centres of respiration are damaged, when the concentration of this gas is high, or when it is used over a prolonged period of time. . . . In asphyxiated patients the blood oxygen concentration is almost nil, but the blood carbon dioxide level is elevated above normal. Since in these patients carbon dioxide no longer acts as a respiratory stimulant but is actually a respiratory depressant, there is no rational basis for its administration. This is also true in cases of severe carbon monoxide poisoning, for medullary damage is present in all states of severe anoxia. For these reasons the use of carbon dioxide as a respiratory stimulant is dangerous. The carbon dioxide level in the blood will adjust itself if oxygen is supplied in adequate amounts to the tissues. This has been demonstrated to be true both experimentally and clinically."

In 1952 David B. Dill, Chief of the Medical Services of the Army Chemical Centre, U.S.A., questioned many resuscitation experts about it. The inquiry showed that "carbogen" was gradually abandoned for pure oxygen, and that now the mixture is practically never used. The author concluded thus: "It is recommended that the admixture of carbon dioxide with oxygen for artificial respiration be abandoned."

When those documents came to our knowledge we were extremely surprised, considering the favour carbogen has enjoyed for more than 30 years. We made up our minds, therefore, to form an opinion of our own by operating in

the following way: dogs, after anaesthesia, were asphyxiated by different processes (drowning, strangulation, CO₂, or CO poisoning, etc.). When breath stopped and before reaching the critical value of blood pressure, we applied artificial respiration, either with air, oxygen, or carbogen. Inhalations were pursued for a certain period of time with the chosen gas. We made the usual records of respiration and circulation. Blood was analysed as to its content of oxygen and carbon dioxide, its density, pH, alkali reserve, free CO₂, haemoglobin; in short, we made our inquiry as thorough as possible. In no case, out of about 50 experimented dogs, did we find carbogen superior to oxygen alone.

Those results were observed in all the various kinds of asphyxia, even in carbon monoxide asphyxia, which was always considered as the major indication for carbogen. In that particular case we actually did not notice a faster elimination of carbon monoxide if carbogen was administered instead of oxygen. The same fact, too, had been already claimed by other authors—namely, by Walton *et al.*⁴ Teleky,⁵ and Schwerma *et al.*⁶ However, unlike the Americans, we did not notice any harmful effect of carbogen. And so we quite agree with them that carbogen should be withdrawn from resuscitation kits.

Moreover, this measure will have further advantages. Carbogen is more expensive than oxygen and its supply is difficult in the provinces. Oxygen can be easily provided on account of its many applications in industry. Lastly, carbogen is contraindicated in some cases, such as intoxications by CO₂ (wells, fermenting vats, CO₂ fire-extinguishers more and more widely spread, etc.), intoxications by lung irritants (chlorine, phosgene, nitrous fumes, etc.). If resuscitation kits do not include carbogen, there is no danger of an unwarned rescuer using it when contraindicated. He will but dispose of oxygen, which proves useful in any type of asphyxia.—I am, etc.,

Accidents with Injections

SIR,—It is, perhaps, a pity that Dr. C. F. Scurr does not qualify his statement that the aspiration test should always be used before subcutaneous injection, in his excellent article on accidents with injections (*Journal*, June 2, p. 1289). Dr. Scurr, in an earlier passage, writes of the possible danger of infection during mass inoculation. In a previous letter (*Journal*, July 30, 1955, p. 323) I suggested that when an aspiration test was made the danger of infecting the syringe thereby entailed using a fresh sterile syringe for each injection. Methods now advocated for mass inoculation aim at avoiding re-sterilization of the syringe, as this presents a grave practical problem, and are thus mainly concerned with preventing that back flow of blood or tissue fluid into the syringe which an aspiration test encourages. The method of Fleming and Ogilvie¹ and the purpose of the specially designed syringes of Gross² and Voorhorst³ might be brought to naught by an aspiration test, and the valve described by Gispén⁴ of course renders such a test impossible.

If it is decided, in respect of any immunization agent, that in spite of every precaution other than aspiration the risk of entering a blood vessel is still too great to be accepted, recent methods directed towards avoiding syringe contamination are also unacceptable when injecting such material. Three courses then lie open to the mass inoculator. First, he may use a freshly sterilized syringe (not only re-sterilize the needle) for each person: the demands on time, manpower, or equipment (or on all of these) will be excessive. Secondly, he may ignore the risk of transference of infection which aspiration presents: the taking up of many doses into the syringe at each filling might then be permitted, since fear of aspiration, though admittedly after raising the pressure in the subcutaneous tissue, is the

accepted bar to doing so. It might even be thought that, if the risk of infecting the syringe is being taken, there is no need to re-sterilize the needle. This, of course, would be a false argument, since infection of the needle, either outside or inside, might occur in cases where, in spite of suction, the syringe remained sterile. Even without such an unwarranted extension, I doubt if many doctors would accept this second alternative, and I am sure Dr. Scurr would not be among them. Thirdly, the inoculator may give up injection by needle and syringe in favour either of needleless injection by high velocity jet or of intradermal multipuncture. I would suggest that it is indeed along such lines that progress will be made, but the former method needs development of equipment, while the latter must first be shown to be immunologically effective. While syringe and needle are used I feel that the precaution of withdrawing the plunger (aspiration test) before injection must be forgone during mass inoculations.—I am, etc.,

Divine Healing

SIR,—It is necessary to distinguish between divine healing and faith healing. The former, according to the terms of reference to the B.M.A. investigating committee, was intended to mean, I understand, the healing of patients, by divine intervention in answer to prayer, who are suffering from incurable diseases such as inoperable carcinoma. Such healing is beyond explanation by any of the ordinarily recognized "laws" of scientific medicine, but, as Dr. Jane H. Thompson suggests in her excellent letter (*Journal*, June 9, p. 1363), it is not impossible to believe that there are spiritual laws beyond "the physical and mental which keep people in health or cure them when they become diseased." This is what I would suggest as healing in the third dimension and was practised by our Lord and His apostles. One thinks of Einstein's revolutionary discovery and those who found that the atom was a little electric world in which was pent up the most appalling, and hitherto undreamed of, power. Similarly, our Lord and His apostles were evidently in possession of almighty power in the spiritual realm, the third dimension.

The letter of Dr. Nigel Loring (p. 1363) fails utterly to allow for this possibility, and his "blind faith" is an unfortunate expression and a confession of his own myopia. The definition of "faith" (in Hebrews xi. 1) is "the substance of things hoped for, the evidence of things not seen." He also speaks of "observation and experiment" as if the scientist would ever be so smug and complacent as to think that present knowledge was final. Keen Christians are perplexed, however, when they find their faith and prayers apparently unrewarded. I think that one must go on in faith and prayer, committing our case, whether curable or incurable, to God, believing in His eternal purpose for good for all who acknowledge His presence in all departments of their lives. Prayer will be answered undoubtedly in one of two ways—that is, either by cure of the disease or by grace to bear it.

Prayer and faith must not be divorced from the use of all available medical and surgical services. For surely the latter are intended to create better conditions for healing, which are ultimately always divine. If the surgeon removes a gangrenous appendix, or sews up a gastric perforation, the healing of the wounds is entirely by "nature"—which is only a word used so often to avoid acknowledging the God who is the author of the laws by which "nature" works. Looking at it this way, let us acknowledge at once that all healing is divine, in the last analysis. As to "faith healing," this may be simply and solely a psychological phenomenon. The faith may be in a man, or a charm, or a grotto, or a "saint," or a mere superstition, nothing divine about it. It works in functional disorders; and, now that psychological medicine has developed into a special

branch during the last 30 or 40 years and the region of the human mind has been explored, the laws of mental healing are known, and dramatic cures are no longer looked upon as "miracles." But the "lay" mind would still think a "miracle" of healing had been performed if, for example, a girl with hysterical paralysis were suddenly cured by mind therapy.

The need for this kind of therapy is surely evident; for I understand that 50% of the beds in this country are occupied by mental cases. The strain and stress of modern life (hurry and worry, domestic, social, economic, and business anxieties) seem to be having a serious influence on the nervous system via ductless glands, upsetting function and possibly leading to organic disease. One thinks of toxic goitre, hyperpiesis, coronary disease, and afflictions of the nose, bronchi, oesophagus, colon, bladder, and stomach. Duodenal ulcer is commonly associated with nervous tension, and this must be considered in treatment. These considerations seem to indicate the great importance of mind treatment, which is in the second dimension. We have been very slow to appreciate the fact that thinking can be damaging even to the physical body. "As a man thinketh in his heart, so is he." Compare our quite recent recognition of the importance of the blood—the circulation being discovered by Harvey in 1615. Yet 4,000 years ago it was written: "The life of the flesh is in the blood"; "The blood is the life."

So it is that few medical men understand the things of the third dimension—the spirit, which again is superior to the mind and exerts a profound influence on a man's thoughts. If the B.M.A. called for evidence of revolution and reconstruction of character through faith in Jesus Christ, there would be tens of thousands of indisputable testimonies. Those who have experienced this "miracle" might be excused for expecting "miracles" in the lower dimensions of mind and body—that is, healings of the mind and body outside scientific psychological and physical experience—such as occurred in the days of our Lord and His apostles. This is what we mean by divine healing.

I would not deny the occurrence of such miracles, but most will agree that they are very rare. And why? I can think of two reasons. One is, as I have indicated already, that it is divine guidance that has led us to the wonderful discoveries which enable us to enjoy to-day such health and healing, which we attribute to "nature." The other is that a study of the scriptures indicates that in this world of sin and death the righteous suffer with the wicked until such times as the "curse" is removed from mankind and all nature is redeemed and restored to life incorruptible. In dealing with the supernatural, one must consider divine revelation: for until we understand what is already well known in experience in the spiritual realm we shall never be able to discuss these things intelligently or make further progress. The atheist, agnostic, and sceptic have neither part nor lot in this matter.—I am, etc.,

Chigwell

N. BEATTIE.

SIR,—I can assure Dr. M. Curran (*Journal*, June 30, p. 1545) that by no means all his co-religionists, whether priests or doctors, adopt his own attitude of intransigence in the matter of co-operation with clergy of other Christian denominations and with non-Roman doctors. He may not be aware that in quite a number of districts where doctors, clergy, and ministers are established as a group and meet regularly for discussions, etc., the local Roman Catholic priest is also to be found taking his part in the giving of lectures and contributing to the discussions. In many cases Roman Catholic doctors are participants in such group meetings.

It is significant also that in *The Doctor's Profession* (S.C.M. Press), first published in 1949, the editor should have occasion to remark in his preface that "this book is the fruit of the work of a group which was almost equally composed of Roman Catholics and non-Roman Catholics, with a slight preponderance of the latter. It is worth recording that this was not planned from the outset. It merely

happened that people who were deeply concerned about these questions were to be found both among Roman Catholics and other Christians. The members of the group found also that they were able to discuss many controversial questions without either suppressing their own point of view or exaggeratedly emphasizing it." In neither of the circumstances cited above did the Roman Catholics who participated feel that they would "be giving recognition to the beliefs of the English Church as a spiritual body and would be denying our own faith."

The Roman Catholic doctors invited to submit evidence before the (Anglican) Archbishops' Commission were in no danger of being led astray by "heretics": they were merely being asked to express their opinions on certain facts, and it would be natural for them to do this in the light of their knowledge of the spiritual ministrations given to the sick in their own Church.

One would have thought that this, so far from compromising their faith, would have given them an excellent opportunity to witness for it.—I am, etc.,

Leamington Spa.

F. S. SINKER.

SIR,—It is surely fortunate that the B.M.A. committee which prepared the report on divine healing did not attempt to define miracle. It kept to its appointed task of providing evidence (*Supplement*, May 12, p. 269).

The correspondence which has appeared in the *Journal* in the past weeks confuses two different issues. First, the question is asked, Do miracles of healing occur to-day? Secondly, many believe that there are spiritual laws which, if understood and applied, would result in unusual healing of disease. The B.M.A. committee could obtain no convincing evidence that unusual healing has occurred: "The cases claimed as cures of a miraculous nature present no features of a unique and unexpected character outside the knowledge of any experienced physician or psychiatrist." This view falls into line with that expressed in the leading article of the *Journal* of June 18, 1910 (p. 1483), when the whole subject was fully reviewed in the light of the experience of those days and excellently written up by leaders of the profession.

To the Christian these findings offer no particular problem. He believes that God as creator and sustainer of this world can do a miracle when and where He chooses. However, the evidence of the Bible suggests that His miracles have been mainly limited to certain periods of history. They were supremely shown in the life and work of Jesus Christ.

Of the so-called "spiritual laws" which influence healing there is much that we do not understand, and those who speak of them often use phrases the meaning of which is hard to ascertain. What, for instance, does Dr. J. Burnett Rae (*Journal*, June 30, p. 1544) mean when he speaks of "lifting them [our therapeutic means] to a higher power and a finer end"? There are two important principles by which we may be guided. If a claim be made that the physical state of a patient's diseased tissues can be affected, then we, as doctors, believe that such changes can be observed and possibly measured by independent witnesses. They are subject to the "proof" of our senses. As Professor Alstead succinctly expressed it in an excellent article which appeared in the *Manchester Guardian* on August 29, 1955, "It may be objected that spiritual healing belongs to the realm of the spirit and that it cannot be measured with the yardstick of the clinical laboratory. To this I would say that if the spiritual healer enters the field of clinical medicine and makes claims in terms such as I have tried to explain then he must submit to the discipline of clinical science."

On the other hand, if such claims of physical change be not made and the benefit which the healer offers is purely spiritual, this too is subject to a yardstick which we should do well to use. The New Testament makes clear to us that the work of the Holy Spirit is concerned primarily with a man's relationship to God and with the quality of life which he leads. There is very little to lead us to suppose that special gifts of healing are imparted in the course of His normal activity to-day.—I am, etc.,

Haemophilus Infection in Bronchiectasis

SIR,—I was interested to read the article on haemophilus infection in bronchiectasis by Dr. E. C. Allibone, Mr. P. R. Allison, and Dr. K. Zinnemann (*Journal*, June 23, p. 1457). I drew attention to the prevalence of haemophilus in chronic non-tuberculous lung conditions in childhood in 1927.¹ I cannot, however, endorse their confidence in the effects of treatment with antibiotics, which seem to me to be ineffective in eliminating the organism in such cases. Whereas in 1927 I regarded it as rather probable that the haemophilus was the actual cause of the persistent illness in these children, I would now rather take the view that the disease is bacteriologically non-specific and the result of bronchial obstruction with partial collapse and secondary infection in the collapsed areas. In fact, I would now rather regard the haemophilus as a secondary invader. It is a very common organism to find in the respiratory tract. The authors do not describe "relapse" as occurring in their cases. I am not clear what meaning they attach to this word. I think it can hardly be supposed that reinfection occurs. The odds against this happening would be enormous; besides, they describe relapse as occurring on the average every six weeks. Their observations would therefore indicate that the haemophilus is not eradicated but only temporarily suppressed.

I am also not very happy about the use of the term "purulent bronchiectasis" in children. We rarely see the disease which used to go by this name—that is, a persisting bronchial dilatation with fetid sputum. No doubt workers in the northern cities see more cases of the type described in my M.D. thesis of 1927, but the number of cases in this country has steadily been diminishing. We see very few cases of primary tuberculosis with collapse, and in most of our cases of whooping-cough or non-specific respiratory infection collapse is very transient and bronchiectasis distinctly rare.—I am, etc.,

Apartheid in Blood Transfusions

SIR,—Might not Dr. David J. Adderley (*Journal*, June 30, p. 1546) be mistaken, and himself the victim of an emotionally charged concept? To assert that there is no essential difference between blood from different sources involves a large assumption, and, so far as I am aware, not sufficient work has been done to substantiate it.

It is known that there is a gradient of increasing proportion of group O blood from east to west across Europe. Thus, at a time when the ABO groups were unknown, it would have been safer to transfuse, say, an Irish person with blood from an Irish source rather than with blood from, say, Poland. No one will imagine that the last work has been done on the constituents of blood or its various groupings. With such a difference as between populations within Europe, there is at least a prima facie case for postulating differences between bloods from different continents. Before Dr. Adderley suggests offering gratuitous advice to the profession in South Africa, let him reflect that its ideas may not be altogether wrong. Let us not confuse scientific integrity with support for a political theory of racial equality.—I am, etc.,

Wednesbury.

J. TORLEY.

Post-menopausal Oestrogen Production

SIR,—Might we make a plea for the use of a standard method of estimating oestrogenic activity from vaginal smears? Dr. R. A. Struthers in a recent interesting article on post-menopausal oestrogen production (*Journal*, June 9, p. 1331) employs a method of grading which makes it difficult to compare his findings with those of many other workers in this field. Authorities such as Shorr,¹ De Allende and Orias,² and Horwith³ all use a cornification index which is calculated as the percentage of cornified squames in

several unselected fields of superficial, intermediate, and basal cells. On the other hand, Dr. Wachtel,⁴ in her recent article entitled "Suggestion for a Cytological Test of Cancer Cure," calculates the cornification index "by counting the percentage of cells with pyknotic nuclei among 200 unselected superficial and intermediate squames. The basal cells are omitted from this count."

It seems logical to assume that a cornification index provides a better yardstick and is less liable to personal interpretation than any other forms of grading, but it would be of greater value if it was always calculated in the same way. Working at Dr. P. M. F. Bishop's endocrine clinic, we have found that a count of all the vaginal epithelial cells—that is, including the basal cells—gives a more accurate clinical picture.

We would also like to know if Dr. Struthers had any particular reason for obtaining smears by scraping the anterior wall of the upper vagina as opposed to aspiration from the pool of secretion in the posterior fornix. We find the latter method gives a much more representative slide and avoids contamination from the lower third of the vagina.—We are, etc.,

Maladjusted Children

SIR,—Dr. M. Park (*Journal*, June 23, p. 1487) is disappointed at the poor response to his appeal for action based on the report of the Committee on Maladjusted Children,¹ set up with commendable initiative by the Ministry of Education. This lack of response, I fear, reflects the disappointment of many in the medical field at the nature of the main recommendations of this informative report. There is a marked difference of emphasis from the evidence submitted to the committee by the British Medical Association² and from the recent memorandum of the Royal Medical-Psychological Association.

An adequate service must meet the needs of the school child, the pre-school child, the post-school child, the child at the non-maintained school, and the emotionally handicapped parent. The most important categories, the pre-school child and the emotionally handicapped parent, can be least effectively dealt with on these recommendations. To deal with the child from the non-maintained school a call is made for new legislation. The proposed administrative structure is a complex of three local authority departments (education, school health, public health), grafted on to which is the regional board concerned. To the perils and difficulties of divided authority is added a contortion of the educational system to supply a community family mental health service. This proposed service would needlessly duplicate the service already supplied freely to all categories of patients by the regional hospital boards under the terms of the National Health Service Act, 1946; this family-orientated service has grown apace in the last five years and is based on the collaboration of the general practitioner and the school medical officer, one responsible for initiating referral direct from the home and the other from the school.

Much attention has properly been given by the Ministry of Health to the mental health problems presented by the psychotic patient; the obviousness of the problem and the number of occupied hospital beds have compelled attention. Affecting as it does approximately 0.5% of the population, psychosis is, relatively, a minor problem in mental health when due regard is given to the problem of emotionally handicapped individuals, who amount to an unquestioned 6%, perhaps 30%, and possibly a higher percentage of the population. The Ministry of Health has certainly not ignored this greater problem, but we are still awaiting a

broad appraisal of the situation and a planned development of services to deal with it. The moment is possibly ripe for setting up a committee of the Ministry of Health to inquire into the problem of the emotionally handicapped person—child, adolescent, and adult.

Dr. Park rightly points to the value of local postgraduate instruction in child psychiatry for medical practitioners. Since February, 1954, we have organized at Ipswich a weekly clinical discussion or demonstration for medical practitioners in this area. Under the aegis of the East Anglian Regional Hospital Board and the Ipswich Group Hospital Management Committee we have supplemented this in the last three years with a one week's course in child and family psychiatry. Full-time attendance has been 17, 24, and 41 respectively. School medical officers have been in the majority, due to the ready recognition of the course by the Ministry of Education and the encouragement given to their attendance. General practitioners have displayed keen interest and a number have attended. But their attendance at local courses would be greatly facilitated if the Ministry of Health made locum provision possible by a more generous recognition of courses under Section 48, National Health Service Act, 1946; the Minister is empowered to enter into arrangements, not only with universities and medical schools, but also with "any other persons for the provision of courses." Londoners are fortunate in having access to courses at the Tavistock Clinic.—I am, etc.,

Ipswich.

The Insatiable Critic

SIR,—In a review (*Journal*, May 26, p. 1221) of my small book, *Smoking and its Effects*,¹ Dr. Richard Doll complains that I did not pay enough attention to results obtained by the "direct observation of mortality among non-smokers and heavy smokers." To me the significant fact was that non-smokers are liable to contract lung cancer, and this is stated in the text.

The name of Doll (as also that of Hill) figures in the index more often than that of any other author, and in a book of 144 pages no less than 22 are devoted to an account and discussion of his work.—I am, etc.,

London, W.C.1.

Paediatric Anaesthesia

SIR,—With reference to Mr. Albert Davis's (July 7, p. 45) remark on the complacent attitude of anaesthetists towards paediatric anaesthesia, he must be aware that the main difference between his methods as a house-surgeon and those of modern anaesthesia is in the use of the intravenous route. By this means quiet sleep is produced by a short-acting barbiturate, muscular relaxation achieved by a relaxant drug, and analgesia maintained by inhalation of weak concentrations of anaesthetic gases, supplemented when required by intravenous analgesics.

In ambulant patients these ideal conditions are achieved only at the expense of delayed recovery of the ambulant state. In adults it is possible to ease the terrors of an inhalation induction by the use of very small intravenous doses of barbiturates or by the use of the ultra-short-acting thialbutone sodium. This was recently discussed by the Anaesthetic Section of the Royal Society of Medicine.

To insert and keep a needle in the vein of a wriggling terror-stricken child can be a very difficult procedure and may cause as much psychological trauma as the application of a face-mask. There is the added risk of depositing some of the irritant drug extravenously or even intra-arterially, with dire results. The intravenous induction can be achieved in children in some cases. I have worked with a dental surgeon

who is a superb teller of fairy stories to children and practically hypnotizes them, so that they know nothing of the injection.

With regard to tonsillectomy and other major surgery in in-patients, the terrors of anaesthesia can be removed completely by efficient and well-timed premedication. For a considerable time in one of my hospitals we have had great success in "tonsil children" by the use of methylpentynol as a premedicant. Mr. Davis would be very welcome should he care to visit us.—I am, etc.,

London, W.4.

DONALD BLATCHLEY.

Progressive Massive Fibrosis

SIR,—Dr. J. P. Anderson's suggestion (*Journal*, June 23, p. 1484) is, we think, a good one, but he might be interested in some work published in 1954.¹ This was concerned with the effect of isoniazid on the radiological rate of progression of progressive massive fibrosis. In retrospect the trial was not perfect, but there are considerable difficulties in giving therapy to large numbers of working miners over long periods, particularly if injections are involved.

Dr. A. T. Doig's suggestion (p. 1484) is more difficult to discuss. His hypothesis is, if we understand him correctly, that progressive massive fibrosis is caused by collapse secondary to pulmonary fibrosis or mucous plugs in lungs containing macules of coalworker's simple pneumoconiosis. As regards the former, this presupposes a considerable amount of fibrosis in the coal macule, whereas the pathological evidence would suggest that there is little, if any, collagen to be found in it. The evidence also suggests that the macule causes dilatation of the terminal bronchiole and not collapse, and we do not know of any other evidence to support Dr. Doig's hypothesis. As regards the latter, if it were a main cause of progressive massive fibrosis one would expect progressive massive fibrosis to appear frequently after pneumonic shadows are seen in the lungs. This again is contrary to our observation, as we pointed out in our paper. It is possible, however, that alveolar collapse is one of several mechanisms whereby an established mass increases in size.—We are, etc.,

"P.U.O."

SIR,—Like Gerontius, I saw with "horror, horror and dismay" the title of the article by Dr. J. V. O. Reid (*Journal*, July 7, p. 23), "Pyrexia of Unknown Origin." I believe it is correct to say that P.U.O. was coined as a term by the Army medical services in the first world war. Since the Services could hardly be expected to tolerate the suggestion of anything unknown, it is right to point out that the letters P.U.O. stood for pyrexia of undetermined origin.—I am, etc.,

London, W.8.

MICHAEL HARMER.

Rovsing's Sign

SIR,—I was most interested in Mr. W. W. Davey's article on the above subject (*Journal*, July 17, p. 28) and would like to express my entire agreement with his statements. For many years I have been trying to disillusion house-surgeons as to the value of this sign as a diagnostic aid in acute appendicitis. For some reason this sign always seems to be given extraordinary significance in their training, but, as Mr. Davey points out, is in no way specific of an appendicular lesion. I have demonstrated the most classical Rovsing's sign in many other conditions, such as torsion of an ovarian cyst, torsion of a piece of omentum, and in cases where no pathology was found at subsequent operation.

It would therefore be well for this sign to be erased from the diagnostic criteria of acute appendicitis.—I am, etc.,

Slough, Bucks.

ROBIN BURKITT.

JULY 21, 1956

Obituary

Miss MARTHA MARQUARDT

Miss Martha Marquardt, formerly secretary to Paul Ehrlich, died on Saturday, July 14. We are indebted to Sir HENRY DALE, O.M., for the following tribute.

Miss Martha Marquardt had been personal secretary to Paul Ehrlich from 1902 until his death in 1915—a period which included the whole of the last and, perhaps, the most permanently important phase of his great contributions to medical science. In those years he effectively launched his new campaign of chemotherapy and led it to its first practical triumph in the discovery and successful application of calyculin and its derivatives. To anybody who had opportunities of contact with Ehrlich during that period of tunities of contact with Ehrlich during that period of prodigious activity it must have been obvious that Miss Marquardt's tireless efficiency, and the intensity of her devotion to all his interests, played an important part in enabling him, with his prematurely ageing physique, still to reach such a pinnacle of achievement.

When Ehrlich died, in 1915, Martha Marquardt was still in her earlier forties; and she was then to devote more than another 40 years almost entirely to the commemoration of his life and his personality, and to collecting the records of his career. In 1924, in honour of what, had he lived, would have been his 70th birthday, she wrote and had published in Germany an intimate personal memoir, *Paul Ehrlich als Mensch und Arbeiter*, recalling his very unusual personality and methods of work with a charming and humorous affection. She found herself, however, increasingly unhappy in her native Germany, and became a voluntary exile in Paris. There she wrote, for German readers, an attractive little book which sketched, in successive chapters, various aspects of the daily life of the ordinary working Parisians. Her main concern, however, was the collection of everything that had any bearing upon Ehrlich's life and work—reprints of his published papers, copies of the letters and manuscripts of his published papers, copies of the letters and with which she had typewritten while she worked for and with him, and of any unpublished theses and addresses which she could trace. The second world war caught her there, in Paris, and it is not easy to understand how she survived it. She never spoke of the suffering and privation which it must have entailed for her; but she told me, only quite recently, that she had twice had to face, and had successfully resisted, threats of personal arrest and of the seizure of her treasured Ehrlichiana, first by the German army of occupation, and then by the French army of liberation, puzzled by the presence of this German woman, apparently still hiding in Paris and hoarding a mass of German documents. When she managed at length to bring her plight to the notice of the late Sir Almroth Wright, who had been one of Ehrlich's closest English friends, he brought her to London, and found means for her support, and opportunity in what is now the Wright-Fleming Institute of St. Mary's Hospital for her to undertake the fuller and more ambitious life of Ehrlich, which Sir Almroth encouraged her to write. This book, entitled simply *Paul Ehrlich*, published by Heinemann in 1949, and later in Germany and the U.S.A., contains a wealth of material of great value for an understanding of Ehrlich's personality and career; but Miss Marquardt was no longer young, and she had never acquired the chronological instinct of an experienced biographer. She had mined, moreover, against advice, to write this book directly in English, with which her familiarity was never so close as she seemed to believe. In spite, therefore, of a friendly and laborious effort to bring her draft into line with normal English usage, this book never appeared to me to have the spontaneity and lively charm of the shorter character-sketch which she had written in German 25 years earlier.

Her life's greatest ambition, however, remained yet to be fulfilled. Her plea for a complete edition of Ehrlich's scientific writings, important items of which had never yet been

published, enlisted my own full sympathy. As soon as the conditions made it possible, Miss Marquardt obtained the support of the Wellcome Trustees for a visit to Frankfurt, where she was able to gather further items for the collected edition, from the war-battered institute which had once been Ehrlich's. After some failures, a firm of publishers was found ready to accept a stable responsibility for the enterprise, with the help of a guarantee from the Wellcome Trust; and Dr. F. Himmelweit accepted, and has discharged with a growing enthusiasm, the main editorial function, with the devoted co-operation of Miss Marquardt, and my own supervisory responsibility. And now there is a note of genuine tragedy in the thought that Martha Marquardt has gone, full of courage and enthusiasm until the mere weight of years bore her down, a few days or weeks only before the overdue publication of the first volume of the "collected edition" for which she had worked and waited so eagerly.

We announce with regret the death of Dr. F. W. CHEESE on June 10 at Stourbridge at the age of 80. Frederick William Cheese spent most of his childhood in South Africa, where his father had emigrated following the death of his wife. When his father died he returned to England with his brother and two sisters. He studied medicine at St. Bartholomew's Hospital, graduating M.B., B.S. in 1906. He proceeded M.D. (Durham) in 1908. After a period of resident appointments at St. Bartholomew's, Dr. Cheese went into practice in Harpenden. During the first world war he served in France with a field ambulance and sustained severe frostbite of the fingers, a disability which proved to be a considerable handicap. In 1920 he re-entered general practice in Ludlow, moving to Cliftonville in 1930. He was chairman of the East Kent Division of the B.M.A. from 1939 to 1940. In 1942, at the age of 66, he was compelled to leave Margate under the emergency regulations then in force on the South Coast. He was dispossessed of his practice without compensation, being given five days to remove his chattels. This remained a source of rancour and bitterness to the end of his days. With his one surviving sister, Dr. Cheese went to Stourbridge. There followed a period as medical officer of an ambulance train, but he found the travelling too arduous, and in 1944 succeeded to the practice of the late Dr. A. R. Sharrod, of Stourbridge. From 1945 to 1947 he was chairman of the Dudley Division. Frederick Cheese was a mixture of the old and the new. He was remarkably in touch with modern developments in medicine, yet retained a traditionalism which showed itself in his punctiliousness in his habits and dress. He was never seen out except in a butterfly collar, clerical grey suit, bowler hat, and chamois leather gloves. His chauffeur always followed him into the patients' houses, carrying his bag. He remained in work until illness overcame him. He was unmarried.

S. D. M. W. writes: The untimely death of J. F. DIGNAN (*Journal*, July 7, p. 49) has brought to light how great were the feelings of love and trust which he inspired in his patients. Their grateful devotion to him reminds us of how strong an influence our profession wields in the lives of those who come to us for help and relief of their suffering. Taking over his hospital department in the emergency, I had the melancholy task of breaking the sad news to many of his patients who came expecting to see him. Their spontaneous expressions of grief were universal and came from their hearts. They had lost a friend, someone who cared for their troubles and took infinite pains to do all he could, both clinically and in the wider field of social rehabilitation, to ameliorate their lot. One patient who said, with tears in her eyes, "Oh, I shall miss him; he was so kind," has, I think, given him in her simple phrasing an epitaph as honourable as any which a man might hope to deserve.

Medical Notes in Parliament

PAY CLAIM REJECTED

Lieut.-Col. LIPTON (Brixton, Lab.) asked the Minister of Health on July 16 on what grounds he refused to disclose the increases in doctors' pay asked for by the British Medical Association. Mr. TURTON—Because, so far, there has been no claim published by the profession. The communication on this subject has been only in the form of a preliminary memorandum sent to my Department and to that of the Secretary of State for Scotland. To this a reply has now been sent stating that in present circumstances we would not feel justified in giving consideration to any claim for a general increase in medical remuneration.

Lieut.-Col. LIPTON—Before we can decide whether the reply is justified or not, cannot we be told what the doctors asked for? Why all this secrecy? Mr. TURTON—Because there has been no claim published by the profession. I must act under proper procedure, and not anticipate publication when I have only received what is a draft memorandum.

ADMISSION TO MENTAL HOSPITALS

Dr. DONALD JOHNSON (Carlisle, Con.), who has been questioning the Minister of Health for some time about the admission of involuntary patients to mental hospitals, brought the matter up for discussion on the motion for the adjournment on July 10.

He regarded the figure given him, in answer to his questions, of some 20,000 people a year being put into mental hospitals against their will as alarmingly high. Only some 15% of the number had been under outside observation in hospital wards. In other words, some 17,000 people were "swept up," mainly on a summary reception order, and detained in mental hospitals for an indefinite period up to a year. This was done on the opinion of two or three people, who, though of professional status and empowered to sign certificates, were as liable to error as the remainder of mankind. Mental hospitals were overcrowded to the extent of 15.6%. The more practical way of solving the problem was by exercising more discrimination over admissions. This could be done, he suggested, by the establishment of observation wards in general hospitals, in which patients could be viewed in surroundings as detached as possible from mental illness, and could be seen by general physicians not quite so preoccupied with their own specialty as were psychiatrists. Such surroundings would provide a respite during which the patient could perhaps surmount an acute crisis, and resume his place in the community without having acquired the stigma of having been a patient in a mental hospital. He quoted figures given by the L.C.C. in their evidence to the Royal Commission, that 4,746 persons were admitted to observation wards during 1953; and of these, 1,274, almost a quarter, were discharged at the end of the 17-day observation period, and a further quarter moved as voluntary rather than involuntary patients. It was clear to anyone with only a superficial acquaintance with the ways of mental hospitals that the quarter who were discharged were discharged much more quickly than if they had become entangled in the mental hospital machine.

New Outlook

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, thought Dr. Johnson did less than justice to the great work that had been done towards removing the "stigma" from mental hospitals. The substantial increase in the number of voluntary patients, from 51% in 1946 to 75% in 1955, showed that there was a new outlook. Correcting a misapprehension that had grown up as a result of accommodation designated under Section 20 of the Lunacy Act being referred to as "observation wards," she pointed out that the primary purpose of Section 20 was to provide hospitals to which persons who needed to be placed under

control as well as given treatment without delay could be removed without formality beyond the action of the duly authorized officer. It was for cases of emergency, where there had to be prompt removal of a patient. Before the Health Service Act such patients could be sent only to public assistance institutions.

Professional opinion about the use of Section 20 had been divided for many years. In 1954 the number of Section 20 cases was 24,470, of which 7,141 were admitted to mental hospitals, 7,638 to mixed hospitals, and 9,691 to general hospitals. There was no clear evidence that the types of patient sent to the three kinds of hospitals differed much. Yet more than half the patients sent from Section 20 wards in general hospitals to mental hospitals were sent as certified patients, whereas of those admitted in the first place to Section 20 wards in mental hospitals only one-quarter continued under legal detention. It therefore seemed that the proportion of voluntary patients resulting from admissions into mental hospitals was higher than from admissions into other hospitals.

Mr. J. E. S. SIMON (Middlesbrough, West, Con.) asked why that should be so.

Miss HORNSBY-SMITH said it was a matter of medical controversy, and she would rather not give an opinion. Of the total Section 20 admissions, 12.7% were discharged from mental hospital wards within the detention period, whereas the discharge rate from the mixed and general hospitals was 33.1%. The differing results indicated in these percentages supported the view that many patients admitted direct to mental hospitals were willing to stay on as voluntary patients. The Royal Commission on the Law relating to Mental Illness could be expected to deal with all the procedures for compulsory admission, and it would be premature to anticipate any suggestions that they might make.

Car Parking by Doctors

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Transport on July 11 whether, in framing his regulations on parking meters, he would arrange that medical practitioners in the course of their work would be exempted from charges if they parked their cars in streets in which parking meters were installed. Mr. HAROLD WATKINSON's reply was "No." A general exemption of this nature would be contrary to the principles underlying the proposals for parking in the Road Traffic Bill. Dr. STROSS thanked the Minister for his recent letter, and asked whether he proposed to retain his inflexible attitude for ambulances and fire-fighting vehicles. Would he consider speaking to the B.M.A. about the whole matter? Mr. WATKINSON said there was nothing inflexible about his attitude. He had power to make exemptions, but he preferred to wait until he had the detailed survey of London parking that was being made. No one would gain more from that than the doctors if they could move about more freely.

Harley Street Congestion

Mr. ERIC JOHNSON (Manchester, Blackley, Con.) asked the Minister of Transport if he was aware that cars were being parked in a single line on one side of Harley Street, and in a double line on the other side; and if he would authorize the diagonal parking of cars on one side, which would accommodate more cars and take up less of the roadway. Mr. HUGH MOLSON, Parliamentary Secretary, said he knew about the excessive parking in Harley Street, but the suggestion would not improve matters. It would be as well to await the outcome of the special survey of parking facilities in inner London. Mr. JOHNSON said that the Parliamentary Secretary's view was not shared by residents in Harley Street, who thought the suggestion would undoubtedly improve matters. Mr. MOLSON stated that it would reduce from 10 to 8½ the number of cars which could be parked in 100 ft. (30 m.), it would take 19½ ft. (6 m.) off the carriage way instead of 15 ft. (4.5 m.), and it would be more obstructive to passing traffic. The SPEAKER: In other words, it is not a very good idea.

I.T.A. Decision on Tobacco Advertisements

The POSTMASTER-GENERAL, replying to Mr. P. GORDON WALKER (Smethwick, Lab.) on July 11, declined the suggestion that he should make regulations under Section 4(4) of the Television Act, 1954, prescribing that there should be no tobacco advertisements within 15 minutes before or after children's programmes. Mr. GORDON WALKER said that, in view of what had been stated by the Minister of Health about the connexion between smoking and cancer, it was indefensible that there should be incitement to smoking in close conjunction with children's programmes. Dr. HILL replied that the programme companies had decided not to include advertisements for tobacco in these programmes. That seemed to him reasonable. To go beyond that, bearing in mind newspaper advertisements, seemed to him in mind newspaper advertisements, seemed to him grandmotherly. Mr. BERESFORD CRADDOCK (Spelthorne, Con.) called attention to the B.M.A. discussion on July 10, in which he said seemed to be a direct contradiction to the implications in the question. Dr. HILL: It is not strictly my field, but let nothing I say appear to controvert the acknowledged statistical relationship between heavy cigarette smoking and cancer of the lung.

NEW MEASURES ON RADIATION HAZARDS

The Government's intentions towards putting into effect the recommendations contained in the Medical Research Council's report on *The Hazards to Man of Nuclear and Allied Radiations* were given to the House of Commons on July 16 by the MINISTER OF HEALTH. They amount to a complete review of existing safety standards, and in particular to appointment of a special committee under the chairmanship of Lord Adrian to examine the practice in diagnostic radiology and the use of radiotherapy in non-malignant conditions.

Mr. Turton, who was answering many questions and opinions expressed in a debate on the report, said the findings in the report were reassuring. They did not reveal any present danger from the peacetime uses of radiation. But we were entering a new age in which nuclear energy might become the principal source of power, and it was necessary to have a thorough understanding of the extent of the dangers that might accompany scientific progress, and in particular the possible harmful genetic effects. Clearly, they must try and work out the safety limits, and avoid any extra radiation that was not absolutely necessary. It was remarkable that the American investigation of the biological effects of atomic radiation, and that conducted in this country, had—working independently—reached broadly similar conclusions.

The second conclusion in the British report dealt with those exposed by occupation to additional risk. The Atomic Energy Authority would have no difficulty in carrying out these recommendations, and they would be carried out. It might mean a certain amount of shift rearrangement. On conclusion three, relating to the dose level to the whole population, he said that the total amount of man-made radiation was 27% of the natural background, and there was still a long way to go between that and the 200% that was permissible according to the conclusion.

In regard to fall-out (conclusion four), taking the maximum permissible amount of radio-strontium as 1,000 units, so far and the amount regarded as dangerous as 100 units, so far the amount of strontium in the fall-out from all the tests was only 1 unit. He was advised that there was no evidence of any irregularity in fall-out.

Limiting Test Explosions

The Prime Minister, said Mr. Turton, had repeatedly stated that the Government were prepared to discuss methods of regulating and limiting test explosions which took account of their own position as well as that of other powers. Specific proposals had been put forward to the United Nations disarmament subcommittee on Anglo-French

initiative on March 19. The Prime Minister had also stated last week that, while Britain would prefer such discussions to be pursued within the context of a comprehensive agreement on disarmament, they did not exclude any other method of discussion acceptable to those concerned, and would do their best to see that progress was made.

Occupational hazards in medicine arose among those engaged in hospitals on x-ray diagnostic and therapeutic work and using radioactive substances. An advisory committee under the chairmanship of Sir Charles Darwin had prepared a comprehensive code of practice for use in Health Service hospitals. This was undergoing final revision and would be issued shortly. But it was important that they should now consider whether the code should be modified or supplemented in the light of the Medical Research Council's report, and the matter had been referred to the radioactive substances advisory committee for consideration. To assist in carrying out the code, and applying protective measures in hospitals and industry, a radiological protection service had been set up by the Minister of Health and the Medical Research Council. They were continuing and extending the work carried out for many years by the National Physical Laboratory.

An important part of the recommendations was that the present practice in medical diagnostic radiology should be reviewed, and the use of radiotherapy in non-malignant conditions critically examined. These were essentially clinical matters, which must be considered, and advice given by representatives of the medical and dental professions for the benefit of all their colleagues. The Government had decided to appoint as soon as possible a special committee composed of scientists and professional men to review this question and make recommendations. It would be appointed after consultation with their Royal Medical Colleges and corporations, the British Dental Council, the Faculty of Radiology in Dentistry, and other professional bodies. Lord Adrian had consented to be chairman.

Pedascopes were already under review by the radioactive substances advisory committee. He was inviting that committee to review also luminous watches and clocks and television apparatus, and advise him about them as soon as possible.

It was suggested in conclusion that for future genetic studies it was essential to collect further information when births, marriages, and deaths were registered. Detailed recommendations would be discussed with the Registrar-General. The committee were to reassemble after the summer recess and submit to the Medical Research Council their recommendations for further work. In recent years the Council had sponsored a substantial programme of research, including the genetic effects, and present expenditure in this was more than £400,000 a year. The Government regarded this matter as of the highest priority, and immediate action would be taken when further recommendations were received.

More Alert

Dr. EDITH SUMMERSKILL (Warrington, Lab.), opening the debate, said that if the House was to discharge its duty to humanity seriously it must become more alert to the appalling dangers of nuclear energy.

She would have thought that the House should have had a statement from the Minister of Health on this report. He was responsible for protecting the health of the people. But in replying to questions on this subject the Minister had been complacent and, indeed, had revealed that he was apparently not aware of the most serious conclusions of the committee.

It was emphasized throughout the report that the scale of nuclear tests determined the danger in the future, yet only the previous week Japanese scientists had stated that the United States had exploded the biggest weapon of a series of eight nuclear tests which began in May. In view of some of the statements which were being made she wondered whether the soldiers were determined to ignore the advice of the scientists until it was too late.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **June 30**
(No. 26) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1956					1955

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications in England and Wales in the week ending July 7 (27th week) were as follows (with those for the previous week in parentheses): paralytic 72 (47), non-paralytic 42 (34), total 114 (81).

Some of the districts with populations of 15,000 or more in which the notification rate exceeds 15 per 100,000 in the year to date are as follows: Macclesfield M.B. 50, Whitehaven M.B. 87, Ennerdale R.D. 52, Darlington C.B. 22, Yeovil M.B. 75, Yeovil R.D. 25, Guildford M.B. 52. No districts with populations of less than 15,000 have serious outbreaks at present. Total notifications in the calendar year to the end of the 27th week are the third highest in the years since 1947, and notifications in the 27th week were the third highest compared with the same week in the other years in this period.

Week Ending July 7

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 682, whooping-cough 2,405, diphtheria 7, measles 3,429, acute pneumonia 259, acute poliomyelitis 114, dysentery 1,235, paratyphoid fever 22, and typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest rises in the number of notifications of infectious diseases in England and Wales, during the week ending June 30, were 516 for measles, from 3,224 to 3,740, and 208 for whooping-cough, from 2,164 to 2,372, and the only large fall was £2 for dysentery from 1,519 to 1,466.

The largest increases in the incidence of measles were 166 in Lancashire, from 342 to 508, 94 in London, from 280 to 374, 66 in Hertfordshire, from 46 to 112, and 55 in Northamptonshire, from 55 to 110. A small rise in the incidence of whooping-cough was recorded in most areas, but the largest fluctuation in the local trends was a fall of 44 in Lancashire, from 409 to 365. The notifications of scarlet fever numbered 642, 19 fewer than in the previous week, and the largest variations in the local trends were a fall of 27 in London, from 62 to 35, and a rise in Lancashire of 24, from 69 to 93. 8 cases of diphtheria were notified during the week, being 3 more than in the preceding week: 5 of these cases were notified in Kingston-upon-Hull C.B.

The notifications of acute poliomyelitis numbered 81, and these cases were 9 more for both paralytic and non-paralytic cases than in the preceding week. The largest returns were Lancashire 33 (Manchester C.B. 18, Liverpool C.B. 4, Middleton M.B. 4, Salford C.B. 2), Yorkshire West Riding 9 (Barnsley C.B. 3, Leeds C.B. 2), Cheshire 6 (Macclesfield M.B. 3), and London 5 (Camberwell 2).

The chief features of the returns for dysentery were a fall of 106 notifications in Wales and a rise of 61 in Yorkshire West Riding. The largest centres of infection during the week were London 238 (Lewisham 39, Wandsworth 27, Greenwich 20, Lambeth 19, Southwark 18, Stepney 18, Battersea 16, Deptford 16, Woolwich 12), Lancashire 213 (Colne M.B. 22, Nelson M.B. 20, Blackpool C.B. 19, Liverpool C.B. 18, St. Helens C.B. 15, Worsley U.D. 14, Bacup M.B. 12, Bolton C.B. 10, Manchester C.B. 10), Yorkshire West Riding 210 (Sheffield C.B. 38, Leeds C.B. 35, Wakefield C.B. 32, Dewsbury C.B. 14, Doncaster C.B. 13, Morley M.B. 12), Essex 70 (Barking M.B. 20, Waltham Holy Cross U.D. 12), Kent 69 (Dartford M.B. 34, Eastry R.D. 18), North-

umberland 61 (Ashington U.D. 52), Warwickshire 59 (Conventry C.B. 25, Birmingham C.B. 20), Leicestershire 49 (Leicester C.B. 34), Sussex 42 (Rye M.B. 29, Brighton C.B. 11), Suffolk 40 (Ipswich C.B. 40), Middlesex 37, Nottinghamshire 36 (Beeston and Stapleford U.D. 17), Surrey 32 (Esher U.D. 13), Yorkshire North Riding 28 (Middlesbrough C.B. 20), Lincolnshire 26 (South Kesteven R.D. 12), Hertfordshire 26 (Stevenage U.D. 26), and Durham 25.

Medical News

Royal College of Surgeons.—Cardiff has been chosen for the next provincial meeting of the Royal College of Surgeons, which will be held in 1958 or 1959. This was decided at the council meeting on July 12, and follows the outstanding success of the College's Manchester meeting last December, a meeting which was not only the College's first provincial assembly but also its first scientific meeting. Sir HARRY PLATT was re-elected President. Sir RUSSELL BROCK was elected Vice-president, and Mr. LAWRENCE ABEL re-elected Vice-president. On July 5 the College announced the results of a poll, in which 1,888 Fellows voted, for two places on the council: Sir RUSSELL BROCK (1,506 votes) and Sir ARCHIBALD MCINDOE (1,215 votes) were re-elected; Mr. R. H. MAINGOT (867 votes) failed to secure a seat. A most generous benefaction to the College was made known at the Buckston Browne dinner on July 11 when Sir ARCHIBALD MCINDOE handed to the President a cheque for £7,500—the first of seven yearly instalments—from the Simon Marks Charitable Trust. Sir SIMON MARKS, chairman of Marks and Spencer Ltd., said at the dinner that the gift was a tribute to Sir Archibald's surgery. The money will be used by the College to support basic research on surgery in its own departments. The following lecturers have been appointed by the College council: Mr. L. W. PLEWES (Joseph Henry lecturer for 1957), Professor W. D. WRIGHT (Edridge-Green lecturer), and Professor G. HADFIELD and Dr. C. P. RHOADS (Imperial Cancer Research Fund lecturers for 1957).

Direction of Research.—This subject has recently been studied by a Government committee. Now it is to be the turn of research directors and administrators, who will discuss it at an international symposium at the National Physical Laboratory in the autumn. In April the Government issued as a White Paper the report of the Jephcott committee which had been examining the organization and working of the Department of Scientific and Industrial Research. The committee was strongly against the D.S.I.R. becoming "like an ordinary Government department," as was proposed in a draft Bill, preferring instead the creation of a council on the lines of the Medical Research Council and the Agricultural Research Council. This council, recommended the committee, although it would be appointed and responsible to the Minister, should be executive, not simply advisory. In this way, with the introduction high in the chain of authority of "a number of distinguished scientists and industrialists whose professional authority will be recognized," the committee believed that the climate for research in the department could be improved. The problem of the best use of limited research staff and facilities will be taken a stage further at the N.P.L. symposium, which is being held from September 26 to 28. Here the subject will be the "Direction of Research Establishments," bringing the discussion to the research group or laboratory level. Among the speakers are Sir HAROLD HIMSWORTH, F.R.S., secretary of the Medical Research Council, and Sir CHARLES HARINGTON, F.R.S., director of the National Institute for Medical Research. The meeting is restricted to directors of research and research administrators. Besides those from Britain, there will be many delegates from Europe, other parts of the Commonwealth, and the United States. They will debate

Intra-arterial Oxygen

Q.—What is the value of intra-arterial oxygen injections in peripheral arterial disease? Is there a centre in the British Isles where this treatment is under trial?

A.—The value of intra-arterial oxygen injections in peripheral arterial disease is still undecided. The effect of injecting a small volume of gas into the artery of a limb is to produce a short period of ischaemia at the periphery due to the obstructive effect of the bubbles in the smaller vessels. The effect is not confined to oxygen but occurs also with other gases. The period of ischaemia is followed by one of hyperaemia, which persists for a longer time than would be expected were it due simply to ischaemia such as might have been produced with a tourniquet. The exact physiological mechanism of the phenomenon, although the object of interest and experiment, is still obscure.

Repeated intra-arterial injections of oxygen as a method of treating peripheral arterial disease is under trial at the Royal Victoria Hospital, Belfast.

Percentile

Q.—What does "50th percentile" mean? Is this just a jargon term that could with advantage be replaced by some more familiar phrase?

A.—If a large series of measurements is arranged in increasing order, the p th percentile is, roughly speaking, the value below which precisely $p\%$ of the observations fall, and above which there are $100-p\%$. The 25th percentile and the 75th percentile are often called the "lower and upper quartiles" respectively, and the 50th percentile is called the "median." Although the 50th percentile happens to have a short and fairly familiar name, the longer terminology is not entirely useless, since in describing the distribution of a number of measurements it may be useful to quote a number of different percentiles, including the 50th.

The calculation of a percentile from any given series of measurements will usually involve interpolation between adjacent observations on either side of the required value. If there are n observations, the median is defined as the $\frac{1}{2}(n+1)$ th of the ordered series, if n is an odd number, and as the average of the $\frac{1}{2}n$ th and $(\frac{1}{2}n+1)$ th if n is even. The median will in general be different from the average (or "arithmetic mean"). For example, for the following set of measurements: 2, 3, 5, 10, 20, the mean is 8, but the median is 5.

Pyridoxine

Q.—What are the clinical actions of pyridoxine (vitamin B_6)? Has it any acute or chronic toxic effects in man?

A.—There has been no evidence of clear-cut deficiency of vitamin B_6 in man, but benefits have been claimed with this vitamin in the treatment of diseases such as pellagra and beriberi, which are primarily due to deficiencies of other B vitamins. Possibly diets which are lacking in vitamin B_1 or nicotinamide tend to be deficient in vitamin B_6 as well. Skin symptoms resembling those found in animals deficient in vitamin B_6 may be induced in man by the antivitamin desoxypyridoxine, and may be cured by giving the vitamin at the same time. Large doses of vitamin B_6 have been advocated for the treatment of excessive vomiting, especially during pregnancy, but it is rather doubtful whether the treatment is more than a placebo. Rats can tolerate doses of up to 1 g. of vitamin B_6 per kg. of body weight without ill effects, but higher doses are toxic. In agreement with this low toxicity in the rat overdosing in man has never been known to cause ill effects.

Inheritance of Polycystic Kidney

Q.—How is polycystic kidney inherited?

A.—Most, perhaps all, instances of polycystic kidney, except for the variety causing signs and symptoms in infancy and early childhood, are due to a dominant gene. Accord-

ingly the risk of having polycystic kidney for the children of a man with the condition is 1 in 2. The children of a man known to have the condition should therefore be examined clinically and radiologically, when young adults, for the presence of polycystic kidney. Those who are found to have the condition should be warned that if they themselves have children these, too, will have a 1 in 2 risk of developing polycystic kidney. Those who are found on examination when adult to be normal can, however, be reassured that they will not transmit the condition.

NOTES AND COMMENTS

Varicose Ulcer.—Mr. ROWDEN FOOTE (London) writes: I am most disturbed by the answer on varicose ulcer ("Any Questions?" June 23, p. 1499). I think great harm may be done to a multitude of patients if this advice is taken. Compression treatment for oedematous and ulcerated legs has stood the test of many hundreds of years. Your correspondent does not, however, seem to have heard of the "elastoplast" or dry-elastic bandage. I submit it might have been better to have published an extract from Thomas Baynton's famous work of one hundred and fifty years ago, *A New Method of Treating Ulcers of the Legs*, than to have answered the question in the way you have. The answer ignores the cardinal essentials of treatment, which we all know to be compression treatment followed by massage, exercises, and elastic bandages. Again, surgery along the lines of Madelung's operation is recommended. This procedure did not survive for many years after its introduction in 1884 owing to its high mortality and uselessness. Finally, the application of zinc oxide, soft paraffin, and a crêpe bandage is advised by the *Journal* in 1956. This is entirely beyond my comprehension.

OUR EXPERT replies: I must remain entirely unrepentant in the face of Mr. Rowden Foote's letter. There is certainly no one method in the treatment of varicose diseases and their complications, and there was nothing in my answer to disparage "elastoplast" or other supporting bandages, or treatment by physiotherapy. Mr. Foote may not be aware of the fact that treatment in bed in elevation will lead to the almost automatic healing of varicose ulcers. Often all that is needed locally is an application to prevent adherence of dressings. The zinc ointment recommended has the advantage of protecting eczematous areas. The healed ulcer scars produced in this way are extremely sound, and any form of post-operative support after the period of convalescence is most unusual. Perhaps three brief case outlines from a large series may be helpful: *Case 1*, a woman of 53 with recurrent ulceration over the internal malleolus extending over four years which had failed to respond to hospital treatment on Bisgaard lines. The ulcer healed with two weeks' postural treatment, operation was carried out, and the leg has remained well without external support. *Case 2*, a woman of 46 who had had six children and recurrent ulceration of the left internal malleolus extending over five years. She had had a variety of treatments as an out-patient, including supporting treatment and physiotherapy. At the time she came under observation she was completely incapacitated by a very infected ulcer. Healing was secured with three weeks' postural treatment, operation was carried out, and the patient is well. *Case 3*, a man of 62 with a 16 years' history of multiple ulcers around the lower third of the leg and diffuse eczema from the instep to the knee. He had been given up as incurable by hospital and his doctors. The condition cleared up with three weeks' treatment in elevation, operation was carried out, and the patient remains well. Perhaps these observations will suggest to Mr. Foote that I am more aware of the various methods of treatment than his letter would suggest, and also to dispel his fears about the harmfulness of the treatment recommended.

Counter hypertension with

RAUWILOID+VERILOID

... a safe yet powerful
combination

The standardized hypotensive alkaloids of *Rauwolfia serpentina* ('Rauwiloid') and *Veratrum viride* ('Veriloid') together provide a most effective and safe oral treatment for moderate to severe degrees of hypertension. 'Rauwiloid' widens the margin between the emetic and the antihypertensive doses of 'Veriloid', and enables therapeutic doses of 'Veriloid' to be given in almost every case of hypertension. This combination of drugs exerts a steady and prolonged hypotensive effect, and produces the minimum of discomfort to the patient.

"The addition of 'Rauwiloid' makes 'Veriloid' easy to administer, more effective and practically does away with unpleasant side-actions".

Amer. J. Med., (1954) 17:629

'Rauwiloid + Veriloid' tablets each contain 1 mg. of the alkaloids of *Rauwolfia serpentina* and 3 mg. (by biological assay in terms of reference standard) of those of *Veratrum viride*. The starting dosage is one tablet three times daily. The tablets are available in bottles of 100 and 500.

Full literature on request.

'Rauwiloid' and 'Veriloid' are registered trade-marks. Regd. Users:

THE NATURE OF GENIUS*

BY

ERNEST JONES, M.D., D.Sc., F.R.C.P.

Consulting Physician, London Clinic of Psycho-analysis

One hundred years ago there came into life a being whose long years of work and insight were to make such contributions to knowledge as profoundly to influence the civilization of every country. And we may safely say that the full impact of that influence has yet to be experienced. Whoever stands in my place in another hundred years from now will in his commemorative speech—and I am confident there will be one—be able to report further progress in the assimilation and application of Freud's discoveries to an extent which it is impossible for us now to predict.

I chose the title of my lecture for its brevity, but it would have been more modest and more accurate had I entitled it "Some of the Factors Conditioning the Workings of Certain Forms of Productive Thinking." You will allow me to rectify it in this sense.

There is a quite stupendous literature on the subject of what Ostwald called "geniology," which would necessitate a large volume merely to summarize. This is certainly not the place to attempt any such compilation, but it is worth while commenting on the relative fruitlessness of so many of the attempts to solve the problem of genius. I should attribute that largely to the emotional ambivalent attitude so commonly shown in the approach to the topic. It has been well said that "there is a sort of doom overshadowing the very conception of genius: everyone who approaches it is drawn into a murky orbit of adoration and contempt, idolatry and scorn, profundity and shallowness." On the one hand, there are the writers who display a dithyrambic narcissistic identification with geniuses which allows the authors to praise their own glory under the guise of adoration. The Marquis de L'Hôpital asked: "Does he eat, drink and sleep like other men? . . . I represent him to myself as a celestial genius, entirely disengaged from matter." Such writers indignantly deny that genius has any relation to mere talent. De Quincey, for instance, maintained that the two are "not merely different, but are in polar opposition to each other." One author even regarded genius as "a psycho-biological mutation," from which it is only a step to contemplating the future selective breeding of geniuses.

On the other hand, more envious writers have laboured to find various ways of directly or indirectly disparaging men of genius and their achievements. The most popular one, from the time of Lombroso and Nordau onwards, is to insist that geniuses are psychopaths and mostly tainted with insanity, their achievements being lucky and more or less accidental by-products. The literature on this aspect of the problem is very extensive, but I have not found it illuminating. One can also detract from any credit due to the genius by asserting it was the result purely of heredity, so that we owe him no praise. One of the most original writers on the topic, Lange-Eichbaum, goes so far as to maintain that what constitutes a genius is the height of fame to which his worshippers raise him, this being the reason why the decision of who precisely is a genius varies from one period to another. But perhaps he did not sufficiently distinguish here the matter of subjective recognition from that of the actual objective achievement.

In the first place we may ask whether there really is such a thing as genius—that is to say, any attribute that differs essentially in its very nature from those present in all human beings. It is a question that has been often debated, but I propose to answer it from the start with a decided negative, and in doing so I find myself in agreement with such a high authority as Kant. All Freud has taught us concerning the regular laws of mental development goes to confirm the view that the manifold differences between various individuals, and indeed between the various races of mankind, are quantitative rather than qualitative, and this conclusion is only slightly modified by the reflection that a quantitative difference may on occasion be so striking as to give the impression of something qualitative and absolute. The question seems to me to resemble that concerning the presence in mankind of something qualitatively different from anything present in other animals—namely, the divine gift of a soul—and I need hardly say that this also finds no support in either biological or psychological researches. Indeed, the original meaning of the word "genius" was a designation for a semi-divine spirit who on appropriate occasions visited certain fortunate mortals and inspired their creations, after which it could presumably wander forth in search of other habitats. We still retain this sense of a discarnate spirit when we speak of a *genius loci* or of the "genius of a language" which institutes changes independently of any individual volition. It was only in 1700 that the term began to designate the actual person who was thought to be inspired by something mysterious within.

We apply the term "genius" more often to artists, particularly poets, whose intuition at times seems to border on the miraculous, than to men famous for more purely intellectual achievements. It is very possible that the conditions of creative genius are not identical in these two groups. At all events I am so much less at home

*Address delivered at the Royal Society of Medicine on the occasion of the centenary of the birth of Sigmund Freud.

with the former that I propose here to refrain from any consideration of its nature, and will refer you to Ernst Kris's masterly study of artistic creativeness. Even the intellectual group itself is by no means homogeneous. We speak of the genius of Napoleon, for instance, because of the degree in which both his military and his administrative capacities transcended those of the average being. I will therefore narrow my field still further to that of scientific production of the highest order.

Attributes of Genius

The number of those whose claims to belong to this Olympus are universally recognized is very small. After listing such names as Newton, Darwin, and Einstein we begin to enter a more debatable territory. "The genius of Freud" is a phrase that has been used so widely that I think we must subscribe to a truth contained in it. Characteristically enough, Freud himself vehemently dissented from its being applied to him. Even as far back as 1886, when he was 29, he wrote to his betrothed: "There was a time when I grieved that Nature had not, in one of her gracious moods, impressed on me that stamp of genius as she sometimes does. Since then I have long known that I am no genius, and I no longer understand how I could have wished to be one. I am not even very talented; my whole capacity for work probably lies in my character attributes." On one occasion in later life when it was applied to him he burst out with the protest: "Geniuses are unbearable people. You have only to ask my family to know how easy a person I am to live with. So I cannot be a genius." This disclaimer, however, was based on a very partial definition of genius, so we need not take it too seriously. But to ask in what sense the term can properly be used of Freud leads us into the heart of our subject and raises a number of difficult problems.

The numerous attempts to define genius have not proved very helpful. On one occasion some thirty definitions were listed, but for present purposes we may be content with that offered by the *Encyclopaedia Britannica* as "the highest conceivable form of original ability, something altogether extraordinary and beyond even supreme educational prowess." One notes here what is certainly a characteristic attitude of the beholder, that of astonishment or even amazement, one that is doubtless the source of the intense admiration the productions of genius so often evoke. It gives rise to the notion of mystery about the achievements of genius, and hence to that of its supernatural nature. Of all their characteristics Révész selects this one of *surprise* as being the most central, to which all others are accessory, and he perspicaciously remarks that it is typical for this feeling to be repeated, however often one contemplates the achievement.

Intuition; Spontaneity; Periodicity

This seems to accord with the frequency with which geniuses often receive their inspiration in a sudden flash that startles the recipient himself. It is a feature that has always been recognized. Both Plato and Aristotle commented on it, and they associated it with the divine source of the inspiration. The description of Apollo in the third book of *Hyperion* seemed to Keats to have come by chance or magic—to be, as it were, something given to him. He said also that he had often not been aware of the beauty of some thought or expression until after he had composed and written it down. It had then struck him with astonishment and seemed rather the production of another person than his own. Alfred Russel Wallace wrote: "Finally both Darwin and myself, at the critical period, had our attention directed to the system of *positive checks* as expounded by Malthus in his *Principles of Population*. The effect was analogous to that of friction upon the specially prepared match, producing that flash of insight which led us immediately to the simple but universal law of the 'survival of the fittest.'" This is, however, a feature by no means always present. The flash of insight which Wallace de-

scribed did presumably happen to him, but Darwin himself seems to have reflected on the suggestion more calmly. No one can have accepted revelation more tardily and gradually, even cautiously and very timidly, than Darwin, whose dawning vision came only as the result of many years of hard work.

In a disquisition on this element Lessing wrote: "How many conclusions would seem theoretically irrefragable had not genius succeeded in demonstrating the contrary," a statement that applies peculiarly aptly to much of Freud's work. In describing a recent discovery in physics Dr. Gabor made the interesting remark: "This statement has that touch of offending common sense which is the hallmark of every truly important scientific discovery." Freud's discoveries satisfied this criterion in full measure. Many philosophers and psychologists have shown conclusively that in theory there can be no such thing as unconscious mental processes, and our common sense fully agrees; yet, as Charcot said in a phrase Freud was fond of quoting, "*ça n'empêche pas d'exister*." I think we shall agree that there was enough of this element of surprise with which Freud's work has been greeted to warrant our attaching at least this one to the attributes needed to qualify for the title of genius.

Allied to this feature of intuitive inspiration is the characteristic spontaneity with which the productions of genius appear. They can never be brought about by a deliberate effort of will, and nothing can ever force them. Lowell has wittily said that "talent is that which is in man's power; genius is that in whose power man is," and Voltaire with equal wit expressed it thus: "The works of genius are to compilations what love is to marriage; Hymen comes when one calls and Cupid when it pleases him." Most writers on the subject are agreed that the achievements of a genius are out of his power. Goethe, who could speak from personal experience, laid it down that "all productivity of the highest kind, every significant piece of insight, every discovery, every great thought that proves fruitful and leads to further consequences, stand in the power of no one, and are beyond all earthly might. A human being has to regard them as unhelped-for gifts from above which he has to receive and revere with joyful thanks." Another poet put it in this way: "Genius does what it must and Talent does what it can." It is clear that this attitude of passive surrender towards the flowing in of the valuable ideas must be significant for the psychology of the productive process.

A third feature which has often been noted is that of periodicity. Moebius, for example, made a study of the cycles of productivity displayed by Goethe, and the same feature has been noted with Beethoven and many other geniuses. Freud himself often maintained that his productivity was at its maximum in cycles of seven years, though he had to strain the evidence somewhat to make it fit this precise span. Still, his most original productions are only a year or two out from his estimate: "Cocaine"; *Aphasia*; *Interpretation of Dreams*; *Theory of Sexuality*; *Totem and Taboo*; *Beyond the Pleasure Principle*; *Inhibitions, Symptoms and Anxiety*; and the *New Introductory Lectures* make a series that approximate to this observation. As might be expected, the notion of periodicity has been interpreted in clinical terms of cyclothymia, but with only occasional evidence in support of this. Freud, for instance, despite plenty of external grounds for despondency, suffered from only one mild and transitory attack of depression in his whole life, and his variation in moods never transcended the normal ambit. It seems to me that most of these cycles in productivity are sufficiently explained by the natural rhythm of life, particularly the variations in libidinal tension that belong to this.

The features just described may be encountered indiscriminately with all forms of genius, and I shall now consider three or four further ones which are much more characteristic of scientific production than of artistic inspiration. The most obvious of these is the indispensable one of absolute honesty. It was Goethe who laid down the law that "the first and last task required of genius is love of truth."

Originality

Then we come to the somewhat vexed matter of originality. It is certainly a more frequent occurrence for a man of science to make a new discovery than for a poet to invent an entirely fresh theme or even phrase, but, on the other hand, the title of genius is only very occasionally bestowed on the discoverer of new facts or ideas in science. Here between what he calls the *new* and the *essentially new*. The simply *new* concerns discoveries of a new fact which may never have been known before. Or it may concern a theory which modifies a previous one by adding some new consideration or factor. The *essentially new*, however, signifies an entirely fresh and different way of looking at things. Wordsworth shortly defined an act of genius as "the introduction of a new element into the intellectual universe." Thus Einstein's theory of relativity, although it modifies and adds to Newton's theory, was not evolved out of it as an extension; it came about from looking at certain physical phenomena in a radically new way.

George gives two examples to illustrate his point, and they are worth quoting. As a result of Sir Joseph Thomson's classical experiments, the phenomena of atomic physics were for 30 years described in terms of a particle of electricity, the now familiar electron. This concept served admirably to account for a wide range of phenomena, but certain optical ones caused a difficulty. Then de Broglie, in 1925, introduced an entirely different way of regarding an electron—namely, in terms of a wave—and to this day both these concepts have to be used for different purposes without any conclusion having been reached about which of the two is the more fundamental. Then, again, for aeons—in fact, until the turn of this century—all disease had always been regarded as being due to something which was not present in health attacking the body, whether this was a malignant demon, a draught of cold air, or an infectious agent. Drugs and other forms of treatment were simply designed to and counteract the harmful things that were producing the illness. It was not until within living memory, in observations on scurvy culminating in Gowland Hopkins's brilliant experiments, that it occurred to anyone that various diseases could be due merely to the *absence* of something in the body. That was an essentially new way of looking at the matter, and it has resulted in our present mass of complex knowledge about the various vitamins.

Darwin's doctrine of natural selection is another good example of an entirely new way of regarding the complex phenomena of living creatures. This feature has been commented on in respect of Freud. I will quote from a recent writer: "From time to time men of outstanding gifts alter our outlook on the world in one relatively restricted field or in another. But changes in the fundamental categories in terms of which we interpret the world and each other, are rare the very framework of our thought and language, are rare in history; and more rarely still can we attribute such a change to one man. But about Sigmund Freud there can be no doubt."

A New Idea

Freud's genius is peculiarly interesting in that it has led to looking at mankind in an essentially new way, although what he actually discovered was not in itself so very new. It has been possible to trace most of Freud's ideas to earlier sources; whether he actually obtained them in that way or only from his personal investigations is another matter. That holds goods for the division of the importance of sexuality conflict between its two halves; the importance of repression in human life and even its specific connexion with the psychoneuroses; the significance of repression, and so on. In fact, so far as I know, there was only one idea he discovered which had never been previously recorded. It was a very important one: the universal fear of castration among men. Dr. Henri Ellenberger, who has devoted some years

of research to the matter, extending through mediaeval to classical times, assures me that in spite of the age-old custom of castration in various communities he has not been able to find any mention of the *fear* of it in the writings of any historian, philosopher, or even psychiatrist. I have, however, recently come across the record of a patient who suffered from complete impotence as the result of his dreading castration at the hands of his father as a small child, and who was restored to complete potency when that fear was removed. The episode took place some three thousand years ago, and the gentleman was given the name of Iphiclus, "famous might," so the cure was very thorough. Psychotherapists received high fees in those days. The particular one who effected this cure, Melampus, who was reputed to antedate Aesculapius as the first physician, received a third of a kingdom and the king's daughter for his wife as a reward for curing her of a frenzy. In those days marriage with an ex-patient was not frowned on.

That for three thousand years this dread fear was never mentioned is a testimony to the desperate efforts we make to prevent ourselves from becoming aware of it. Freud may of course have been cognizant of the story in Greek literature, but if so it would afford one more illustration of the peculiar nature of his genius. For this consisted not so much in the discovery of new things but in the fearless and pioneering exploration of them. Through his detailed investigations, and not at all by personal propaganda, he compelled a section of the community, those with ears to hear, to accept a number of unwelcome but extremely important truths. He took seriously what had previously been hinted at, often merely whispered, and there is no doubt that an unusually high courage was an essential element in the achievement of his genius. Furthermore, although some achievements of genius have an unmistakable relation to the atmosphere of the period when they were accomplished, so that one feels someone else would surely have done the same thing, this was assuredly not true of Freud. One may legitimately doubt if anyone else would have come forward had Freud not done so. We might well have had to wait another hundred years or more for someone of his stature.

Sense of the Significant

Closely akin to this mysterious feeling for what is true seems to go a sense of the really significant. This enables a genius, or compels him, to generalize a finding where a lesser mortal would have cautiously gone on collecting more evidence before venturing on a general statement. Freud, although he would be accounted a man of sober and reflective judgment, afforded several instances of this kind of superlative boldness and sureness. When he discovered in himself the fear of castration he felt instinctively that the same must be true of all men, and when he also came across the Oedipus complex he did not hesitate to hold it valid not only for all those now on this earth but also for those who populated it many thousands of years ago. These were breath-taking generalizations, and it is not surprising that so many have balked at accepting them or have tried to limit them to certain societies only.

This remarkable capacity for perceiving with somnambulant sureness what is absolutely and universally true is of great interest. It transcends the simple love of truth itself, essential though this may be. I think it must occur at special moments when there is an unusual, and often only temporary, fusion of all the elements in the mind in a peculiar degree of harmony. The sureness arises from the completeness with which the ego is receiving in an unquestioning fashion the message from the preconscious. At that moment there is a complete coincidence between the striving of the id, the permission of the super-ego, the acceptance by the ego, and the external perception of the problem being studied. Emerson well said that "to believe your own thought, to believe that what is true for you in your private heart is true for all men—that is genius." Schopenhauer made a similar point when he said: "Always to see the general in the particular is the very foundation of genius."

Power of Concentration

The third attribute worthy of mention here is that of the power of concentration. There is no doubt that in the majority of instances important scientific discoveries have meant a great deal of hard work as well as intense concentration. Buffon, the great naturalist, considered that genius was nothing else than a greater aptitude for patience than that possessed by other men, which is rather like Carlyle's well-known dictum that "genius is first of all a transcendent capacity of taking trouble." Ramón y Cajal, the distinguished neurologist, described the process of scientific discovery as follows: "The ideal case would be that of a scientist who during his period of mental incubation would pay no heed to any thought that is extraneous to his problem, like a somnambulist who listens only to the words of the hypnotizer." And another writer, referring to "the self-surrender so familiar to creative minds," says: "The concentration of such a state may be so extreme that the worker may seem to himself or to others to be in a trance." In that connexion there comes to my mind an account Freud's daughter gave me of the time when he was composing the great final chapter of *The Interpretation of Dreams* in the summer of 1899. She recollected that when he was interrupted by being called to a meal he walked as if in a trance, oblivious of his surroundings.

At this point we enter the realm of depth psychology, and numerous problems throng upon us. What is the significance of this extraordinary concentration and intensity? What powerful impulses are driving their way at such moments? For there is every reason to suppose that men of genius are characterized by possessing exceptionally strong emotions and usually a correspondingly strong capacity for containing them. The tension induced by the preceding efforts to find a solution gradually mounts until it reaches a climax. The great mathematician of genius, Henri Poincaré, in describing how he made his own discoveries, said: "One is struck by these appearances of sudden illumination, obvious indications of a long course of previous unconscious work. . . . These sudden inspirations are never produced except after some days of voluntary efforts which appeared absolutely fruitless." Einstein has given a very similar description, and in the Fliess correspondence there are numerous allusions to the exhausting stress and strain Freud experienced in the continuously hard work of attaining his various pieces of insight. Kretschmer speaks of the great scientists' "passionate emotions developing which drive their thought constantly in the same direction, producing the utmost tension until at last a short-circuit occurs: somewhere a spark leaps to a new spot where up till then no human thought had ever passed."

What is the relation of the conscious interest in a particular problem to the unconscious forces that have produced so much tension? Müller-Freienfels maintains that what is characteristic is the being thrilled and gripped by the problem in some mysterious way that transcends in strength the mere desire to know, but perhaps he underestimates here the strength of just that desire in the unconscious. It is, however, noteworthy that he compares the thrill in question with the emotion of passionate love, and we are familiar enough with the connexion between the sexual instinct and the desire to know; it is a matter that Freud expounded fully in his work on Leonardo. Evidently there must be a special coincidence between the unconscious impulses and some essential feature of the objective problem. In the preliminary cogitation various shiftings and similar mechanisms are going on in the unconscious, the purpose of which is to achieve a sufficient degree of harmony with the censoring functions of the super-ego by means of which the accompanying guilt is kept in abeyance. At the successful moment there must have been achieved a quite remarkable degree of integration between the ego, the super-ego, and the id. It is no doubt this successful degree of synthesis, the overcoming of all barriers, that accounts for the sense of elation at the final moment of triumph. As is well known, such a complete synthesis is rarely more than a temporary one. The

super-ego which has been circumvented soon resumes its sway, and elation is followed by self-criticism, disparagement, and even doubt about the solution reached. I have described at some length these phases which Freud underwent during and after one of his most difficult achievements: the composing of *Totem and Taboo*.

Prerequisites of Genius

I now come to a modest contribution which I think could be made to our knowledge of the conditions governing the productivity of genius. It had long struck me that an essential prerequisite of such productivity must lie in a particular scepticism on the part of the genius. He must have refused to acquiesce in certain previously accepted conclusions. This argues a kind of imperviousness to the opinions of others, notably of authorities. Furthermore, he often has the capacity of seeing the existence of a problem where others have passed it by; he has refused to take something for granted as being either without meaning or too insignificant to bother about. This aloofness sets him free to speculate and investigate. The classical example of scepticism being deliberately employed is of course that of Descartes, who tried to start by doubting everything. The task, however, proved harder than he had expected, and his scepticism did not prevent him from indulging in rather wild speculations in his theory of vortices.

I once asked Freud what he thought was the explanation of the extremely free thinking that scientific pioneers and discoverers must have. He did not answer the question directly, but he pointed out that such freedom is always obtained under the condition that another aspect of mental functioning is inhibited. The example he took was that of Forel. In the face of the puritanical atmosphere with which he was surrounded in Switzerland, Forel ventured to publish a book on sexual problems which at that time was considered shockingly outspoken. On the other hand, he became an extremely bigoted opponent of the custom of imbibing alcohol in any form. His fanaticism in this respect was so intense as to leave its mark on the present-day Zurich with its flourishing *Alkoholfreier Verein* that is to be seen nowhere else. He infected his successor Bleuler with the same fanaticism, and Jung attributed Bleuler's breach with him to the circumstance of Freud having induced Jung to depart from the faith and to taste the forbidden liquor.

It may well be that the compensatory inhibition of which Freud spoke is the explanation of a feature often remarked in men of genius—namely, a certain naïveté, marked simplicity, and ignorance of the ways of the world. One writer even commented on what he called the *scheinbare Dummheit* (apparent stupidity) often found in such men, though this must surely apply only to a small minority. I note, however, that Thomas Mann, in his famous description of Goethe, comments on "the union in one human being of the greatest intellectual gifts with the most amazing naïveté."

The scepticism and imperviousness to opinion of which I have spoken were prominent features of Freud's personality, and they extended over a wide field. Not long after getting to know him, however, I was struck by an exactly opposite feature, one which, it is true, operated in a far more limited field. I refer here to a curious credulity, a willingness to believe what he was told, whether it was really likely or not. To it I would ascribe his well-recognized difficulty in forming an accurate estimate of personal character, a deficiency of which he himself complained. In my biography I have given many examples of this credulity, which at times bordered on superstitiousness, but it is worth while commenting on what is perhaps the best-known example of it, since it was that feature which ultimately led him to make one of his very greatest discoveries. I refer to the years when he accepted as true the seduction stories of his patients, which I am sure the vast majority of physicians would have doubted at once and regarded as one more example of the unreliability of hysterics and their tendency to fabrication.

In relating this experience in later years Freud spoke of how despondent and baffled he felt when he found how

deceived he had been and that most of the stories were quite untrue. Baffled he doubtless was, but contemporary evidence in his letters to Fliess reveals that, so far from being despondent, he felt a quite inexplicable elation. He wrote the memorable words: "Can these doubts be only an episode on the way to further knowledge? . . . Between ourselves I have the feeling more of a triumph than of defeat." He could not know at that moment, though his unconscious evidently did, that he was on the brink of one of his most momentous discoveries—the significance of incestuous wishes in infancy.

Pascal pointed out that greatness is never at one extreme but consists of the union between two extremes, an idea which Sainte-Beuve later labelled the theory of the *entre-deux*. My own suggestion is a particular application of this.

In a proper scientific spirit I then wondered whether this observation I had made concerning Freud's personality could have any more general validity as a condition for the productivity of scientific men of genius, and the studies I have made of many of them encourage me to think that it may be so. Allow me to relate a few examples. I will start with the earliest in point of time, Copernicus. His work revolutionized our conception of man's place in the universe and reduced his glorious habitation to an insignificant speck of matter in space, so that Sir Arthur Balfour in one of his cynical moments could describe the story of mankind as "a disreputable episode in the history of one of the minor planets." Actually it is not certain that Copernicus was really convinced that the earth revolved round the sun, but he evidently ventured to doubt whether the sun went round it. So much for his scepticism. His reputation and the immortalizing of his name rest on that alone. But there is another side to the story, which throws light on the motives impelling him to his new conception.

It will be remembered that, starting from the Greek doctrines of perfect heavenly orbits, Ptolemy had constructed an extremely ingenious geometrical scheme of the universe as then known. He found it necessary, however, to introduce a number of what are called epicycles, and moreover to give some of them the form of an ellipse. The scheme worked fairly well for many centuries, but the progress in astronomical knowledge gave it what might be called increasing fits of indigestion which could be cured only by introducing more and more epicycles, so that ultimately the picture became one of bewildering complexity. Many attempts were made in the sixteenth century to simplify matters, including that by Copernicus. Now what really stirred Copernicus was a feeling of dismay and reprobation at Ptolemy's impiety in daring to depart from Aristotle's dictum that all the heavenly orbs and orbits must have the form of a perfect circle to conform with the perfection of form of a perfect circle to conform with the perfection of form of the Divine Creator. Copernicus had an absolute belief in Aristotle's infallibility. Therein lay his credulity. And it drove him to search for methods of remedying Ptolemy's irreverence. He then found that by imagining the sun as the centre of the solar system he could devise a scheme, however faulty it afterwards proved to be, that could be built up with the desirable perfect circles. So he died a happy man. He was not the first to do the right thing for a wrong reason—Columbus had given an even more spectacular example not long before. Nor was he by any means the last.

Credulity of Great Men

We then come to the greatest genius of all times, Sir Isaac Newton. It would need an extremely expert mathematician indeed to elucidate the elements of scepticism and credulity entering into his great discoveries in science, nor is it likely that the data for doing so exist. On the other hand, it is easy to show that both these attributes were prominent in Newton's personality. His published scientific work is marked by a rigid objectivity, and it was he who proudly proclaimed the famous sentence, "*Hypotheses non fingo*" (I never manufacture hypotheses). He resolutely refused even to speculate on the actual nature of light or of gravita-

tion, but contented himself with studying their mode of operation. Yet he had in earlier days spent much fruitless time in conducting experiments in alchemy, in the search for the philosopher's elixir, and the means of transmuting metals into gold, and this at a time when alchemy had long passed its prime. Most of Newton's biographers have suppressed the important fact that throughout his life theology was much more important to him than science, and, moreover, theology of a peculiarly arid and bigoted order. There was an astonishing contrast between the extreme credulity he displayed concerning the literal statements of the Old Testament and the scepticism he evinced concerning the cardinal doctrines of the New. He followed Bishop Ussher in dating the Creation from 4004 B.C., and on that basis and the data about the long lives of the patriarchs spent years in conjuring up a chronological history of all the nations of the world, in the course of which he came to unbelievably fantastic conclusions. He was especially engrossed in unravelling the obscure symbolism of the Books of Daniel and of Revelations. From the former he deduced that the tenth horn of the fourth beast must refer to the Roman Catholic Church and confidently predicted its downfall in the year 2000. Similarly, Halley's comet would probably after five or six revolutions fall into the sun so that the earth would be burnt up. He was also a devotee of Jacob Boehme's mysticism. Yet, on the other hand, although he was a constant adherent of the Church of England, he subscribed to the Arian doctrines which deny that of the Trinity and even went further in doubting the divinity of Jesus.

Newton had a markedly irritable and suspicious temperament, and much of the controversy that disfigured his life arose from his credulous belief in the statements of over-candid friends. In later life these qualities deteriorated for a while into paranoid delusions of persecution; perhaps in this connexion it is not irrelevant to remark that Newton never fell in love and never married.

Faraday, the supreme physicist of the nineteenth century, had also his vein of credulousness. He said: "In early life I was a very imaginative lively person who could believe in *The Arabian Nights* as easily as in the *Encyclopaedia*, but facts were important to me and saved me." Throughout his life he was an adherent of the obscure sect of Sandemanians, followers of the religious prophet Robert Sandeman, and for three years regularly preached sermons before them. One must place this in contrast with Faraday's exceptional intelligence in other spheres, since it would be commonplace otherwise.

Darwin was a man of far more placid temperament, and it is probable that any turmoil of emotions found their expression in the psychosomatic afflictions to which he was a martyr. Although destined for the Church, he came gradually to doubt the truth of the official religious doctrine that mankind had been created in God's image for the edification and glory of the Lord of the Universe; in this he was influenced by Lyell's work in geology and perhaps also by his grandfather's teaching on evolution. But his scepticism was tempered by a credulous attitude towards other authorities. Even after his great discovery of the operation of evolution through natural selection he still believed in Lamarck's doctrine of evolution through the inheritance of acquired characters, a doctrine his own work had rendered superfluous and indeed erroneous. It was because of it that he developed his extraordinary theory of pangenesis, according to which minute gemmules in the blood convey the acquired alterations to the germ cells, cells which we know now to be impervious to any such influence.

His friend and contemporary Huxley offers a very interesting contrast to the genius Darwin. Although possessing a wider knowledge than Darwin, and gifted with more originality and a greater intellectual daring, Huxley's actual achievements are of a different order. On first reading Darwin's theory he exclaimed: "How extremely stupid of me not to have thought of that." Now, Huxley was endowed with any amount of scepticism, of indeed a rather pugnacious brand. It has been said of him: "He allowed

himself no prejudice, no sentimentalities, no illusions." But there is no record in his life of any evidence of credulousness to match it and, according to my view, to enable him to make really great discoveries.

Perhaps it is worth mentioning in the present connexion the remarkable epidemic of belief in the cruder aspects of spiritualism that infected several of the leading English physicists early this century: Sir William Barrett, Sir William Crookes, Sir Oliver Lodge, and Sir George Stokes. The number of times the mediums in which they trusted were exposed as frauds made no difference to the tenacity of their beliefs.

Psycho-Analytical Considerations

It would not be out of place on this occasion if I concluded with a reference to some psycho-analytical considerations. The only point I wish to bring forward here is the suggestion of a possible correlation between the credulousness on which I have been laying stress and the characteristically receptive nature of genius. A credulous attitude betokens an uncritical, excessive open-mindedness towards environmental stimuli, and this must go hand in hand with a similar uncritical open-mindedness towards the ideas pressing forward from the preconscious and ultimately from the id. It can afford to be uncritical here because of the relaxing of the inner censorship when harmony is established for the moment between the three mental institutions, ego, super-ego, and id. All this, however, represents only the preliminary stage of the process—an essential one, it is true. It is followed by a far more critical stage during the final act of formulating the new theory or conception. In this stage there is a strict criticism of the incoming ideas combined with an exclusion or even oblivion of the outer world when outer stimuli are regarded as a hostile interference, as in the case of Archimedes they certainly were. The intense concentration of this stage may culminate in the state of trance mentioned earlier.

Now in the first stage the passive, almost self-effacing role of the ego in accepting the ideas pressing in from the preconscious must surely be associated with the more feminine aspect of the personality or, as Freud preferred to term it, "the attitude of passive aims." It cannot be chance that so many words describing the process are taken from bodily analogies. The very word "inspiration" signifies a taking-in act on the part of the body. Poets often speak of being pregnant with their fancies, and the words "to conceive" and "to produce" equally apply to bodily activities. A writer can describe his mood as being in labour with an idea or actually giving birth to one. Furthermore, it is noteworthy how often, as constantly happened with Freud himself, the fomenting gestation of thought that precedes that final illumination is accompanied by just that kind of bodily discomfort that suggests the pains of labour. That women have more direct means of expressing this instinct would then account for the undeniable fact of major creative thinking being almost a prerogative of the male sex. It is their substitute, the only one available to them, for the gift of bodily creation bestowed on women.

Conclusion

I will conclude by recalling your thoughts to the man in whose honour this address is given. It will probably be generations before all the implications of his ideas are fully worked out and the stimuli he provided for us fully acted on. Revolutions in thought such as he brought about do not happen very often in history, and it may well be long before another similar one takes place. We do not even know in what sphere of psychology to expect it; it might be one in the genetics of the mind or, on the other hand, in the field of social psychology. In the meantime what can we feel but gratitude towards the memory of a man who gave so richly and so generously? Truly one may well say with his favourite prince: "I shall not look upon his like again."

AMNION IMPLANTATION IN PERIPHERAL VASCULAR DISEASE

BY

E. TROENSEGAARD-HANSEN, F.R.C.S.

Charing Cross Hospital

The purpose of this article is to report the effect on intermittent claudication of implanting human amnion into the thigh in 40 cases of peripheral vascular disease. This procedure was adopted because it had been observed (Troensegaard-Hansen, 1950; Shaw and Troensegaard-Hansen, 1952) that amnioplasty carried out for the treatment of leg ulcers in cases of peripheral vascular disease was followed not only by healing of the ulcer but also by a reduction in the severity of intermittent claudication. That such reduction might not be due solely to the healing of the ulcer was suggested by the fact that several patients claimed that their claudication was less than it had been before the ulcer appeared.

Material

The present series consists of 40 male patients. Their ages varied from 35 to 89, with an average of 60 years. They were selected as being in groups 1 and 2 of intermittent claudication (Professor Boyd's classification). The claudication was due to arteriosclerosis in 38 cases and to Buerger's disease in 2. Symptoms had been present for more than six months in the majority (Table I), and conservative treatment had been applied without significant effect in all of them. Three had been subjected to sympathectomy without effect on the claudication.

The pre- and post-operative condition of the patients was assessed by their tolerance to exercise, the presence or absence of rest pain, the radioactive sodium test, oscillometry, radiography, and skin temperature recordings.

Methods of Investigation

Tolerance to Exercise.—The criteria for tolerance to exercise were walking distance and ergometry. By walking distance is meant the distance which the patient can walk under controlled conditions before the onset of pain in the calf. By ergometry is meant controlled exercise on an ergometer. Two types of ergometers were used. In the first type, devised by Mr. N. C. Lake, the patient rhythmically depresses and releases a pedal, so raising a known weight through a standard distance once per second. This frequency was indicated to the patient by a swinging pendulum. The second ergometer was of the bicycle type, and was pedalled at a standard rate against a constant resistance. The patients' tolerance to these exercises was expressed as time (seconds) required to produce pain in the calf, and is referred to in Table I under ergometry as pain threshold in seconds. Rest pain was assessed in terms of severity, frequency, and duration.

Radioactive sodium tests (see below) were done on normals, on claudicants, and on patients having varied treatment.

Oscillometry was carried out, using a Pachon type of oscillometer. The maximum deflections were noted at different pressures and recorded (Table I).

X-ray examination of the patients' legs for evidence of arterial calcification was carried out.

Skin temperature of the limbs was recorded by means of a mercury skin thermometer.

Radioactive Sodium Test

The radioactive sodium test as described by Kety (1949) and modified by D. Walder (1953) was used for estimating the variations in blood circulation of the limb. This test has been used to determine changes in the arterial blood flow occurring after the use of certain vasodilators. As small variations can be detected the test is suitable for indicating changes that might occur following the treatment devised. Forty radioactive sodium tests have been done up to the time of writing. 24 cases in 16 cases both before and after implantation. 24 cases had only post-implantation tests, as these were early cases before the radioactive sodium test had been started. In this test from 0.06 to 0.15 ml. of saline containing 30 microcuries of radioactive sodium was injected into

the calf muscle to a depth of 2.5 cm. from the surface, and its rate of disappearance from the area was judged by the decrease in counting rate from a Geiger counter strapped to the calf, this being recorded on a ratemeter. For the first four minutes the patient stood at rest; he was then exercised by making him rise on his toes once per second, timed by a swinging pendulum for a period of two minutes. Finally, the readings were continued while he was at rest for a period of five to eight minutes. The fall in radioactivity was plotted logarithmically against time. In normal patients (Fig. 1) the fall was regular and the rate of fall increased during exercise. In a patient with intermittent claudication the graph deviated from the normal during the period of exercise (Figs. 2 and 3). The occurrence of the "hump" (A and B in Fig. 2) was thought to be due to poor arteriolar

circulation with a capillary reflux, thus raising the sodium level. Although the curves are as a rule reproducible it has been found so far impossible after implantation to reproduce the pre-implant "hump" in three cases in spite of their being exercised to exhaustion. The slope of the curves varies, and it was thought the steeper the slope the greater the vascularity of the limb. However, it must be considered that the site of

FIG. 4.—Same case as Fig. 3. Right leg after control implant, showing claudication curve. Note inter-exercise hump at A.

the injection must in some way be responsible for the slope; thus an injection made into vascular muscle must give a steeper clearance than one made into fascia, fat, or areolar tissue.

Lastly, we have tried to find some explanation of the

hump of the claudication graph. Accordingly, radioactive isotope sodium was injected into the calf of a normal patient. The arterial flow in the thigh was blocked by a sphygmomanometer cuff, the pressure of which was raised above the systolic blood pressure. The graph compared with that of a patient suffering from mild intermittent claudication. In the same case

FIG. 5.—Macerated inactive amnion showing loss of cell nuclei. (×175.)

the venous flow was then occluded by a sphygmomanometer cuff with a pressure just sufficient to block the venous return. The radioactive sodium test in this case, however, showed no hold-up. It is therefore assumed

FIG. 6.—Active amnion with nuclei in stroma and epithelium. (×175.)

that the features of the radioactive sodium test are attributable to arterial flow and its variations, and not to venous occlusion.

Procedure of Amnion Implantation

Human amnion was collected immediately after delivery and stored at 0° C. for five days. It was then cleaned on the chorionic side only, care being taken not to damage the epithelial layer. The tough adherent mucus was removed, after which the membrane appeared to be clear. The amnion was boiled for three minutes and was then ready for immediate use. For storage purposes this procedure must be followed by stretching and drying in warm air, with subsequent re-boiling before use

to ensure sterility, but this does not seem quite so effective as the former method for immediate use.

The amnion was then implanted under local analgesia in the form of two pieces each 7 by 5 cm. tightly rolled

FIG. 7.—Same case as Figs. 3 and 4. Normal curve after satisfactory implant.

TABLE II.—Details of Six Specimen Control Cases

Case No.	Age	Diagnosis	Duration of Disease	Ergometry Pain Threshold in Seconds		²⁴ Na (Radioactive Sodium)		Pain Threshold to Walking		Oscillometry in Deflections		Follow-up and Results

It would be unjustifiable on present evidence to draw any conclusions about the resting levels of the circulation in the muscles concerned before and after treatment. However, it is noticeable that sometimes the slope of the radioactive sodium curve is steeper after implantation than before. This has been interpreted as being due to an increase in the circulation, but it is possible that the slope of the curve may depend on whether the injected radioactive sodium has initially lodged in tissue of high or low vascularity. Patients who complain of claudication state that their pain is diffuse, but if they are questioned carefully one finds the pain localized to the following sites: high in the calf or low down just above the upper limit of the Achilles tendon, the middle of the shin, and the dorso-medial and dorso-lateral aspects of the foot. Only too often do these patients show tender areas which have been corroborated by other workers. It is therefore natural to suppose that certain muscles show signs of ischaemia in preference to others and that special sites are commonly affected.

The cone of scattered radiation which emerged from the foot opening of the machine spread out as would be expected from the geometrical arrangement of the useful beam area and the foot-opening area.

Some of the scattered radiation measurements were repeated with the addition of a demonstration pair of shoes, complete with wooden feet and legs, inserted into the machine as a dummy customer.

Minor radiation leaks were found around the wooden base of the machine where the top (which includes viewing-hood and foot platform) unscrews from the base when maintenance is required on the x-ray equipment.

American Radiation Measurements

In the *British Medical Journal* (1950) some American results are quoted and references given. The figures quoted in this paragraph are taken from these references. The American fluoroscopes described ran at about 50 kV, 3 to 8 mA tube current, and focus skin distance 7.5 to 20 cm. There is no mention of any added filtration. Many machines had a push-button timer, giving exposures of 5 to 45 seconds; about 20 seconds was the most popular time. Many measurements were quoted, made on 12 machines, by means of a Victoreen r meter in a shoe, and the range of dosage was from 30 to 350 r per minute. Values for the radiation

SIDE ELEVATION.

PLAN VIEW

FRONT ELEVATION

Test on recent model shoe-fitting fluoroscope. (Filter described as 0.5 mm. aluminium and 1.5 mm. bakelite.) Dosages, unless otherwise stated, were measured without shoes on platform, and were measured when "Man" button was pressed. "Woman" dose is approximately 75% of this, and "Child" dose approximately 60%. A 1/4-in. (6-mm.) sheet of rubber simulating shoe soles reduces dosage received by feet while on platform to one-third.

scattered out through the foot opening were nearly all above 100 mr per hour at 10 feet (3 metres) distance, and 15 mr per hour at 25 feet (7.6 metres) distance. Close to the machines, almost all the radiation dose rates quoted were higher than the corresponding results in the Diagram (which relate to a British-made machine).

Possible Hazards from Shoe-fitting Fluoroscopes

In discussing the radiation dose rates described above, it is useful to consider the people at risk. Thus there is the customer in the shoe-shop who may have a brief look at his feet for a few seconds in the fluoroscope on the one or two occasions each year when he buys shoes. Alternatively, there is the customer who may peer at the screen picture for some time, with each of several pairs of shoes in one shop, and then go on to other shops and repeat the procedure. As well as irradiating his feet, the customer is subjected also to scattered radiation which reaches him through the foot opening of the machine and through the material of the viewing hood.

A special case of irradiation of the customer arises with children. The shoe-fitting fluoroscope does enable a parent to see an image of the child's feet in its shoes, and so form some idea of the fit of the shoes. However, from the point of view of radiation dosage, children are regular customers in the shoe-shop, and may have new shoes as often as every three months. Possible radiation effects to be considered include skin erythema, and there arises the general question of irradiating growing tissue, with the special case of irradiating the epiphyses of the foot. Cases are described in the literature in which the epiphyses round the knee were irradiated to slow down or stop growth of the leg (Spangler, 1941). Another case is described by Frantz (1950), in which a haemangioma of the leg and thigh of a baby was irradiated with 1,600 r of 135 kV x rays (4 mm. aluminium filter) during a period of six months; as the child grew there was gross shortening of the irradiated leg, as compared with the gross shortening of the irradiated leg, as compared with the unirradiated one. Bisgard and Hunt (1936) describe experiments on the irradiation of femurs in young rabbits 3-5 weeks old. Subsequent microscopical examination showed cell damage in the epiphyses after 300 r or 200 r doses, but not after 100 r doses.

Besides irradiating customers, scattered radiation from these fluoroscopes irradiates the shop assistants. In a busy shop, with several assistants, a machine may be used many times a day, so that the dose accumulated by assistants over a period of time should be considered. There is the possibility also of irradiating the "people next door" (including above and below), but this is unlikely because the fluoroscope radiation is at low kV and so is readily absorbed in building materials such as brick and concrete. Along with the shop assistants one may include the customers in the shop; however (apart from actually using a fluoroscope), they will receive much less radiation than the shop assistants.

In addition to radiation hazards from fluoroscopes there is also the possibility of electrical hazards. In effect, one stands on a wooden box containing a generator giving several mA at about 50 kV. A substantial, well-earthed, and preferably x-ray-proof housing for this equipment is obviously desirable.

Radiation Hazards—Discussion

Comment here is confined to the measurements made on British machines, and the American results quoted above are not considered beyond noting that most of these American results are much higher than the corresponding British ones.

In considering the irradiation of the customers' feet by the useful beam, a standard of comparison is required. In the Recommendations of the International Commission on Radiological Protection* (1954), it is recommended that

*Generally abbreviated to I.C.R.P.

maximum permissible levels of radiation dose, for large populations, be kept below one-tenth of those recommended for radiation workers. In the particular case of irradiation to extremities such as the feet, this large-population maximum permissible dose is 0.15 r per week. Assuming that averaging of weekly dosage over a three-monthly period is permissible, this is equivalent to about 2 r per three months. The recent type of British machine (with its additional 0.5 mm. aluminium filter) gave a dose rate in shoes of about 4 r per minute. Thus the permissible 2 r per quarter year would allow, for example, three exposures of 10 seconds each, or two exposures of 15 seconds, and so on, in each three-monthly period. The dose rates measured in the shoe-shop machine were twice those of the recent type machine, which suggests either using shorter exposures or reducing the useful beam intensity, to keep doses within the permissible limit.

Useful beam intensities are progressively reduced when the "Woman" and "Child" control buttons are used; the reduction is from 100% ("Man" button) to 60% ("Child" button). The I.C.R.P. recommendations refer to adults, and suggest also that lower limits are desirable for children. It may be desirable also to alter such limits for children of different ages. Although the reference quoted above shows that 100-200 r is required in a single dose to give detectable changes in epiphyses, children must be regarded as regular shoe-fitting fluoroscope viewers for periods of many years, so that it is the dose accumulated over a period of time which is the one to be considered, and this is the type of dosage considered by the I.C.R.P. in drawing up its recommendations on permissible weekly dose.

The "large population" figure of 0.15 r per week quoted above is suggested as an administrative level below which repeated radiation monitoring of the exposed personnel is not required. However, there is a further consideration, as, for example, the many papers at the International Conference, Geneva (1955), which discussed the genetic aspects of the total radiation dose accumulated by a population. A brief discussion of shoe-fitting fluoroscope doses and population dose is given in the next section.

It is interesting to compare shoe-fitting fluoroscope doses with those measured during x-ray diagnostic procedures. The I.C.R.P., for example, gives these figures for diagnostic fluoroscopy at 60 kV pulsating, 3 mA, and 35 cm. target-skin distance:

Equivalent filter	1.5 mm. Al	2 mm. Al	3 mm. Al
Average surface dose rate	7 r/minute	4.5 r/minute	3 r/minute

Other authors (Ardran and Crooks, 1952) also discuss fluoroscopy with additional aluminium filters up to 3 mm. thick. Comparing their results with 3-mm. filters with their results with no additional filter, they report reduced skin dosage with the 3-mm. filters, but no significant reduction in screen brilliance where the beam went through a patient; where there was no patient in the beam there was a reduction in screen brilliance. Applying these results to the shoe-fitting fluoroscope suggests that increased filtration would reduce dose to the customer while diminishing the screen brilliance only outside the outline of shoes; and a reduction of glare from the brightly lit periphery of the screen would assist observation of the foot image. In the present machines the tube runs at about 50 kV; a higher kilovoltage and more filtration may give as bright an image with less customer dosage.

From the results given in the Diagram, a calculation could be made of the dosage received by shop assistants standing in the area of scattered radiation; this would be compared with the value of 0.15 r per week used above. It is difficult to estimate how many times a machine is used in a week, to estimate the individual exposures are, and where the assistants stand; and so measurements were made by issuing film badges to some assistants, who wore them for a week. Only a minimal radiation dose (less than 10 mr) was

measured on these films. The *British Medical Journal* (1950) quotes American results: 77 shoe salesmen carried film badges at work; two-thirds of these badges received no detectable amount of radiation, and of the rest only two received a dose around the maximum permissible level, and that at foot level (one of these film badges was carried in the trouser turn-up). It appears, therefore, that so long as the customer is adequately safeguarded shop assistants will receive little radiation dose.

Total Radiation Dose to the Population

Shoe-fitting fluoroscopes make some contribution to the total dose of radiation accumulated by the whole population of this country. Total dose is of interest because of its connexion with genetic effects in the population (International Conference, 1955), and the dose to be considered is that received by the gonads.

To compute the dose contributed by shoe-fitting fluoroscopes to the population of this country for a period of say a year, it is necessary to assume various typical figures about the machines used. The dose rates in question around a typical machine (see Diagram) are the 4 mr per hour figure against the viewing-hood for the customer examining his feet, and might be between 30 and 4 mr per hour for the nearest shop assistants, and about 4 mr per hour for other customers sitting in the vicinity of the machine (these values are not the actual tissue dose rates used in the calculation). It might be estimated that, for the whole population, each person examines one pair of shoes a year with a fluoroscope, and also that each exposure lasts 10 seconds. Other average figures might be three assistants exposed to the radiation from each machine and about 30 pairs of shoes examined each working day in each machine. If these figures are used, and multiplied by the estimated number of machines in use in the country, a typical value for the gonad dose to the whole population in a year can be determined.

As a basis for comparison, we may consider the background radiation, which is the radiation everyone receives continuously from cosmic radiation and from the small amounts of natural radioactive material in our surroundings. If the population dose from shoe-fitting fluoroscopes is compared with that received by the population from background radiation it is found that the shoe-fitting fluoroscope dose rate is of the order of only 1/1000 of the natural background dose rate. Therefore the genetic aspect of shoe-fitting fluoroscope doses is negligible, and will still be so even if the various figures assumed above are increased considerably.

Possible Control Measures

Various control measures could be applied to shoe-fitting fluoroscopes; dosage to customers' feet could be limited by specifying a maximum dose rate in the useful beam, perhaps also with limits on the kilovoltage and current of the x-ray tube. The specification of some minimum filtration in the useful beam is very desirable, and some form of timing device may be necessary to limit the length of each individual exposure. If viewing could be done by a special shop assistant who kept partly dark-adapted (full dark adaptation is used in diagnostic fluoroscopy), a less bright fluorescent image could be used and the radiation doses would be reduced. To limit the dose to shop assistants, the minimum screening of the x-ray equipment and viewing-hood could be specified, or a maximum permissible dosage rate fixed, to be measured against the outside of the equipment. The effect of scattered radiation coming from the foot opening of a machine could be minimized by pointing the foot opening towards a wall and away from the centre of a shop. It may here be noted that the machines tested could be used for a limited number of short exposures before the radiation dose from them reached the limit recommended by the I.C.R.P.

The I.C.R.P. states clearly that the overall responsibility for the protection of personnel from radiation rests with the head of a radiological department; this will be the manager

in a shoe-shop. Manufacturers of machines could be asked to make sure that their instructions for the use of their machines describe these responsibilities. In the absence of a manager, responsibility would be delegated to another member of the shop staff who understands the hazards involved and the appropriate control measures. For the customer there could be warning notices, to draw his attention to the dangers of excessive exposure to x rays, and perhaps a reminder could be issued to the customer each time the machine is used.

New machines would be expected to conform to the specified requirements on installation, and some form of periodical checking would be desirable to ensure that these requirements continue to be met.

A Ministry of Health committee has already begun work on the drafting of proposals for control measures; these proposals will be submitted to the appropriate committees of the Medical Research Council for criticism; and they will be discussed with interested parties in the shoe trade.

Summary

The shoe-fitting fluoroscope is a familiar object in many shoe-shops. Results of measurements of radiation dose in and around British machines are presented. The hazards to adult and child customers from these doses of radiation are discussed. It is suggested that regulations are needed, in the public interest, to control doses of radiation given by these machines, and possible control measures are suggested. The machines tested could be used for a limited number of short exposures before the radiation doses from them reached the limit recommended by the International Commission on Radiological Protection. A Ministry of Health committee is considering proposals for control measures.

Southern Europe, from Spain to Bulgaria, according to reports given at a recent W.H.O. conference in Athens on malaria, has achieved remarkable progress in reducing the incidence of the disease. Before the introduction of D.D.T.-spraying at the end of the last world war there were about four million cases of malaria a year in this area. The figure is now estimated to be less than 10,000. Progress was also claimed for the Eastern Mediterranean countries, a reservoir of malaria throughout the ages. In this region of some 170 million people there are said to be 100 million who live in areas where malaria is a threat. As late as 1949 about 40 million people regularly suffered attacks of malaria. Since malaria campaigns have been extended this figure has been reduced to about 14 million. The conference, attended by some 50 eminent malariologists, decided that it would be technically possible to eradicate malaria from the countries that surround the Mediterranean and the wider areas which constitute the European and Eastern Mediterranean regions of the World Health Organization. Dr. PAUL RUSSELL, of the Rockefeller Institute, said the solution of administrative and financial problems was the key to success in malaria education. Resistance to modern insecticides was also discussed, but, despite the hazard, an optimistic view was taken of the possibility of eliminating the disease. Professor GEORGE MACDONALD reported that experiments at the Ross Institute in London had shown that mosquitoes inherit resistance to insecticides according to Mendelian laws.

TECHNIQUE FOR BY-PASS OPERATIONS IN FEMORAL ARTERIAL DISEASE

BY

KENNETH OWEN, M.B., F.R.C.S.

AND

C. G. ROB, M.Chir., F.R.C.S.

Surgical Unit, St. Mary's Hospital, London, W.2

The results of resection and end-to-end grafting in the treatment of obstruction of the femoral artery due to obliterative arterial disease have been disappointing, there being a very high incidence of further thrombosis. This has led many surgeons to reconsider the by-pass type of operation recommended by Kunlin *et al.* (1951) and more recently used by F. B. Cockett (1953, personal communication), Crawford and de Bakey (1955), and Linton and Menendez (1955).

So far as the positioning of the patient is concerned, those authors appear to have used the positions designed for complete exposure of the femoral and popliteal vessels. The usual position, with the patient lying on the affected side and the unaffected leg flexed, gives good access to the lower femoral and popliteal arteries but obscures the upper femoral.

Method

A method of operation has been devised which gives good simultaneous access to the common femoral and popliteal arteries by two surgeons operating together in a synchronous combined procedure. The patient lies on the unaffected side, and a small wooden table, designed so that its legs are firmly engaged on the operating table, is placed over the normal leg (this table was designed by J. Crawford Adams for use in hip (arthroplasty operations)). The table is covered with a "sorbo" rubber pad on which the diseased leg rests (Fig. 1).

FIG. 1.—The operative position, showing the type of table used to support the diseased leg.

The position is maintained with the normal back rest and chest support used in kidney operations. These are placed fairly high so as to allow slight rotation of the patient should a better access to popliteal or groin incision be required. One surgeon sits opposite the popliteal fossa and the other faces the groin. Each assistant sits opposite his surgeon.

The popliteal incision is made first in order that the popliteal artery may be inspected and its suitability for end-to-side

anastomosis assessed. Should it be suitable, the second operator makes a small vertical incision exposing the common femoral artery bifurcation, while the first operator continues his popliteal dissection. A tunnel is then made from one incision to the other, this being started with an index finger from each end. In some patients it may be possible to complete the tunnel by digital dissection, but in others a long instrument such as a sponge-holding forceps or Lloyd Davies artery forceps is passed. A plane is found easily from the upper end passing deep to the sartorius medial to the femoral artery. The tunnel may be made to transverse the adductor magnus by enlarging the normal arterial hiatus or a fresh opening may be made. This is the only point where even slight difficulty has been found, and slow, careful exploration with a finger from the lower incision may be needed. The exact anatomical site of the tunnel is difficult to determine throughout its length, but it is probably within the subsartorial canal for most of its distance. This dissection is almost bloodless. A tube is then introduced through the lower incision and guided through the tunnel by the instrument from the upper end. An oesophagoscope has been found to be a useful tube (Fig. 2). It is

FIG. 2.—The passage of an oesophagoscope from popliteal to femoral incision.

essential to ensure that the graft will pass easily through the tube. The purpose of the tube is to allow the graft to be threaded through the tunnel without any possibility of uneven tension or kinking or twisting. The graft has a number of small silk sutures or ink marks placed in a straight line down its length as a further precaution against twisting. The graft or implant is then drawn through the oesophagoscope with long biopsy forceps and the oesophagoscope withdrawn. After carefully assessing the length required, the ends of the graft are trimmed and each operator proceeds to make his end-to-side anastomosis, the lower being to the popliteal artery and the upper to the common or superficial femoral. The method of anastomosis is that used by F. B. Cockett. With this technique a by-pass procedure is a relatively short operation. It may be done by two surgeons, working synchronously, in little over an hour. In single-handed surgery the position is of advantage as it allows good access without turning the patient. Slight adjustment can be made to the position by rotating the leg and patient through a few degrees so as to improve the lighting and access without any change in the towelling.

The by-pass type of operation is of too recent introduction for any opinion to be formed on its merits, but it was thought that this simple technique might be of use to others who are experimenting with by-pass operations.

NITROFURANTOIN IN CHRONIC URINARY INFECTION ASSOCIATED WITH RENAL CALCULI

BY

MARY G. McGEOWN, M.D., Ph.D.

Department of Medicine, Queen's University, Belfast

In the recent literature there have been numerous references to the use of nitrofurantoin (N-(5-nitro-2-furfurylidene)-1-aminohydantoin; "furadantin") in the treatment of urinary infections. Many reports consist of series of cases of urinary infection, both acute and chronic, associated with varying complicating factors such as urinary stasis, prostatectomy, or urolithiasis, which greatly increase the difficulty in interpreting the results of therapy (Norfleet *et al.*, 1953; Kaplan and Hobgood, 1954; Draper *et al.*, 1954; Hasen and Moore, 1954; Waisbren and Crowley, 1955). In some reports an improvement in the patient's symptoms was claimed as evidence of successful treatment, although the urine was not rendered sterile. The only report of its use in Great Britain appears to be that of Heffernan *et al.* (1955), which gives the results of treatment in 12 cases of infection following prostatectomy or associated with carcinoma of the prostate, in none of which the urine was rendered sterile.

Nitrofurantoin has a wide spectrum of antibacterial activity against both Gram-positive and Gram-negative organisms. *In vitro* it is active against *Staph. pyogenes*, *Str. pyogenes*, *Str. faecalis*, *Str. mitis*, *C. diphtheriae* and diphtheroids, *A. aerogenes*, *E. coli*, and many strains of coliform organisms, many strains of *Proteus*, *Paracolon* species, *Salmonella*, and *Shigella*, and *N. gonorrhoeae*. Although some strains of *Ps. pyocyanea* show *in vitro* sensitivity, most workers have not found it clinically useful against infections with this organism. It has been used with success against infections with most other organisms which show *in vitro* sensitivity.

The results of nitrofurantoin therapy in 21 cases of urinary infection associated with renal calculi, or persisting after the removal of calculi, are reported here. The patients have been followed for a minimum period of three months after the end of treatment. Only those cases in which the urine was rendered sterile are regarded as successful. Sensitivity tests of the infecting organisms were carried out, and were repeated on cessation of therapy in the unsuccessful cases.

Selection of Cases

The patients were chosen arbitrarily from the out-patients attending the Stone Clinic, attached to this department. They all had a chronic urinary infection associated with the presence of a calculus (8 cases) or persisting after the removal of a calculus (13 cases). They had been observed by me to be infected with the same organism for periods varying from 3 to 24 months. In some patients the urine was known to have been infected before they came under my care, but this is not noted in Table I. All the patients had received adequate courses of sulphonamides and sometimes antibiotics without success, and in some cases these had been repeated several times. In the females a catheter specimen of urine, or a mid-stream boiled bottle specimen in the males, was obtained immediately before the treatment was begun. This was repeated on the last day of treatment, or the day following it, and again three months later. Two patients who did not attend at the end of the course of

nitrofurantoin have been excluded from the series. Details of the patients are shown in Table I. They were all ambulant and afebrile, and none complained of symptoms that could be directly attributed to the presence of infection.

Dosage

It was decided to give a large dose of nitrofurantoin despite the increased likelihood of toxic effects, because the infections had all proved resistant to treatment with other agents. The patients were weighed and given tablets to correspond to a dosage of 10 mg. per kg. body weight per 24 hours. They were instructed to take the tablets during a meal to prevent nausea, as has been recommended by Trafton *et al.* (1955). If nausea was severe or vomiting occurred the dose was gradually reduced until this was controlled, the treatment being continued at the highest level the patient could tolerate. Fourteen patients succeeded in taking the complete course of 10 mg. per kg. per day for 14 days. Three completed the course at a dose of 7 mg. or more per kg. per day. Two did not persist with

P, penicillin. O, oxytetracycline. St, streptomycin. C, chloramphenicol. Sul, sulphamethizole. R, resistant. S, sensitive. Sensitivity tests were carried out using the standard disk technique. Nitrofurantoin sensitivity: 1+, zone of no growth 2.5-5 mm. around 381 µg. disk; 2+, zone of no growth 2.5-5 mm. around 174 µg. disk; 3+, zone of no growth 2.5-5 mm. around 86 µg. disk; 4+, zone of no growth 2.5-5 mm. around 33 µg. disk; 5+, zone of no growth greater than 5 mm. around 381 µg. disk; 6+, zone of no growth greater than 5 mm. around 174 µg. disk; 7+, zone of no growth greater than 5 mm. around 86 µg. disk; 8+, zone of no growth greater than 5 mm. around 33 µg. disk.

the treatment after seven days, even at a reduced dose, because of severe vomiting. Two patients had 7 mg. or more per kg. for 9 days and 7 days respectively.

Bacteriology

Each urine specimen was taken in duplicate, and cultures were taken in the hospital laboratory and personally by me in an attempt to exclude the possibility of contaminated urine. In all cases the results were in agreement. No attempt was made to identify separate strains of the different organisms cultured, as this was not intended to be a bacteriological study. The standard disk method was used for determining the sensitivity of the organisms to nitrofurantoin, the disks containing 381, 174, 86, and 33 µg. of nitrofurantoin respectively. An effort was made to make the inoculum as standard as possible, and the cultures were read at 6 hours and again at 18 hours, it being emphasized by Richards *et al.* (1955) that these factors influence the apparent *in vitro* sensitivity to nitrofurantoin.

Results

The results for individual patients are shown in Table I. Ten patients (48%) had sterile urine on the fourteenth or fifteenth day—that is, immediately after the conclusion of treatment. In four patients (19%) the original organism was replaced by another organism. In seven cases (33%) the original organism was still present at the end of treatment. In six patients (28%) the urine was sterile three months after the cessation of treatment. In one patient the original organism had reappeared, and two others had an infection due to a different organism. One patient reappeared with a urinary infection due to a different organism two weeks after the course of treatment. Two patients have been followed for five months. In one the original infection has recurred, although the urine was sterile at three months, but there is a large calculus in one kidney. The other patient's urine has remained sterile for five months, although she repeatedly relapsed after a few days when given courses of sulphonamides.

Bacteriology.—Nitrofurantoin appears to be particularly useful against infections with *Enterococcus*, *Staph. pyogenes*, and *Proteus*, as can be seen in Table II.

TABLE II

Organism	No. of Times Isolated	No. of Times Eradicated
Coliform	11	3
Coli (aerogenes) .. .	1	1
Enterococci	5	5
<i>Staph. pyogenes (aureus)</i> .. .	2	2
<i>Proteus</i>	2	1

Toxicity.—As might be expected from the relatively large dose of nitrofurantoin, toxic symptoms often occurred. These are shown in Table III. As already stated, only 14

TABLE III

Toxic Symptom	No. of Times
Nausea (slight)	5
Nausea (moderate to severe) .. .	9
Vomiting	4
Headache	3
Flushing	2
Prostration	1
Skin rashes	0

of the 21 patients were able to tolerate the complete course. Seven patients did not notice any abnormality while taking nitrofurantoin. The toxic symptoms were similar to those reported by other workers, except for the occurrence of transient attacks of flushing in two patients. Although almost all the patients were women, none was free from toxic symptoms. The drug was given to one child aged 2½ years without any ill-effect. There were no instances of skin rash in this series, but rash has since occurred with two other

patients. In most cases toxic symptoms were controlled by slightly reducing the dosage, but in a few it was not possible to continue the treatment.

Discussion

In this study the number of cases was small and a detailed statistical analysis did not seem warranted. It was felt that the patients could form their own controls, since they had been continuously infected with the same organism for prolonged periods, and it was therefore unlikely that the infection would disappear spontaneously. The fact that the urine was sterile in one-third of the patients three months after the end of treatment increases the value of these results.

The cases in which the infecting organism was replaced by another organism have here been regarded as failures, although this has not been the practice of some other workers (Richards *et al.*, 1955). The replacement of a coliform infection by *Proteus*, for instance, is unlikely to prove beneficial to the patient. However, the occurrence of such cases suggests that the incidence of cure is likely to be higher in cases without the complicating factor of calculus damage.

The sensitivity of the infecting organism to nitrofurantoin, as would be expected, corresponded fairly well with the result of treatment. In all the successful cases except one the organism appeared to be very sensitive to nitrofurantoin; in the remaining case it appeared to be only slightly sensitive. It has also been noted by Mintzer *et al.* (1953) that *in vitro* tests may occasionally fail to correspond to the clinical effectiveness of the drug. In one unsuccessful case the organism appeared to be very sensitive *in vitro*, but there is a large calculus in one kidney.

In one of the unsuccessful cases the sensitivity of the organism appeared to have somewhat decreased after 14 days of treatment, but in the others the sensitivity was unchanged. In two cases resistant colonies were noted in cultures both at the beginning and at the end of treatment, although they did not seem to have increased in number. This suggests that two strains of the same organism of differing sensitivity were present or, alternatively, that there were resistant mutants of the same strain. The presence of such resistant organisms in an otherwise sensitive infection is of potential importance in cases in which it might be desirable to give a prolonged course of treatment.

In this group of patients infection had been present for long periods and had proved refractory to treatment with other drugs. The difficulty of eradicating urinary infection in the presence of a calculus is well recognized. The fact that infection frequently tends to persist, or occur for the first time, after the removal of a calculus is not often mentioned. In this type of patient it is particularly important to cure the infection, in view of the part it may play in increasing the incidence of recurrence of calculi. There is also the added danger of chronic pyelonephritis to the function of an already traumatized kidney. The urine became sterile in 48% of these cases, although only 28% remained sterile three months later. The high relapse rate, and the fact that in some cases the original infection was replaced by another one, does not detract from the therapeutic value of nitrofurantoin. They merely indicate that the damaged renal tract is especially prone to become infected. In cases of refractory urinary infection it would appear that nitrofurantoin is a drug of considerable value.

Summary

Nitrofurantoin was used in the treatment of 21 cases of refractory urinary infection associated with the presence of renal calculi or persisting after the removal of calculi. In 48% of cases the urine became sterile after 14 days. In 28% the urine remained sterile for three months.

The *in vitro* sensitivity of the organism corresponded fairly well with the result of treatment. Resistant colonies were observed in otherwise sensitive infections,

and the presence of such resistant organisms might prove to be of importance if it was desired to give prolonged treatment.

Toxic symptoms were often encountered, but could usually be controlled by slightly reducing the dosage.

This work was carried out during the tenure of a grant from the Medical Research Council. The furadantin was kindly supplied by Duncan, Flockhart and Co., of Edinburgh. I wish to thank the Department of Clinical Pathology of the Royal Victoria Hospital for help in this study, and the Department of Microbiology, Queen's University, for advice and guidance, and for the use of the facilities of the department. I am grateful to Mr. E. Morrison, and the other surgeons of the Royal Victoria Hospital, Belfast, who allowed me access to their patients. I wish to thank Nurses P. Crawford and R. Hand, who collected the urine specimens

URINARY SYMPATHIN EXCRETION OF NORMAL INFANTS AND OF INFANTS WITH PINK DISEASE

BY

JAMES W. FARQUHAR, M.B., M.R.C.P.E.D.

Senior Lecturer, Department of Child Life and Health

T. B. B. CRAWFORD, Ph.D., B.Sc.

Lecturer, Department of Pharmacology

AND

W. LAW, Ph.D., M.B., B.Sc.

Research Worker, Department of Pharmacology
University of Edinburgh

The condition known variously by the name of "pink disease" and by a number of other descriptive or eponymous titles was described by Feer (1923) as a disorder of the vegetative nervous system. The fact that he employed atropine in treatment, however, suggests that he may have failed to appreciate the full significance of his hypothesis.

A very severe case of pink disease which was admitted to the Royal Edinburgh Hospital for Sick Children in October, 1953, appeared to one of us (J. W. F.) to show so many suggestive features of an overacting sympathetic nervous system that it was thought justifiable to embark on the determination of the infant's urinary sympathin (adrenaline and noradrenaline) excretion. The result was of sufficient interest to stimulate the investigation of further cases and of control subjects.

Method of Investigation

Urine was collected accurately for 24-hour periods from 19 healthy infants, most of whom were resident in nurseries under the care of the local authority, usually because of some temporary dislocation of family life. A number were

convalescing from minor illnesses in hospital, and in these cases the collections were obtained over the 24 hours immediately before discharge. Urine was collected similarly from four infants who presented the undoubted clinical features of pink disease.

All the control subjects and three of the affected infants were males in whom accurate urine collection was possible by means of small-sized latex colostomy tubing which was strapped to the penis and allowed to drain into a specially prepared collecting bottle. The fourth patient with pink disease was a female, and great difficulty was experienced in obtaining an accurate collection of urine despite the use of an indwelling catheter.

The urine was collected in bottles containing 5 ml. of 2N H₂SO₄ and 0.5 ml. of chloroform to stabilize the sympathin. Aliquots of the measured 24-hour specimen were used for assay. One aliquot (50–100 ml.) was submitted to acid hydrolysis by heating at pH 2 (adjusted with 2N H₂SO₄) for 20 minutes in a boiling-water bath. This treatment releases some (Euler and Hellner, 1951) but not all of the catechol amines excreted in a conjugated form (Euler and Orwén, 1955). The sympathin excreted in the free state was determined, using another aliquot of the urine which was not submitted to acid hydrolysis.

The sympathin determinations on the hydrolysed and unhydrolysed urine were carried out by a method to be described in detail elsewhere by Crawford and Law. It consists essentially in the extraction of the sympathin by passage of the diluted urine at pH 7 through a column of a weak cation exchange resin "amberlite IRC-50" previously buffered to pH 7–7.5. The adsorbed sympathin is recovered from the column by elution with dilute sulphuric acid. Most of the inorganic salt in the eluate, brought to pH 3.5 with dilute sodium hydroxide, is precipitated by the addition of 2–4 volumes of a mixture of equal volumes of acetone and ethanol. The supernatant is evaporated to dryness at 35° C. under reduced pressure. The residue is dissolved in distilled water (3 ml.) to give the "final urine extract." The sympathin content of this solution is determined fluorimetrically, using Lund's (1949, 1950) method modified in such a way that equal quantities of adrenaline or noradrenaline or mixtures of the two amines give similar intensities of fluorescence (Crawford and Law, unpublished).

When individual determinations of adrenaline and noradrenaline in the urine extract were required, separation of the two amines was effected by submitting an aliquot of the final urine extract to paper chromatography (Crawford and Outschoorn, 1951, modified as described by Vogt, 1954). The concentrations of the separated amines in the eluates from the appropriate paper strips were determined fluorimetrically.

The method of extraction of urinary sympathin described by Euler and Hellner (1951) was used in the first case of pink disease investigated (Table III). The sympathin in the urine aliquot is adsorbed on to aluminium hydroxide formed in the urine by the addition of aluminium sulphate followed by adjustment of the pH to 7.5 with dilute sodium hydroxide. The separated precipitate is dissolved in dilute sulphuric acid and the inorganic salts are removed by precipitation with acetone-ethanol mixture (see above) after adjusting the pH to 3.5. The supernatant is evaporated to dryness under reduced pressure at 35° C. The residue was dissolved in 0.9% (w/v) sodium chloride and the sympathin concentration in terms of noradrenaline determined by bio-assay, using the rat's blood pressure preparation (Crawford and Outschoorn, 1951).

A recovery of 82% (S.D. 6) was obtained by the amberlite IRC-50 method in 51 experiments in which adrenaline or noradrenaline (3–30 µg.) was added to urine. No significant difference (P=0.05) in the recoveries of adrenaline or noradrenaline, or in the recoveries from hydrolysed and unhydrolysed urine, was found. Similar control experiments in which the two amines were separately determined following extraction by the amberlite IRC-50 method and separation by paper chromatography showed a recovery of 50%

(S.D. 9) for 2 to 15 µg. of either amine (10 estimations). Again the recoveries for adrenaline and noradrenaline did not differ significantly (P=0.05).

The figures cited in the tables are corrected values, the correction factor for each experimental result being obtained from a recovery experiment carried out concurrently with the analysis.

Excretion of Sympathin in Normal Infants

Determinations of the sympathin excretion in single 24-hour urine samples from each of 14 healthy male infants aged 6–18 months gave a mean value of 16.5 µg. (S.D. 4.0) for hydrolysed urine and 13.2 µg. (S.D. 3.4) for the sympathin excreted in the free state (Table I). The results for

hydrolysed urine are similar to those given by Burn *et al.* (1953), who found 12–18 µg. (in terms of noradrenaline) in the 24-hour urine samples of three children aged 3–24 months.

Separate determinations of the adrenaline and noradrenaline excretion by five normal male infants of 10–12 months showed 69% (S.D. 4.7) of the free sympathin to be noradrenaline, while of the sympathin in hydrolysed urine noradrenaline accounted for 61% (S.D. 5.8) of the total (Table II).

Clinical History and Sympathin Excretion of Infants with Pink Disease

Case 1

The patient, aged 9 months, was the second child of healthy unrelated parents. His original progress was entirely satisfactory, but at 7 months he developed chicken-pox, complicated by a severe attack of bronchitis, which was clearing at 8 months when he developed whooping-cough and further respiratory infection. His symptoms of increasing anorexia

and irritability had followed the onset of pertussis. There was no history of exposure to mercury in teething, grey, or worm powders, in ointment, disinfectant, or nappy washes. The development of classical and very severe pink disease was progressive, and the infant became so profoundly anorexic that tube-feeding was necessary. He was extremely miserable, had typical cold and puffy red hands with peeling developing after some weeks; sweating was profuse, and resulted in the typical body rash which the infant rubbed and scratched continuously. He was uncomfortable in any position, had a persistent tachycardia, was hypertensive (140/106), was photophobic, and had marked dilatation of the pupils. He shed his four teeth, and his tongue became small, hard, and blanched, the tip eventually sloughing. The abdomen became progressively distended with gas until it caused him distress.

At this stage rectal examination revealed his bladder to be grossly distended, the wall apparently being thin and relaxed. Micturition was hesitant and dribbling, the difficulty being similar to that sometimes observed after a dose of ephedrine. After an ounce or so of urine had been passed by dribbling micturition, catheterization produced a large residuum. Neither then nor later was any obstruction demonstrated, and it became the practice to assist the infant to empty his bladder completely twice daily by pressure on the abdominal wall and from the rectum.

Investigation of the patient's urinary output of mercury in 24 hours at an early stage failed to reveal anything abnormal and his serum sodium and chloride were normal, although it should be stated that he had been receiving half-strength saline frequently each day as the excessive loss from the skin was obvious.

Much of the clinical picture suggested overactivity of the sympathetic nervous system, and the urinary sympathin excretion was determined. The result was given as 74 µg. of pressor substance (in terms of noradrenaline) in 24 hours (Table III).

* Extraction by the method of Euler and Hellner (1951). Extracts assayed on rat's blood pressure preparation with (—) noradrenaline as standard.

It was decided to observe the effect of reflex heat and of an anti-adrenaline drug on the patient, and the result may be seen on the graph. Skin temperature readings were recorded with a thermistor and the rectal temperature with a

premature-baby thermometer. The pulse and blood pressure were also recorded, and as some measure of the effect on the relaxed bowel the abdominal circumference was measured around its maximum point. As may be seen, reflex heat (provided by an electric blanket to the right arm, leg, and half of trunk) failed to produce release of the vasospasm, but within five minutes of injecting tolazoline ("prisco") the skin temperature was rising to normal and remained there, the bowels opened copiously, and urine passed normally. There was only a slight fall in the blood pressure, but it is known that tolazoline may not influence hypertension successfully because of its potentiating effect on cardiac output.

The results were so satisfactory that it was decided to begin treatment with this substance. Initially the oral route was employed, but, possibly owing to delayed gastric empty-

Effect of reflex heat and tolazoline in Case 1.

ing, the signs of pink disease were uninfluenced. Intramuscular injection of 5 mg. every six hours was started, with complete control of the vasospasm. The hands and feet were warm, and sweating became normal. The baby was happier, abdominal distension decreased, and urinary function improved but was impeded by a more or less continuous priapism which seemed to be due to the drug. The tongue became normal in appearance apart from the healing irregular anterior margin.

Treatment was continued for five days, and at that time only the gross wasting, some fullness of the abdomen, and weakness remained. On the fifth day of treatment, however, the temperature rose steeply and widespread signs of bronchitis appeared. Chlorotetracycline was given, but the patient rapidly deteriorated, dying in 24 hours.

Post-mortem examination was carried out by Dr. A. R. Macgregor. The main features noted were a purulent bronchitis and a patch of bronchopneumonia. Nothing peculiar to pink disease was noted. Chromaffin tissue was subjected to careful histological examination and no abnormality was found. The genito-urinary tract was normal. Sections of the tongue showed that muscle necrosis formed the floor of the ulcerated margin, granulation tissue was forming, and there was much polymorph and mononuclear infiltration. Beyond the areas of necrosis cellular infiltration was noted for some distance, but the arteries in the healthy parts showed no pathological changes, and in the infiltrated areas nothing was found that could not be explained as secondary to the surrounding inflammation.

Case 2

A boy aged 6 months, the second child of healthy unrelated parents, had been well until six weeks before admission, when he began to lose weight and to be restless, fretful, and sleepless. His appetite deteriorated. For one week he had been very photophobic, and for a few days had been sweating profusely, a rash had appeared on the trunk and limbs, and his hands and feet had become pink and cold. There was no history of exposure to mercury.

On examination he had clearly lost weight and there was obvious photophobia. A sweat rash was present and the hands and feet were typically pink, puffy, and cold. The heart rate at rest was 144 a minute, and the systolic blood pressure 130 mm. Hg. The abdomen was a little full and the bowel was constipated, but the bladder was not enlarged. Blood biochemistry, urinalysis, and lumbar puncture gave normal results. No abnormal urinary excretion of mercury was found.

During the next few days his appetite improved, but the clinical condition was unchanged. One week after admission a 24-hour collection of urine was obtained and the sympathin excretion determined (see Table IV). On the following day

TABLE IV.—Urinary Excretion of Sympathin ($\mu\text{g./24 hr.}$) in Case 2

Collection Date	Treatment to Urine	Extract from Amberlite IRC-50	Eluates from Paper Chromatograms

his temperature rose to 101° F. (38.3° C.) and after 24 hours pus cells appeared in the urine. The infection was cleared with sulphadimidine, but during the next week the signs of pink disease became more pronounced. In the third week of his stay in hospital his response to reflex heating (see Table V) was negative, and a further 24-hour collection for

Temperatures were recorded at five-minute intervals, but, for reasons of space, only selected time intervals are given here. The temperatures were always stable for 20 minutes before heating began, and the latter was applied for 30 minutes by means of a pre-heated electric blanket.

sympathin determination was obtained. Chlorpromazine treatment was begun at once in dosage of 10 mg. six-hourly by intramuscular injection. After 48 hours his clinical condition appeared to be worse, and although his right hand was warm the other extremities did not respond to reflex heating. Urine excreted over 24 hours was again collected and the sympathin content determined. His temperature, which had been unstable, rose again owing to a coliform urinary infection, which was treated with sulphonamide. It was decided to observe the effect of "hydergine," which is a

mixture of equal parts of dihydroergocornine, dihydroergocryptine, and dihydroergokryptine. This was given by subcutaneous injection in dosage of 0.03 mg. three times a day, but his signs remained uninfluenced. While the question of using hexamethonium was being discussed he began to improve and no treatment was given. He was discharged convalescent, and remained well.

Case 3

A boy aged 11 months, the first child of healthy unrelated parents, had made good progress from birth until the age of 9 months. He then became progressively irritable, miserable, anorexic, photophobic, and sleepless. His mother commented on the redness of his hands and feet, and she had noted him to be "soft and floppy." For one month before the development of symptoms he had been having one mercurial powder each day. When seen by one of us (J. W. F.) his condition was beginning to improve. He weighed 1.5 lb. (680 g.) less than he had done two months previously. He was apyrexial, but the heart rate was 168 a minute at rest. He was hypotonic, photophobic, and miserable; his feet and hands were pink and cold, and there was particularly his hands were pink and cold, and there was slight peeling. The blood pressure was 160/100 at rest. His abdomen was a little distended with gas, and the rectum was not filled with small pellet-like scybala. The bladder was not palpable. The lower two central incisor teeth had erupted and were obviously loose. The pupils were not abnormally and dilated. Other pathological processes were excluded, and the diagnosis was in no doubt. Urine was collected over three 24-hour periods and analysed for sympathin (Table III).

As the infant was clearly improving no treatment was attempted, and it was possible to discharge him for convalescence at home.

Case 4

The patient, a girl, aged 7 months, was the fifth child of healthy unrelated parents. From the third month she had appeared to be restless, "wriggling as if in pain," and miserable at night. Three weeks before admission she developed photophobia of increasing severity. Her appetite rapidly deteriorated, she lost weight, and she became increasingly irritable.

On admission she was very cross and obviously uncomfortable. She wriggled about in the prone position and on her knees with her head firmly buried in the pillows. When faced with the light she closed her eyes tightly and often attempted to cover them with her hands. There was no obvious eye trouble. The hands and feet were cold and distinctly pink, but showed only minimal peeling. A mild heat rash was visible over the abdomen. The heart rate was 180 a minute at rest, and the systolic blood pressure was 130 mm. Hg. The abdomen was a little full but there was no loading of the bowel, and although the bladder was palpable rectally it was not abnormally distended. Other pathological conditions were excluded and the diagnosis was certain.

Urine collections were attempted, but the sex and the baby's extreme restlessness rendered accuracy impossible. All faecal contamination had to be excluded. An indwelling catheter was inserted, and a plastic apron was so attached to the perineum that urine escaping from around the catheter should have been directed into the collecting-bottle. The volumes of urine were so small in each 24 hours (60-70 ml.) that their completeness must be doubted. The results are given in Table III. This infant improved steadily on oral tolazoline.

Discussion

Many and widely varying hypotheses have been advanced in attempts to explain the cause and clinical features of this strange condition. Among these are encephalitis (Francioni and Vigi, 1928), preceding bacterial infection (Rodda, 1925), viral infection (Cobb, 1933), mercurial hypersensitivity (Warkany and Hubbard, 1948, 1951), arsenical poisoning

(Meyer and Weise, 1933), "arseno-plumbism" (Calvin and Taylor, 1935), ergot poisoning (Debré and Nevot, 1939), avitaminosis B (Orton and Bender, 1931; Warthin, 1926), avitaminosis E (Forsyth, 1941), emotional deprivation (Leys, 1950; Leys and Cameron, 1952), allergy (Helmick, 1927; Fanconi and Botsztein, 1948), adrenocortical hypofunction (Cheek and Hicks, 1950), adrenocortical hyperfunction (Cheek, 1954), and a neurosis of the vegetative nervous system (Feer, 1923; Selter, 1927). Of these the possible part played by mercury has attracted the greatest attention in recent years.

Hamilton (1819), in Edinburgh, wrote a classical description of the clinical features of mercurialism, and attention was drawn to their resemblance to pink disease by Warkany and Hubbard (1948, 1951). Not all the features of mercurialism are present, however, in pink disease, nor are all the features of the latter to be noted in mercurial poisoning. Not all affected babies excrete abnormal amounts of mercury in their urine. Hypersensitivity of some infants to the mercury content of medicaments absorbed from the alimentary tract or from the skin has been postulated, but Holzel and James (1952), in comparing two regions in England, found that the disease appeared to be commoner in the region using less mercurial teething powder. Dimercaprol has not fulfilled its earlier promise in treatment (Southby, 1953), and it has even been reported as having been used successfully in patients who excreted no mercury before, during, or after treatment (Houet, 1952). Doubt concerning the role of mercury in the causation of pink disease has been expressed recently by McCance (1955).

Similarly, the parts played by other toxic materials, by vitamin deficiency, and by emotional deprivation have been called in question, and it is clear that no one of these factors is responsible for all cases of pink disease.

There is no convincing evidence of the presence of an encephalitis, although it must be remembered that the condition is sometimes seen in association with the Guillain-Barré syndrome. Feer (1923) was impressed by the apparent disturbance of autonomic balance, and he described pink disease as a "disorder of the vegetative nervous system." Orton and Bender (1931) reported finding in their cases degeneration of cells in the lateral horn of the cord, which they considered to be the effector cells of the splanchnic sympathetic. Like the other inconstant histological changes in the central nervous system, however, these may have resulted from the prolonged illness rather than have been evidence of the basic disorder. Stolz and Wöringer (1926) claimed to have found hyperplasia of chromaffin tissue in pink disease, but this has not been substantiated by others.

Many of the clinical features of our cases, and particularly of the first, provide evidence which is suggestive of overaction of the sympathetic nervous system. Arteriolar spasm and the closure of the precapillary sphincters produce capillary anoxia and are responsible for the production of the cold pink, puffy hands and feet, and they were responsible for the necrosis of the tongue in the first case. Hypertension is a logical sequel. Sympathetic activity may be seen in the tachycardia, the bowel and bladder relaxation, and the pupillary dilatation which may be observed. Objection has been raised, however, to the condition being a pure sympathetic overaction in view of the excessive sweating which is such a feature of pink disease. Although cholinergic, it is nevertheless a sympathetic function, and could be explained on the basis of the disturbance being a diencephalic one with resultant stimulation of both the adrenergic and the cholinergic sympathetic nerve endings. It had been hoped that further information on this point might have been obtained by treating the second case with chlorpromazine, but this controversial drug shed no light on the matter.

Alternatively it is possible that the excessive sweating may be a compensatory mechanism for losing heat, in view of the impaired heat regulation resulting from arteriolar spasm. Undoubtedly the heavy sweating is responsible for the prickly-heat rash which so many infants show, and for the reduced plasma chlorides, especially in less temperate

climates than our own. It is more difficult to explain the excessive salivation and the hypotonicity, although the latter may be the result simply of anorexia, poor calorie intake, and sleeplessness, while these in turn may be due to itching, discomfort, and even pain. Excessive salivation may result from sensory stimulation of the mouth, and in Case 1 this may have arisen from the necrotic changes in the tongue. No explanation for the photophobia presents itself, although spasm of the retinal vessels was suspected in our first case. The arteriolar spasm responsible for the pinkness and coldness of the hands and feet is variable. It is common to discover the hands more severely affected than the feet at one examination, only to find the position reversed in the same child a little later. Furthermore, spontaneous relief of spasm in the hands may take place when the feet are still involved, or vice versa, and while the blood pressure is still raised and the heart rate rapid.

These observations would be compatible with a centrally determined variation in sympathetic stimulation in various efferent nerves, or changing sensitivity of end organs to a circulating sympathomimetic substance. Leys (1950) considered that the signs could be explained only on the basis of a disturbance of the whole autonomic system at the diencephalon, and suggested that the condition was a "diencephalopathy." McCance (1955) was of the opinion that pink disease is essentially a manifestation of gross overactivity of the sympathetic system.

Vulliamy (1952) demonstrated very clearly that the arteriolar spasm existing in pink disease was too intense to allow of release by reflex heat, whereas the injection of an adrenergic blocking agent, tolazoline, resulted in almost immediate vasodilatation. Relief of symptoms in six of seven cases treated with tolazoline was noted by Peterson and Laughmiller (1954). It is possible that this is the result of the histamine-like action of tolazoline, and not of its anti-adrenaline activity; but Bower (1954), who reported failure or delay in the response of infants with pink disease to reflex heating, confirmed the release of arteriolar spasm by such ganglion-blocking agents as hexamethonium bromide and pentolinium tartrate. All of these drugs are capable of abolishing most of the signs of pink disease, with the exception of photophobia. These observations on the results of treatment provide suggestive evidence of a possible part played by sympathetic overaction.

Attempts to prove such overactivity, however, by demonstrating the presence of abnormal amounts of sympathomimetic substance in the plasma have met with variable success. Glanzmann (1937) suggested that the adrenal medulla produced an increased secretion of adrenaline in children with pink disease. He found that plasma from affected cases when diluted with Ringer's solution resulted in dilatation of the pupil of the enucleated frog eye, whereas similar dilutions of plasma from normal children had none. This mydriatic effect he attributed to adrenaline. Cheek (1951) investigated the adrenaline content of the plasma in affected and control cases, and found no significant difference, but scrutiny of his results has led to doubt about their value.

The urinary excretion of sympathin is probably a more reliable index of the daily output of adrenaline and nor-adrenaline than efforts to detect them in the plasma. Burn *et al.* (1953), in a preliminary report, recorded normal urinary sympathin excretion in two cases of pink disease. The present investigation was undertaken shortly after the publication of their letter and before it had come to our notice. The result in the first case indicated that sympathin excretion might in fact be increased in pink disease and stimulated further studies, and the determination of the normal range became necessary (Tables I and II). The results obtained in Cases 1 and 3, and with one exception the results obtained in Case 2, demonstrate that urinary sympathin excretion in these infants was greater than in the normal control group (Table III). The results in Case 4 were apparently within normal limits, but there was some doubt about the completeness of the urine collection. The results of separate determinations of adrenaline and nor-

adrenaline in two of the urine samples from Case 2 (Table IV) indicate that there was no marked change from the normal in the proportions of adrenaline and nor-adrenaline in the urinary sympathin.

The variability of the physical signs in individual cases suggests that if they are the result of sympathetic overactivity the intensity of sympathetic stimulation varies from time to time along the various efferent nerves of the sympathetic outflow. Should such clinical features be the result of stimulation at the sympathetic nerve endings rather than the response to a circulating sympathomimetic substance, then more intensive signs would be expected to follow the production of a very much smaller total quantity of pressor substances. This would explain why the urinary output of sympathin in pink disease is less than in phaeochromocytoma, although the clinical pictures may resemble each other so closely as to be mistaken for one another (Hubble, 1951; Vulliamy, 1952).

The sympathetic nervous system is known to be responsible for the maintenance of the *milieu intérieur*. Stress results in its increased activity, and many different physical or emotional insults could produce its overaction. At an age when the immature central nervous system may react to the stress of febrile or other incidents in certain children by convulsive seizures it seems at least plausible that the posterior hypothalamus may react to certain insults in certain predisposed subjects by prolonged and exaggerated activity on the part of the sympathetic system. Pink disease has been recorded in the course of Schüller-Christian disease, and was attributed to granulomatous irritation of the posterior hypothalamus (Stahlie and Winkel, 1950).

The physical signs of the condition, its resemblance to the effects of a phaeochromocytoma, and its response to ganglionic and adrenergic blocking agents are suggestive of such a mechanism.

The present investigation has shown that in infants suffering from pink disease the urinary excretion of sympathin may be greater than in normal control infants who were subjected to similar restraint during the period of urine collection. While these results indicate that sympathetic overaction can be present in children with pink disease, they do not provide evidence that this is invariably so. Definitive treatment of pink disease will require to be the treatment of the underlying case, whether that be toxic, infective, or emotional, but ganglionic and adrenergic blocking agents may be used to relieve symptoms by decreasing sympathetic tone.

Summary

The physical signs of pink disease and their response to adrenolytic substances suggest that they may be produced by an overacting sympathetic system.

Such babies may have a higher daily excretion of sympathin than controls of the same age.

Pink disease may represent the misdirected zeal of an inexperienced defence mechanism to a number of obnoxious stimuli in certain predisposed infants.

Our thanks are due to Professor R. W. B. Ellis and to Professor J. H. Gaddum for their advice and encouragement; to Professor Ellis, Dr. J. O. Forfar, and Dr. D. M. Douglas for permission to investigate cases under their charge; to Dr. H. P. Tait for granting permission to make urine collections in a number of the city residential nurseries; and to the nursing staff of these nurseries, of the Royal Edinburgh Hospital for Sick Children, and of the Edinburgh Northern Group of Hospitals who supervised this difficult task.

HYPERTHYROIDISM DEVELOPING DURING P.A.S. THERAPY

BY

S. TANDHANAND, M.D., F.C.C.P.

AND

R. BURI, M.D., D.T.M.&H.

Department of Medicine, Siriraj Hospital, University of
Medical Sciences, Thailand

Since the bacteriostatic effect of P.A.S. on tubercle bacilli in man was described by Lehmann (1946), its relative clinical value and toxicity have been amply confirmed. Among its many toxic effects one must include its effect on the thyroid gland. Medical reports on this subject are few. Madigan *et al.* (1950) were the first to mention an increase in skin temperature in patients who were receiving P.A.S. therapy, although the rectal temperature remained normal. They attributed the finding to the direct pharmacological effect of P.A.S. resulting in peripheral vasodilatation—an effect seen in febrile as well as afebrile patients. The increased heat loss in afebrile patients was compensated by an increase in the basal metabolic rate.

Komrower (1951) drew attention to the fact that P.A.S. was responsible for the thyroid enlargement in his patient, who developed clinical myxoedema during P.A.S. therapy over a period of about six months. Clausen and Kjerulf-Jensen (1951) reported somewhat similar findings in three cases, and four more cases were reported by Bergqvist and de Maré (1952). Further reports came from Librach (1952) and Davies and Galbraith (1953).

A series of 11 cases of thyroid enlargement during P.A.S. therapy was reported by Brinkman and Coates (1954) from the Trudeau Sanatorium, Trudeau, New York. Two of their cases developed myxoedema as well as thyroid enlargement. The enlargement appeared after 4 to 12 months' treatment with P.A.S., except in one case in which goitre appeared after seven weeks' treatment. In addition, Hamilton (1953) recorded an unusual finding of exophthalmos with a hyperplastic-hypothyroid type of enlargement.

The gradually increasing number of reports of the thyroid gland being affected during P.A.S. therapy are

all on the hypothyroid type. The following case presents the opposite picture—that is, hyperthyroidism, hitherto not mentioned, apart from the high basal metabolic rate alluded to by Madigan *et al.* (1950).

Case Report

A Thai married woman aged 32 attended the out-patient department for treatment of pulmonary tuberculosis in November, 1953. She had been treated by her doctor for the previous two years with apparently little improvement. Physical examination at that time proved the lesion to be in the left upper lobe, confirmed by x-ray examination. Sputum examinations were positive for tubercle bacilli. Her temperature was 37.7° C. (99.8° F.), pulse 118, respirations 24, and body weight 47.1 kg. (7 st. 5½ lb.). She was given P.A.S. (12 g. daily) and isoniazid ("rimifon") (300 mg. daily). After a pneumoperitoneum a few days later her condition improved steadily, and by December, 1954, her weight was 53.3 kg. (8 st. 5½ lb.), pulse 88, respirations 20, temperature 36.7° C. (98° F.), and sputum examinations were negative. However, she began to notice that her neck was somewhat enlarged, and by January, 1955, it was so obvious that she had to wear a scarf to conceal it. She felt easily tired, irritable, and hot even in relatively cool weather. Her weight dropped to 51.6 kg. (8 st. 1½ lb.) in spite of a voracious appetite.

The B.M.R. was +25.1%; cholesterol, 140.2 mg. per 100 ml.; neck measurement, 33 cm.; respirations 20; temperature 36.5° C. (97.7° F.); pulse 104. When the cause of the thyroid enlargement was realized P.A.S. was discontinued and streptomycin was given together with isoniazid. Subsequent to the withdrawal of P.A.S. the hyperthyroid state improved steadily—B.M.R. was +16.8%; cholesterol, 200 mg. per 100 ml.; neck measurement, 31 cm.—with no symptoms referable to hyperthyroidism. By November, 1955, the B.M.R. was +13.3% and the neck measurement 31 cm. (apparently her normal size).

Discussion

The clinical pattern and laboratory findings in this case leave us with no alternative but to conclude that P.A.S. caused thyroid enlargement and hyperthyroidism. It may be argued that the basal metabolism may be high even in afebrile cases, as previously noted by Madigan *et al.* in patients during P.A.S. therapy, but the fact that the B.M.R. changes in our case were correlated with blood cholesterol levels during and after cessation of the drug would be strongly in favour of hyperplastic hyperthyroidism. However, determinations of radioactive iodine uptake and of protein-bound iodine in the serum, especially the latter, could settle the problem, but unfortunately these were not available to us.

Isoniazid by itself is known to cause thyroid enlargement, but this was not the responsible factor in our case, as the drug had been given throughout the treatment period. Angel *et al.* (1955) discussed the role of P.A.S. in the production of thyroid enlargement with or without myxoedema. They investigated the iodine metabolism of the surviving thyroid slices, and were of the opinion that P.A.S. does not inhibit the accumulation of inorganic ¹³¹I in thyroid tissue, but is rather like thiouracil and somewhat weaker in action. P.A.S. inhibits the formation of di-iodotyrosine and thyroid hormone, and the action is a direct one, although the possibility of an additional indirect action cannot be entirely excluded. Macgregor and Somner (1954) and Brinkman and Coates (1954) found iodine ineffective in the relief of goitre due to P.A.S., but remissions of the symptoms and goitre were seen following the use of thyroid. Balint *et al.* (1954) reported some benefit from iodine.

The mechanism, outlined above, of the role of P.A.S. in the production of goitre does not seem to fit in with what happened in our case, undoubtedly a case of hyperthyroidism. It may be possible that in this case the P.A.S. in some way, (?) acting like thiocyanate, blocked the formation of thyroid hormone by excessive production of thyrotropin

leading to thyroid hyperplasia; instead of the gland behaving as in hypothyroidism, the patient's diet intake may have contained enough iodine to overcome the blockage by sudden excessive formation and release of thyroid hormone (Paschkis *et al.*, 1941). Alternatively, all the cases so far reported might have had a transient period of hyperthyroidism followed later by hypothyroidism, which might have happened in our case had we continued with the drug for a longer period.

Summary

A case of P.A.S.-induced hyperthyroidism is reported. An attempt is made to explain the mechanism. The literature on hypothyroidism and thyroid enlargement caused by P.A.S. is briefly reviewed.

GONADAL AGENESIS WITH TETANY AND SEVERE OSTEOPOROSIS

BY

T. J. GEFFEN, M.D., M.R.C.P.

Lately Registrar to the Medical Unit, University College Hospital

In 1938 Turner described a syndrome occurring in a group of 10 women, all of whom exhibited sexual infantilism, short stature, cubitus valgus, and webbing of the neck. Varney *et al.* (1942), reporting further cases, noted an increased excretion of urinary gonadotrophins. Albright *et al.* (1942) stressed the fact that the syndrome was associated with ovarian insufficiency, and that this was due to primary agenesis and was not secondary to pituitary hypofunction. In these and subsequent reports many further congenital abnormalities have been noted with varying frequency, and osteoporosis of a degree and distribution similar to that sometimes found in senile patients has often been observed. Much less commonly a similar syndrome has been described in men, and other cases have been seen in which one or more of the developmental abnormalities have been lacking.

One abnormality that has been found not infrequently in these patients is coarctation of the aorta. As this lesion occurs much more commonly in males, it seemed noteworthy to Polani *et al.* (1954) that it should be so often present in a group of people most of whom were women. They considered the possibility that their patients, though possessing genitalia of infantile female appearance, might in fact be genetic males. Animal experiments have shown that if the gonads are destroyed before sexual differentiation has occurred, the subjects will develop feminine genital tracts regardless of the true genetic sex (Jost, 1947). Polani and his group, using a method for sexing a subject by examination of the skin nuclei (Hunter *et al.*, 1954), found that three

apparently female patients with Turner's syndrome and coarctation of the aorta were in fact genetic males.

If, as seems likely from these findings, most patients with Turner's syndrome are males, it is not surprising that efforts to treat their "ovarian" agenesis by substitution therapy with female sex hormones have failed to be very satisfactory. It also now seems preferable to use the term "gonadal agenesis" to describe the condition.

In the following case the patient suffered from gonadal agenesis and spontaneous tetany of unknown immediate cause. In addition, marked generalized osteoporosis was noted radiologically. This combination does not seem to have been noted previously, and so seems to merit description even though no good cause for the association can be suggested.

Case Report

A domestic servant aged 25 was referred to Dr. C. E. Dent at University College Hospital by Dr. B. Miles, of Hereford, for investigation of her tetany. She had never menstruated, but, apart from this, had felt normal until 1953, when she began to suffer from episodes of painful cramps and stiffness of the hands and feet, infrequent at first but gradually becoming more common and more severe. By the beginning of 1955 severe attacks were occurring every two to three weeks. She had been well otherwise, apart from a respiratory tract infection two months before admission. Complete dental clearance, apparently for caries, had been carried out early in 1953. She said that she was the backward member of her family. Her parents were not related, and they and five siblings were well and of normal stature.

On examination she was a co-operative but rather simple patient (I.Q. 75), who looked older than her years. No abnormality was noted in the cardiovascular, respiratory, or alimentary systems. Her height was 60 in. (152 cm.) and her span 61 in. (155 cm.). There was no webbing of the neck, but the carrying angle was increased and slight ptosis was present. The axillary hair was sparse, but there was a growth of fine downy hair on the trunk and limbs. The nipples were infantile and there was complete absence of breast tissue. Although she did not exhibit tetany spontaneously while in hospital, Chvostek's and Trousseau's signs were always positive. She showed no tendency to overbreathe.

Mr. G. R. Clare, who examined the patient under anaesthesia, reported: "The labia majora were firm and of normal shape. On the medial surface the labia minora were represented by two small skin tags which were about 2 cm. long. The clitoris was anatomically normal but smaller than usual. The vestibule, remnants of hymen, and vagina were normal in size, but the vaginal skin looked less well oestrogenized than usual for a woman of this age. The cervix and body of the uterus were infantile, measuring 2.5 cm. from external os to fundus uteri. The ovarian ligaments were palpable on both sides. The distal part of these appeared thicker. No separate gonad was palpable. The whole appearance of the genital organs was one of marked hypoplasia except for the vagina, which was of normal size."

Investigations.—Plasma electrolytes: sodium, 146 mEq/l.; potassium, 4.55 mEq/l.; chloride, 102.5 mEq/l.; bicarbonate, 25.4 mEq/l.; calcium, 8.4–9 mg./100 ml.; inorganic phosphorus 4–5 mg./100 ml.; magnesium, 2 mg./100 ml. Alkaline phosphatase, 10.2 King-Armstrong units; blood pH determined by Dr. Wynn, St. Mary's Hospital, 7.45; blood urea, 21 mg./100 ml. Electrophoresis of the plasma proteins was normal apart from a slight increase of alpha-globulin. Electrocardiogram: prolonged QTc (0.45 second) and T wave inversion in leads II and III and V₁–5. The patient absorbed 95% of her dietary fat in a five-day period. The 24-hour urinary output of 17-ketosteroids,

HAEMOLYTIC ANAEMIA IN SICKLE-CELL TRAIT

BY

A. A. CHAZAN, M.B., Ch.B.

Senior Registrar

AND

J. G. A. MCSORLEY, M.B., M.R.C.P.Ed.

Consultant Haematologist

Group Laboratory, Whittington Hospital, London

It is generally accepted that cases of sickle-cell trait show no haematological abnormality other than sickling (Chernoff, 1955). Edington and Lehmann (1955), however, suggested that the trait itself may be "by no means harmless," and ascribed the cause of death in an African woman with the sickle-cell trait to a haemolytic crisis, possibly precipitated by a superadded infection. Griffiths (1955) has referred to a sickle-cell crisis occurring in a case of sickle-cell trait during pregnancy. No details were given.

We give below an account of a patient with the sickle-cell trait in whom a haemolytic episode developed during a superadded infection.

Case Report

The patient, a 35-year-old Jamaican, was admitted to Whittington Hospital on February 17, 1955, complaining of general malaise and cough. Three days before admission he felt cold and hot in turn and had vague body pains. On the day before admission he had difficulty in breathing and developed a pain in the right side of his chest, with a cough which produced a small amount of white phlegm.

His previous history was difficult to obtain; all that could be elicited was that he had landed in England from Jamaica five months previously, that he had suffered from unspecified "fever" in his home country, and that he had been working with a fellow Jamaican who had a cough which produced a bloodstained sputum for which he was being treated as an out-patient at another hospital.

Physical examination showed the patient to be a well-nourished negro with a temperature of 105° F. (40.6° C.), pulse 100, and respiration rate 24. Examination of the chest suggested consolidation at the bases of both lungs, with scattered rales and crepitations over the lung areas. Abdominal examination revealed a barely palpable spleen. Examination of the other systems was negative.

Special Investigations.—The initial blood count was: Hb. 60% (8.9 g.); red cells, 3,110,000 per c.mm.; P.C.V., 28%; M.C.V., 93 cubic microns; M.C.H.C., 32%; reticulocytes, 4%; white cells, 3,100 per c.mm. (Standard techniques as in Wintrobe, 1951.) Examination of the blood film showed marked anisocytosis and increased polychromasia of the red cells. Some target cells, "raspberry"-shaped and spiculated forms, together with one normoblast, were seen. A sickling test with 2% sodium bisulphite was positive in 10 minutes. The E.S.R. (Westergren) was 9 mm. in one hour. The serum bilirubin was 1.4 mg. per 100 ml. and the urine contained a great excess of urobilinogen. The direct Coombs test, cold agglutinin test, and specific haemolysis tests were negative. Complement-fixation tests with the antigens of influenza A and B, psittacosis, and Q fever were persistently negative, and the M.G. streptococcus titre was negative at 1 in 4. The Wassermann reaction and Kahn test were negative. Paper electrophoresis of a haemoglobin solution (barbitone buffer pH 8.6, 0.06 M solution) revealed a pattern of haemoglobin A plus haemoglobin S, the latter pigment comprising one-quarter to one-third of the total haemoglobin mass. Foetal haemoglobin tested for by the alkali denaturation technique (Singer *et al.*, 1951) was 0.12% (within normal limits). No other abnormal haemoglobins could be demonstrated. Sternal marrow showed slight hypoplasia with active normoblastic erythropoiesis. The myeloid series and

17-ketogenic steroids, and 17-hydroxysteroids (determined by Dr. J. D. Nabarro) was within normal limits. The 24-hour urinary output of gonadotrophins was between 20 and 80 mouse units. Reports on vaginal smear (Dr. G. I. M. Swyer): "Mainly mucus and debris. The few cells are of basal type—that is, very hypo-oestrogenic."

Bone x-ray films showed delayed epiphyseal fusion. There was marked diffuse osteoporosis affecting both central and peripheral bones. This was most gross in the pelvic bones, spine, and long bones of the limbs, but the skull and small bones of the hands and feet also showed definite though less marked changes. There was no specific evidence of osteomalacia or hyperparathyroidism—that is, no signs of cyst formation or subperiosteal erosion and no Looser's zones. Report on biopsy from cortex of tibia (Dr. H. Sissons): "Osteoporosis. The cortex is thinned but is otherwise normal. No evidence of osteomalacia is present, and the histological appearance of the intracellular matrix of the bone is normal."

The patient's genetic sex was determined by Dr. Swyer by examination of the skin nuclei and those of the polymorphonuclear leucocytes, and proved to be male.

Course and Treatment.—In an attempt to exclude an endocrine deficiency as the cause of the tetany, methyl-testosterone, 20 mg. daily for two periods of six days, and stilboestrol, 2 mg. daily for two periods of six days, were given. The calcium and phosphorus levels rose and fell slightly during this time, but the changes did not seem to be related to the treatment. The simultaneous calcium balance study also showed no significant changes, but was unfortunately very inaccurate owing to curious fluctuations in bowel function. Neither form of therapy nor the raising of the plasma calcium level to 9.7 mg./100 ml. with intravenous calcium gluconate succeeded in abolishing the Chvostek or Trousseau sign.

Discussion

There can be little doubt that this patient has gonadal agenesis in association with some of the other congenital defects of Turner's syndrome. Although such patients not infrequently have osteoporosis limited to the spine, infrequently have osteoporosis such as this has not generalized and marked osteoporosis as this has not been mentioned, nor has the tetany. In the few cases in which serum calcium levels have been recorded they have been normal or slightly raised, as found by Albright *et al.* (1942).

The cause of this patient's tetany remains obscure. Although the serum calcium level was somewhat low, it was hardly low enough to produce tetany without the operation of some additional factor. Also the tetany persisted even when the calcium level was raised almost to normal. None of the other known causes of tetany was apparent in this case.

Although it seems reasonable to suppose that the co-existence of the rare condition of gonadal agenesis with the equally rare conditions of marked clinical tetany and generalized osteoporosis could hardly be a chance occurrence, no cause for the association could be shown.

Summary

A case of gonadal agenesis is described in which, in addition to many of the usual features, spontaneous tetany and generalized osteoporosis also occurred. No metabolic explanation for this association can be offered.

I am grateful to Dr. C. E. Dent, in whose department the balance studies were performed, for permission to publish this case and for assistance with the preparation of this paper.

megakaryocytes were normal and there was a small increase in plasma and reticulum cells. No abnormal cells were seen. Culture of sputum yielded a growth of *Staph. aureus* sensitive to penicillin, chlortetracycline, chloramphenicol, and streptomycin. Blood culture yielded a coagulase-negative staphylococcus. Acid-fast bacilli were not detected in sputum, gastric washings, laryngeal swabs, or faeces. C.S.F. was normal and the Widal reaction was negative.

Despite treatment with "estomycin" there was no improvement in the clinical condition, but within 48 hours of starting chloramphenicol the patient felt better and his temperature returned to normal. The temperature stayed normal for only 48 hours on chloramphenicol alone and estomycin was restarted and chloramphenicol stopped. Two pints (1,140 ml.) of blood was transfused on February 26 as the haemoglobin had fallen to 52% (7.7 g.). The serum bilirubin indirect reaction was 1 mg. per 100 ml. on February 19 and increased amounts of urobilinogen continued to be excreted in the urine for a period of three weeks. The temperature continued to swing wildly, and on February 27 signs of an effusion developed over the right lower lobe. Paracentesis was performed and the fluid showed small numbers of leucocytes—almost all lymphocytes—with large numbers of red cells. No bacteria were seen in the films stained by the Ziehl-Neelsen method. Routine and Löwenstein-Jensen cultures were sterile. The patient's general condition improved slightly, but the chest signs remained unchanged. On March 16 signs of bilateral iridocyclitis developed.

Further Investigations.—X-ray examination of the chest on March 29 showed fine diffuse miliary foci throughout both lungs, and the appearances were reported as being suggestive of acute miliary tuberculosis. The E.S.R. was 30 mm. in one hour and the Mantoux test was positive at 1 in 1,000. On April 1 the total serum proteins were 6.4 g. per 100 ml. with an albumin:globulin ratio of 0.7:1. Paper electrophoresis of the serum proteins showed a marked increase in globulin. The serum calcium was 11 g./100 ml. and Sulkowitch's test on the urine showed moderate amounts of calcium. Liver biopsy was carried out on April 7, and this was reported on by Dr. C. C. Bryson as showing slight focal chronic inflammatory reaction, fine pericellular fibrosis, and one minute "miliary" epithelioid focus.

On cortisone, isoniazid, and streptomycin the patient's lung condition had practically cleared after one month, but the iridocyclitis was still active. The E.S.R. was now 6 mm. in one hour. The mean corpuscular fragility test (Parpart *et al.*, 1947), which was carried out on May 2 (65 days after transfusion), was 0.375% NaCl equivalent (normal range 0.400 to 0.438% NaCl). On June 13 the peripheral blood picture was as follows: Hb, 100% (14.8 g.); white cells, 6,700 per c.mm. (neutrophil polymorphs 82%, eosinophil polymorphs 1%, lymphocytes 15%, monocytes 2%); platelets, 213,000 per c.mm.; film: normal. No haematological abnormality other than sickling could now be detected.

Discussion

In thalassaemia minor, infection, sometimes of an obscure nature, has been reported to be associated with decreased activity of the bone marrow and a drop in the haemoglobin level steeper than usual, while during periods of freedom from infection the drop in haemoglobin level is more gradual (Matoth *et al.*, 1955).

Weiss (1953) concluded that the sickle-cell trait was associated with a significantly increased incidence of the acute exudative form of pulmonary tuberculosis in American negroes, and stated that "the sickle-cell trait, ordinarily of no particular importance, may assume clinical significance in relation to other disease states." However, Vandepitte *et al.* (1953) could not confirm this association in Africans in the Belgian Congo.

Edington and Lehmann (1955) question the accepted view that the sickle-cell trait is a benign congenital anomaly and refer to the finding of haematuria due to pathological

lesions in the kidneys in such cases. In their case of sickle-cell trait death was due to haemolytic crisis and septicaemia associated with the expulsion of a hydatidiform mole in a 23-year-old woman. Post-mortem histology revealed the characteristic findings of a sickle-cell crisis. They considered that "the terminal crisis was probably initiated by the septicaemic condition and was directly responsible for death."

In the case referred to by Griffiths (1955) a sickle-cell crisis occurred in a case of sickle-cell trait during pregnancy. In a personal communication Griffiths confirms that "gross intravascular haemolysis" was present and that other possible causes of haemolysis were not demonstrable.

In our case a haemolytic anaemia developed in a patient with sickle-cell trait during an infection. This anaemia was probably precipitated by the intercurrent disease—sarcoidosis or (atypical) tuberculosis. It is significant, however, that changes in red-cell morphology in the first blood film suggested the need for a sickling test. It is appreciated that both sarcoidosis and miliary tuberculosis *per se* can (rarely) be associated with a haemolytic anaemia. Nevertheless in view of the findings of Edington and Lehmann (1955) and Griffiths (1955) it seems reasonable to suggest that the red cells in cases of sickle-cell trait may be more susceptible to haemolytic mechanisms during intercurrent infections or pregnancy. If this assumption is correct other similar cases should soon be reported.

It is, of course, possible that this man was a heterozygote for the thalassaemia gene and that he was symptomless until under increased stress sickle-cell thalassaemia disease became manifest. We consider this possibility as virtually excluded—though of course only a family study could give a decisive answer—for the following reasons: foetal haemoglobin was absent, the adult haemoglobin was present in a considerably greater proportion than the sickle-cell haemoglobin, and the fragility was only slightly decreased, being of the same order as seen by us in two other cases of sickle-cell trait. There are few references to accurate osmotic fragility tests in cases of sickle-cell trait. Chernoff (1955) states that the osmotic fragility is normal in sickle-cell trait and "somewhat decreased" in sickle-cell anaemia. We have since found a low normal fragility (0.400%) and a decreased fragility (0.382% NaCl) respectively in two further cases of asymptomatic sickle-cell trait. These cases had no anaemia and were discovered only on routine sickling tests. Electrophoretic and foetal haemoglobin studies showed them to be apparently simple S-trait cases. It appears that more observations on the osmotic fragility test in sickle-cell trait cases should be made. In any case, it would appear that we can no longer accept the view that the sickle-cell trait is a harmless anomaly unassociated with anaemia or morphological changes in the red blood cells under all conditions.

We wish to thank Dr. H. E. S. Pearson, physician in charge of the case, Miss M. Crowley, biochemist, and Miss A. Wallace, senior technician.

The National Association for Mental Health has established a public information committee under the chairmanship of LORD FEVERSHAM. Its objects are to acquaint the public with the possibility of preventive measures against mental illness, the need for education in principles of mental hygiene, and "the great need to stimulate and support programmes of research in the mental health field." The committee includes psychiatrists, educationalists, and others.

Medical Memoranda

Perforating Wound of the Portal Vein

Injuries to the portal vein following abdominal trauma are rare. Santos and Carichio (1950) discovered reports of 20 such cases, and in three of these the portal vein had been injured by a gunshot wound of the abdomen (Hallopeau, 1910; Romanis, 1916, 1916-17; Giorgi, 1920, 1921). In a personal communication Sir Gordon Gordon-Taylor also recalls a case of portal vein injury during the 1914-18 war. A case of perforating injury of the portal vein following an abdominal wound by an industrial gun is reported because of its rarity and the unusual missile.

CASE REPORT

A man of 38 was admitted to hospital one hour after accidentally shooting himself in the upper abdomen with a cartridge-fired nail-gun, which is used in the housing industry and is able to drive a 1½-in. (4.4-cm.) nail through a railway sleeper. In this instance the nail passed through the upper abdomen and loin and then pierced both the ceiling and the roof of the house in which the accident took place. He became shocked within a few minutes of the accident and developed pain in both shoulders while being conveyed to hospital.

On examination he showed classical signs of gross internal haemorrhage and shock. His blood pressure was 55/30. In the middle of the epigastrium was a ½-in. (1.3-cm.) charred puncture wound, and a small ½-in. (0.6-cm.) exit wound was found in the loin just to the right of the first lumbar vertebra. Upper abdominal tenderness and guarding, with a positive release sign, was present. Bowel sounds were heard and rectal examination was negative.

Immediate resuscitation with dextran and blood was begun, and antitetanic and anti-gas-gangrene serum, along with penicillin and streptomycin, were given.

Chest x-ray films were normal and x-ray examination of the abdomen showed no free gas under the diaphragm, no foreign body, and no bony damage to the lumbar spine. A provisional diagnosis of intraperitoneal haemorrhage due to liver injury was made. After transfusion with 3 pints (1,700 ml.) of blood, the patient's condition had improved sufficiently for him to undergo operation.

Operation under general anaesthesia was begun three hours after wounding. The exit wound of the back was excised and sutured. The patient was then turned over and the abdomen was opened by an upper midline incision and the puncture wound excised. A large quantity of dark fluid blood was immediately encountered in the peritoneal cavity and 3 pints (1,700 ml.) was aspirated. There was a small penetrating wound on the upper aspect of the neck of the pancreas. On opening the lesser sac no blood was found. Reflection of the upper border of the neck of the pancreas to expose the source of the retroperitoneal haemorrhage produced brisk venous haemorrhage, which was controlled by digital pressure. Mobilization of the duodenum and pancreas was carried out to expose the portal, splenic, and superior mesenteric veins. Two oblique lacerated wounds some 7-8 mm. in size were found on the anterior and posterior surfaces of the portal vein at the point of junction of the three great veins. After exposure of the site of injury haemorrhage could be controlled only by digital compression, and the assistance of a second surgeon became necessary. Linen tapes and bulldog clips could then be applied to the three major vessels with satisfactory control of the haemorrhage. The perforations were closed with

an atraumatic, continuous, everting fine silk arterial suture. The suture lines were "watertight" on removal of the controlling clips and tapes.

Further exploration revealed no injury to adjacent structures or to any other contents of the abdomen. The puncture wound of the liver was excised and sutured. The upper abdomen was drained and the incision closed in layers.

The patient's condition at the end of the operation was satisfactory. Six pints (3,400 ml.) of blood was administered intravenously during the operation to replace blood loss.

Post-operatively, he was maintained on intravenous infusions, gastric suction, and heavy dosage of penicillin and streptomycin. No anticoagulants were used. He made steady progress for 48 hours after operation, when he had sudden pain in the right hypochondrium and a rigor with a temperature of 104° F. (40° C.). The only abnormal finding was some tenderness in the right hypochondrium. The chest was clear clinically and radiologically. A retroperitoneal infection was considered the most likely cause of his symptoms, and intravenous chlortetracycline was given for three days. Blood culture taken at this time proved sterile. He subsequently ran a low-grade pyrexia, and three days after operation he developed jaundice, which lasted for six days. A further rigor, with a temperature of 103° F. (39.5° C.), occurred on the ninth day, and intravenous chlortetracycline was again used, for five days. The haemoglobin had now fallen to 56%, and after transfusion with 2 pints (1,140 ml.) of blood it rose to 68%. A minor rigor occurred on the eleventh day, but thereafter the temperature fell to normal. The most likely explanation of these rigors was that a low-grade portal pyaemia developed after injury and suture of the portal vein.

Subsequent progress was uneventful and he was discharged from hospital one month after operation. When last seen, six months after operation, his haemoglobin was 100%, and all liver function and blood chemistry values were normal.

COMMENT

Four similar cases have been reported in the literature. In 1910 Hallopeau successfully repaired a gunshot wound of the portal vein in a 35-year-old woman. In 1920 Giorgi reported a similar case in a 35-year-old man, but the patient died five months later from an ascending urinary infection. During the 1914-18 war Gordon-Taylor successfully dealt with a portal vein injury in a soldier. Romanis (1916, 1916-17) had a case similar to that of Gordon-Taylor, but although repair of the portal vein was successful the patient died on the ninth post-operative day from a secondary haemorrhage from an eroded renal artery. In all the cases quoted above the wound involved only one surface of the portal vein.

Although laceration of the portal vein is a serious injury it is of note that none of the patients died as an immediate result of the injury. This is all the more remarkable, as four of the cases occurred between 1910 and 1920, when facilities for transfusion were almost non-existent. The fact that the patients were 38 years of age or younger probably played an important part in their survival. Santos and Carichio (1950) believe that portal vein bleeding is tolerated better than other forms of haemorrhage.

The present case is unusual in that the missile pierced both the anterior and posterior surfaces of the portal vein and so double suture was necessary.

The treatment of a linear wound of the portal vein where no loss or destruction of the vein wall has occurred is best carried out by suture. This method was used successfully in three of the five cases. Where a defect of the vein wall exists operative repair presents a difficult problem, as suture may unduly narrow the lumen. Moreover, ligation of the portal vein in man for periods longer than 20 minutes is

said to be fatal except in hepatic cirrhosis (Thole, 1939). A vein graft may not be immediately available to repair such defects of the vein wall.

Operating upon dogs, Csillag *et al.* (1953) have successfully repaired 20-mm. defects of the portal vein by suturing a serosal covered loop of bowel over the defect. They think that this method may be life-saving in cases of traumatic defects of the great abdominal veins in humans.

We thank Mr. H. Gordon Ungley for permission to publish this case and for his help and advice in the preparation of this article, and Sir Gordon Gordon-Taylor for kindly allowing us to publish details of a personal case of portal vein injury and for helpful criticism.

Intestinal Obstruction as a Late Complication of Fibrocystic Disease of Pancreas

The three main clinical types of fibrocystic disease of the pancreas were first clearly distinguished by Dorothy Andersen in 1938. They are: (1) intestinal obstruction in the newborn infant; (2) persistent respiratory disorders in the young baby; and (3) the "coeliac syndrome" with wasting, failure to thrive, and fatty stools in the young child.

The separation of the disorder into these three groups raises the interesting question why they tend to occur in different age groups, and especially why intestinal obstruction should be comparatively common in the neonatal period yet very rare later. In 18 of Bodian's (1952) 116 cases of fibrocystic disease of the pancreas neonatal obstruction (meconium ileus) occurred; yet in none of his case records is there a description of intestinal obstruction occurring after early infancy. In the literature describing some hundreds of cases I have been able to find only two instances of this complication. The first (Levy, 1951) was in an infant of 7 months on whom laparotomy was done; the tentative diagnosis of intussusception was not confirmed, and at the subsequent necropsy it was demonstrated that the intestinal obstruction had been caused by putty-like material blocking the small bowel. The second (Fisher, 1954) occurred at 15 months of age, and in this case the obstruction was relieved successfully by ileostomy and pancreatin therapy.

The following report describes a case in which intestinal obstruction, occurring at 16 months, was overcome by medical treatment.

CASE REPORT

A baby girl was first admitted to hospital at 9 weeks with a history of failure to thrive despite her good appetite. She was the second child of healthy parents whose first child had died at 2 years from "pneumonia and coeliac disease." The diagnosis of fibrocystic disease of the pancreas in the present case was made from the typical clinical appearance, and was confirmed by the absence of trypsin from specimens of faeces and duodenal juice. She was discharged home, much improved, at 3½ months on a dried milk

preparation with pancreatin granules, 10 gr. (0.65 g.) before each of five feeds daily. With only one mild and temporary relapse at 5½ months, when the dosage of pancreatin was increased, she remained well until her present admission to hospital at the age of 16 months.

The recent history was of mild upper respiratory infection two weeks before admission, when the child seemed "off colour" and lost her appetite. Two weeks later she became absolutely constipated and had one small food vomit. Because of the anorexia no further pancreatin was given by her mother. The following day two very small hard lumps of faeces were passed, but two days later glycerin suppositories and two enemata produced no faeces or flatus and she was then admitted to hospital.

On examination she was a rather underweight and irritable child with bouts of abdominal pain. The abdomen was distended and resonant, with audible bowel sounds but no visible peristalsis. A mass was palpable in the right iliac fossa, rather vague in outline and doubtfully indentable. The rectum was empty and no blood or mucus was passed. A barium enema showed a filling defect in the caecum, thought to be either a faecal mass or, less probably, an ileocolic intussusception. As the patient's general condition was good, it was decided to keep her under observation for some hours. On the following morning she started to vomit large quantities of dark brown fluid, and hourly gastric aspiration with intravenous glucose and saline drip was instituted. Laparotomy was now decided upon, but was postponed until adequate hydration had been restored. That evening a small amount of flatus was passed per rectum and operation was further postponed. Olive oil enemata were given four-hourly, alternating with oral pancreatin, 40 gr. (2.6 g.) four-hourly, and were well tolerated throughout the night. Next day five dark yellow sticky stools were passed, with consequent relief of abdominal distension. Oral fluids were now tolerated and intravenous infusion was discontinued. A course of chlortetracycline was given for the respiratory infection. She continued to have three or four soft stools each day, and her recovery thereafter was uneventful.

COMMENT

In this case of fibrocystic disease of the pancreas early acute intestinal obstruction occurred at 16 months. It was evidently caused by inspissation of small-bowel contents and is presumed to have been due to the omission of pancreatin during an acute infection. This state of affairs is symptomatically analogous to meconium ileus in the newborn. One wonders if there is some difference between faeces and meconium to account for the markedly different incidence of intestinal obstruction in neonates and in older children; and, also, what part pancreatin does in fact play. It appears from the three reported cases that in inadequate dosage it may precipitate obstipation, and yet some children with fibrocystic disease of the pancreas do not obstruct although they have never had pancreatin.

The necessity for surgery in these cases seems to depend on the evidence for and against intussusception. In our case there had been no blood passed per rectum and the x-ray appearances were more typical of faecal obstruction than of intussusception. The child's good general condition allowed us to temporize, and a medical regime of oral pancreatin and oil enemata rapidly relieved the obstruction.

I am grateful to Dr. John Apley for permission to publish this case and for all his help.

Reviews

NURSING OF THE NEWBORN

Nursing Care of the Newly Born Infant. By W. S. Craig, B.Sc., M.D., F.R.C.P.Ed., M.R.C.P., F.R.S.E., in collaboration with M. F. G. Buchanan, M.B., Ch.B., M.R.C.P., D.C.H., R. J. Pugh, M.B., Ch.B., M.R.C.P., D.C.H., and Miss M. Pattullo, R.G.N., S.C.M. Chapter on Mothercraft contributed by Miss M. J. W. Taylor, R.G.N., S.C.M., M.T.D. (Pp. 472+viii; illustrated 35s.) Edinburgh and London: E. and S. Livingstone. 1955.

The outstanding feature of this well-produced volume is its illustrations, of which there are no fewer than 224. The book is intended primarily for pupil midwives and should prove extremely valuable to them and, indeed, to all paediatric nurses and others who have to care for the newborn. Stress is laid on the development of the normal infant, and the pathological conditions are dealt with subsequently. The physiology and pathology of breast-feeding are clearly explained and the principles of nutrition well discussed. Minor disorders—a very important section—trauma, congenital malformations and infections follow, and then a chapter on the care of the premature infant. The last four chapters are devoted to selected clinical problems, the treatment of emergencies, selected nursing problems, and laboratory and therapeutic aids.

It is unfortunate that the dose of vitamin K advised is 5 mg. four-hourly—which is certainly a dangerous overdose for any premature baby. The illustration of a subcutaneous infusion shows the fluid being given by syringe into the axilla, and it is suggested that hyaluronidase should be added to the fluid before administration. This is not the best method. In discussing oxygen therapy no mention is made of retrolental fibroplasia, nor is there any instruction about controlling the oxygen tension. Resuscitation is thoroughly considered, and the overriding importance of gentleness is stressed repeatedly. However, in case the midwife's patience gives out, insertion of a finger into the baby's mouth, artificial respiration, mouth-to-mouth insufflation, and smart tapping of the buttocks are all recommended, and intragastric oxygen is to be preferred, few midwives will have this available and may therefore be tempted to apply these other remedies, which may be to the detriment of the infant. Professor Heaf is misnamed Heath, and the reference to vaccination in the index is given as p. 426, but there is no mention of the subject there. Apart from these and a few other minor considerations the book is to be thoroughly recommended.

WILFRID GAISFORD.

AMINO-ACID METABOLISM

A Symposium on Amino Acid Metabolism. Sponsored by the McCollum-Pratt Institute of the Johns Hopkins University. Edited by William D. McElroy and H. Bentley Glass. (Pp. 1,048+vi; illustrated. £5.) Baltimore: Johns Hopkins Press. London: Oxford University Press. 1955.

This volume consists of papers by some 80 contributors, and discussions on these, presented at a symposium on amino-acid metabolism held at the Johns Hopkins University, under the sponsorship of the McCollum-Pratt Institute, on June 14-17, 1954. A feature in the planning and publication of these contributions was the selection of one or two participants who would summarize the present state of knowledge of the metabolism of a group of closely related amino-acids. The book is arranged according to these various groups and in the order in which they were presented at the symposium. Thus under Part 1 is a general consideration of amino-acid metabolism; Part 2 includes the metabolism of glutamic acid, proline, ornithine, citrulline, and arginine; Part 3, the metabolism of histidine, leucine,

isoleucine, valine, and lysine; Part 4, the metabolism of methionine, cysteine, and threonine; Part 5, the metabolism of glycine and serine; Part 6, the metabolism of aromatic amino-acids; and finally there is a summary by Dr. Bentley Glass.

Our understanding of the expanding interrelationships of the several groups of amino-acids probably constitutes the most outstanding feature of recent advances in amino-acid metabolism. From the beginning to the end of the symposium great stress has been laid on the numerous transaminations that occur and on the amino-acid pool, to which at least sixteen amino-acids contribute. But these form only part of the interrelationships where glutamic and aspartic acids stand at a crossroad from which, as Bentley Glass states, "there radiate the connections between the tricarboxylic acid cycle and the ornithine-citrulline-arginine cycle; and the proline-hydroxyproline pathway projects from glutamic acid in yet another direction." Then histidine connects on the one hand with pentose metabolism, and in its own demise participates in the synthesis of the nucleotides and of the new methyl groups needed in making methionine, choline, etc.; while in a third connexion it links back to the crossroads where stands glutamic acid. Valine, leucine, and isoleucine are synthesized by parallel and interconnecting paths, and through their degradation terminate in aceto-acetate, fatty acid metabolism, and the Krebs cycle. In their synthesis valine and isoleucine are tied up to threonine and homoserine, and through the latter to the complex consisting of the methionine-homocysteine-cystathionine-cysteine-homoserine group. Lysine metabolism also hinges round glutamic acid as the nodal point. The aromatic amino-acids trace back to the carbohydrates, and in their degradative metabolism they are assembled into pigments, hormones, auxins, and vitamins. And so one could go on, for the number of different amino-acids is now over the 50 mark. This symposium also demonstrated that we now have a deeper insight into the mechanism of action of various coenzymes, in particular of folic acid derivatives. One of the most important discoveries is the ferrous-sulphydryl type of enzyme.

This is a book for the biochemical specialist written by an international group of experts but presented in a very readable form. The editors and the publishers are to be congratulated on an outstanding production.

D. P. CUTHBERTSON.

SURGICAL DIAGNOSIS ILLUSTRATED

Surgical Diagnosis. By Philip Thorek, M.D., F.A.C.S., F.I.C.S. Drawings by Carl T. Linden. (Pp. 320+xi; illustrated. 96s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. 1956.

This is a very unusual book, both from the brevity of its text and the profusion of its illustrations. To have covered the whole subject of surgical diagnosis in 300 pages is a remarkable feat, but to have provided illustrations which might almost replace the text is even more remarkable. Still the more remarkable is the fact that both are so good. The author has a quite exceptional power of compressing all the essentials of description in the briefest possible space; the artist has an equal power of expressing the descriptions in visual forms. It is a very rare and happy combination.

The book might perhaps be best described as a luxury synopsis—a gold mine to the senior student, or still more to the experienced surgeon who wishes to refresh his knowledge with a minimum of effort. To the ordinary student it would be somewhat of a snare, for the science and practice of surgery cannot be learnt from pictures, even of this quality. But later on when he comes to revise the knowledge and the greater his experience the more will he appreciate at their true value the cogency of the text and the superb artistry of the illustrations.

GLUCAGON

Soon after the discovery of insulin it was noted that certain extracts of the pancreas might induce a rise rather than a fall in the level of blood sugar when injected intravenously into animals. The name glucagon was applied to this hyperglycaemic factor of the pancreas as early as 1923.¹ Since then many commercial preparations of insulin have been shown to contain this factor, especially American preparations. British and Danish preparations are crystallized by a different method and are free of hyperglycaemic activity.²

Glucagon can be extracted from the pancreas of various mammals,^{3,4,6,8} including man,⁷ and also from the gastric and duodenal mucosa^{3,4,8} and from the abdominal lymphatics and spleen.⁸ A similar substance has been isolated by some workers from the urine of normal human beings,⁹ from diabetic patients, and from the urine and blood of animals made diabetic with alloxan,¹⁰ though others have not confirmed this.⁷ Glucagon appears to be an endocrine secretion of the pancreas. It is not found in the external secretion³ and can still be recovered in normal amounts after ligation of the pancreatic duct^{3,4} and after destruction of the β -cells of the islets by alloxan.^{3,4,6} This suggests that it may be secreted by the α -cells. The suggestion is supported by the occasional occurrence of familial hypoglycaemia in infants with otherwise normal endocrine and hepatic functions, in whom no α -cells can be found and in whom there is no hyperplasia or adenoma of the β -cells.¹¹ Conversely, hyperplasia of the α -cells is found

in a strain of mice with hereditary obesity and hyperglycaemia.¹² Conclusive proof of the origin of glucagon from the α -cells is, however, still lacking. Treatment with cobaltous chloride damages or destroys α -cells but reduces the glucagon content of the pancreas only partially¹³ or not at all.^{8,14} Synthalin A is said to destroy α -cell function more completely and to lead to hypoglycaemia.¹⁷

Glucagon is a polypeptide, similar to insulin in its physical properties but differing in its amino-acid content.¹⁸ It has recently been crystallized.¹⁹ Its primary action is to stimulate phosphorylase activity in the liver, thus increasing glycogenolysis and leading to hyperglycaemia.³ There are several reasons for regarding the liver as the primary site of action of glucagon. Glycogenolytic activity can be demonstrated in liver slices.³ The effect of glucagon *in vivo* is greater when it is injected directly into the portal circulation than after intravenous injection.²⁰ After intravenous injection of glucagon in man the glucose content of the hepatic vein is raised more abruptly than the peripheral venous content.²¹ The effect of glucagon is enhanced when the liver glycogen content is high¹⁶ and is depressed when this is reduced in animals by a prolonged fast^{4,6} or in man by hepatic cirrhosis.²¹ The hormone is without effect in animals after removal of the liver.^{4,6,22} The action of glucagon is impaired in the presence of diabetic ketosis in animals, again probably as the result of reduced glycogen in the liver.²⁴ In man, labile diabetics are inclined to show less response to intravenous glucagon than obese diabetics or normal people,^{25,26} but this is not invariably so.⁵

The precise role of glucagon in the regulation of carbohydrate metabolism and in the pathogenesis of diabetes mellitus is not fully understood. It is not antagonistic to insulin, in the sense that it does not inhibit the peripheral utilization of glucose²⁷; rather, the two hormones seem to act in synergism. Perfusion experiments on the pancreas²⁸ and experiments involving anastomosis between the pancreatic circu-

lation of one animal and the systemic circulation of another²⁴ suggest that the secretion of both hormones is regulated by the blood-sugar level and that their activity is reciprocal. Secretion of glucagon is stimulated by hypoglycaemia and secretion of insulin by hyperglycaemia. Irregular oscillations in the fasting level of blood sugar have been observed in man and in the dog. The venous level falls as the arterial level rises and vice versa, suggesting that the fluctuations are related to the supply and utilization of glucose. The fluctuations are abolished by eviscerating the animal, thus depriving it of all sources of glucagon, and are restored by injecting glucagon, but they are unaffected by abolishing adrenal medullary activity with ergotamine and by removing the adrenal glands.²⁹ It has been suggested that the main function of glucagon is to make the liver glycogen stores available for insulin activity at the periphery, but if insulin is absent or is present in relatively low concentrations glucagon may actually promote deposition of glycogen in the liver, since its effect upon phosphorylase activity is reversed in the presence of high concentrations of glucose.⁶ There is also evidence that glucagon may be concerned in the satiety mechanism, since gastric motility and hunger sensations can be depressed by intravenous administration in man.³⁰

The diabetic state resulting from total pancreatectomy in man or in animals is less severe and requires smaller doses of insulin than severe spontaneous diabetes mellitus or diabetes due to alloxan.^{31,32} Moreover, dogs from which 90 to 95% of the pancreas has been removed require more insulin than those subjected to total pancreatectomy.³³ Again, spontaneous diabetes in man and alloxan diabetes in animals improve after total pancreatectomy, and sensitivity to insulin increases.^{34,35} These phenomena suggest that the secretion of glucagon by the α -cells persists in the pancreas of human diabetics and of animals with alloxan diabetes, and that the removal of this hyperglycaemic influence explains the benefit which results from subsequent removal of the pancreas. Whether glucagon is important in the pathogenesis of diabetes mellitus is quite another matter. Only when given by intravenous infusion does it enhance the glycosuria of animals subjected to partial pancreatectomy, and even then the effect is transient.²³ Even high doses of glucagon given over a long period do not induce diabetes mellitus.³⁶ Finally, there is no significant difference in the glucagon content of the human pancreas at necropsy as between diabetic and non-diabetic subjects.⁷

The relationship of glucagon to pituitary growth hormone is pertinent to its possible role in diabetes

mellitus. The administration of growth hormone has been shown to liberate glucagon into the portal blood in animals^{24,37} and to produce a transient hyperglycaemia in man.³⁸ The hyperglycaemic substance found in the urine of normal animals disappears after hypophysectomy.⁹ There is also evidence that the α -cells are influenced by the growth hormone. They diminish in number and size, at least temporarily, after removal of the hypophysis, while the β -cells are unaffected,³² and in mice with hereditary obesity and hyperglycaemia the hyperplasia of the α -cells is abolished by the same procedure.¹² α -Cells predominate over β -cells in the embryo; the proportions are equal in the newborn, and with advancing childhood the ratio of α -cells to β -cells gradually falls, reaching 1:4 by the end of the growth period. In human diabetics α -cells predominate, especially in childhood, but the disproportion is not as great as in diabetes due to alloxan in animals, and the proportion of α -cells varies from case to case and does not parallel the severity of the diabetes nor the requirements of insulin.³² Though administered growth hormone is undoubtedly concentrated in the islets (as shown by isotope experiments),³⁹ and though it undoubtedly induces islet hyperplasia, the specific effects upon the α -cells are much less predictable and vary considerably according to the species of animal studied and the staining technique used.¹⁵

There is some evidence that glucagon plays a part in lipid metabolism. Different workers disagree about its effects on ketosis. Some say that it inhibits ketosis,⁴⁰ others that it has no influence.^{6,36} Still others believe that the pancreas contains two factors, one of which increases ketosis, while the other inhibits it.²⁴ Glucagon also depresses the synthesis of fatty acids and promotes their oxidation, as shown by the rate of incorporation of labelled acetate.⁴¹ Destruction of the α -cells by cobaltous chloride in rabbits leads to hypercholesterolaemia.⁴² Glucagon has been shown to restore the serum lipids to normal after pancreatectomy in animals, but these results may have been due to contamination by insulin.⁶ Possibly such effects as glucagon has on lipid metabolism are purely secondary to those exerted on carbohydrate metabolism.³⁵

Undoubtedly there is good evidence that glucagon is a second hormone of the pancreas. It is probably secreted by the α -cells of the pancreatic islets, and it may be under the control of the growth hormone. Glucagon appears to be one of the factors concerned in the regulation of the level of blood sugar both in health and in the diabetic state, but its role would seem to be no more than a subsidiary one.

ANTIBODIES AGAINST CANCER

Ever since the discovery of antibodies as a defence mechanism against microbial disease, the idea of employing them against cancer has been an attractive one. The quest justifies itself on the grounds of the marvellous specificity of antibodies and the varied manifestations of the immune mechanism. But if there is no antigenic difference between cancerous and normal tissue then all these efforts are in vain. The best-established evidence on the question, that of E. Weiler¹ and of M. Seligmann and colleagues,² is to the effect that cancer cells merely lack an antigen which the corresponding normal cell possesses. To make practical use of this negative feature of the cancer cell will require something akin to genius. T. S. Hauschka,³ reviewing the situation in 1952, wrote, "Eventual demonstration of specific neoplastic antigens appears dubious, since the critical results to date have been largely negative."

Nevertheless, a cancer antigen may be sitting in the cell waiting to be discovered and made use of. The hypothesis is in any case impossible to disprove. A cancer antigen may be defined as a substance present in the cancer cells and absent elsewhere in the body which is antigenic either in its own host or in another. The old idea of a substance peculiar to all the tumours of a species is giving way to more modest views, of a substance peculiar to certain kinds of tumour or even a substance peculiar to each individual tumour. But the old idea has by no means been completely rejected. There are two main biological ways of attempting to detect such a cancer antigen—namely, by showing that the tumour evokes a specific immune reaction either in its own host or else in another host. Either of these methods could yield evidence of a cancer antigen which might remain undetected by the other, though in general the more delicate discrimination might be expected to occur in the host of origin. It is for this reason that the failure of Weiler and of Seligmann *et al.* to find a cancer antigen need not cause despondency, for the method they used was to inoculate the tumour into another species, which may have been incapable of making the subtle distinction necessary.

J. B. Graham and R. M. Graham,⁴ on the other hand, recently examined the sera of 48 cancer patients

for antibodies to their own tumours by the complement-fixation technique, using as antigen an extract of the tumour containing chiefly desoxy-nucleoprotein. They found antibodies in twelve sera, the majority of negative sera coming from patients with far-advanced lesions. The cancers were mainly squamous-cell carcinomas of the cervix. It could be argued that the antigens concerned may also be present in normal tissue or that they may be irrelevant to host resistance to the tumour; for example, they may be bacteria or moulds infecting the tumour or even abnormal secretory products of the tumour, whose destruction would not hinder tumour growth. The authors' results suggest, however, that there was a relationship between these antibodies and a favourable prognosis. Further evidence of this kind, on a sound statistical basis, would contribute more than anything to a solution of the problem. Another recent report of a positive kind comes from Japan, where K. Kobayashi and H. Kawasaki,^{5,6,7} following up the early German work in this field, found antigens present in cases of human gastric cancer which were absent from normal gastric mucosa. They prepared antibodies in rabbits, and antigens by extracting the tumours either with alcohol or saline. This result would appear to contradict the earlier-mentioned work, but gastric cancer may be a special case, or different substances may have been extracted. Hardly any two extraction methods are the same. Recent developments suggest that the most promising substance to extract may be the nucleoprotein, as done by Graham and Graham.

R. W. Baldwin^{8,9} has studied tumour immunity using a highly inbred strain of rats and transplanted tumours which had recently been induced in the same strain. He caused the transplant to regress by means of ligation or by injection into it of an alcoholic extract, and found that in some cases of slow-growing tumour the animal was immune to further implants of the same tissue. The author is inclined to attribute the result to a genetic divergence of the tumour from its strain of origin rather than to a specific cancer antigen. The wisdom of this is confirmed by an accompanying paper of A. and L. Cohen,¹⁰ who report an apparent spontaneous mutation in such a transplanted tumour in its very first passage. This finding illustrates the weakness of attempts to detect specific cancer immunity with transplanted tumours: they are all open to the possibility of non-specific genetic divergence. It is becoming more and more evident that only the cure of a tumour in its own host, preferably where metastases exist, will carry any real conviction in these *in vivo* studies. In the special case of the so-called virus tumours of

fowls and certain mammals, antisera prepared against the virus associated with the tumour have often been completely effective in destroying the tumour. If certain forms of human cancer, for example leukaemia, were found to be caused by a virus then spectacular therapeutic results with antisera might be expected. A clinical study recently published by A. A. Strauss and colleagues¹¹ gives an account of their successful treatment of cancer of the rectum by electrocoagulation. They believe that the theoretical basis of this treatment is that partial destruction of the tumour allows the body's immune mechanism to hold in check the remaining cancer cells. The evidence for this explanation is, at best, suggestive, though it may eventually be substantiated.

In short, the evidence so far gathered that cancer can evoke a specific immune response is slender. But it is certainly sufficient to justify further study, particularly by the new techniques in immunology which appear from time to time; the recent development of a method for studying the surface antigens of human epidermal cells is a case in point.¹² Finally, it may be said that therapeutic measures based on the immune hypothesis, provided they can prove their worth, are by no means to be discouraged.

SUSPENSE CONTINUED

On Monday this week Mr. R. H. Turton, the Minister of Health, said in reply to a question in the House of Commons that the present average net earnings of a general medical practitioner are £2,222 a year, and that the corresponding figure for 1939 was £938. The Minister thus once again gives a misleading picture. He should have compared the present average with the average computed on the basis of what general practitioners should have been earning in 1939 according to the recommendations of the Spens Committee: and this figure is £1,111, not £938. Once more the Minister persists in ignoring the Spens recommendations. Lieutenant-Colonel Lipton asked Mr. Turton whether he would admit "that but for the difficult economic circumstances at the time, he would consider that the doctors have a good case for an increase." Mr. Turton reiterated that "in present circumstances it would not be right to give consideration to a claim for a general increase in remuneration." Thereupon Dr. Edith Summerskill asked the question which every doctor in the Health Service is now asking: "How does the Minister reconcile that answer with the recommendations of the Spens Committee?" Mr. Turton's reply to this was as follows: "The Spens Committee did not lay down any contractual obligation in this matter. It

based its recommendation on what should be the level at which doctors entered the National Health Service."

This reply needs looking at closely. Mr. Turton seems to be referring only to the G.P. Spens Report, as the questions were directed to the earnings of general practitioners. The omission of reference to the Consultants Spens Report was therefore fortuitous, but the same principles govern both. The first part of Mr. Turton's reply suggests that the Government is trying to wriggle out of the matter by denying there was a contractual obligation. Does the Minister really think this will wash? The Government of the day in 1946 accepted the recommendations of the committee it had itself set up, and the profession accepted them too. Is the Government of 1956 going to repudiate these? The second part of Mr. Turton's reply is curious. It should be read in the context of the terms of reference of the G.P. Spens Committee:

"To consider after obtaining whatever information and evidence it thinks fit what ought to be the range of total professional income of a registered medical practitioner in any publicly organized service of general medical practice; to consider this with due regard to what have been the normal financial expectations of general medical practice in the past, and to the desirability of maintaining in the future the proper social and economic status of general medical practice and its power to attract a suitable type of recruit to the profession; and to make recommendations." (Our italics.)

"To consider this with due regard . . . to the desirability of maintaining in the future the proper social and economic status of general practice" are the operative phrases in the terms of reference. It was these words that persuaded both general practitioners and consultants that they could enter a National Health Service with at least some confidence of fair treatment at the hands of successive governments. Mr. Turton probably knows that the future did not come to an end in 1948, 1951, or even in 1956, but is a continuing process. If he persists in his attitude of appearing to repudiate the two Spens Reports, then the medical profession will be faced with the gravest position that has arisen since the appointed day in July, 1948, and no doubt the representatives of the Negotiating Committee who met the Minister of Health on Wednesday made this clear to him.

PILLS ON THE CARPET

During 1950-4 ferrous sulphate tablets caused 39 accidental deaths in England and Wales, 38 of these being of children aged 1-4, the remaining one being of an adult woman. Children in this age group, and most

particularly those aged 1-2 years, are specially at risk to this cause of death. While this is for the obvious reason that they explore the environment by putting interesting bits of it into the mouth, J. O. Craig¹ has produced evidence suggesting that many of the poisoned children have exaggerated oral traits. In 25 cases of accidental poisoning of young children seen by him he took careful histories from the mother in order to find out whether the child showed in its behaviour any signs of oral craving. To compare with these he obtained from the mothers the "oral histories" of 25 children in a surgical out-patient department. In the poisoning group he classified 6 cases (24%) as normal, and in the control group 18 cases (72%). Moreover he found that a number of mothers whose children had been poisoned were exceedingly emphatic about their children's oral cravings, and he found some evidence too that certain of the children whose history was normal nevertheless probably had oral tendencies. The existence of pica in children has in the past often been brought to notice in relation to lead poisoning, though the fact that it is common in mild degrees in all strata of society must be well known to every observant layman. In Craig's control series, for instance, the severity of oral traits was considered to be "moderate" or "marked" in six cases (24%). Given a teeming population of exploratory toddlers, therefore, about a quarter of whom may be expected to seek oral gratification of their curiosity to a noticeable extent, it is not surprising that medicines, pills, and tablets, especially pills and tablets, should fall into their clutches. What is surprising perhaps is the prominence of medicaments² as causes of death, for deaths are relatively uncommon from such agents as petrol, paraffin, cleaning materials, and poisonous plants, though they do occur.

When this topic was discussed in the Section of Child Health at the B.M.A. Annual Meeting at Brighton the speakers expressed themselves very strongly on the danger of pills and tablets that resemble sweets.³ Dr. Keith Simpson handed round some samples of pills that were indistinguishable from sweets, and the risk of marketing such preparations is clear. Even so, the drug manufacturers are not altogether to blame; they fulfil a demand, and a demand that comes from our own profession, which no doubt in turn is reflecting the patients' wishes. The director of one firm making ferrous sulphate tablets has recently stated⁴ that, though his firm now markets white and virtually tasteless tab. ferr. sulph. co. N.F. (in response to comments in the professional press), they are not being prescribed; the demand "is for the coloured, sugar-coated tablets." While a toddler putting anything and everything into his mouth might not discriminate much between a coloured and a plain tablet, it seems reasonable to suppose that at least some children are more attracted to the bright and colourful than to the plain white (or perhaps black). Again, there is much to be said for invariably marketing certain preparations in "cello-

phane" envelopes or small packets. Ferrous sulphate might well be one of these, as suggested by I. O. B. Spencer,⁵ and the antihistamines and barbiturates are also a special danger. Doctors and chemists can help too by telling parents about the dangers to children of some of these drugs, especially those that are relatively harmless to adults.

NEW MORTUARIES

The publication of a White Paper¹ on the planning of mortuaries is an encouraging sign to those who work in public mortuaries that in future something may be done for this neglected type of local government building. Even to-day in our most populous regions as well as in country districts there are public mortuaries which are little more than accommodation for the dead, and they may or may not be fitted with a refrigerator. These buildings do not have the publicity appeal of new infant welfare clinics or mass x-ray machines; no votes are likely to be gained by the erection of a modern mortuary; consequently the development of this public service has been stringently economical. While it is not the misfortune of every family to have to visit a public mortuary to identify a relative—an experience that must be harrowing and likely to remain in the memory for a lifetime—anything that can be done to create pleasant and clean surroundings is surely worth while. Moreover, the working conditions for the pathologist should also be considered, not only so that his work may be efficient and accurate, but also to facilitate the demonstration and teaching, mainly postgraduate, which a modern mortuary provides.

The White Paper is therefore particularly welcome at a time when it is possible that some rationalization of mortuary services may be possible, and it should prove a useful guide to county architects and builders. An anomaly exists at present in many places, including London and Middlesex, that the mortuary is provided by the borough council, which is responsible for its maintenance as well as for the remuneration of the mortuary keepers, but it is used by coroners and pathologists, who are paid by the county council. Such is the pride of many borough councils that they would rather maintain a small and inadequate mortuary of their own than share with an adjacent borough in the development of a suitable mortuary and so halve their maintenance costs.

The general principles outlined in the White Paper are sound, though presumably of necessity in this short publication many important details have been omitted. For example, clerestory windows provide excellent natural lighting, while studio roofs are to be avoided. Terazzo flooring is cold but very clean, while composition floors break up in the damp. Electric points for inspection lamps and saws should be readily available. Features such as these can easily be studied if coroners and pathologists are consulted (as is suggested) in the planning of a mortuary, rather than the details being

left to a sanitary inspector, as has happened many times. Perhaps more should have been said on the choice of mortuary attendants. It is clearly no more practicable for a busy and skilled pathologist to sew up the cadavers than it is for a surgeon to wash and sterilize his instruments. To carry the analogy a little further, few surgeons would nowadays shave and prepare an abdomen or scalp for operation. The pathologist could likewise be helped if skilled assistance was available for such tasks as loosening the calvarium and exposure of the sternum. A reasonable salary and conditions of work should attract the right men as attendants. The policy of appointing an unskilled labourer to the post of mortuary keeper on grounds of economy is unjustified, and can go far to nullify the improvements which a modern mortuary can provide. The second part of the White Paper describes the planning of a mortuary without post-mortem accommodation. It is difficult to envisage a mortuary where no necropsies would ever be required, and the purpose of these pages is obscure.

ATOMIC HAZARDS

On October 17 next the nuclear power station at Calder Hall, Cumberland, will begin a regular supply of electricity to the Central Electricity Authority's grid. Britain's place in the forefront of research in atomic energy and its application to peaceful purposes will thus be signally marked, though some years will elapse before enough power is available to relieve the coal shortage. Meanwhile other reactors are being constructed, and the safe disposal of atomic waste will be an increasing problem. Some of it is being discharged into the sea, and studies of radioactivity in fish, seaweed, and sand have been progressing for some years now.¹ Natural radioactivity in the sea is at an exceedingly low level, radioactivity in the sea is at an exceedingly low level, and plants living more than a few hundred feet below the surface receive much less natural radiation than those living on land. Whether this affects their rate of evolution is a speculation that might be worth pursuing; such a study could indeed provide useful data on the commutagenic effects of natural radiation, and only considerable technical difficulties have prevented more being done on these lines. Possibly the relative lack of ionizing radiations in the ocean depths has allowed life to develop more slowly there, and might even account in part for the survival of the coelacanth. But because the rate of interchange between surface and deep water varies in different parts of the world, and active materials vary in the rates at which they decay, the particular places chosen for the disposal of waste have to be studied with some care. Apparently the Black Sea is one of the best depositories for fissile material, since the time taken for the deep water to move near the surface and be replaced by new water mixing downwards—the flushing time—is about 2,500 years. In the Atlantic and Caribbean the flushing time is probably only a few hundred years,

and the water now at the bottom of the Atlantic may have been at the surface in Arctic latitudes only 150 years ago. While short-lived fission products can be safely disposed of in the ocean depths, there is still some uncertainty about the safety to commercial fisheries, and thus to man, of dumping there such long-lived fission products as radio-strontium.²

The more immediate health hazards to which the British Atomic Energy Authority's workpeople are exposed seem to be so well controlled that its second report¹ can say "employment in the Authority is safer than in most comparable industries," and in the year covered (April 1, 1955, to March 31, 1956) there has been no case of occupational illness or death, and no fatal accident.

ZOXAZOLAMINE

A new substance, zoxazolamine, has recently been examined for its power to relieve spasticity in muscles. W. Amols¹ tested it on 28 patients with a variety of neurological disorders, and found that, when it was given alone, its effect was too small to be clinically useful, but if it was given with chlorpromazine then muscle relaxation was obtained. The dose of chlorpromazine varied from 10 to 50 mg. by mouth, and the dose of zoxazolamine was 500 mg. by mouth. Favourable results were obtained in most patients with spastic extremities. Those with decerebrate rigidity, torticollis, or disease of the basal ganglia were not benefited. Patients with grand mal seizures were made worse.

Zoxazolamine² has also been given to 100 rheumatic patients in whom the muscular stiffness made remedial exercises impossible. To these no chlorpromazine was given, and good results were obtained in 85; in these relief of the stiffness and aching was often complete within 30 minutes after taking the dose. In most patients the dose was 500 mg. three or four times a day. There were toxic effects in 43 patients, and in 13 of these the effects were serious enough to make further treatment impossible. They suffered from chills and fever, burning of the eyes, and rashes. The drug has also been given to children with cerebral palsy who had spasticity.³ Large doses varying from 30 to 140 mg. per kg. body weight produced a decrease of muscle tone on passive flexion, but there was no consequent improvement in function in about half of the patients, and a high proportion of patients experienced side-effects.

A still further report⁴ has been made on the use of this drug in spastic adults. A relaxing effect was best seen in patients with lesions of the spinal cord and was undoubted in 14 out of 18. The effects on patients with diseases affecting the brain, especially paralysis agitans and paraplegia, were less predictable and in some the drug made the symptoms worse. On the other hand, in one patient with encephalomyelitis, who suffered from severe spasms of the adductors of the thigh, great relief was given.

MEDICAL BLOOD PREPARATIONS

BY

L. G. BOGOMOLOVA, M.D.

*Director, Medical Preparations and Blood Substitutes
Laboratory, Blood Transfusion Research Institute,
Leningrad, U.S.S.R.*

This is the first of two articles by Dr. Bogomolova, one of the delegation of Russian doctors who visited Britain last autumn as guests of the B.M.A. Her second article, on "Blood Substitute Solutions," will appear next week.

Blood transfusion as a method of treatment has become widely used in every field of medicine. Scientists, however, have not confined themselves to studying the method of blood transfusion ; they have long since come near to finding means of utilizing the individual fractions of blood in treatment.

As far back as 1932 Filatov and Kartashevski, of the Leningrad Institute of Blood Transfusion, worked out the problem of transfusing blood plasma and erythrocytes, isolated from each other (Kartashevski and Filatov 1934), and plasma transfusion has now found wide application in medical practice for shock, burns, hypoproteinaemia, etc.

As is well known, blood plasma, in its turn, may be subdivided into a number of components, the so-called fractions. Each of these plasma fractions is endowed with a definite physiological activity, in proportion to which its use may be evaluated. For example, albumins are applied as a blood substitute in controlling shock. Globulin is a particularly important fraction of the plasma proteins. It is known that the concentration of immune antibodies in a purified gamma-globulin is 25 times greater than in whole blood. Fibrinogen is a protein of great physiological importance in blood coagulation.

In addition to using individual fractions of blood, it is possible to combine them and thus utilize interaction of the individual fraction. In recent years the Leningrad Institute of Blood Transfusion has produced several such preparations. The substances so obtained may be divided into the following groups: blood substitutes; haemostatics; stimulating preparations—that is, substances which accelerate the healing of wounds and sores; preparations for the treatment of anaemia; plastic preparations—that is, those required for plastic restorative purposes in surgery.

Blood Substitutes

Mention should be especially made of dried blood plasma. We have elaborated methods of storing dried plasma which enable us completely to avoid infecting patients with the virus of hepatitis. These methods consist in adding to the blood an antiseptic (tripoflavin) or sulphamides and then extracting the plasma and drying by the vacuum-freezing method (Krotova, 1952; Krotova and Depp, 1952).

The method of transfusing the erythrocyte mass, one of the blood fractions, has lately found wide application. We have proved that preserved erythrocytes can be kept for 30-40 days (Krotova, 1952).

Another preparation belonging to the group of blood-substituting media—namely, dried haemoglobin—is worth mention. Up till now it had not been obtained in a pure state, since, as a rule, a part of the haemoglobin is transformed into methaemoglobin in the process of drying. We have now worked out a method of preparing restored haemoglobin in a dry state (Andrianova, 1955). It is a red powder that contains no impurities and readily dissolves in water.

and-salt solutions. A small dose of dried haemoglobin added to the blood serum suffices to raise the effectiveness of the latter.

Haemostatics

The second group of preparations comprises those intended for local haemostasis. These include the haemostatic sponge, dry thrombin and fibrin "cotton-wool," antiseptic biological tampon, fibrin powder, and haemostatic suppositories.

Haemostatic sponge is produced from blood plasma; it is of porous structure and looks like an ordinary rubber sponge. The haemostatic sponge is very hygroscopic, and, when applied to the bleeding spot, absorbs the blood and brings about its rapid coagulation (Bogomolova, 1951). It has been proved that the sponge left in the tissues of the body during haemostasis completely dissolves.

The neurogenic factor has been found to play an important part in the mechanism of action of the haemostatic sponge. Experiments on dogs have shown that sponge mechanically occludes the bleeding vessel and causes greater coagulation of the blood flowing from the bleeding-point; it acts also, above all, on the receptor apparatus of the vascular system and causes a reflex contraction of the bleeding vessels, which is of decisive importance in haemostasis. It has been found of great use in surgery.

The latest experiments carried out at the institute have helped in elaborating a technology for the production of haemostatic sponge from the blood of beef and dairy cattle. In use, these sponges are saturated with antiseptics, and are devoid of any antigenic properties (Klement, 1955).

Dry thrombin of the Leningrad Institute of Blood Transfusion is another haemostatic preparation (Andrianova, 1952). It arrests the bleeding of injured organs and is of particular importance in closed cavities. Thrombin, in combination with fibrinogen, is used in cases of special plastic operations when a physiologically adhesive material is required. This method is particularly convenient in skin-grafting. In such cases the strip of skin is impregnated with a thrombin solution, while the site on which the skin is to be grafted is anointed with a fibrinogen (or plasma) solution. The strip is applied to the previously prepared site, on which a clot of fibrin is formed that acts as a glue.

"Cotton-wool" made of blood fibrin belongs to the same class of haemostatic preparations (Filatov, 1955; Filatov and Teodorowitch, 1954); it also dissolves. Experimental investigations have proved that "homo-cotton-wool"—that is, cotton-wool obtained from homogenous blood—may be applied for haemostatic purposes in cases of injury of the internal organs. In such cases it is recommended that the cotton-wool should be dipped in a thrombin solution.

All the above biological haemostatic drugs can be widely applied. When left in the tissues of the body they completely dissolve, without bringing about any reactions. This has been confirmed by numerous clinical observations made by various investigators.

Biological antiseptic tampons containing antibiotics, such as penicillin and streptomycin, as well as antiseptics, are recommended to stop bleeding from infected wounds. Research carried out by a number of authors has shown that when a tampon saturated with penicillin or streptomycin is introduced into an infected cavity the antibiotic slowly penetrates into the blood, as from a depot. Investigation has revealed that a medium therapeutic dose of antibiotic appears in the blood within four days (Melnikova, 1954).

One of these preparations, the antiseptic biological tampon, composed of blood plasma with gelatin, is a porous, dry elastic mass of a light yellow colour (Bogomolova and Alexandrova, 1954). It can be made in any size or shape, and is packed so that it can be used for first aid to wounded on the spot.

Stimulating Preparations

The next group, the so-called stimulating preparations, includes sterilized serum made from the blood of donors. The preparation is obtained by appropriate treatment of human blood serum, which is then subjected to repeated

sterilization in an autoclave at a temperature of 125° C. As a result of the high temperature and pressure, the serum albumin disintegrates, and a gently acting protein preparation is thus created. It is a transparent brown fluid and is supplied in 10-ml. doses (Filatov, 1953).

Clinical experience has shown that the best results are obtained with sterilized serum when it becomes necessary to improve the processes of regeneration—that is, chiefly in cases of non-healing ulcers. The sterilized serum is used when treating gastric and duodenal ulceration and other diseases. It is introduced intramuscularly in increasing doses, ranging from 1 to 10 ml. daily, the course of treatment comprising 10 to 20 injections. Up to the present the Leningrad Institute of Blood Transfusion has treated more than 1,000 cases of peptic ulcer with sterilized serum. A favourable result was recorded in 90% of these, and complete healing in 40%. No aggravation or exacerbation of the disease process was observed, and there were no reactions or complications (Filatov, 1950).

Highly interesting data were obtained when sterilized serum was used as a solvent for penicillin. It appeared that when penicillin dissolved in sterilized serum is introduced intramuscularly it becomes possible to preserve a high concentration of the preparation in the body for a much longer time, and, what is of particular importance, to increase markedly the medicinal effect of the antibiotic (Filatov, 1955).

Yet another preparation, named haemohormonostimulin (Bakscht *et al.*, 1955), has been suggested for stimulant therapy. It is made of retroplacental blood and contains valuable hormones, the introduction of which jointly with the serum is particularly effective. Haemohormonostimulin is injected intramuscularly in single doses of 40–80 ml.—or, occasionally, in repeated doses—in cases of climacteric neuroses, ovarian insufficiency, climacteric dermatoses, and other instances of hormonal disorders in women. According to our data, the results obtained from haemohormonostimulin are undoubtedly superior to those produced by the use of conventional hormonal preparations, including synthetic ones. We believe that such a positive effect of haemohormonostimulin can be explained by the fact that on its introduction there takes place a combined action of the hormones and serum of pregnant women, so rich in active substances.

Treatment of Anaemia

Treatment of Anaemia

Various preparations made from animal blood have long been used to stimulate blood formation in cases of anaemia. These include haematogen, haemol, and other blood constituents. Since blood preparations do not by themselves produce a rapid and lasting restoration of blood in cases of anaemia, the task was to combine them with medicinal drugs. The preparations so far suggested do not, however, meet the physicians' requirements, since they produce only

A new haemoglobin-containing preparation, called haemostimulin (Kouralava 1954), has been tried at the Leningrad Institute. It is made of animal blood with trace elements added to it. As is well known, in addition to iron, necessary for the building up of haemoglobin molecules, a number of other metals, evidently acting as catalysts, participate in the process of blood regeneration. Such metals include copper and cobalt. Owing to the happy combination of its components, haemostimulin exercises a strong stimulating influence on blood formation and is successfully employed in treating hypochromic anaemia of various aetiology. When this preparation is administered to anaemic patients the haemoglobin content rises by a daily average of 1 to 1.5%.

In a number of cases haemostimulin has rapidly cured anaemia when the usual methods of treatment have proved unsuccessful.

Preparations for Plastic Surgery

This group of new preparations consists of those designed for plastic surgery. The first in importance are fibrin films, made of human blood as well as of the blood of beef and dairy cattle.

Films made of human blood can be used for plastic operations in cases of defects in the dura mater and peritoneum, and to cover wounds of the internal organs. Cheaper and more easily available fibrin films made of animal blood may be used externally (Filotov and Goschkina, 1950).

The question naturally arises: are not such films harmful to human tissues, since they are made of heterogenous blood and possess anaphylactogenic properties? It is well known that foreign protein, particularly when repeatedly applied, always brings about phenomena of general and local anaphylaxis. By properly treating animal blood we succeeded in eliminating the anaphylactogenic properties of heterogenous films.

Fibrin films are elastic. This property helps one to cover evenly the injured portions of the skin, thereby protecting the bared nerve-endings from external stimulation; the flow of nerve impulses from the injured area is also eliminated—a highly important point, according to Pavlov's teaching.

Fibrin films are also transparent. This makes it possible to observe the condition of the wound without risk of secondary infection during dressing and without further trauma to the wound. They also have a great capacity for adsorption, which is highly important clinically, both with regard to the extraction of toxin from the wound and rapid drying, and with regard to the creation of bactericidal depots—impregnation with bactericides having previously been done.

The fibrin film is capable of dissolving when acted upon by micro-organisms. This property is of some importance in the treatment of burns and other skin injuries, since dissolution of the film on the infected site makes it possible to recognize infection quickly, and thus prevent its spread over the whole of the wound (Goschkina, 1954).

Impregnation of the fibrin film with bactericidal substances prevents infection from spreading on the surface of the burn. The bactericidal action manifests itself the whole of the time the film is on the wound—that is, up to the moment when the film dries.

Clinical observations in over 2,000 cases of burns have proved that the films speed up the healing of burn wounds by four to five days as compared with other methods. They have been widely used in treating not only burns but abrasions, bedsores, and other skin injuries, but also for the repair of defects in serous membranes and the integuments of the organs. Considerable clinical experience has proved the unquestionable effectiveness of the fibrin film.

Of other preparations produced at the Institute of Blood Transfusion mention should be made of bioplastics. Two types of these have been made: (1) Rapidly resolving plastics for the construction of splints for use in gastro-intestinal anastomosis. Bioplastic splints are not only designed to facilitate gastro-intestinal anastomosis, but when left in the intestines they are a source of valuable nourishing substances (Filatov and Andrianova, 1952). (2) Slowly resolving bioplastics for use as intra-osseous splints in cases of fracture.

All the suggested plastics have been tested as resolving materials in plastic surgery, and the results have been good.

JOINT MEETING OF BRITISH AND
AMERICAN PAEDIATRIC SURGEONS

[FROM A SPECIAL CORRESPONDENT]

The British Association of Paediatric Surgeons held its third annual meeting, in conjunction with the surgical section of the American Academy of Paediatrics, in London on July 17, 18, and 19. Throughout was shown evidence of the close attention now being given to many previously neglected problems in this field and the high standard of results being achieved by the specialist children's surgeon.

The president was Mr. DENIS BROWNE (London).

Cardiac Surgery in Infancy

An expert panel consisting of Dr. W. T. MUSTARD (Toronto), Mr. D. J. WATERSTON and Dr. B. G. B. LUCAS (London), and Mr. F. R. EDWARDS and Dr. JOHN HAY (Liverpool) held a discussion on recent developments in cardiac surgery in infancy. Dr. MUSTARD started the ball rolling by stating his views on coarctation of the aorta in young infants. He stressed the diagnostic difficulties at this age, but said that if all babies with tachycardia had their femoral pulses palpated the condition would be recognized more often. At present he believed many babies with coarctation died before they were seen by a cardiologist, their deaths being ascribed to such causes as malnutrition. Dr. Mustard said the real problem was whether or not to operate in infancy. In his opinion the child with cardiac failure who did not respond to medical treatment should have an operation. This might be needed urgently, and he operated in the middle of the night if necessary. Mr. WATERSTON agreed about the urgency of treatment in young babies with coarctation who developed heart failure early. A number of them had fibroelastosis, and this was responsible for some deaths after operation. It was his practice to make a biopsy of the wall of the auricular appendage in an endeavour to diagnose fibro-elastosis. The panel agreed there was no way of doing so clinically, but Dr. MUSTARD felt that biopsy might not always be reliable. Dr. HAY said that he thought it important to study the natural history of the condition. This showed that if the young child with coarctation was well he should be left alone in infancy.

Turning to cyanotic heart disease in infancy, Mr. EDWARDS said the essential problem was to know how many of these cases were worth operating on at that age. Certainly cases of Fallot's tetralogy who went into failure early could be helped by a Blalock or Potts operation. He thought it difficult to know just how large an anastomosis to make, for what would be adequate later might be too large at the time. Because of this one had to be prepared to repeat the Blalock procedure on the other side at about 4 years of age. It was best, Mr. EDWARDS continued, if these children could be treated conservatively until they reached 5 or 6 years. Dr. HAY considered the indications for operation on young infants with cyanotic heart disease. He had found that what mattered most were cyanotic attacks and a failure to gain weight normally. Mr. WATERSTON agreed, and suggested a third indication—anginal attacks, which were not uncommon in these babies. He emphasized that cyanotic attacks tended to stop in hospital, and in this regard the mother's history should always be accepted.

Dr. LUCAS said the greatest anaesthetic problems were in the infants aged from a few weeks to several months. A relaxant and as little anaesthetic as possible should be given. Whilst hypothermia was necessary if the cerebral circulation was to be shut off, it was also useful in babies who had a defective ventilating system. For such cases he favoured operating at a temperature of 28–29°C. Dr. MUSTARD agreed that in all these cyanosed babies some degree of hypothermia was necessary, and he favoured 31°C.

Meconium Plugs

Dr. J. L. EMERY (Sheffield) reported the results of pathological studies on a number of babies who had intestinal

obstruction as a result of impacted meconium, yet were not cases of Hirschsprung's disease or meconium ileus. It seemed that the abnormality must be in the meconium itself, which was still, Dr. Emery pointed out, somewhat of a mystery substance. A plug of white meconium was often found in these cases at the tip of the mass. The viscosity of meconium was related to its water content, and this had been found to be lower at the distal tip of segments of meconium seen at necropsy to be obstructing the bowel. This dry meconium could lead to stercoral ulceration.

Mr. R. E. ZACHARY (Sheffield) described the clinical features of these cases. There were two groups. Firstly, those with plugs of meconium, leading to abdominal distension and vomiting, which were passed after rectal examination or following a rectal wash-out. Secondly, a group of babies admitted between 4 days and 5 weeks of age who had perforations of the colon by hard masses of faeces. In six such cases coming to necropsy it had been possible to exclude Hirschsprung's disease and meconium ileus. Mr. Zachary pointed out that, though the first group had a benign course, there was the danger of death from inhalation.

Mr. P. P. RICKHAM (Liverpool) described a case of obstruction of the small intestine by meconium which had calcified. At operation there had been no evidence of meconium peritonitis. But after its removal and enterostomy the intestinal contents recalcified and solidified in three days, and finally the baby died at 28 days. At necropsy there was no mucositis and the bowel was normally innervated. He reported the condition, without being able to explain its nature, to draw attention to this subject.

Tension Emphysema

Mr. T. Y. NELSON (Sydney) read a short paper on tension emphysema in infants—a special group in which the emphysema was limited to one lobe, usually an upper or the right middle lobe. He thought many cases were due to hypoplasia of the bronchial wall and deficient cartilage in the bronchus going to the affected lobe. In others, a persistent ductus arteriosus, an anomalous vessel, or a flap of bronchial mucosa was responsible. Clinically there were two types. Some presented as emergencies in the neonatal period with respiratory distress and gross mediastinal displacement. Others were seen later in infancy, usually following an infection, though there was often a history, dating from birth, of wheezing or panting. These lobes could be distinguished from tension cysts by the fine lung markings which were seen radiologically. Though resection of the affected lobe was necessary, Mr. Nelson thought it might be an advantage if some form of more conservative treatment could be found which would enable lobectomy to be delayed until later. However, he did not think we yet had a suitable method.

Metabolic Response to Operation

Mr. A. W. WILKINSON (Aberdeen) read a paper in which he drew attention to some of the peculiarities and differences in renal function after injury in adults, children, and infants. Regardless of the nature of injury, older children showed the same kind of alteration in urinary function after injury as did adults, and seemed equally capable of the close conservation of sodium during, and after, potassium diuresis, even in the presence of intense oliguria. The dangers of overloading children, especially after burns, with water and sodium were as great therefore as in adults. In the first two months of life, however, the changes in urinary composition after operations such as pylorotomy were somewhat different, though there might be a similar but less marked transient potassium diuresis and sodium conservation. Whilst there was some individual variation, Mr. Wilkinson said there was nevertheless a fairly clear pattern of behaviour which was different. If it were true that the potassium diuresis in older subjects was a means of making endogenous water available for continuing such essential purposes as insensible water loss and urine formation, and the simultaneous sodium conservation allowed the maintenance of an

adequate volume of extracellular fluid, some explanation must be sought for the different urinary composition in the young child. He thought the apparent immaturity of renal function in the newborn might be adapted to the greater total, and particularly extracellular, fluid volume at and soon after birth. If this were so, it might be that the newborn child provided more of its continuing water requirements from extracellular fluid than did the adult or older child. It did seem, however, as if the newborn child, like other young animals, arriving as it did with 15% more body water than the adult, was well prepared for the restriction of its fluid intake which was one of the features of the first day or two of life. This different water content and distribution in the young baby, in combination with kidneys which did not conserve sodium after injury as closely as the kidneys of older children and adults, suggested that the apparent immaturity of the infant kidney was a useful biological device.

Other papers read during the meeting dealt with cystic hygroma, portal hypertension in children, septic umbilical arteritis, funnel-chest deformities, eventration of the diaphragm, and the use of colon for reconstruction of the oesophagus.

INSTITUTE OF PATHOLOGY AT
NEWCASTLE

OPENING BY SIR HAROLD HIMSWORTH

The new Institute of Pathology (illustrated below) at Newcastle General Hospital was opened by Sir HAROLD HIMSWORTH, F.R.S., Secretary of the Medical Research Council, on July 28. The Institute provides accommodation under one roof for three laboratory services until now largely separated: the pathology department of the hospital, which also serves many hospitals outside the Newcastle Group; the Public Health Laboratory Service's laboratory which deals with Northumberland, most of Tyneside, and part of North Durham; and the Blood Transfusion Service's regional laboratory and headquarters. The directors of the three departments are Dr. B. E. TOMLINSON, Dr. A. I. MESSER, and Dr. SHEILA MURRAY, respectively.

Unity of Medicine

After the chairman of the Newcastle Regional Hospital Board, Mr. E. F. COLLINGWOOD, had welcomed the guests, Sir HAROLD HIMSWORTH spoke. The new Institute had a twofold significance, he said. It brought to the region laboratory facilities in keeping with the needs of modern medicine; it remedied deficiencies under which they had long laboured. But over and above this it embodied an imaginative appreciation of future trends. In every branch of natural knowledge technical advances opened up new possibilities of progress in contingent fields. At this ceremony, said Sir Harold, many of his audience would be remembering James Spence, whose ideas pervaded so much forward thinking in medicine. It was Spence's virtue always to see beyond institutions to their purposes; as he had never failed to maintain, human endeavour was not

independent of its instruments, and its whole course could be diverted by inappropriate arrangement.

Medical knowledge was indivisible, continued Sir Harold, yet the demands of practice had created specialties, and nowhere was this more true than in pathology. Hospital pathology was tending to become divorced from public health work, and services like blood transfusion from both. That those engaged in these different activities should be separate specialists was probably inevitable, but that they should become isolated from each other was not. If they were to make their essential contribution to the advancement of medicine and their activities were not to degenerate into mere elaboration of technical expertise, then they must be brought into one community, living, working, and thinking together. This was the outstanding contribution of the new Institute. It united in one home the specialists of three separate but related services.

After Sir Harold's address the building was blessed and dedicated by the Archdeacon of Northumberland, the Ven. I. H. WHITE-THOMSON.

The Building

The Institute is sited between the gynaecological ward and the old hospital. Its construction involved the demolition of the former hospital department of pathology and a chapel. The Institute is a four-storeyed building, with a reinforced-concrete frame and floor. The ground floor, partly below ground level, is largely the preserve of the Blood Transfusion Service. Here there are rooms for bleeding and for the use of blood donors; laboratories, staff rooms, and offices; and a large blood bank, sterile room, and crystalloid laboratory. On the ground floor also is some of the hospital pathology department—the mortuary, viewing-chapel, and undertaker's room; the post-mortem rooms and students' gallery; and various staff rooms. However, most of this department is accommodated on the first floor, where are the histological, haematological, and biochemical laboratories; examination- and waiting-rooms for out-patients; and space for a combined museum and lecture room, and a photographic section. The Public Health Laboratory occupies the second floor, and besides its working-rooms there are laboratories for research, virology, and epidemiology, and the Service's regional administrative offices. On this floor also is a library for the use of all three departments. The top floor of the Institute is designed as an animal house.

The Institute, which covers some 68,000 sq. ft. (6,300 sq. m.), cost £240,000. Construction began in January, 1954, and was virtually complete in June this year. The architects were Messrs. Scherrer and Hicks, of London.

MEDICAL INSURANCE AGENCY

The annual meeting of the Medical Insurance Agency was held on July 26. Professor R. B. Green and Dr. Dougal Callander were elected members of the committee of management for three years, and the following were re-elected for the same period: Dr. Janet Bottomley, Sir John McNee, Mr. R. L. Newell, Dr. Henry Robinson, Sir Arnold Stott, and Dr. E. R. C. Walker. The report of the committee disclosed a new high level of service to the medical and dental professions, reflected in an ever-growing total of rebates on premiums. The audited statement of accounts for the year 1955 was adopted, and allocations to medical and dental charities were approved which, by the use of the covenant system, will result in their benefiting by an amount of about £22,000. The constantly expanding business handled by the agency on behalf of its clients has entailed the acquisition of additional premises, which have been secured in Flaxman Terrace, closely adjacent to the back of B.M.A. House. The staff has also been much augmented for a similar reason; and the new premises enable the accommodation required for them to be adequately provided. The total premium income collected by the agency is now almost two million pounds a year. Dr. James Fenton was re-elected chairman and Dr. Henry Robinson was re-elected hon. secretary.

SIR,—In discussing my report of a case of massive tumour embolism from Sully Hospital (*Journal*, February 25, p. 435), Dr. R. C. Jennings (*Journal*, March 17, p. 630) has raised the important point of bronchial involvement by metastatic pulmonary tumours. I agree that the presentation of an adrenal cortical carcinoma as an intrabronchial neoplasm is rare, but in our case the pathologist thought that this pleomorphic tumour was far more like an adrenal carcinoma than a primary bronchial tumour. It had an unusual and distinctive appearance which, in our pathologist's experience,

has not been encountered in the lung in the absence of an accompanying adrenal tumour. Nevertheless, we concede that the question is debatable.

On the wider subject of bronchial invasion by metastatic tumours in general, it was formerly thought that this phenomenon was rare. Seiler, Claggett, and McDonald¹ reviewed 52 cases from the literature, and reported 10 cases from the Mayo Clinic of metastatic malignant tumours suitable for resection. Gross bronchial involvement was demonstrated in 7 of their cases, in 4 of which bronchoscopic biopsy was positive. Though information was only given in 27 of the combined series of cases, bronchial involvement was noted in 17 and bronchoscopic biopsy was positive in 10 (16% of entire series).

Liebow,² who states that "an isolated metastasis may centre about, and even invade, a bronchus so as to suggest a primary lesion," illustrates this with examples from the kidney and colon. Judged by thoracic surgical reports, these are the commonest primary sites concerned, and the following cases, all of colonic origin, from the relatively recent practice of Sully Hospital are illustrative.

Case 1.—A woman aged 60 years first complained of left-sided chest pain in December, 1954. Seven months later radiography showed a collapsed left lower lobe; at bronchoscopy the left lower lobe bronchus was seen to be obstructed by growth, and biopsy showed necrotic tumour cells. In July, 1955, left lower lobectomy was done, the lobar bronchus being occluded by growth which microscopically was an adenocarcinoma of intestinal origin. Five months later she complained of colicky lower abdominal pain of six weeks' duration, and admitted having had bouts of diarrhoea over the previous seven months. Anterior resection involving hysterectomy was performed in January, 1956, for a papillary adenocarcinoma of the recto-sigmoid junction. She remains well at present.

Case 2.—A man aged 53 years complained in March, 1950, of bouts of constipation extending back over a year. Barium enema demonstrated a stricture in the ascending colon; right hemicolectomy was done, but no pathological report is now available. Nine months later he first noted cough and dyspnoea, which became gradually worse till he came for treatment two years later. Radiography showed collapse of the left lung; at bronchoscopy growth was seen occluding the lower end of the left main bronchus, and biopsy showed necrotic tumour cells. In February, 1953, left pneumonectomy was done, the main bronchus being occluded by growth which microscopically was adenocarcinoma of intestinal origin. A year later small metastases were suspected in the right lung. In April, 1956, six years after colonic resection and three years after pneumonectomy, he complains of some cough, but is still at work. Radiographically several circumscribed shadows in the right lung are slowly increasing in size.

Case 3.—In April, 1949, a woman then aged 56 years complained of six months' mucous diarrhoea and rectal bleeding. Abdomino-perineal resection of the rectum was done for an ulcerated adenocarcinoma invading the rectal wall but not involving lymph nodes. She remained well till May, 1956, when she had several haemoptyses. Radiology showed a large tumour in the right upper lobe; at bronchoscopy a tumour was seen growing from the lateral aspect of the right main bronchus so that the right upper lobe orifice could not be identified; biopsy showed well-differentiated mucus-secreting adenocarcinoma of intestinal origin. Further operation has been declined.

—I am, etc.,

Penarth, Glam.

Chloroquine and Bleaching of Hair

SIR,—In the course of trials with chloroquine in the management of hypersensitivity states and of certain forms of rheumatoid arthritis, I came across two instances of universal bleaching of hair within six months after starting the drug in daily doses of 400 mg.

The first lady, aged 30, was taking chloroquine, 200 mg., since January, 1956, and attended my out-patient clinic in June of this year. I was immediately struck by her cheerfulness and optimism, so different from the previous occasions when she had bitterly resented the limitation in her

activities caused by the disabling rheumatoid arthritis. Her change of outlook was not brought on by any recovery of her arthritis but by universal bleaching of her hair, including the eyebrows, which she considered a great improvement. She was quite sure that the bleaching was due to chloroquine. I was doubtful until I came across Dr. Sharvill's letter in the *British Medical Journal*.¹ Dr. Sharvill also referred to previous publications on this subject.^{2,3}

A week later another lady, aged 46, was seen to have been converted from a dark blonde into a very fair one within five months of commencing chloroquine. Fortunately, she too seemed pleased with her apparent rejuvenation and was disappointed when the drug was cut down to one tablet daily, as her symptoms of hypersensitivity following infection earlier this year had subsided. In both instances the patients were more than satisfied with their new appearance as a result of chloroquine medication. Not all patients, however, prefer the albino type of depigmented hair. It might therefore be wise to mention this remote but possible action of chloroquine to patients about to undergo prolonged treatment with the drug.—I am, etc.,

Liverpool, 1.

Steroid Anaesthesia

SIR,—Dr. L. H. Lerman is to be congratulated upon the excellent manner in which he presented his preliminary communication (*Journal*, July 21, p. 129) on the clinical use of "viadril"—a new steroid anaesthetic. Just over a month ago Dr. Margaret Rooms and I published our findings from the use of this drug in a series of one hundred cases¹ and can confirm the conclusions arrived at by Dr. Lerman. Since then we have had an opportunity to use viadril as the basic anaesthetic for a number of intra-thoracic operations and can reaffirm the opinion that this drug enables "controlled respiration" to be obtained with greater facility than when thiopentone is so used²—that is, smaller doses of pethidine and muscle-relaxants being necessary. The necessity of an intravenous drip obviously rules out the use of steroid anaesthesia—in its present form—as a routine for short operations. For long and exacting operations, however, its use is to be recommended, as patients have such a remarkable sense of well-being during the early days of the recovery period instead of varying degrees of misery. This sense of well-being appears to be similar to that experienced by patients undergoing cortisone therapy.

An excellent review of the whole subject of steroid anaesthesia appeared recently in a contemporary journal.³—I am, etc.,

Maternal Death from Aspiration Asphyxia

SIR,—Once again Dr. R. B. Parker has rendered a signal service to the art and practice of obstetrics (*Journal*, July 7, p. 16), and if I may venture again to intervene it is chiefly to emphasize some of the points he makes, and to try to indicate the conclusions to which his article appears inevitably to lead.

In the first place it is right to insist that no patient undergoing forceps delivery should ever die from aspiration of vomit; for, as Dr. Parker says, such deaths are entirely preventable. The prevention of these tragedies is attainable if certain quite simple rules are observed.

(1) The lithotomy position should not be used in forceps delivery unless regional analgesia, in some form, is employed. It is difficult to ensure that the stomach is empty, for it empties slowly and intragastric pressure is high in labour, especially with

the patient in the lithotomy position.¹ Most people agree that it is an abomination to inflict a wide-bore stomach tube on a patient at the close of a long and tiresome labour, and it is doubtful whether even this procedure ensures an empty stomach. The adoption of the lithotomy position for forceps delivery arose because of the failure to differentiate between gynaecological patients who are properly prepared for anaesthesia and obstetric patients who hardly ever are so prepared.

(2) The lateral position effectually abolishes the risk of aspiration of vomit. It is the position into which all patients are put when recovering from an anaesthetic to obviate any risk from obstruction to the airway from vomiting. The use of the Sims position, in fact, results almost inevitably in the head and shoulders of the patient assuming a semi-prone position during anaesthesia. All this is elementary, but it is failure to grasp the simple facts which is chiefly responsible for the fatalities. I have repeatedly invited anyone to produce records of even a single case of death from aspiration of vomit when the patient has been delivered in the lateral position, and as nobody has responded it must be an extremely rare event, if, indeed, it ever occurs. From the obstetric angle I venture to assert that there is no procedure necessary during forceps delivery which cannot be satisfactorily carried out with the patient in that position, provided one is familiar with it. It is merely a question of orientation.

(3) The method of anaesthesia is clearly a matter of importance. Many of us who have used open ether for forceps delivery for many years are convinced of its supreme safety.² Although vomiting frequently occurs, the coughing reflex is nearly always retained, and in any case if the lateral position is used all the conditions are present for safe delivery. It would seem from the evidence available that elaborate anaesthetic machines may in certain circumstances be a contributory factor in a fatal result, and I seriously suggest that the rigid lithotomy supports in hospital are particularly dangerous in forceps delivery. In regard to the question of the passage of an endotracheal tube, it must be remembered that this presupposes that the patient is already fairly deeply anaesthetized. Now, as vomiting and aspiration of vomit tend to occur during the induction of the anaesthetic,³ of vomit tend to occur during the induction of the anaesthetic, it is in itself a procedure by no means devoid of risk. Presumably it would be performed with the patient in the dorsal position, which would diminish but not eliminate the danger.

Bleak as the prospect is, there are certain hopeful indications. One is, of course, Dr. Parker's impressive analysis of the situation, which should at least make those responsible for hospital obstetrics think very seriously. Secondly, meetings have taken place between obstetricians and anaesthetists in regard to this important matter, though any agreement on a solution appears, so far, to have eluded them, imperative though this is. Perhaps the most encouraging feature is that in at least two large teaching hospitals some (if not all) of the obstetric staff are teaching the lateral position for forceps delivery.—I am, etc.,

A. H. MORLEY.

Debt to the Middle Ages

SIR,—Sir Francis Walshe's stimulating address at Sheffield University (*Journal*, June 23, p. 1441) displays the debt, long overdue, which we owe to the Middle Ages in Europe. If I may say so, it is to America also that we owe a debt for a good deal of the research work done on the Middle Ages by another famous neurologist, but also clearly a distinguished classical scholar, Dr. James J. Walsh.¹ It is interesting to note that Alfred North Whitehead² says on our debt to the Middle Ages: "The Middle Ages formed one long training of the intellect of western Europe in the sense of order. There may have been some deficiency in respect of practice."

Now this contrasts rather with what was actually effected. James J. Walsh,³ writing on the reform of the Prussian hospitals, whose state had fallen so low in the nineteenth century, due to the poor standard of nursing, etc., that the century, due to the poor standard of nursing, etc., that the surgeons threw in their hand, said: "It was the Aegean task of cleaning up these stables as far as Prussia was concerned that was put on Virchow's (1821-1902) shoulders, and with his usual thoroughness he proceeded to learn

all he could about hospitals, so as to use his information to the best advantage. Above all he studied the history of German hospitals and gathered details that proved very interesting. He found that in the late Middle Ages—i.e., thirteenth and fourteenth centuries—there had been a marvellous development of hospitals throughout Germany. It is probable that practically every town of more than 5,000 inhabitants had a hospital. Virchow actually found that during the thirteenth century alone close on 100 hospitals had been founded in various parts of Germany. When he unearthed the efficient cause of the hospital organization he found it was to be traced to the movement set on foot and the initiative awakened by a single Pope, Innocent III (1198-1216). As Virchow said, it may be recognized and admitted that it was reserved for the Roman Catholic Church and for Pope Innocent III not only to open the course of Christian charity and mercy in all its fullness but also to guide the life-giving stream into every branch of human life in an ordered manner." He added for this reason alone, if for no other, the interest in this man and in his time will never die out.

Virchow found that these early German hospitals had been very well conducted. Indeed, when Pope Innocent III brought about their foundation through his encouragement and practically positive command (for every bishop on his visit *ad limina* was told that the Pope expected him to build a hospital in his diocese), the pontiff provided not only the model of a hospital in Rome but also the religious order, that of the Holy Ghost, to care for it. (Virchow was buried with Lutheran rites, but was known to be a professed agnostic.) In conclusion one would like to mention the very powerful letter of J. B. Oldham to *The Times* some weeks ago, which constrains one to hope for a British Virchow to bring our own hospitals up to date.—I am, etc.,

G. L. GATELY.

Unconscious Mental Activity?

SIR,—The letters of Dr. S. Sament and Dr. E. R. Banner (*Journal*, July 14, p. 103) seem to bring our understanding of general mental processes up to date. Dr. Sament is right when he claims that the advantage of the Pavlovian system of conditioned reflex psychology is that it is open to experimental check under controlled conditions, but he does not make it clear that this will inevitably lead to progression in a circle, inasmuch as the method itself is based on reflex activity of a specialized nature, and investigating reflexes by means of reflexes, while providing plenty of opportunities for permutations and combinations, is not going to advance independent knowledge of mental processes. Dr. Banner wants to hold on to his Freud, but under new names. A rose by any other name, gentlemen, will smell the same. I do sympathize with him, however, while feeling that he is not really offering us a solution so much as an elegant complication.

Can we now take one step forward into the untried? Both your correspondents concentrate entirely on the brain. But the source of the dynamic unconscious (I am proud to use this fine term myself) is the whole body. The brain is a specialized organ where the activity of the body is translated into conceptual thought. The origin of this conceptual thought is physical—the body, neither more nor less. Schopenhauer called the body "the immediate object of experience." We do not know anything that we do not experience, and we do not experience anything beyond the activity of our bodies. Freud drew attention to certain barriers to the full understanding of the body, and attempted to overcome them. In order to do this he gave names to certain fairly well defined states of dynamic equilibrium, best observed in the form of their development in the child. But once he had named these states they lost their dynamic (naming things is the curse of science) and became concepts

when the public are advised to report their slightest ill-health and to avoid serious consequences.

Recently I encountered several instances where the mother was rightly alarmed, and at the time I was worried and puzzled by the "illnesses," although they may be classed officially as "minor" or "unrelated" in retrospect. One was a case of nephritis, which dated from a positive Mantoux test and took three weeks to settle. In another, fifteen days after a successful B.C.G. vaccination, a boy developed giddiness, drowsiness, and vomiting, with a pyrexia of 102° F. (38.9° C.) with no clinical signs—it lasted for three days. In a third, twelve days after his first B.C.G. vaccination, he developed epigastric pain, a temperature of 99° F. (37.2° C.), a tachycardia of 120 and multiple itchy papules. Four weeks later the temperature was still 98.6° F. (37° C.), and a few papules were still present ten weeks later. A diagnosis of B.C.G. bacteraemia was provisionally made. The fourth case was of a baby of 19 months old who vomited 24 hours after her first poliomyelitis vaccination, with a temperature of 101° F. (38.3° C.)—subsequently she was drowsy, with heavy breathing and a streaming head-cold, which cleared up suddenly after 36 hours.

Such cases further confuse the difficult problems of recognizing the new virus and collagen diseases, the toxic effects of certain new drugs, and even a surgical emergency during cortisone therapy, with which the general practitioners are already faced. Unless a much closer follow-up of all cases is made, how can the organizers of the B.C.G. and polio vaccination campaigns conscientiously advise that the vaccines are "safe"? How can they be sure that a further vaccination will not produce a "serious complication," if a minor reaction occurred previously? Surely the medical profession, and the parents, are entitled to more than "presumptive" evidence before embarking on widespread vaccinations.—I am, etc.,

London, N.7.

CHARLES O. KENNEDY.

Early Management of Poliomyelitis

SIR,—Having read the article "Early Management of Poliomyelitis," by Dr. E. G. Brewis (*Journal*, June 30, p. 1539), I was surprised at his remarks regarding the admission of patients to hospital, in which he advocates that, despite the diagnosis becoming more certain, in the event of the family doctor considering that the patient be admitted to hospital this course should be firmly resisted. The essential aim of treatment of anterior poliomyelitis is the prevention, if possible, of paralysis. In my opinion, anterior poliomyelitis of itself is not a disease to be dreaded, but the possible complication of involvement of the nervous system and subsequent paralysis is the reason why this disease must be treated with caution once it has been diagnosed.

To ensure that adequate measures are taken to prevent or minimize the complication of paralysis, admission to hospital, in my opinion, is strongly indicated except for very unusual circumstances, and this view is advocated by the Ministry of Health in their circular on poliomyelitis, dated July, 1954, in which, on page 7, it is stated that, "upon being informed of a case, the medical officer of health, or his representative, should visit the patient's home and help to get him into a suitably equipped hospital if this has not already been done."

In addition to my duties as medical officer of health, I am also fortunate to be in charge of a number of isolation beds at South Petherton Hospital, Somerset, and from January, 1947, to March, 1956, inclusive, 162 cases of anterior poliomyelitis, ranging from mild cases to cases of bulbar and respiratory paralysis and extensive limb paralysis, have been treated. The case fatality of these cases was one. I attribute in great part any success which might be claimed to the fact that practitioners in my area recognize the prophylactic value of adequate rest, and arrange with me for the patient's admission to hospital as soon as the case is diagnosed. I am convinced that the average parent is

not capable of ensuring that the patient receives the same degree of rest as can be given in hospital. The disease, rightly or wrongly, occasions considerable distress and worry to parents, and this sense of worry is communicated to the patient. Frequently I have examined patients in their home when often they are restless and anxious, but on removal to hospital, where there is a calm air of reassurance, the patient's general condition is much improved.

Dr. Brewis, in his indications for admission, refers to extensive paralysis of limbs or back, weakness of the shoulder girdles, which may precede involvement of the diaphragm, difficulty in swallowing or breathing, and I maintain that if the admission of patients is delayed until such indications are present then the risk of grave paralysis or of death is very considerable. Further, to ask a family practitioner to retain such cases at home until the indications for admission, as put forward in the article, are present places an intolerable responsibility on the practitioner. In certain cases of this disease the time between onset of the disease and of paralysis or severe complications can be relatively very short, and, unless trained nurses are available who have the knowledge and experience to appreciate any deterioration of the patient's condition, nursing of cases at home could easily result in the patient's admission being so delayed that death is almost inevitable. The policy of refusing admission could be a factor in the fatality rate which Dr. Brewis gives in his article, and to which he refers as making "lamentable reading."

Case histories of five patients, illustrating the necessity of cases being nursed in hospital, are available, but space does not permit them to be printed.

In conclusion, might I observe that two blood samples in cases, or suspected cases, of anterior poliomyelitis in children aged 2–10 years are now requested for diagnostic purposes? The use of a surface anaesthetic such as "xylotox-extra" (lignocaine with methocaine hydrochloride) renders the operation almost painless and greatly facilitates the taking of blood, particularly of the second sample.—I am, etc.,

Yeovil.

P. P. FOX.

Living on a Pension To-day

SIR,—In working on a book on the above, I feel that one or two typical budgets from retired doctors would be helpful and illuminating. Any figures given me would, of course, be used under complete anonymity, only the definition of "a doctor" or "medical specialist" being used.

The heads under which I am listing annual expenditure are rent or capital on loan, rates, household repairs and maintenance, food, clothes, domestic help of any type, tobacco, drinks, entertainment, car (if any), holidays, insurance, medical incidentals. I am particularly anxious for budgets on the £250, £350, £450, £550 a year level, but one or two about £1,000–£1,250 would be equally welcome.

To senders of budgets used I shall post a proof of the chapter on budgets, so that they may profit by the exchange.—I am, etc.,

Windrush Cottage,
Fairlight,
Near Hastings, Sussex.

CECIL CHISHOLM.

Unusual Injury

SIR,—An unusual injury came to my notice which I thought might be of some general interest.

My patient was making some adjustment which involved groping with his left hand behind the dashboard of his car, during which the metal strap of his wrist watch shorted one of the ammeter connexions to earth. The heat generated was apparently sufficient to melt one of the links and he sustained a second-degree burn some ½ in. (1.27 cm.) by 1 in. (2.5 cm.) on his wrist.

This danger in low-voltage circuits may not be generally appreciated.—I am, etc.,

Fleet, Hants.

C. R. TILLY.

Obituary

W. POINTON DICK, M.R.C.S., L.R.C.P.

Dr. W. Pointon Dick, adviser to the Government of the Gold Coast on the prevention, control, and treatment of tuberculosis, died suddenly in Accra on July 8, after a few days' illness, at the age of 51. Born on May 28, 1905, at Ealing, where his father, Dr. W. B. Dick, was in practice, William Pointon Dick was educated at Brighton College and entered the medical school of St. Thomas's Hospital in 1927. His student career was calamitously interrupted by five years of ill-health, culminating in a major chest operation, which left him with some degree of permanent disability; yet with characteristic courage and determination he went on to qualify M.R.C.S., L.R.C.P. in 1941.

After a resident post at Hereford General Hospital, Pointon Dick joined the medical staff at Harefield Sanatorium. He went from there to the Ealing Chest Clinic, and in 1943 took charge of one of the first mass miniature radiography units to operate in this country. His work in this field soon bore the mark of an original and inquiring mind. He was able to show how repeated surveys of a given population group can be used to reduce the local incidence of pulmonary tuberculosis to a very low level. His critical studies on the tuberculin patch test did much to establish a standard technique at a time when this test was in general use. In 1951 he was seconded to the Medical Research Council and as an attached member of its Tuberculosis Research Unit took part in the earlier stages of the B.C.G. vaccination trial, results of which have only recently been published. A year later he was appointed to the Government of the Gold Coast as a specialist under the Colonial Office, to investigate and advise on tuberculosis control in that country.

It was in Africa that Pointon Dick can be said to have found his true vocation. The climate suited him and his health improved, so that he was able to bring the full resources of his clinical and epidemiological experience to bear on the formidable problems that confronted him. What measure of success he achieved, in the short space of time that was afforded him, vital statistics will certainly reflect and work to be published may yet illuminate. It is already obvious that a sound basis has been laid under his imaginative guidance for his successors to build on. His loss will be mourned, not less by those in West Africa who owe him perhaps more than they know, than by his many friends in this country, whose deep sympathy will go to the wife and young daughter that he leaves.—B. C. T.

Mr. J. B. DAVID, honorary secretary of the Gold Coast Branch of the British Medical Association, writes: On any of the roads linking the scattered towns in this widespread tropical country one might come across Pointon driving his magnificent car at breakneck speed but with superb skill. He would be on one of his innumerable journeys to supervise the treatment of tuberculosis. In his younger days a well-known racing driver, he still retained unimpaired the ability to manage fast cars at speed. Also in his younger days he had conquered the scourge of tuberculosis in himself, and had come out to the Gold Coast to organize a service to limit the ravages of the disease among the inhabitants. During his time here he had endeared himself to all, both British and Africans, and had come to love the country where he worked. With very little fuss, he had

succeeded in building the foundations of a service which, if he had been allowed to live, had all the promise of unique success in the future. His experience and advice were available freely and, by reason of his prodigious journeys, to a very wide area, and it was somewhere on the last of these tours that he picked up the virus which ended his life. His work here had only just started, but its scope is shown by the concourse of all sorts of people who attended his funeral, Africans, high and low, British, friends, and patients. In stature he was a small man, but great in spirit, and his passing will leave a void here which will not easily be filled.

R. M. DOWDESWELL, M.D.

The sudden and untimely death on May 31 of Dr. Roland Dowdeswell, occurring as it did on the eve of his taking up a new laboratory appointment in Rhodesia, has been a great grief to his many friends. He was 54 years of age.

Roland Melville Dowdeswell was born in Bengal on October 23, 1901, and was educated at St. Paul's School and Emmanuel College, Cambridge. He went on to St. Thomas's Hospital for his clinical training, qualifying M.R.C.S., L.R.C.P. in 1928. He took the Cambridge degree of B.Chir. in 1932 and proceeded to M.D. six years later. In 1930 he obtained the certificate of the London School of Hygiene and Tropical Medicine and entered the Colonial Medical Service (now Her Majesty's Overseas Civil Service), and worked for several years as a medical officer in the Northern Frontier and Kavirondo provinces of Kenya. His particular interest was in bacteriology, and, in recognition of his ability in this field of medicine, he was in due course posted as bacteriologist at the Medical Research Laboratory, Nairobi. In 1948 he was appointed deputy director of laboratory services in Kenya, from which post he retired in 1950. He was honorary secretary of the Kenya Branch of the British Medical Association in 1939–40. After leaving the Colonial Medical Service he held appointments successively as visiting professor of bacteriology in the University of Beirut, and, since April of last year, as director of laboratories at the El Caloub Public Health Demonstration Project in Egypt under the World Health Organization. His contributions to medical literature included articles on typhoid agglutinins in the native population (1937) and schistosomiasis in the Kavirondo district of Kenya Colony (1938) in the *Transactions of the Royal Society of Tropical Medicine*, and a description of an outbreak of dysentery in a school in the *Lebanese Medical Journal* in 1953. He is survived by his widow, formerly Miss Sheila Patterson, whom he married in 1941, and three sons.

J. C. C. writes: Roland Dowdeswell's talents were varied and his interests were by no means confined to his professional work. He was an enthusiastic tennis and squash-rackets player, a distinguished chess player, and, perhaps most surprisingly, an intrepid big-game hunter. But above all there remains to refer, even though it be inadequately, to his unique personality, his critical and questing spirit. It is perhaps this which will be of the most enduring value, at least for those who knew him well and who cannot fail to have been affected by its influence. The keynote of his character was an all-pervading integrity, a sustained endeavour not only to think out basic principles of living but to live according to those principles. Such courageous sincerity is rare, but, if Bernard Shaw's dictum that "hardly any of us have ethical energy enough for more than one really inflexible point of honour" is true, then Roland Dowdeswell was one of those exceptional folk who had that sort of energy, and he lived to prove that living on those lines is not impossible.

R. SCOT SKIRVING, M.B., F.R.A.C.P., F.R.A.C.S.

Dr. R. Scot Skirving died peacefully at his home at Sydney, New South Wales, on July 15. He was in his 97th year, and, although the news of his death naturally caused no surprise, it came as a wrench to some of his friends in whose minds Scot Skirving was implanted as an age-long tradition. They had invested him with a cloak of permanence, and could hardly believe that he was no longer with them. On his 90th birthday he wrote of "the many kind references to my antiquity and persistence in living," and continued, "I am absurdly old, and I think with shame how little I've done with my long life." Therein lay his modesty: he might well have been proud of his achievement.

A member of a well-known Haddington family, Robert Scot Skirving graduated M.B., C.M., with honours, from Edinburgh University in 1881. He was elected a Fellow of the Royal Australasian College of Surgeons in 1936 and a founder Fellow of the Royal Australasian College of Physicians two years later. After graduation he was house-physician to Sir Douglas MacLagan, and then house-surgeon to Professor James Spence at Edinburgh Royal Infirmary. Scot Skirving's younger brother, "Archie," who died in 1930, became a well-known Edinburgh surgeon, but Robert, though he would have succeeded anywhere, chose to go to Australia, then known as "the distant colony," in 1883. "Though I love it still," he wrote recently, "Sydney is no longer the jolly little friendly town of Victorian days." But, like Robert Louis Stevenson in distant Samoa, his thoughts ever returned to the scene of his student life. Always a lively correspondent, he maintained a close touch with Edinburgh University, of which he was the oldest living graduate, and in recent years he was especially pleased to be visited by the Principal, Sir Edward Appleton, Professor D. M. Dunlop, and Dr. Douglas Guthrie. Many will remember how he recalled the past and told stories in his own delightful and witty fashion, illuminated by apt quotations from the poets, and especially from the Scriptures. He knew his Bible well, having lived in an age when the Bible was regarded as a textbook for every discipline.

It cannot be said that Scot Skirving ever retired from practice: even in his later years his services were in demand. His was a general practice in every sense of the term, and earlier in his career he had actually officiated, at the same time, as physician to one large Sydney hospital and as surgeon to another. He welcomed many British colleagues to Australia when the British Medical Association met at Melbourne in 1935. I had the pleasure of hearing him give a remarkable address at the postgraduate medical school at Sydney in 1953. It was entitled "Pneumonia, Then and Now." In a clear and audible voice the nonagenarian lecturer recalled the changes which he had seen since the time when lobar pneumonia was a common and devastating disease. Few of his hearers could recall such an age. The cheering which followed the lecture continued for several minutes. His younger friends—and to him anyone under 80 years was a "mere adolescent"—will not soon forget this grand old man whose charm of manner and whose gift for friendship endeared him to so many. —D. G.

We are indebted to Sir ROBERT HUTCHISON for the following appreciation: Robert Scot Skirving, I believe, was the

oldest Edinburgh medical graduate, as well as the doyen of the profession in Australia. I met him only once in the flesh, when the British Medical Association held its Annual Meeting at Melbourne in 1935, although I had known other members of his family since my early life: but we struck up a friendship which led to our exchanging letters every few months since that time, and his last letter to me is dated June 28. In his early years Scot Skirving went to sea in sailing ships, but left the sea for medicine and graduated at Edinburgh in 1881. He settled in Sydney, which he had visited on one of his voyages, and soon acquired a high reputation as a physician both in hospital and in private practice. He was very highly esteemed in his own city, and doctors visiting Sydney from the United Kingdom never failed to look him up. He told me in his last letter that not long ago he had met Russell Brain and Lionel Whitby in this way. Since the death of his wife a few years ago he had been rather lonely, and suffered also from much impairment of sight, which was a great grief to him, as he was fond of reading and a man of considerable culture. Altogether, Scot Skirving was a rather remarkable man.

HERMON WHITTAKER, M.R.C.P.

Dr. Hermon Whittaker died suddenly on July 18 at the age of 45. Hermon Whittaker was born on October 18, 1910, and developed severe diabetes in 1926 at the age of 15. On leaving his school in Yorkshire he became an assistant to a pharmacist, who thought so poorly of diabetics that he advised him to change from this career. Later he was guided into medicine and qualified M.R.C.S., L.R.C.P. from King's College Hospital in 1941, becoming an M.R.C.P. in 1944. His life as a doctor was devoted to the treatment of diabetics. He was first assistant in the diabetic department at King's College Hospital for many years and was in charge of the children's clinic there. Later, as a consultant, he developed an ever-growing diabetic clinic at Queen Mary's Hospital for the East End. He was the chief adviser and stimulator in the work of the Diabetic Association for diabetic children. Among other things he pressed for the provision of residential homes and schools for neglected diabetic children and for holiday camps for diabetic children. He never spared himself, nor did he allow his own insulin life ever to interfere with the task in hand. His medical work and place will be difficult to fill, as his medical colleagues know. But he will be missed even still more by the thousands of diabetics he handled as if their lives were more important than his. In his quiet competent way he engendered a personal trust and love which will be a sad loss to them and to his co-workers. He leaves a widow and two sons.

Dr. WILFRID OAKLEY writes: As Dr. Whittaker worked for so long with me in the diabetic department at King's, I would like to add a few words of appreciation of his character and work. His wide knowledge of the management of diabetes was derived from personal experience and clinical observation rather than from scientific journals, and I always felt that he was even more interested in his patients than in their diseases. This approach to the problems of his fellow-diabetics was an example both to students and to colleagues, and was the underlying cause of his popularity with his patients. Quite apart, however, from professional ability, Hermon Whittaker will be remembered by his friends for his quiet sense of humour, his fairness, and his courage; he never thought too highly of life or death, which was perhaps why he faced the latter with the same fearlessness with which he lived the former. Diabetic children owe him a debt which he would never have wished repaid.

Miss MARTHA MARQUARDT

The obituary of Miss Martha Marquardt was printed in the *Journal* of July 21 (p. 181).

Dr. HARRY SUGARÉ writes: May I very humbly follow Sir Henry Dale and write my personal tribute to the late Miss Martha Marquardt, who had been personal secretary to Paul Ehrlich from 1902 until his premature death in 1915? Although, as Sir Henry rightly points out, her book *Paul Ehrlich*, written in English and published by Heinemann in 1949, "never appeared . . . to have the spontaneity and lively charm of the shorter character-sketch which she had written in German 25 years earlier"—namely, *Paul Ehrlich als Mensch und Arbeiter*, yet it is a mine of most interesting information for a good understanding of Ehrlich's personal life, traits, and his scientific career for those readers who are not familiar with the German language. Martha Marquardt, as well as Professor Carl Browning, emeritus professor of bacteriology in the University of Glasgow, were of considerable help to me by their long correspondence when I prepared a paper on the life and work of Paul Ehrlich delivered on the very day of the centenary of the birth of Paul Ehrlich, March 14, 1954, to the Leeds Jewish Medical Society, with Professor C. L. Oakley, Brotherton professor of bacteriology in the University of Leeds, in the chair. I value such correspondence most highly. In the preparation of this paper I received much help from Martha Marquardt. I look forward with great interest to the publication of the first volume of the collected edition of the scientific writings of Ehrlich.

Mr. T. G. CROMBIE, surgical registrar at the Queen Alexandra Hospital, Cosham, Portsmouth, under the South-west Metropolitan Regional Hospital Board, died on June 29 at the age of 33. Thomas Gilmour Crombie was born on November 3, 1922, and received his medical education at Edinburgh University, graduating M.B., Ch.B. in 1944, when he was awarded the Mouat Scholarship in the practice of the physic. After graduation he held appointments at the Walsall General Hospital and the country branch of the Royal National Orthopaedic Hospital at Stanmore, and then served in the R.A.M.C. from 1945 to 1947. Admitted F.R.C.S. in 1950, two years later he was appointed surgical registrar at Portsmouth under Mr. R. T. Campbell, first at St. Mary's Hospital and latterly at the Queen Alexandra Hospital.

R. F. R. writes: The untimely death of T. G. Crombie has caused the deepest grief to those of us who were privileged to be his closest friends. Crombie was a man of sterling character and forceful personality, who concealed beneath a somewhat cynical exterior an unfailing kindness of heart and devotion to his ideals. By nature outspoken and critical, his honesty of purpose was always apparent and deeply respected even by those who found themselves in disagreement with him. He was a brilliant conversationalist who never missed a point in debate, and whose shafts of wit enlivened any company in which he happened to be present. A week-end spent at his home in Portsmouth was always a memorable for—among other things—the humour and laughter which were inevitably associated with his charm. As an undergraduate at the University of Edinburgh, Crombie achieved the uncommon distinction of playing in the University fifteen during his first term. A Scottish cap was confidently forecast for him, but characteristically, having decided that he could not afford the time from his studies, he gave up the game completely at the end of his first year. Eighteen months ago he developed the first symptoms of the illness which was eventually to prove fatal. He was well aware of the probable outcome, but his outstanding courage was more than equal to the occasion. With strength of character undimmed, he carried on to the end. To his wife, who bravely tended him during his last days, and to his young son, we extend our deepest sympathy.

Mr. R. T. CAMPBELL writes: Thomas Gilmour Crombie bore with characteristic grit and determination the discomfort and anxiety of two major operations and the culmination of a long illness which he knew full well could have only one end. His sterling qualities, however, remained with him to the last, and his passing is mourned deeply by his many medical and nursing friends, and not least by the many patients who benefited from his kindness and skill.

Dr. A. J. H. ILES, consulting radiologist to the Taunton and Somerset Hospital, died in hospital at Taunton on July 3, nine days before his 78th birthday. Born at Taunton on July 12, 1878, the son of Dr. A. R. Iles, Alfred John Hopkinson Iles was educated at Repton School and at St. Thomas's Hospital. His medical training was interrupted by service in the South African War, during which, as a sergeant, he was responsible for the x-ray equipment for the whole Army in South Africa. The entire equipment, he used to say, was kept in a cellar and hardly used. On demobilization he returned to his medical studies and qualified M.R.C.S., L.R.C.P. in 1907. After qualification he held the appointments of assistant lecturer in surgery, demonstrator in physiology, and clinical assistant in the x-ray and electrical department at St. Thomas's before joining his father in general practice at Taunton, taking with him his interest in radiology. This interest led to his appointment as the first honorary radiologist to the Taunton and Somerset Hospital, a post which he held until his retirement in 1938. In the following year he was elected a Fellow of the Faculty of Radiologists. In addition to radiology, Dr. Iles was intensely interested in the use of electricity and massage in the treatment of injuries. He had a natural gift for inventing gadgets, and this gift he applied in many ways to his work and his hobbies. The outbreak of the first world war in 1914 saw him back in service with the R.A.M.C. The war produced a rapid advance in electrical and massage treatment. His abilities were quickly recognized, and he was asked to form and control the electrotherapy and massage centre in the medical base depot at Etaples. After the war he gradually gave up general practice and concentrated on radiology and physiotherapy. A member of the British Medical Association for nearly fifty years, he was honorary secretary of the old West Somerset Branch from 1922 to 1924 and president of the Branch in 1924-5. In 1932 the Branch became the West Somerset Division of the new Bath, Bristol, and Somerset Branch, and he was chairman of the Division in 1934-5 and president of the Branch in 1937-8. When the Association held its Annual Meeting at Cardiff in 1928 he acted as one of the honorary secretaries of the Section of Radiology and Physio-Therapeutics. For many years he was assistant county controller and director of the Somerset branch of the British Red Cross Society. In 1937 he was elected mayor of Taunton, during which year King George V visited Taunton, the first visit of a reigning monarch for 400 years. He acted as deputy mayor from 1938 to 1945. A staunch freemason, Dr. Iles was granted many masonic honours, and at the time of his death was provincial grand master of the South-western counties of England in the Royal Order of Scotland. He married Miss Florence M. Pink in 1906. His wife died in 1950; there were no children of the marriage.—L. P. M.

Dr. REUBEN LIPMAN died at his home in Liverpool on July 14 after a long and distressing illness, bravely borne. The eldest of seven children, Reuben Lipman was born at Leeds on October 23, 1900. His abilities carried him to high school and subsequently to Leeds University. His preparation for medicine was thorough. After taking an honours B.Sc. in physiology in 1921, he proceeded to the M.Sc. in the following year and to his medical degree in 1925. Soon after graduation he entered general practice in Leeds, and a few years later settled in the Aintree district of Liverpool. With this practice he remained connected up to the time of his death. During his student days Lipman had become interested in psycho-analysis, and it was in this

specialty that he later built up a private consulting practice. In 1934 Dr. Lipman was appointed to the staff of the Liverpool Psychiatric Clinic, then a voluntary institution, and continued his work there when, in 1948, the clinic was transferred under the National Health Service. His therapeutic skill was in constant demand. Though he remained a firm adherent and a clear exponent of psycho-analytic principles, he spurned no form of psychotherapy which he considered would be of help to the individual patient. This tolerance and breadth of outlook much increased the range of his powers and rendered him virtually irreplaceable on Merseyside. For several years he was a valued member of the South Liverpool Hospital Management Committee. It could be said that Reuben Lipman entered into life at many points, often with distinction, always with infectious enthusiasm: military training, athletics, games, swimming, boxing, painting, photography, and the pleasures of the countryside—all enriched his experience; and up to the time of his illness he took every opportunity he could for study abroad. He was an active member of the British Medical Association, the Royal Medico-Psychological Association, and the Liverpool Medical Institution. Among the qualities we shall miss most were the warm-hearted kindness of his nature and his staunch and loyal friendship. Many owe much to his generosity of spirit and to his unobtrusive practical help, and throughout his professional life one could rely on his unflinching presence in response to a difficult situation. At those times his insight and self-command enabled him to intervene without trace of self-assertion, yet powerfully and constructively, disarming factious opposition. The setbacks of his last illness found his courage unquenchable. He passes from our sight, untimely as it seems, and at the height of his powers: he is mourned by numberless patients, friends, and colleagues.

In 1928 Dr. Lipman married Miss Lili Raphael, of Darlington, who survives him, together with their two sons and two daughters—dental surgeon, research physicist, doctor, and student of dentistry, respectively; and it is to them that our thoughts and sympathies turn.—S. B. H.

Dr. J. O. W. DICK died from poliomyelitis at Oxford on July 14 at the age of 39. James Orford Wallace Dick was born on November 6, 1916, the son of the late Mr. J. R. Dick, F.R.C.S.Ed., of Scarborough. Educated at Wellington College and Trinity Hall, Cambridge, where he took his B.A. in 1937, he completed his medical training at the London Hospital, obtaining the degrees of M.B., B.Chir. in 1941. After graduation he held appointments at the London Hospital and Haymeads Hospital, Bishop's Stortford, before entering the R.A.M.C. in 1942. He volunteered for the Airborne Division and was with a glider battalion in France and Germany. For a time he held the appointment of deputy assistant director of medical services, and later was in command of a field ambulance in Norway and Greece, with the rank of lieutenant-colonel. After the war he spent another year at the London Hospital, and in 1948 settled in practice at Abingdon, Berkshire. He is survived by his widow, formerly Miss Mary Sykes, whom he married in 1943, and four children. His first daughter died in 1953.

J. R. E. writes: Orford Dick was a man of many interests who, throughout his all too short life, refrained from following a few to the exclusion of others. A natural athlete, he played games for enjoyment and recreation, not as an end in themselves. It was fitting that he should elect to enter general practice, in which he at once gained the confidence and affection of his patients. He set himself a high standard in everything he did. An integrity of purpose which in a lesser man might have had unhappy results only enhanced Orford Dick's popularity, and his love of life and his ready laugh made him a delightful companion. Much of his happiness was derived from his home life, for his marriage was a blessed one. His patients have lost a highly respected doctor and his fellow-practitioners a charming and loyal colleague. All who knew him have suffered keenly by his premature death.

Medical Notes in Parliament

Fluoridation of Water Supplies

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister of Health on July 20 how he assessed the required dose of fluoride to be added to water in experimental fluoridation areas; and to what extent he had followed the recommendation of the Report of the United Kingdom Mission to North America on the best way of determining the present level of ingestion of fluoride in human beings. Mr. R. TURTON said that the right level for the fluoridation of water in the studies in this country was determined as a result of investigations into the effects of water which naturally contained fluoride, and in the light of over 10 years of experience in other countries. It had been found that at one part per million a very high degree of protection against caries was given, but the mottling caused by higher concentrations was avoided. As regards the mission's suggestion for a survey of fluoride excretion, a pilot investigation confirmed the results obtained in other countries.

Strontium on Welsh Mountains

Mr. TUDOR WATKINS (Brecon and Radnor, Lab.) asked the Lord Privy Seal what effects strontium had had on Welsh mountain sheep. Major G. LLOYD-GEORGE, the Home Secretary, who replied on July 25, said that, in studying the distribution of radioactivity arising from fall-out, measurements had been made of the strontium-90 associated with the calcium in various biological materials. Among the representative samples of sheep bones examined, a few from very localized mountain areas in Wales had shown higher values than those from other areas. Even so, the levels were too low to have any detectable effects on the sheep.

French Ban on Pharmaceutical Goods

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) questioned the President of the Board of Trade about recent limitations placed on the importation into France of finished pharmaceutical products from England, and what reciprocal action he would take. Mr. PETER THORNEYCROFT stated on July 26 that a ban was imposed last January on imports into France of certain made-up pharmaceutical goods. After consultation with the French authorities he was satisfied that the ban was imposed for reasons of public health and safety, and not as a deliberately protective or discriminatory measure. The question of reciprocal action did not therefore arise. He was, however, considering an approach to the French authorities to find out by what means imports from the United Kingdom could be brought within their health requirements.

Chiropody Associations

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Labour on July 26 whether his attention had been called to a statement in *Careers Guide*, April, 1956, an official publication of his department, that the only training accepted as leading to a suitable qualification for inclusion in the British Register of Medical Auxiliaries was that approved by the Society of Chiropodists; whether he was also aware that the Institute of Chiropodists, formerly the Joint Council, and the Society of Chiropodists were mentioned as appropriate bodies in the Health Service Medical Auxiliaries Regulation, 1954, and that the qualifications awarded by both bodies were generally regarded as of equal value; and what action he proposed to correct this misstatement. Mr. ROBERT CARR, the Parliamentary Secretary, replied that the statement in the *Guide* was strictly correct. The complicated position in this profession might, however, have been more fully explained, and he would consider how best this information could be conveyed to the schools interested. Mr. HASTINGS: The

Minister of Labour, when Minister of Health, decided after careful study that these two bodies were of equal esteem. How comes it that as Minister of Labour he takes a different view? Mr. CARR replied that the Minister did not take any different view. The information in the booklet was strictly correct, but he would see what he could do to have it amplified. Mr. HASTINGS said it was stated in the booklet that only the Society of Chiropodists was an approved body, whereas, as was made clear in the statement of the Ministry of Health, both these bodies were regarded as of equal esteem. How could that be? Mr. CARR thought this was one of the few cases where they could both be largely right. The British register was maintained by the B.M.A., which recognized only the Society.

East Africa Inquiry

Mr. SOMERVILLE HASTINGS asked the Secretary of State for the Colonies on July 25 what he was doing to implement the recommendation of the East African Royal Commission that a medical commission should be sent out to make recommendations on the control of endemic and epidemic disease and preventive medicine generally. Mr. LENNOX-BOYD replied that a committee, under the chairmanship of Professor A. C. Frazer, of Birmingham University, had investigated the medical and health services in Uganda and its report would shortly be debated in the Uganda Legislative Council. The Governments of Kenya and Tanganyika saw no present need for a visit by an expert body. In Tanganyika a draft plan for the development of the medical services over the period 1956-61 was before the Legislative Council. He shared the view of the East African Governments that in these circumstances the recommendation referred to need not be followed up.

The Pay Claim

Mr. C. OSBORNE (Louth, Con.) asked the Minister of Health on July 30 what were the average net earnings of a general medical practitioner in the Health Service; what they were in 1939; and by what percentage they had risen. Mr. R. TURTON replied that the present average net earnings of a general medical practitioner after meeting his practice expenses were £2,222 a year. The corresponding figure for 1939 was £938, and the percentage increase was therefore 136.9. Mr. OSBORNE asked if the Minister would agree that, as the value of money had fallen by one-third since 1939, doctors were no better off; and that those working in rural areas who were on tap seven days a week fully earned what they got. Mr. TURTON.—I agree that both those working in rural areas and in urban areas deserve well of the community. Lieut.-Col. M. LIPTON (Brixton, Lab.).—But for the difficult economic circumstances of the country the doctors would have a good case for an increase. Mr. TURTON.—My reply to the claim was on the basis that in present circumstances it would not be right to give consideration to a claim for a general increase in remuneration. Dr. EDITH SUMMERSKILL (Warrington, Lab.).—How does the Minister reconcile that with the recommendations of the Spens Committee? Mr. TURTON.—The committee did not lay down any contractual obligation. They based their recommendations on what should be the level at which doctors entered the Service.

Danger in a Theatre

Mr. J. J. ASTOR (Plymouth, Sutton, Con.) asked the Minister of Health if he would make a statement on the recent death of a patient in the South Devon and East Cornwall Hospital, Greenbank, Plymouth, which was found due to infection caused by inadequate and dangerous conditions in the operating theatre. Mr. TURTON.—I have asked the regional hospital board for a full report on this case.

Mr. ASTOR asked what representations had been received by the South-west Regional Hospital Board over the last eight years from the hospital management committee and medical staff about the inadequate and dangerous conditions in the operating theatre at the South Devon and East Cornwall Hospital. Mr. TURTON stated that the board received

five representations from the hospital management committee about the condition of this operating theatre; the earliest was in April, 1950, and the most recent in January, 1955. The committee, however, recommended higher priority for two other capital schemes in their group. Mr. ASTOR asked if, in view of these unfortunate circumstances, the Minister would consider in similar cases intervening when medical opinion was in conflict with the hospital management committee. Had the management committee published the reason why it did not give priority to the rebuilding of this theatre? Mr. TURTON replied that it was clear that the committee took the view that the maternity unit was even worse than the operating theatre. He had now received a proposal for a new operating theatre. It was submitted on June 19, and he had approved the preparation of sketch plans on July 23. That work would go forward in due course.

Tranquillizer Drugs

Mr. BLENKINSOP asked the Minister whether he would give guidance in his *Notes to Prescribers* to general practitioners as to the cost of tranquillizer drugs. Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, said the Minister would certainly consider whether there was any information which general practitioners might find useful if circulated to them in this way. Mr. BLENKINSOP asked that the Ministry should encourage a campaign to make clear that these drugs, which might cost up to 35s. for a bottle of 50, were of very doubtful value. Miss HORNSBY-SMITH replied that *Notes to Prescribers* were supervised by an editorial committee on which the B.M.A. was represented. She agreed that this might be something they could consider, but it was only recently that these drugs had been introduced. Dr. EDITH SUMMERSKILL (Warrington, Lab.) said it was because they had been recently introduced that they were being widely advertised among doctors.

Ophthalmic Tests.—Under the supplementary ophthalmic services about 415,200 tests were made in 1954 in the area of the London executive council, and 443,200 in 1955. Spectacles were prescribed in about 359,600 cases in 1954, and in 385,100 cases in 1955.

Research on Genetics.—During the financial year 1956-7 expenditure by the Medical Research Council on research on genetics is estimated at approximately £70,000.

Medico-Legal

LIBEL ACTION SETTLED

The libel action¹ brought by the Royal College of Obstetricians and Gynaecologists against Associated Newspapers Ltd., and others, in respect of an article which appeared in the *Daily Sketch* on January 4, 1956, was settled before Mr. Justice Pearce on July 25.

Mr. H. Milmo for the plaintiffs said that the article entitled "Must Our Babies be Born in Pain?", published under the name of Dr. Jon Collen, asserted that the Royal College had acted in a shameful manner towards a medical practitioner, who it was stated was the man primarily responsible for the new look in obstetrics, that they had prevented him from working in any hospital in the country, and had caused him to be harried and cold-shouldered by the medical profession. He said that this grave attack upon the honour and propriety of the Royal College was utterly false and without foundation. The defendants had apologized, published a note in the *Daily Sketch* of January 6 regretting the wording of the article, and agreed to pay the Royal College substantial damages, in addition to their taxed costs of these proceedings. Mr. N. Faulks for the defendants said he desired to associate himself with everything which Mr. Milmo had said. He expressed the defendants' sincere apologies. Mr. Milmo asked leave to withdraw the record of the action, which Mr. Justice Pearce granted.

The damages are understood to have amounted to £600.

¹ *British Medical Journal*, January 21, 1956, p. 176.

Wykes, Grace O. Yolo, R. C. Young, Barbara K. Zamoyka.

¹With honours. ²Distinguished in pathology. ³Distinguished in medicine. ⁴Distinguished in applied pharmacology and therapeutics. ⁵Distinguished in surgery. ⁶Distinguished in obstetrics and gynaecology.

The following candidates at the Institute of Psychiatry have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE.—F. Grunberg, N. H. Rathod. The following have passed in Part I only: W. H. Allchin, C. P. B. Brook, M. D. Eilenberg, L. Goldie, O. A. F. Grant, J. M. Hinton, G. M. Jacobides, I. P. James, W. I. N. Kessel, N. B. Kreitman, H. McG. McBryde, Naomi I. Penfold, R. Rodriguez Arganaris, M. H. Sheard, H. J. Walton, S. Wolf.

The degree of M.D. was awarded by the Senate on May 16 to T. G. Paxon.

UNIVERSITY OF WALES

The following candidates were admitted to the degrees of M.B., B.Ch. at a Degree Congregation held at Cardiff on July 24:

A. V. Barford, Hannah M. Biddow, June M. Birch, D. H. Blacknall, B. K. Bondzi-Simpson, P. Coy, D. Daley, D. E. Davies, I. A. Davies, J. A. Dodge, J. R. Dove, J. G. Elias, A. G. Evans, D. H. Evans, Ruth E. Francis, D. J. Griffiths, M. F. Holding, D. S. B. James, Enid P. Jarvis, R. A. C. Jones, W. I. Jones, Sheila B. Kidd, G. S. Lodwig, W. S. B. Loosmore, R. G. Penn, G. A. D. Rees, G. E. Roberts, Marise E. Roch, Jean M. Summerell, W. G. Thomas, G. L. Williams, J. M. Williams, Margaret D. Wyatt.

UNIVERSITY OF BIRMINGHAM

Dr. John Hardwicke, Lecturer in Experimental Pathology, has been appointed Deputy Warden of the Manor House.

Professor W. Melville Arnott, Professor A. P. Thomson, Dr. A. G. W. Whitfield, and Mr. Hugh Donovan have been appointed representatives of the University on the Standing Joint Committee of the University, the United Birmingham Hospitals, and the Birmingham Regional Hospital Board for the period April 1, 1956, to March 31, 1957.

UNIVERSITY OF BRISTOL

The dissertations by A. G. M. Davies and Grace E. Woods for the degree of M.D. have been approved.

The following candidates have been approved at the examinations indicated:

FINAL M.B. Ch B.—¹Pauline F. Haswell, ¹D. H. Wright, Miriam M. Alderwick, B. O. Amure, Elizabeth M. F. Andrews, J. H. Andrews, J. C. Bailey, E. P. Beck, ²W. E. Benney, B. T. A. Clarke, Ruth E. A. Coles, H. E. Cramp, J. D. Davison, K. M. Evans, Irene E. Gibbs, P. M. Gill, C. L. G. Hale, A. F. Hickson, A. L. Horton, Rachel M. Hulbert, A. T. Lloyd, Sheila M. McClements, June M. McLeod, T. McMorley, R. W. Morris, A. N. Okoro, K. M. Parry, W. F. Perera, C. K. Protheroe, M. J. Rose, W. J. Stephen, S. J. Strong, J. P. Telling, M. J. Watson, A. H. E.

Williams, Mary B. Wilson, C. H. Wood. In Group 1 only: W. B. Whisker. In Group 11 only: J. S. A. Ashley, B. H. Bee, Edna M. Dumbell, M. J. Lewis, H. E. Millen, R. D. Neale, Hilary S. Prowse.

¹With second-class honours. ²With distinction in public health.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on May 10, with Sir Harry Platt, President, in the chair, the death of Mr. R. P. Scott Mason (Vice-president and member of the Court of Examiners) was reported and the Council unanimously adopted a resolution of condolence.

The President was asked by the Council to convey to Mr. Gerald S. Hughes, of York, its hearty congratulations on having completed fifty years as a Fellow of the College.

Dr. Bernard Johnson (Middlesex Hospital) and Professor Mary Lucas Keene (Royal Free Hospital) were admitted to the Fellowship, having been elected as medical practitioners of twenty years' standing.

The Begley Prize was awarded to C. R. N. Ashbee, of St. Bartholomew's Hospital Medical School.

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows: In Child Health, to Mary K. M. Lindsay; in Tropical Medicine and Hygiene, to D. Buchanan and A. M. Rankin; in Industrial Health, to Doreen P. Allan; in Anaesthetics, to R. P. Holmes.

At a meeting of the Council of the College held on June 14, with Sir Harry Platt, President, in the chair, the Mitchiner Medal was presented to Colonel R. E. Waterston and the Lady Cade Medal to Air Commodore C. A. Rumball.

Professor F. A. R. Stammers was appointed as representative of the College on the Court of Governors of Birmingham University, and Sir William Kelsey Fry on the General Dental Council.

The Begley Prize was presented to C. R. N. Ashbee, of St. Bartholomew's Hospital Medical School.

Diplomas of Fellowship were granted to the following successful candidates:

H. M. Parsons, P. D. G. Pugh, I. K. R. McMillan, P. N. Porritt, G. N. Lumb, P. I. Busfield, S. S. Grové, P. E. B. Holmes, Ruth M. Robinson, J. C. Gazet, A. R. Butterfield, A. M. Morkos, E. P. Abson, I. Coll, A. W. Eklund, D. Guha, J. N. Ormrod, M. N. Dutta, N. G. I. Mehta, V. A. T. Robb, D. St. C. Roberts, A. R. Dalton, Hussain, L. I. McGuire, W. W. Woodward, R. P. Chandler, G. A. Dalton, M. A. Hossain, I. D. Thompson, A. C. Bowring, R. R. Collmann, K. C. D. M. A. Lam, N. C. Little, J. A. MacDougall, G. F. Murnaghan, Gordon K. L. Lam, N. C. Little, J. A. MacDougall, G. F. Murnaghan, S. P. Parkash, J. N. Rohatgi, J. N. Tennant, M. M. Whiteley, S. Bhattacharyya, K. McD. Ewen, L. B. Fleming, J. D. Russell, R. G. D. M. McLaren, T. J. McNair, J. D. Marsh, E. A. D. Cox, W. F. P. White, J. C. Wilson, R. G. Beard, N. A. Blumberg, K. R. Ross, N. G. Gammie, A. B. Holmes, D. Howell, A. M. Jatoi, J. K. Ross, N. G. Rothnie, R. Shannon, J. P. Williams, G. Wynne-Jones, R. P. Yaxley, G. E. Allin, J. B. Borman, M. D. Cameron, M. Clardige, P. B. Clark, G. T. Costello, C. L. Greaves, J. P. Halliday, G. W. Hankins, W. Lane, Mitchell, H. Perkin, P. B. Prasad, A. Singer, J. B. Walker, G. A. Cutler, B. J. Dooley, R. F. C. Jones, W. J. Lyons, N. S. Painter, I. Penn, J. M. Saunders, R. D. Smith, J. D. Crowley, H. T. John.

A Diploma of Membership was granted to E. O. O. Arbenser (Liverpool).

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on May 9, with Sir Walter Mercer, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

P. L. Berger, J. Bingham, A. C. Bowring, M. E. J. Brightman, I. Coll, H. Collinson, G. I. B. da Costa, G. A. Dalton, P. C. Dubey, D. B. Eaton, A. W. Eklund, C. A. Ezike, C. L. Greaves, M. B. Johnson, E. P. J. King, R. P. Leake, J. I. de B. Leembruggen, D. O. Maisels, N. K. G. Mendis, J. H. Miller, A. H. Mizrahy, H. Mohan, J. Morgan, N. R. A. Narayan, K. G. Orr, J. R. Page, H. Perkin, K. P. Prabhu, M. A. Qayyum, L. A. Sarembock, F. W. Shea, C. A. Shearer, D. M. Sinclair, D. P. Singh, R. D. Smith, B. D. Stringer, J. N. Tennant, I. C. K. Tough, R. Yule.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the College held on June 1, with the President, Dr. F. J. O'Donnell, in the chair, Dr. John G. Kirker was admitted to the Fellowship, and Dr. R. A. L. Agnew, Dr. R. W. Barter, Dr. M. D. Joyce, Dr. W. H. Moffatt, and Dr. W. A. Ryan were admitted to the Membership of the College.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

At a meeting of the Council of the College held in Sydney on June 15, the following candidates, who were successful at an examination by the Australian Board of Censors, were admitted to Membership of the College: Dr. W. J. Hickey and Dr. I. J. McGelvie, of Queensland; Dr. P. N. Francis, Dr. J. E. Hassall, Dr. W. B. Hennessy, Dr. J. W. Lance, Dr. P. J. Maloney, and Dr. B. J. Smith, of New South Wales; Dr. J. M. Bradley and Dr. R. E. Seal, of Victoria; Dr. M. D. Begley and Dr. H. Lander, of South Australia; and Dr. J. B. Stokes, of Western Australia.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 14 (No. 28) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications in the week ending July 21 (29th week of the year) were as follows: paralytic 70 (49), non-paralytic 72 (58), total 142 (107). This is an increase of 35 compared with the previous week, the figures for which are in parentheses.

Cases notified from the beginning of the year (with rate per 100,000 population in parentheses) are as follows for districts of relatively high incidence: Macclesfield M.B. 24 (66), Whitehaven M.B. 22 (87), Ennerdale R.D. 18 (63), Darlington C.B. 19 (23), Middleton M.B. 12 (28), Yeovil M.B. 18 (75), Yeovil R.D. 6 (25), Guildford M.B. 30 (60), Carlton U.D. 7 (19), Manchester C.B. 148 (21), Woking U.D. 12 (21), Tottenham M.B. 21 (17), Reigate M.B. 9 (19), Guildford R.D. 11 (23), Hambledon R.D. 7 (21), Hoyland Nether U.D. 3 (19).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus ----, the figures for 1956 thus —. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were less prevalent in England and Wales during the week ending July 14. The largest declines in the numbers of notifications were 168 for scarlet fever, from 682 to 514, 153 for measles, from 3,429 to 3,276, 86 for dysentery, from 1,235 to 1,149, 84 for food-poisoning, from 480 to 396, and 49 for acute pneumonia, from 259 to 210.

The largest falls in the incidence of measles were 66 in Southampton County, from 139 to 73, and 54 in Sussex, from 172 to 118; the largest rises were 93 in Yorkshire East Riding, from 32 to 125, and 57 in Cornwall, from 67 to 124. A small decline in the incidence of scarlet fever was recorded in most regions, and there were no large local variations in trend. 2,404 cases of whooping-cough, 1 fewer than in the preceding week, were notified. The only large fluctuation in the local returns was a rise of 106 in Yorkshire East Riding, from 11 to 117. This was mainly due to an outbreak in Hull C.B., where 91 cases were notified. 5 cases of diphtheria, 2 fewer than in the preceding week, were notified.

The largest centres of dysentery were Yorkshire West Riding 259 (Leeds C.B. 53, Rotherham C.B. 37, Sheffield C.B. 32, Huddersfield C.B. 18, Dewbury C.B. 17, Adwick le Street U.D. 16, Wakefield C.B. 14), London 164 (Wandsworth 43, Lewisham 23, Woolwich 17, Greenwich 14, Hackney 10), Lancashire 137 (Liverpool C.B. 31, Blackpool C.B. 25, Lancaster M.B. 17), Warwickshire 77 (Coventry C.B. 62), Staffordshire 40 (Smethwick C.B. 26), Kent 36 (Dartford M.B. 11, Eassey R.D. 10), Middlesex 35 (Twickenham M.B. 18), Essex 34, Leicestershire 33 (Leicester C.B. 28), Lincolnshire 30 (Grimsby C.B. 22), Sussex 26, Southampton 25 (Farnborough U.D. 12), Nottinghamshire 24 (Nottingham C.B. 13), and Suffolk 22 (Ipswich C.B. 22).

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in June was 97, compared with 116 (revised figure) in the previous month and 104 (revised figure) in June, 1955.

The number of cases in the United Kingdom reported during June, 1956, were as follows: lead poisoning 5, anthrax 3, epitheliomatous ulceration 20, chrome ulceration 14; total 42. There were no deaths.—*Ministry of Labour Gazette*, July, 1956.

Week Ending July 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 530, whooping-cough 2,558, diphtheria 2, measles 3,251, acute pneumonia 221, acute poliomyelitis 142, dysentery 970, paratyphoid fever 16, and typhoid fever 4.

Medical News

Polio Vaccines in the Commonwealth.—Mr. J. R. HANAN, the New Zealand Minister of Health, stated in Wellington on July 23 that they were expecting to receive enough polio vaccine from Britain early this month to vaccinate 25,000 children. Children aged 9 years are to be inoculated, according to an official bulletin. In Australia the Director-General of Health, Dr. J. A. METCALFE, inaugurated a mass immunization campaign with vaccine from the Commonwealth Serum Laboratories, Melbourne, at the end of June. The campaign started with a million doses of vaccine, said Dr. Metcalfe, and the output from the Serum Laboratories was 220,000 doses a fortnight. He predicted that in two years' time Australia would produce enough vaccine to protect everyone in Australia. The June 23 issue of the *South African Medical Journal* includes a report from Dr. J. GEAR, director of research at the Poliomyelitis Research Foundation, Johannesburg, on the inoculation of 15,000 children in South Africa with a Salk-type vaccine made at the Foundation's laboratories. Vaccination was voluntary and was restricted to children under 5 years of age, except in the case of children of doctors and nurses, where 16 was the upper age limit. No cases of paralytic poliomyelitis attributable to the vaccine were notified, and no serious untoward reactions are stated to have occurred. Dr. Gear draws no definite conclusions about the protective value of the vaccine, in view of the relatively small number of children inoculated.

British Report on Narcotics.—In 1955, according to the British Government's report to the United Nations on narcotic drugs, exports of heroin were authorized to Barbados, British Honduras, Gold Coast, Irish Republic, Kuwait, Mauritius, St. Kitts-Nevis, and Uruguay. No heroin was imported, but the drug continued to be manufactured for domestic use and for export. Discussing drug addiction, the report states that this is not a serious problem in Britain. There is very little illicit traffic in manufactured drugs of addiction, and the addict who is also a "pusher" is unknown. Of the 335 known addicts, 179 took morphine, 64 pethidine, and 54 heroin. Among the addicts were 70 doctors, 14 nurses, and 2 dentists. Only four seizures of drugs are reported, all of Indian hemp (*Cannabis sativa*): 147 g. from a Liverpool club; 120 g. from a room in the East End of London; 1,105 g. from a car returning from Liverpool; and 390 g. from a car in Liverpool.

Royal College of Physicians of London.—At the quarterly comitia on July 26, at which the president, Sir RUSSELL BRAIN, presided, Professor W. G. BARNARD and Sir HAROLD BOLDERO were re-elected, respectively, treasurer and registrar. The following were elected censors for the ensuing year: Dr. T. C. HUNT, Sir HORACE EVANS, Dr. A. M. COOKE, and Professor A. KEKWICK. Dr. DONALD HUNTER was appointed Harveian Orator for 1957, and Professor AUBREY LEWIS Bradshaw lecturer for 1957. The award of the Conway Evans Prize to Lord ADRIAN, F.R.S., for his work in the field of physiology was announced. It was also announced that the Bisset Hawkins Medal had been awarded to Dr. G. S. WILSON for his "able development and direction of the Public Health Laboratory Service," and the Gilbert Blane Medal for 1956 to Surgeon Commander J. M. HOLFORD.

Royal College of Obstetricians and Gynaecologists.—At the council meeting on July 28, at which the president, Mr. C. H. READ, presided, all the College officers were re-elected. The vice-presidents are Professor A. M. CLAYE and Mr. V. J. F. LACK; the hon. treasurer Mr. A. C. H. BELL; and the hon. secretary Mr. I. M. JACKSON. Dr. J. T. LOUW was elected hon. treasurer of the South African regional council; the other regional treasurers were re-elected.

Royal College of Physicians of Edinburgh.—A presentation was made to Mr. W. J. PILCHER at the last quarterly meeting to mark his retirement after 34 years' service as College officer. Mr. PILCHER was given an inscribed wrist-watch and a cheque from the Fellows of the College in appreciation of his long and faithful service.

London University.—Professor W. G. BARNARD, treasurer of the Royal College of Physicians of London, has been elected Dean of the Faculty of Medicine in the University of London. He replaces Dr. C. F. HARRIS, and will hold office for two years commencing on October 1. The following have been granted full recognition as teachers: Dr. C. H. LACK (bacteriology, Institute of Orthopaedics), Dr. S. A. MASON (anaesthetics, King's College Hospital), Dr. S. NEVIN (medicine, King's College Hospital), Professor G. PERKINS (orthopaedics, St. Thomas's Hospital), Dr. J. P. QUILLIAM (pharmacology, St. Bartholomew's Hospital), and Dr. G. SIMON (diagnostic radiology, St. Bartholomew's Hospital). Dr. R. G. BIRD (London Hospital Medical College) has been awarded the first Williams Fellowship for medical and scientific research. He is working on *Entamoeba histolytica* at the London School of Hygiene and Tropical Medicine.

Gerontology at Leeds.—The department of medicine at Leeds University has been granted £6,000 a year for two years by the Nuffield Foundation to support the gerontological research unit under Professor R. E. TUNBRIDGE.

Royal Masonic Hospital.—The EARL OF SCARBROUGH, Grand Master of the United Grand Lodge of Masons of England, laid the foundation stone, on July 24, of an 80-bed extension to the Royal Masonic Hospital at Ravenscourt Park, London. The extension will also provide accommodation for a pathology department, consulting-rooms for out-patients, and the nurse-training school. The funds for the new building, estimated to cost more than £700,000, are being raised by an appeal among English Freemasons. The new beds are hoped to be in use in two years' time. At present the hospital has 200 beds.

Ciba Foundation Awards for Research on Ageing.—Seventy-five papers from 17 countries were submitted for the 1956 awards. The following awards were made by the adjudicating panel (Professors C. H. Best, E. Braun-Menendez, A. Hadow, R. Nicolaysen, F. Verzar, F. G. Young, E. J. Conway, and V. R. Khanolkar, and Drs. G. W. Corner and A. S. Parkes): Dr. MADELINE KEECH and Dr. R. REED (Leeds University), jointly, £400; Dr. B. BRONTE-STEWART (Capetown University), £300; Mr. R. L. GREGORY (Cambridge University), £300; and Dr. J. CONWAY (Charing Cross Hospital, London), £200. Five other competitors received awards of £100 each. There will be a similar competition next year, for which the closing date is January 31, 1957. Full details from the Ciba Foundation, 41, Portland Place, London, W.1.

Department of Health for Scotland.—Changes, dating from August 1, are announced in the under-secretaries responsible, respectively, for health services and for town and country planning in Scotland. Mr. N. W. GRAHAM has been appointed under-secretary with responsibility for health services. Mr. T. D. HADDOW, who formerly held this position, transfers to town and country planning on the retirement of Mr. G. H. KIMPTON after 43 years' service with the Department and its predecessors.

"Doctor in the House."—The Victoria Palace Theatre (twice nightly), itself the scene of many an unrehearsed incident in the lighter side of medical student life, was the venue on July 30 of the stage version (by Mr. Ted Willis) of RICHARD GORDON's novel *Doctor in the House*. A hardworking cast, excellently led by Alan White as Tony Grimsdyke, served up the mixture as before with a flavour that has already proved very much to the public taste and will doubtless continue so to be. Mr. Douglas Ives's Bromley, the hospital porter, was straight from any London teaching hospital one could think of—quite perfect.

NEW ISSUES

American Physicians to Visit U.S.S.R.—A party of American physicians, which will include Dr. P. D. WHITE (Boston), Professor H. RUSK (New York), Professor ANCEL KEYS (Minnesota), Dr. J. WATT (National Heart Institute), and Dr. M. FIELD (Boston), are going to Moscow for a short visit in September, according to *The Times*, to discuss medical rehabilitation and epidemiological research in cardiovascular disease. It is understood that the visit has been arranged at the invitation of the Soviet Ministry of Health.

"International Abstracts of Biological Sciences."—The council of Biological and Medical Abstracts Ltd. has decided to change the title of their journal *British Abstracts of Medical Sciences* to *International Abstracts of Biological Sciences*. This is because the range of biological research subjects covered by the journal is being increased. The wider coverage will include translations of Russian papers abstracted in the *Referativny Zhurnal Biologii* and *Referativny Zhurnal Biologicheskoi Khimii*, an arrangement made possible by the help of the Institute of Scientific Information of the U.S.S.R. Academy of Sciences and beginning next January. Among the societies represented on the council of Biological and Medical Abstracts Ltd. are the Biochemical Society, Association of Clinical Pathologists, Society for Endocrinology, Society for Experimental Biology, Nutrition Society, Pharmacological Society, and Physiological Society. The publishers are the Pergamon Press, of 4 and 5, Fitzroy Square, London, W.1, and 122, East 55th Street, New York, 22.

B.O.A.C. Medical Services.—Sir HAROLD WHITTINGHAM has retired from the post of director of medical services, and two appointments are being made in his place: Dr. K. G. BERGIN becomes medical superintendent, air services, and Dr. A. S. R. PEFFERS, superintendent, U.K. medical services. Sir Harold Whittingham will continue to serve B.O.A.C. on a part-time basis as consultant medical adviser. Dr. Bergin was recently elected vice-president of the Aero Medical Association for 1956-7. This is an organization of about 2,000 doctors, with headquarters in America, for the study of medical and research problems associated with flying.

Sir John Stopford, F.R.S. is to be invited to become an honorary freeman of Manchester by the City Council.

Professor A. M. Claye, professor of obstetrics and gynaecology at Leeds and vice-president of the Royal College of Obstetricians and Gynaecologists, left England last month as a Sims-Black travelling professor to Australia and New Zealand. On his return journey he will lecture, on behalf of the British Council, at Singapore, Colombo, and Karachi. He will be away for about five months.

COMING EVENTS

Sixth International Congress of Otolaryngology.—Washington, D.C., May 5-10, 1957. Details from the general secretary, 700, North Michigan Avenue, Chicago, 11, Illinois. The last date for submitting titles of papers and films for presentation is October 1, 1956.

Glasgow Conference on Cardiology.—Details of a post-graduate conference on medical and surgical cardiology, to be held at Glasgow, October 1-5, are given in our advertisement columns (p. 35).

Royal Institute of Public Health.—Dr. P. M. F. BISHOP has been appointed Bengué Memorial Award lecturer for 1956. He will speak on October 17 at 3 p.m. at the Institute, 28, Portland Place, London, W.1, on "The Problem of Obesity."

Italian Congress on Nuclear Medicine.—Pisa, September 30. Details from Centro di Medicina Nucleare, Clinica Medica, Pisa, Italy. The congress is sponsored by the national committee for nuclear research.

Fourteenth International Tuberculosis Conference.—New Delhi, January 5-11, 1957. Details from the conference secretariat, 22, Red Cross Road, New Delhi, India.

Annals of the Rheumatic Diseases.—The new issue (Vol. 15, No. 2) is now available. The contents include:

MEASUREMENT OF BONE DENSITY. Donald Mainland.
ANKYLOSING SPONDYLITIS. D. O'Connell.
ACQUIRED RESISTANCE TO CORTICOSTEROIDS. H. F. West.
PILOT STUDY OF INTRA-ARTICULAR PROCAINE AND HYDROCORTISONE ACETATE IN RHEUMATOID ARTHRITIS. G. R. Fearnley, Rita Lackner, R. I. Meanock, and E. G. L. Bywaters.
UVEITIS AND RHEUMATIC DISEASES. A. Stanworth and J. Sharp.
HAEMODILUTION IN RHEUMATOID DISEASE. M. R. Jeffrey.
DECLINE OF ACUTE RHEUMATISM. R. A. N. Hitchens.
COMPARISON OF CORTISONE ACETATE AND A CODEINE MIXTURE AS ADJUVANT TREATMENT IN JUDETH ARTHROPLASTY. G. P. Arden.
PERICARDITIS COMPLICATING RHEUMATOID ARTHRITIS. A. E. Thomas and W. K. C. Morgan.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Industrial Medicine.—The new issue (Vol. 13, No. 3) is now available. The contents include:

SIXTY YEARS OF INDUSTRIAL MEDICINE IN GREAT BRITAIN. Andrew Meiklejohn.
OCCUPATIONAL MEDICINE AS A VOCATION. James A. Smiley.
THE RELATIONSHIP BETWEEN VENTILATORY CAPACITY AND SIMPLE PNEUMONIOSIS IN COALWORKERS. R. G. Carpenter, A. L. Cochran, J. C. Gilson, and I. T. T. Higgins.
FACTORS INFLUENCING THE RADIOLOGICAL PROGRESSION RATE OF PROGRESSIVE MASSIVE FIBROSIS. A. L. Cochran and R. G. Carpenter, with the assistance of W. G. Clarke, G. Jonathan, and F. Moore.
PNEUMONIOSIS IN CENTRAL INDIAN COALMINES. K. B. Roy.
A STUDY OF DUST TOXICITY USING A QUANTITATIVE TISSUE CULTURE TECHNIQUE. J. Marks, M. Ann Mason, and G. Nagelschmidt.
A QUANTITATIVE TECHNIQUE FOR STUDYING THE EFFECT OF DUST ON PHAGOCYTIC CELLS IN VITRO. J. Marks and M. Ann Mason.
THE USE OF A SIZE SELECTOR FOR DUST SAMPLING WITH THE THERMAL PRECIPITATOR. J. T. Burdick and J. G. Dawes.
THE USE OF THE PULHEIMS SYSTEM OF MEDICAL CLASSIFICATION IN CIVILIAN PRACTICE. M. D. Warren.
DETERMINATION OF ATMOSPHERIC BENZENE CONCENTRATION BY DISPLACEMENT FOLLOWING ADSORPTION ON SILICA GEL. Per Ovtum.
TWO CASES OF POISONING WITH DI-ISOPROPYLFLUOROPHOSPHONATE (D.F.P.). W. K. S. Moore.
ARSINE POISONING. D. Blair Macaulay and D. Austen Stanley.
ASSOCIATION OF INDUSTRIAL MEDICAL OFFICERS: PROGRAMME OF 21ST ANNUAL MEETING.
MISCELLANEA:
THE PRESCRIPTION OF INDUSTRIAL DISEASE. Ronald E. Lane.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, August 7

INSTITUTE OF PSYCHIATRY.—12 noon, Dr. M. S. Guttmacher (Baltimore): Problems of Legal Psychiatry in America.

Wednesday, August 8

POSTGRADUATE MEDICAL SCHOOL, London, W.—2 p.m., Dr. Randolph K. Byers (Children's Medical Centre, Boston, Mass.): Neurological case demonstration.

Thursday, August 9

INSTITUTE OF PSYCHIATRY.—12 noon, Professor C. C. Pfeiffer (Georgia): Muscarinic Stimulation of the Brain Inhibits the Conditioned Response and Counteracts Schizophrenia.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—Elizabeth L. Brown, M.B., Ch.B., Senior Registrar in Chest Medicine, Norwich and East Norfolk areas; G. A. Wall, M.B., Ch.B., F.R.C.S., Registrar in Plastic Surgery, Regional Plastic Surgery and Burns Unit, West Norwich Hospital; A. W. Robertson, M.B., B.S., F.F.A.R.C.S., F.F.A.R.A.C.S., Consultant Anaesthetist, South-west General Hospitals Group; P. A. L. Horsfall, M.B., Ch.B., M.R.C.P., Medical Registrar, North Cambridgeshire and Clarkson Hospitals; P. A. Harbison, M.B., B.S., Surgical Registrar, Ipswich and East Suffolk Hospital; I. P. Crowley, M.B., Ch.B., Surgical Registrar, North Cambridgeshire Hospital; B. J. Poole, M.B., B.S., Registrar in Geriatrics, Norfolk and Norwich Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Costello.—On July 14, 1956, at the Regional Hospital, Galway, Thomas Bodkin Costello, M.D., D.P.H., of Bishop Street, Tuam, Co. Galway.
Dick.—On July 14, 1956, at Oxford, James Orford Wallace Dick, M.B., B.Chir., of Ladygrove House, Abingdon, Berks.
Duguid.—On July 11, 1956, at 4, Hermitage Gardens, Edinburgh, Alfred Duguid, M.B., Ch.B., of 19, Styevehall Croft, Coventry.
Kennedy.—On July 8, 1956, at Dunbar Hospital, Thurso, John Robert Kennedy, M.V.O., M.B., C.M., of 6, Couper Street, Thurso, late of Dunbeath, Caithness, aged 85.
McCutcheon.—On July 6, 1956, at R.N. Hospital, Haslar, Hants, James McCutcheon, M.B., B.Ch., Surgeon Rear-Admiral, ret., aged 79.
Rushworth.—On July 5, 1956, at Wrightington Hospital, near Wigan, Lancs, Cyril Davenport Rushworth, M.R.C.S., L.R.C.P., of Finch Lane, Appley Bridge, near Wigan, aged 37.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Palliative Hormone Therapy in Breast Cancer

Q.—Is it worth advising palliative hormone therapy for a case of advanced cancer of the breast, with secondary deposits, which has already been treated by surgery and radiotherapy? If so, what regime is advised for use in general practice?

A.—In every case of advanced cancer of the breast where surgery and radiotherapy have been tried and have failed, or where, because of the advanced nature of the condition, neither is applicable, hormone therapy should always be given a trial. This method of treatment is effective for a short time in about half of the patients and is occasionally quite miraculous in the benefits which it confers. Patients quite well past the menopause should be given 50 mg. of stilbestrol by mouth daily, and younger patients should be given injections of testosterone propionate—100 mg. three times a week intramuscularly. For further details of the management of such cases the inquirer is referred to an article in the Refresher Course series for general practitioners.¹

REFERENCE

¹ Atkins, H. J. B., *British Medical Journal*, 1953, 1, 1099.

Learning During Sleep

Q.—Claims are made that by the use of a microphone under the pillow relaying teaching material during sleep the learning of languages or long parts from plays can be facilitated, and that attitudes to life can be influenced. To what extent are these claims true?

A.—Despite the claims of a number of experimenters and commercial concerns, there is little or no conclusive evidence that learning can take place or be helped by repetition during sleep. A recent review¹ of ten American studies states that all had weaknesses either in experimental design, statistical treatment, methodology, or criteria of sleep. One statistical attempt to teach morse code to Navy men while they slept was stopped when it was found that "ambitious Navy instructors of the control group had been giving extra day-instruction in order not to be out-taught." Not all time instruction in order not to be out-taught; but other errors the work had been so naively interrupted; but other errors generally crept in. For example, attempts were made to break nail-biting in boy campers by playing the phrase "My fingernails taste terribly bitter" through a loudspeaker 300 times a night for 54 nights. Forty per cent. of the experimental group and none of the control group (20 in each group) stopped biting their nails, which seemed a clear indication of the value of such verbal suggestion during sleep. A number of other kinds of learning material have been used, such as nonsense syllables, ordinary speech in retarded and aphasic children, and English-Chinese vocabularies. None of the studies stands up conclusively on examination. Some of them report "uncertain and improbable" learning during sleep; others, as in the case of the nail-biting, seem at first sight to point to unequivocal learning. The serious difficulty has been in establishing whether or not the subject was asleep. For instance, in the nail-biting experiment the boys were asked, before the experiment started, whether they were awake, and the input was turned off if the boys seemed restless. These are, of course, completely inadequate tests of sleep. (This experiment seems also to have been vitiated by the fact that control and experimental groups were unmatched for age, which is known to be related to nail-biting.) It is common experience that one may wake up and perform some quite

complex action, and forget about it in the morning. Obviously the best criterion at present available is given by the electroencephalogram. It has been used recently in a well-planned study,² the general conclusion of which was that learning during real sleep is impractical and probably impossible. It is conceivable that during the drowsy state between sleep and waking learning may occur, but nothing is known at present about the possible harm that may be done by keeping a subject half awake in this way, nor about the relative efficiency of such learning if it does occur. Matter learned just before sleep seems to be better remembered on waking, probably because there is relatively little to "drive out" the memory. This may have given rise to the idea that learning may take place during sleep itself. At any rate, "for the present sleep-learning is not the simple matter that some experimenters and commercial firms, which sell equipment for this purpose, would lead us to believe."

British Influenza Vaccines

Q.—What is the present position with regard to influenza vaccines in Britain? How effective are they and for how long does the immunity they confer persist? Are there any special contraindications to their use? Where may they be obtained?

A.—The present position concerning influenza virus vaccines is that field trials are being carried out in Britain under the auspices of a committee of the Medical Research Council. These trials are designed to assess both the serological effect and the protective action of various vaccine preparations against influenza. Until the results of the present trials are announced, all that can be said is that somewhat less favourable results have been obtained in Britain compared with those reported in the American literature. Nevertheless, a significant protection was found in the trial of 1952-3, but this was insufficient to warrant a recommendation for use of the vaccine on anything but an experimental basis.¹ The duration of the immunity conferred by existing vaccines is unknown, but is thought not to be better than twelve months unless vaccines containing oil adjuvants are used.

Influenza vaccine, prepared at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital, Paddington, is distributed by Messrs. Parke, Davis & Co., and is obtainable through retail chemists. The only known contraindication is the presence of sensitivity to egg protein.

Vaccination and Atopic Eczema

Q.—Is it safe to vaccinate infants or children who have (a) active atopic eczema, (b) a few residual lesions of atopic eczema, or (c) only a history of atopic eczema in the past? What special precautions are advised to reduce the risks of generalized spread or an allergic response?

A.—The vaccination of infants or children with active atopic eczema, or even residual lesions of this condition, is not advised because of the risk of eczema vaccinatum. Even if there is only a history of atopic eczema, in either the patient or his parents, vaccination in infancy might well be deferred because the introduction of a dermatopathic virus producing damage to the epidermis has been so often followed by acute eczema that the provocative effect of vaccination can scarcely be doubted.

If a child is travelling to a country where smallpox is common it would probably be the lesser evil to take the risk of vaccination. If vaccination is performed on atopic infants or children, the skin should be cleansed with great care and the site of vaccination should be kept totally protected by a porous-plaster dressing, and at night a loose cardboard cylinder might be placed on the other arm to

prevent scratching. An antihistamine, such as elixir of diphenhydramine, 60 min. (3.5 ml.), given three times a day after food, would diminish the chance of an allergic reaction, and with eczematous infants it might be wise to give at the same time an injection of gamma globulin, 500 mg., at 3 months of age, increasing to 1 g. in older children.

Delayed Microscopy in Breast Tumours

Q.—Where immediate histological examination is impracticable, as in certain tropical areas, is local diathermy excision of a possibly malignant lump in the breast, for later microscopy, unjustifiably risky? Radical treatment, in the cases proved to be malignant, would be undertaken within a week or two of the local excision. The only alternative would be to send all doubtful cases to a well-equipped hospital a long distance off for investigation and treatment.

A.—There is no objection whatsoever to excision of a possibly malignant lump in the breast for histological examination, with a view to radical treatment a week or two later. In actual practice, however, the occasions when the surgeon would be in doubt about the diagnosis after macroscopic examination of the excised lump would be very rare, so the only cases in which radical treatment would be delayed for a week or two would be the very early growths which were unrecognizable macroscopically.

Toxicity of Ingested Detergents

Q.—Does the common practice of not rinsing glasses and cups after washing with detergents constitute any danger?

A.—Over the past ten years the experimental results of feeding some of these detergents to animals have been published. Even at levels as high as 1% in the whole diet, toxic effects have not been observed. Other experiments have shown that when added to feeding-stuffs detergents, like antibiotics, may actually improve the growth of certain domestic animals. There is thus no evidence to support a belief that the small quantities of detergents that may be consumed in food or drink put into unrinsed vessels would be harmful. The results of an investigation by a committee of the Medical Research Council into any possible carcinogenic action of detergents are not yet available.

Life Expectancy in Britain

Q.—What is the present life expectancy in Britain at birth, at one month, and at one year of age?

A.—The latest official figures of expectation of life are those published in the Registrar-General's *Quarterly Return* No. 427 (Appendix B) and relate to England and Wales only. They are based on deaths registered in 1954. For males, the expectation of life at birth is given as 67.58 years, and at age 1 year 68.58 years. For females the expectation of life at birth is given as 73.05 years, and at age 1 year 73.69 years. No official estimates are given of expectation of life at one month. For the purpose of answering this question, however, a calculation based on published mortality data for England and Wales in 1954 suggests that the expectation of life at 4 weeks would be about 68.9 years for males and about 74.1 years for females.

Significance of Epimenorrhagia

Q.—What is the likely significance of a reduction in the usual length of the menstrual cycle coupled with some increase in the duration of the flow in a woman of 37?

A.—Epimenorrhagia is more often due to a local cause in the genital tract than to a general condition. Yet the patient may present complaining not of the menstrual disturbance but of the symptoms of resultant anaemia, such as weakness, breathlessness, and insomnia. After excluding a psychogenic factor, for which diligent inquiry must be made, the most likely extragenital cause is probably hypothyroidism. Among the local lesions, pelvic infections (including tuberculosis) and endometriosis are the most likely, especially if there is associated dysmenorrhoea. In pelvic infection the latter is typically premenstrual and more of

a heaviness and dragging feeling, whereas the more acute pain of endometriosis is usually intramenstrual, although it may persist from a few days before to a few days after the period. In both of these conditions one would expect positive physical signs on bimanual examination, notably a restricted mobility of the genital organs and palpable enlargement of the appendages. Fibroids may affect the amount and duration of flow, but if there is also increased frequency of menstruation in the presence of palpable fibroids there is probably some coexistent disease of the appendages.

In the absence of pain and physical signs of local disease, functional epimenorrhagia may be presumed. It most commonly occurs when menstruation is resumed after the end of a pregnancy. In this, as in all functional menstrual disorders, there is a tendency to spontaneous cure in 6 to 12 months.

Obstruction of the Nasolacrimal Duct

Q.—What are the likely causes of obstruction of one nasolacrimal duct in a middle-aged patient who has never had an inflammatory affection of the eye? Dilatation and syringing through the punctum have not relieved the epiphora. What is the best treatment?

A.—The calibre of the nasolacrimal duct varies among different patients, and there is a tendency for the channel to become narrower in middle and later life. In the absence of ocular inflammation the most likely aggravating factor is chronic infection of the nose, because the nasal mucous membrane is continuous with that which lines the nasolacrimal duct. Dilatation and syringing through either lacrimal punctum hardly ever relieves this form of epiphora. Dacryocystorhinostomy offers the best chance of relief, but it should be reserved for cases which suffer from fairly severe epiphora.

Corrections.—In our report of the Section of Orthopaedics at the annual meeting (July 21, p. 167), Mr. W. H. Gervis was wrongly quoted as stating, in his contribution on foot form, function, and footwear in the young, "the arch of the foot in the condition known as flat foot did not collapse but merely rocked over to the medial side." What he said was: "the foot rocked over." In normal standing the lateral border of the foot is weight-bearing, therefore the foot does not resemble an arch. Mr. Gervis demonstrated that the footprint in the first stage of flat foot is that of heel and metatarsal heads only. Therefore only in the first stage of flat foot does the foot resemble an arch-like structure, supported at each end of its span and not in the middle.

In our issue of July 21 (p. 156) the name of a proprietary tablet containing aluminium glycinate was wrongly spelt. The name of the product is "prodexin," not "rodexin" as was stated.

In the report on "Carotid Sinus Syncope" (*Journal*, July 28, p. 228) in the ninth line of the paragraph "waking up" should have read "warning."

In reporting the proceedings of the International Congress of Gastroenterology (*Journal*, July 28, p. 236), it was stated that: "Dr. Trounce and his colleagues were unable to demonstrate, by pharmacological or histological means, any notable loss of ganglion cells such as might explain the abnormal movements in achalasia of the cardia..." Dr. J. R. Trounce and his colleagues write: "Such was not the case. Our paper referred particularly to the lowest segment of the oesophagus, and it was in longitudinal muscle strips from this area alone that we did not observe any outstanding loss of ganglion cells or activity in the majority."

PROBLEMS OF SALMONELLA FOOD-POISONING

BY

Sir WILLIAM SAVAGE, M.D., B.Sc.

Tables I, II, and III are compiled from the annual reports on food-poisoning contained in the *Monthly Bulletin of the Ministry of Health and the Public Health Laboratory Service*. Large as are the figures, they undoubtedly are not a complete record of all cases of food-poisoning. Three important facts stand out from these tables: (1) the steady increase in the number of recorded cases of food-poisoning; (2) the overwhelming proportion of cases which are ascertained to be due to salmonellae; and (3) the very high proportion of "sporadic" cases. It is obvious that the most important problem in food-poisoning is salmonella outbreaks, and their elimination, or at least material reduction, would reduce food-poisoning to manageable limits. For this reason this paper is limited to this group.

TABLE I.—Food-poisoning Outbreaks

Type	1949	1950	1951	1952	1953	1954
Outbreaks	410	539	343	372	492	506
Family outbreaks	265	453	287	340	422	630
Sporadic cases	1,753	2,987	2,717	2,807	4,363	4,880
Total incidents	2,428	3,979	3,347	3,519	5,277	6,016

Note.—All cases, single or multiple, are called incidents, and these are classified into three groups: "Outbreak," two or more related cases in persons in different families; "Family outbreak," two or more related cases in members of the same family; and "Sporadic case," a case which was not, so far as could be ascertained, related to other cases.

TABLE II.—Total Incidents

Causation	1949	1950	1951	1952	1953	1954
Salmonellae	1,369	2,021	1,668	2,098	3,114	3,508
Staphylococci	97	82	65	82	132	127
Cl. welchii	—	24	20	20	25	48
Other organisms	88	43	5	17	6	9
Chemical	3	2	2	1	0	2
Not discovered	874	1,807	1,587	1,301	2,000	2,322

TABLE III.—Incidents with Causation Determined

	1949	1950	1951	1952	1953	1954
Outbreaks and family outbreaks:						
No. of salmonella origin	307	467	301	242	532	647
Percentage of "	64.5	77.1	73.4	69.8	81.9	81.5
Sporadic cases:						
No. of salmonella origin	1,062	1,554	1,367	1,766	2,582	2,861
Percentage of "	98.5	98.5	99.5	99.2	98.2	98.3

Figures for earlier years are given in the *Monthly Bulletin* for June, 1950. The number of incidents reported from 1941 to 1948 are: 1941, 119; 1942, 73; 1943, 244; 1944, 291; 1945, 433; 1946, 685; 1947, 846; and 1948, 804. For these eight years the total was 3,495 incidents, and 3,193 of these were due to salmonellae (91.4%). The total for the whole eight years is conspicuously less than for a single year to-day.

Still further back, during the period 1921–4, by arrangement with the Ministry of Health and the Medical Research Council, local health authorities throughout the country were offered free examination and investigation in my laboratory for all food-poisoning outbreaks. Although the number so investigated was large, it was quite small compared with the number of present-day outbreaks. The enormous increase is striking. On the other hand, three factors have influenced the recognition of outbreaks which in earlier years might not have come to light. One is the compulsory notification of food-poisoning which undoubtedly has supplied information of more outbreaks. Secondly, the extensive laboratory facilities now available all over the country have greatly increased the utility of notification and of scientific investigation. Thirdly, these laboratory facilities have also encouraged medical officers of health to take more interest in food-poisoning. These factors have played an important part, but I do not think they have been responsible for any large share in closing the enormous gap between, say, 20 years ago and to-day.

The most striking features of Table I are the enormous number of "sporadic" cases and their regular increase year by year. The laboratory returns give very little information on these incidents. Steps have been initiated asking for samples of faeces from the home contacts, but I am informed that the results are not very encouraging. It is unrealistic to suggest that these are isolated cases without any connexion with other cases, and this is borne out by the only serious effort I have come across to investigate them.

Dr. G. T. Cook, formerly of the Public Health Laboratory Service, at Oxford, now at Guildford, carried out some investigations on sporadic salmonella cases and is kind enough to allow me to quote his findings.

He visited 27 sporadic cases, 22 due to *Salmonella typhi-murium*, and made detailed inquiries into possible sources of infection. Faecal specimens from contacts and, when indicated, samples of food were examined bacteriologically. In two of the seven men affected the attacks were associated with the consumption of duck eggs the day before onset. Another was linked with previously unsuspected gastro-enteritis in his daughter two days before, who was found to be excreting *Salm. typhi-murium*. Two further cases, apparently unrelated, were probably infected from sandwiches shared at work and prepared by the mother-in-law of one of the patients, a symptomless excretor of *Salm. typhi-murium*. The six women included three infected with *Salm. typhi-murium* who shortly before the attack had tasted, while

cooking, a "mix" containing raw duck eggs, which may have been the source of infection. Nine out of 19 family contacts of these six women were found to be excreting *Salm. typhi-murium*, though none had had symptoms. Among eight cases of children under 5, no evidence of source was obtainable, though two households had positive family contacts. In another group of six older children, one had been associated with duck eggs and another had probably been infected by his mother, a symptomless excreter of salmonellae who had recently returned home from nursing a relative with gastro-enteritis.

In all, the households of 40 sporadic cases were investigated, and in 23 of these one or more positive salmonella contacts were found. Of the 105 home contacts examined, 36 were positive for salmonellae, though only 6 of these had symptoms of food-poisoning.

In view of the fact that these were one-man investigations by a bacteriologist without the full resources of a health department, and that it was usually possible to collect only a single sample from each person, the findings suggest how well worth while really detailed investigations would be, both in the homes and into possible outside sources of infection.

A feature brought out in Table II is the large proportion of incidents for which the cause was not ascertained. Remedies for this unsatisfactory feature are discussed below.

The Salmonella Group

When I started working on this group around 1905 only three distinct serotypes (excluding *Salm. typhi*) were recognized. More were separated over the next few years, and slowly at first and then more rapidly the number has increased to just over 300 different serotypes. The group is united by cultural and chemical characteristics with some variations with special selected agents, but the main distinctions are founded upon antigenic differences. Still further improvements of classification are being obtained by bacteriophage typing. The types most commonly met with in food-poisoning cases in this country are shown in Table IV. The two striking features are the outstanding prevalence

TABLE IV.—Main Salmonella Types Isolated from Food-poisoning Incidents

Salmonella Strains	1949	1950	1951	1952	1953	1954	6-year Total
Endogenous:							
<i>Typhi-murium</i>	1,053	1,593	1,236	1,604	2,438	3,038	10,962
<i>Enteritidis</i> (including subtypes)	51	91	99	145	126	70	582
<i>Thompson</i>	82	67	97	90	84	83	503
<i>Newport</i>	53	77	71	40	50	35	324
<i>Dublin</i>	24	40	23	17	20	15	139
<i>Cholerae-suis</i>	2	2	3	6	12	11	36
<i>Bovis-morbificans</i>	13	23	14	6	81	26	163
<i>Derby</i>	1	7	5	6	11	10	40
<i>Stanley</i>	0	1	4	19	4	3	31
Exogenous:							
<i>Anatum</i>	8	20	11	10	30	20	99
<i>Montevideo</i>	9	18	23	12	18	13	93
<i>Oranienburg</i>	9	11	6	10	29	6	71
<i>Boreilly</i>	1	14	5	15	25	3	63
<i>Minnesota</i>	4	5	5	13	17	11	50
<i>Give</i>	0	2	10	17	8	2	40
<i>Tennessee</i>	2	13	16	5	15	8	59

Endogenous types—those always common in England and Wales.
Exogenous types—mainly isolated only after 1940.

of *Salm. typhi-murium*, constituting 83% of all the strains isolated, and the complete absence of *Salm. paratyphi B* as a cause of acute food-poisoning. Both features are also shown by the reports for earlier years.

None of the group is a natural saprophytic inhabitant of the intestines of men or animals. I wrote in 1920 (Savage,

1920): "These bacilli are not natural inhabitants of the animals used for food and not found more frequently than can be accounted for on the supposition that their presence is due to an actual case of disease or the carrier state after infection." (This was by no means accepted by all in 1920.) They are found causing disease in a very wide variety of animals and with some evidence of host selection. The literature on their distribution is so extensive that only a broad sketch of their animal distribution can be attempted.

Animal Sources

Birds.—Poultry seem to be the commonest reservoir of salmonellae. Ducks are especially significant in relation to food-poisoning because salmonella infections may be widespread on duck farms and the organisms can invade the blood stream and oviduct, with infection of the individual egg, while from dirty infected egg-shells the organism may penetrate the interior of the egg. Smith and Buxton (1951) examined faeces from 500 ducks and found 1.2% positive. Salmonella infections in fowls are even more common, but are much less a source of human food-poisoning, because the two commonest strains *Salm. pullorum* (cause of chick diarrhoea) and *Salm. gallinarum* (cause of fowl typhoid) are practically non-pathogenic to man. A whole range of other salmonellae have also been isolated from eggs, particularly in the U.S.A. *Salm. typhi-murium*, *Salm. thompson*, and *Salm. enteritidis* are important strains isolated from hens or their eggs. Turkeys also suffer from salmonella infections and have been a cause of food-poisoning. Many other birds, such as pigeons, geese, and pheasants, may be infected.

Pigs.—Pigs seem to have a considerable liability to salmonella infections. Scott (1940), in Great Britain, examined batches of mesenteric glands and spleens from apparently normal pigs, and in one factory found salmonellae in 23 of 500 pigs and in 18 out of 500 pigs of another factory. While nine different strains were isolated, the commonest were *Salm. cholerae-suis* (10), *Salm. typhi-murium* (9), and *Salm. thompson* (7). In a more recent investigation in Great Britain (M.R.C., 1947) salmonellae were present in 133 of 1,058 batches of lymph nodes representing 5,285 pigs (2.5%). Smith and Buxton (1951) isolated salmonellae from faeces from 4 out of 600 apparently healthy pigs.

Cattle.—Although probably less common as a reservoir than pigs and birds, cattle are important and illustrate some interesting points. *Salm. dublin* is the main type found, but *Salm. typhi-murium* also occurs, especially in older cattle. Full surveys have not been made, but our present information suggests large pockets of infection in areas geographically far apart. One pocket is in Mid- and West Wales, where Field (1948) has carried out extensive studies. Salmonellosis was diagnosed on 70 farms during 1946–7, in every instance due to *Salm. dublin*, except on one farm with *Salm. typhi-murium*. The cattle mortality rate was about 70%. Another pocket seems to extend over parts of Ireland. Ritchie and Clayton (1951), investigating in 1949–50 presumed healthy cattle slaughtered at Birkenhead abattoirs, found *Salm. dublin* in 10% of faeces and in 3.4% of bile samples from Irish cattle. The corresponding figures for non-Irish cattle were 3.7 and 0.5%. Liver swabs from 25 out of 202 Irish cattle yielded *Salm. dublin*, but swabs from 171 non-Irish cattle yielded none. Smith and Buxton (1951), found only three salmonella-positives among 750 samples of faeces from cattle in Great Britain; all were *Salm. dublin*. In 1950–2 Murdock and Gordon (1953) isolated *Salm. dublin* from 86 (8.6%) North Ireland cattle. In Somerset there were 14 outbreaks of *Salm. dublin* infection in 1947–53, and McCall (1953) reported on three human *Salm. dublin* outbreaks in that county, the largest involving 598 children infected from school milk.

Rats and Mice.—Salmonella infections are common in both species and many survivors continue as excretors of salmonellae. In rats the prevalence varies with the sources of these animals. In places where animals are killed, such as slaughterhouses, the prevalence may be over 6%, and in

Liverpool docks with much food storage Khalil (1938) found 7.3% harbouring salmonellae, all but four strains being *Salm. enteritidis* or *Salm. typhi-murium*.

Cats and Dogs.—Cruickshank and Smith (1949) examined 500 samples of faeces from apparently healthy dogs and found 5 positives, and from 500 apparently healthy cats 7 were salmonella-positive—3 *Salm. typhi-murium*, 2 *Salm. anatum*, and one each of *Salm. montevideo* and *Salm. paratyphi B*. They give particulars of many other investigations on cats and dogs with positive findings. Both animals not only can carry salmonellae but can suffer from definite infections. (This is in accord with findings in a few food-poisoning outbreaks.) The authors make the interesting calculation, based on dog licences issued, that their findings, if a fair sample, represent 20,000 to 30,000 dogs in Great Britain excreting salmonellae at any one time.

Commercially Prepared Egg Mixtures

Egg mixtures raise problems quite distinct from findings from flocks or from single eggs, so are discussed separately. The bacteriology of imported U.S.A. spray-dried egg has been described in detail (M.R.C., 1947). The powder is either prepared from shell eggs or from frozen egg pulp. Two facts stand out. One is that the examination of 7,584 samples revealed salmonella strains in 9.9%. The other is that the use of these mixtures in Great Britain resulted in the introduction of a large number of salmonella types new to this country but present in the U.S.A. and later found to be responsible for food-poisoning outbreaks in this country. In that M.R.C. report four such outbreaks are described, due to the introduced strains *Salm. oranienburg*, *Salm. montevideo*, *Salm. tennessee*, and *Salm. sunsvall*.

Murdock (1954) during 1951–3 examined liquid egg mixtures made up of North Ireland eggs sampled at the stage from homogenizer to the receptacle cans. Salmonellae were isolated 21 times from batches representing 1,610 hen's eggs (2.1%) and 120 times from 249 batches of duck eggs (48.2%). The majority of strains were *Salm. typhi-murium*.

A more comprehensive survey (Report, 1955) undertaken by members of the Public Health Laboratory Service dealt with English egg mixture collected at egg factory stations, classified into three groups—fresh untreated mixtures, chilled mixtures, and frozen mixtures in cans. When hen eggs were used, the first two groups gave 0.3% positive for salmonellae; the frozen egg mixtures gave 2.0% positive. With duck egg mixtures the percentages were respectively 6.1, 0, and 1.7.

Chinese frozen egg mixtures have been examined by Smith and Hobbs (1955). Salmonella strains were isolated from 27% of 128 cans examined. The findings varied according to types of can: tall 22-lb. (10-kg.) cans, 5.9%; 22-lb. (10-kg.) flat cans, 23%; and 44-lb. (20-kg.), 3% positive. The strains isolated were *Salm. pullorum*, *Salm. thompson*, *Salm. aberdeen*, and *Salm. typhi-murium*, but the last was found only twice.

Newell (1955) describes a number of outbreaks and single cases associated with Chinese egg mixtures used in bakeries for cream cakes. Newell *et al.* (1955) reported two outbreaks, in Worthing and Weymouth areas, of paratyphoid fever due to *Salm. paratyphi B* type 3a in cakes filled with imitation cream prepared in two bakeries in which there were unopened cases of Chinese frozen whole egg confectionery. The imitation cream was contaminated in the bakeries from the frozen egg.

This brief summary of the distribution of salmonellae in the animal world of Great Britain shows how widespread are these reservoirs of salmonellae, and suggests that it is here we must look for the origins of the salmonellae in most food-poisoning outbreaks.

In other countries the distribution of salmonellae types shows considerable differences, as indeed we find from the many foreign types introduced by packaged eggs from the U.S.A. Edwards and Bruner (1943) made an analysis of 3,090 salmonella strains from outbreaks in man and animals

up to 1943 in the U.S.A. and distinguished 59 types. Pigs, for example, yielded 27 different types with *Salm. cholerae-suis* (kunjendorf) from 305 outbreaks, 329 cultures, and 28 human outbreaks. *Salm. dublin* was only twice isolated from cattle, but foxes had a high incidence. *Salm. newport* was often found in fowls and human outbreaks, but rarely in swine, while *Salm. thompson* was almost confined to human outbreaks. *Salm. bovis-morbificans* is rare in the U.S.A. and until recently was uncommon in Great Britain, but it seems to be fairly widely distributed in Australia.

Evolution of Salmonella Strains

The enormous number of distinguishable salmonella types, the wide range of animals invaded, and the varying types of infections caused form a complex picture. In my opinion the problems raised can best be linked, and in part explained, by considering them from an evolutionary standpoint. As long ago as 1932 I expressed the view that the salmonella group is in an evolutionary stage as regards the separation of types, selection of animal hosts, and varieties of parasitic functions, and later I elaborated this conception (Savage, 1940). *Salm. typhi-murium* is probably nearest to the common ancestor, catholic in its distribution and undifferentiated in its host selections. Specialism has enabled some strains to attain a high measure of host specificity. *Salm. paratyphi B* has become for all practical purposes a human invasive parasite causing long-continued infection and rarely gastro-intestinal symptoms. It is no longer invasive to the lower animal by natural infection. Other strains with a high degree of host specialization are *Salm. abortus-ovis* for sheep, *Salm. gallinarum* and *Salm. pullorum* for fowls, and *Salm. abortus-equi* for horses. *Salm. dublin* is particularly interesting, for it tends to limit itself to calves and cattle but so far very incompletely, and this characteristic is accompanied by varied patterns of pathological changes which emphasize its instability.

These statements are probably in no single instance absolute, which is exactly what we should anticipate in evolutionary strains. For example, *Salm. paratyphi B* in a very few instances does cause gastro-intestinal symptoms, while there is reliable evidence that dogs and possibly pigs may occasionally be invaded by this otherwise purely human parasite. The general picture of paratyphoid fever is, however, very definite, and not a single outbreak of food-poisoning in the long records of the Public Health Laboratory Service has been ascribed to *Salm. paratyphi B*.

Given suitable conditions for growth, bacteria produce in less than a week as many generations as man takes from the Bronze Age to the present time, so evolutionary changes are to be anticipated with the production of new antigenic types better adapted to extend their distribution in animals. This extension may very well be taking place, but so far the evidence is not conclusive. Evidence concerning the evolutionary character of the salmonella group is reinforced by comparatively recent work demonstrating that type-transformation is possible. Three methods have been successful. One is by growing the organism in antiserum: Bruner, for instance, in 1949, succeeded in transforming *Salm. oranienburg* into *Salm. montevideo*, but was unable to reverse the process.

Factors Necessary for Full Elucidation of Each Outbreak of Food-poisoning

No outbreak can be said to be fully explained unless four factors are solved. These are the bacterial or other cause of the symptoms, the vehicle responsible for conveying the causal agent to man, the reservoir from which the infecting organism originated, and the path from the reservoir to the infected vehicles.

Salmonella Infections

Only salmonellae are under consideration, and their distribution has been discussed. It is of interest to study the relative presence of the different salmonella types in actual

cases of food-poisoning. Those for the last six years available are shown in Table IV. The most striking feature is the overwhelming prevalence of *Salm. typhi-murium*, and we may associate this with its ubiquity of distribution in the animal kingdom. Another interesting point is the fairly regular way *Salm. enteritidis* and *Salm. thompson* take the second and third place, with *Salm. newport* usually fourth. This, I think, is evidence of an association of food-poisoning with animal reservoirs. *Salm. typhi-murium* is of wide animal distribution largely impartial in respect of animal hosts. *Salm. enteritidis* is persistently found connected with diseased cattle, and is perhaps the most frequently isolated strain from emergency-slaughtered cattle in Germany causing food-poisoning. It is especially associated with meat as a food-poisoning vehicle.

The primary and prevalent sources of *Salm. thompson* and *Salm. newport* are still somewhat of a puzzle. Both have been found in lymph nodes of pigs; *Salm. thompson* is a common cause of chicken disease in Great Britain (Buxton and Gordon, 1947) and is not uncommon in imported eggs. It is possible that birds are the primary sources of both strains. The origins of the exogenous strains have been considered under imported eggs. Naturally some strains may be more prominent in particular years owing to special outbreaks due to a particular type—such as the rise in frequency of *Salm. bovis-morbificans* in 1953 associated with a large outbreak in Lancashire due to meat pies.

Vehicles

The main groups were fairly comprehensively worked out many years ago, but it is of value to discover if there have been material changes over the last 20 years or so. This is done in Table V, but it includes outbreaks due to causes

TABLE V.—Vehicles in Food-poisoning Outbreaks

Vehicle	Outbreaks 1919-31*	Outbreaks 1951-3†
Meat, fresh ..	8	4
" somewhat manipulated ..	10	47
" heavily processed ..	37	92
Canned foods ..	8	14
Milk and milk products ..	12	11
Eggs, duck ..	6	45
" other ..	1	12
Shellfish ..	2	1
Sweetmeats (trifle, ice-cream, custard, etc.)	Not separately recorded	36

* From Savage (1932).

† From *Monthly Bull. Minist. Hlth*, 1954, 13, 12; and 1955, 14, 34.

other than salmonellae, as the bacterial groups are not separated. While only a rough guide, the figures show that the vehicles to-day are essentially the same and in very much the same proportion as 30 years or so ago, with one striking exception—that is, the great increase in eggs as a vehicle (partly because of failure to recognize their importance). This is particularly so for duck eggs. The overwhelming importance of manipulated meat food is about the same for both periods. There are, however, other differences between the two age periods not brought out in the table. One is the much greater safety of canned food to-day; many of the outbreaks now recorded as associated with canned foods are due to the infection of such products after removal from the can. The present ice-cream regulations have greatly increased the safety of this food. Changing food habits and commercial practices have resulted in a far more extensive consumption of meat foods prepared in quantity in works outside the places of consumption, and, if specific infection occurs in places where such food is prepared, resultant outbreaks are usually much more extensive than those from the old-time home or shop-made brawn, pressed beef, and the like. A good example, described by Miller *et al.* (1955) is the very extensive outbreak of salmonella food-poisoning (*Salm. bovis-morbificans*) in 1953, extending over a large part of West Lancashire and involving over 1,149 persons, with 5 deaths. The vehicle was meat pies, all made in one bakery but using meat supplied by a number of butchers.

Another example of widespread salmonella infection from meat is the very extensive outbreak in 1953, extending over many parts of Sweden (Lundbeck *et al.*, 1955) due to *Salm. typhi-murium* and involving 8,845 known cases with at least 90 deaths. The meat was all distributed from one large abattoir, the infection probably being introduced by infected animals and spreading widely through the abattoir by direct transfer, infected faeces playing a large part. Examination of carcasses showed *Salm. typhi-murium* of the same phage type in 11.2% of glands and 9.6% of muscles, while the pork carcasses yielded even higher percentages. Of 360 personnel examined 53 (15%) showed the same strain of salmonella.

An important factor to be considered in relation to the vehicle is its suitability for bacterial multiplication. Large numbers of salmonellae appear to be necessary to cause food-poisoning, and this usually involves multiplication outside the human body. Hormaeche and Salsamendi (1936, 1939) found that human volunteers might ingest as many as 2,000-4,000 million salmonellae (*Salm. typhi-murium*) without any ill effects.

McCullough and Eisele (1951) carried out a very large number of feeding tests with human volunteers, and the following findings illustrate the influence both of dosage and of strain variations within the same type.

Salm. meleagridis.—Of the three strains used strain III was the most virulent, and illness was caused in a minority of cases with about 750,000 bacteria; with a 20-million dose of strain I, only one out of five was ill, but with a 30-million dose four out of six were ill.

Salm. anatum.—With the two most toxic strains doses of 3,500,000 and 1,250,000 were the lowest to cause symptoms, but with the third strain 45,500,000 bacilli merely caused mild ill effects and then only in one out of six fed.

Salm. newport.—More toxic, but of 16 fed with doses of 152,000 to 385,000 bacteria only two became ill; with 1,350,000 three out of six were ill.

Salm. derby.—No illness until 15,000,000 fed, and then only three out of six affected.

Salm. bareilly.—Dosage 125,000: out of six fed, one ill. Dosage 695,000: out of six fed, two ill. Dosage 1,170,000: out of six fed, four ill.

Salm. pullorum.—A large number of strains used, but only when the dose ranged from 1.3 billion to 10 billion did any illness result, and that was slight and brief.

These findings emphasize the significance of the nutrient vehicle and explain a common experience that articles such as trifle, part consumed at time of preparation, are usually harmless, while next day, if kept under conditions favouring multiplication of bacteria, they cause widespread illness.

This numerical factor explains how frequently salmonella carriers can work on food premises for long periods without causing outbreaks if the conditions deny opportunities of inoculation of nutritive foods. Thomson (1954) has shown that salmonella carriers of typhoid and paratyphoid bacilli may excrete enormous numbers of these bacilli in their faeces, but I have not found any information on whether this applies to carriers of food-poisoning salmonella.

Paths of Infection

Frequently the most unrewarding part of an investigation is tracing the path from the reservoir to the vehicle. The following points have to be considered.

The consumption of meat from a salmonella-infected animal, either obviously ill or without noticeable changes even to a trained meat inspector. Outbreaks from emergency-slaughtered animals used to be fairly common in Germany. Food-poisoning bacilli may be transferred by animal products, usually milk, the bacilli being either derived from cows suffering from a salmonella infection (usually *Salm. dublin*) or gaining access from infected dung. Infection of the food by salmonella-carrying intermediaries such as rats, mice, cats, and dogs. The risk is materially increased when rats are prevalent in places where

food is prepared. Savage and White (1922-3) isolated *Salm. enteritidis* from 6 out of 96 rats from slaughterhouses, and Ludlam (1954) found salmonellae in only 4.4% of rats from mixed types of premises, but in 6.4% from 94 rats from a butcher's by-products factory.

Originally sound food in catering premises, shops, or homes may be specifically contaminated either directly by the incorporation of infected egg mixtures or indirectly by such egg mixtures contaminating various food-preparing machines or utensils difficult to clean and when unsterilized allowing bacterial multiplication.

Infection from Human Carriers of Salmonella

This path requires special consideration in view of the undue prominence accorded to it by many doctors and particularly medical officers of health. An ascertained human salmonella carrier amongst the food preparation staff is often accepted as the proved source of infection without any real evidence. Salmonellae are excreted by man under three conditions: (1) during an actual attack of food-poisoning, (2) persistence of the bacilli after recovery either for a limited time (temporary carriers) or for a prolonged period (chronic carriers), or (3) from a symptomless but infected person.

After an attack of salmonella food-poisoning the bacilli can readily be isolated from the faeces, but they diminish in a fairly orderly sequence for some weeks, after which they usually cannot be isolated apart from a minority which may persist longer or even become chronic carriers. A few examples illustrate this sequence.

Kwantes (1952), reporting on a *Salm. typhi-murium* outbreak in Llanely in 1949, was able to follow up 112 cases. Those faeces-positive in each week were 112 (end of one week), 60, 34, 16, 9, 9, 3 (end of nine weeks). The 61 symptomless excretors were also followed up, and their rate of elimination was roughly comparable to that of actual cases, with two cases (5.5%) still excreting at the end of seven weeks. Lennox *et al.* (1954), investigating a milk-spread *Salm. typhi-murium* outbreak, found a slow rate of clearance from the faeces for three weeks and then a rapid and fairly uniform decline each week, leaving only 2 positives out of 60 cases at the end of seven weeks, with persistence of 1 or 2 positives until 18 weeks.

Miller *et al.* (1955) investigated the clearance rate of 563 cases infected with *Salm. bovis-morbificans*. Only 14 were still excreting after four to five weeks; these were reduced to four after 13 to 14 weeks, and several were still positive after 15 weeks.

A few infected persons undoubtedly become chronic carriers, for scattered through the literature are records of individuals found positive after one or two years. A percentage figure cannot be given for such chronic carriers, but probably it is low and below that for paratyphoid fever carriers. Investigations carried out by the Public Health Laboratory Service (personal communication) yielded the following figures:

Of 3,303 children under 15 years admitted to hospitals	7 positive
" 2,968 mothers at antenatal clinics	11 "
" 2,467 persons waiting admission to mental hospitals	5 "
" 1,091 adults waiting admission to general hospitals (none gastro-intestinal cases)	1 "

In all, out of 9,829 persons examined 24 (0.24%) were positive for salmonellae, 14 strains being *Salm. typhi-murium* and 6 other strains being represented. Bearing on this point, Armstrong and Allison (1955) examined 200 gall-bladders removed after death and 50 cholecystectomy specimens, and only one was positive (*Salm. typhi-murium*). Some weeks without systemic invasion, but more permanent continuance must be associated with lodgement in internal organs such as the spleen or gall-bladder. In this connexion the experiments of Ørskov *et al.* (1928), and Ørskov and Moltke (1928) on oral feeding of mice with salmonellae are of great interest and support this view.

Consumption of left-over foods, etc., by staff is common in places where food is prepared, and may result in staff members being victims in many food-poisoning outbreaks. Distinction between a salmonella carrier and an infected victim is usually difficult, but it should always be attempted. Lines of investigation are the following: (1) Is there any history of a previous gastro-intestinal attack? (2) If the person is a real chronic carrier there is a possibility of a history of food-poisoning outbreaks at previous places of employment. (3) Critical consideration of the connexions of the alleged food-handlers with the infected food and with opportunities of infecting it. (4) Detailed studies on agglutination titres, both H and O, and particularly their fluctuations.

The fourth line of investigation is of considerable value for typhoid and paratyphoid infections, but seems to be of limited utility for the food-poisoning salmonella cases. Not much recent work appears to have been done on this point, but available facts suggest irregular findings for both H and O agglutinins. Miller *et al.* (1955) studied this factor, but owing to shortage of time no agglutination observations were made until after two months, and then rather less than 70% of actual cases showed evidence of antibody production.

In their studies of experimental salmonellosis produced by feeding different salmonellae to human persons McCullough and Eisele (1951) also studied agglutination development reached by those who developed illness of food-poisoning type; their findings are shown in Table VI. Of their 47

TABLE VI

Strain	No. of Cases	No. Titre Change	Non-significant Rise	Moderate Increase	Considerable Increase
<i>Salm. meleagridis</i> ..	16	6	5	2	3
" <i>anatum</i> ..	16	8	2	3	3
" <i>newport</i> ..	5	3	1	—	1
" <i>derby</i> ..	3	1	—	2	—
" <i>bareilly</i> ..	7	4	1	2	—
	47	22	9	9	7

cases, only 16 (34.5%) showed any significant rise in titre. Apparently separate O and H reactions were not used. Also a number of the infections were quite mild. These estimations are important enough for them to be regularly made, and more detailed study may show that they are more helpful than the above figures suggest.

Measures to Reduce the Incidence of Food-poisoning

We appear to be amassing a great deal of highly useful information which pin-points the increase of food-poisoning, throws much light upon the organisms responsible, the reservoirs of infection, and the vehicles infected, but is unaccompanied by adequate measures of prevention. A good deal is being done by health education, by inspection of food-producing and catering premises under inadequate powers of control, and from technical improvements in appliances used in food kitchens and eating-places. All this is valuable, but the plain fact is that food-poisoning continues to increase, and there is evidence of an expanding distribution of salmonella infection in both man and animals.

(1) Detailed Investigation of all Outbreaks to Ascertain More Accurately the Extent of the Problem

Table II shows that for 1953 and 1954 the outbreaks for which no cause was found were respectively 2,000 and 2,322—that is, about 39% of the total reported. This unsatisfactory position is commented upon in the *Monthly Bulletin* of December, 1955, and the authors are probably correct in their supposition that "most of the outbreaks for which no cause was found were small outbreaks reported so late to the medical officer of health that no investigation was worth carrying out."

Another feature, brought out in Table I, is the enormous number of sporadic cases which remain unconnected with other cases, in large part probably from faulty co-operation on their detailed investigation. For these two failures medical practitioners and medical officers of health must both share part of the responsibility. Food-poisoning is at present notifiable by medical practitioners under the Food and Drugs Act, 1938, due to be repealed when the Food and Drugs Act, 1955, comes into operation. Food-poisoning is difficult to define in legal enactments, but the change-over will give the Minister of Health an opportunity of revision in the new memorandum which will be necessary. One suggestion is the introduction of "acute" before food-poisoning (the enteric infections are notifiable under another section) and with an implication on promptitude. Stress should be laid upon the urgency to communicate at once with the medical officer of health, which is hardly sufficiently expressed by the "forthwith" in the Act.

The investigation of a food-poisoning outbreak requires experience, and, although inquiries by the practitioner concerned can be most helpful, wider exploration is indicated, not only within the family, but into such matters as possible infection from food eaten in a catering establishment or intimate association with animals. The medical officer of health should regard these isolated sporadic cases as probably linked to a more extensive outbreak only to be discovered by personal inquiries on his part, linked with the full co-operation of the Public Health Laboratory Service. From wide experience I do not consider that routine inquiries by a sanitary inspector alone are adequate, and direct medical oversight is needed.

(2) More Complete Ascertainment of the Animal Reservoir of Salmonellae

We know much about salmonellosis in animals, but are still very incompletely informed about their quantitative distribution. To extend our knowledge of reservoirs of salmonella strains we need more extensive surveys of animals that may possibly be associated with food-poisoning. A good illustration is *Salm. dublin* infections in cattle. As set out above, we know of a number of scattered pockets of infection, but we do not know its extent in cattle generally or if these infections are on the increase. Recent evidence that salmonella-infected animal foods may spread the disease to healthy animals is a new light on a possible method of spread. Combined veterinary and bacteriological studies could contribute much to our knowledge of salmonella reservoirs.

(3) Reduction of the Risk of Food Infection from Human Carriers of Salmonella

Chronic human carriers are rare, but with the present large number of outbreaks annually there must be at any one time a considerable number of people in the community who are for limited periods temporary salmonella carriers. There is little risk of direct infection to other persons, but a real risk that they may infect foods which foster rapid bacterial multiplication and so become vehicles to spread food-poisoning. These risks occur in places where food is manipulated and where food is prepared for consumption, such as in catering kitchens.

The use of administrative means to ascertain carriers of food infections in catering or food-preparation places is admittedly a difficult problem. It is tackled in Section II (1) of the Food Hygiene Regulations, 1955; but this takes us only a little way towards ascertainment and is far inferior in potential effectiveness to the corresponding recommendations in the standard code of the Catering Trade Working Party.

(4) Improvement of Standards of Hygiene in Commercial Feeding-places

The Food Hygiene Regulations, 1955, go a long way towards this aim and are a decided improvement on previous enactments. At the same time they have a number of

serious defects which limit their effectiveness in controlling food-poisoning. The whole regulations cannot be discussed, but three adverse features may be mentioned. They are charged with indefinite phrases such as "reasonably practical," "sufficient," "suitable and sufficient," "adequate," etc., which cannot fail to be interpreted differently by individual local authorities, so that anything like uniformity of administration is most unlikely. Many local authorities will fear to press for necessary requirements lest, if tested in the courts, these vague phrases may be interpreted by the court against them. The risks of specific infection from inadequately cleaned utensils cannot be ignored, but this seems to have been done in the Regulations. These do not enforce either effective cleaning or sterilization, for "suitable and sufficient sinks" is not enough, and sterilization is not ensured by "an adequate supply either of hot and cold water or hot water at a suitably controlled temperature." The definite risks of carrying infection from day to day from objects so difficult to clean as sausage machines or egg mixers are not covered. Particularly unsatisfactory is the absence of any requirement for the registration of catering establishments of all kinds with the local authority, as recommended by the Catering Trade Working Party. Experience in connexion with another business (ice-cream making) has shown registration to be a most valuable instrument for the hygienic control of such establishments. There is not even a suggestion that every medical officer of health should keep a complete register of all catering premises in his district, and deal in his annual report with the actions taken and results achieved.

Within the last few years many practical surveys of catering establishments have been published, and invariably they disclose numerous hygienic defects, many of which facilitate the transference of food-poisoning organisms to food on the premises. Many of these defects cannot be put right under the new regulations except voluntarily.

(5) Hygienic Control of Bulk Food Preparation

It is essential to ensure hygienic control in premises used for the bulk preparation of meat foods and those distributed in package form. Risks of infection from such foods and appropriate measures of control have been considered in detail by the Manufacturers Meat Products Working Party. They made a number of valuable recommendations, some of which are incorporated in the new Food Hygiene Regulations. Among the Working Party recommendations was the registration of such premises. This is incorporated in the new Food and Drugs Act, 1955, Section 16, requiring the registration with the local authority of premises for "the preparation or manufacture of potted, pressed, pickled, or preserved food intended for sale." Registration will be very useful, but time is necessary to see to what extent the regulations will be tightened to ensure adequate hygienic premises and practices. It would be helpful to work out better bacteriological standards for these premises to assist in this control.

(6) Steps to Reduce Risk of Salmonella Infections from Imported Egg Products

The danger does not arise from unopened shell eggs (except from duck eggs from infected farms) but from pooled mixtures of shell eggs involving the distribution through the mass of any salmonellae present and usually also some multiplication of the bacilli. An important feature is the unknown (to health authorities) and insidious way these infected egg mixtures are distributed all over the country and used by bakers and confectioners in cakes and confectionery products which subsequently do not receive effective heat treatment. A considerable list of salmonella outbreaks so caused could be compiled. This risk is apt to be extended in duration because of the considerable difficulty in effectively cleansing egg-mixing machines in the absence of any regulations requiring their sterilization. The spread of salmonella infection may also occur indirectly,

for dried-egg mixtures that are unfit are sometimes distributed to manufacturers of animal foods. The M.R.C. (1947) report on spray-dried egg includes an examination in 1944-5 of the mesenteric lymph nodes of 5,285 pigs from a number of abattoirs. As stated earlier, from 133 of these nodes salmonella strains were isolated—an incidence of 2.5%. At least 10 of the different types isolated were exogenous types not previously found in this country, and comprised more than half of all the salmonellae isolated. These mixed-egg products are a valuable addition to our food supply, but this is inadequate to justify their use when infected with large numbers of living salmonella organisms. The destruction of pathogenic organisms in egg mixtures is difficult but by no means insuperable. Presumably these products require import licences, which would give power to impose reasonable conditions of safety sufficient to remove or at least largely reduce these risks.

Conclusions

1. After making full allowance for the effects of notification of food-poisoning by medical practitioners and the greater facilities for bacteriological investigation there is clear evidence of a marked increase in food-poisoning in Great Britain over the last decade or so, an increase which shows no signs of diminution but rather of still further increase. Undoubtedly, also, a material number of outbreaks remain unreported and therefore not investigated.

2. Owing to the increased laboratory facilities and the improved technical procedures now available for investigation it is difficult to compare present and past experience, but the evidence points to an extension of salmonella infections in animals. It is not merely that we know more about them; they appear to be more extensive.

3. The increases mentioned in the above two paragraphs have in recent years led to a rise in the number of persons who, either as symptomless cases or transitory carriers, are excreting salmonella strains in faeces.

4. It is suggested that the above three conclusions may be associated with evolutionary changes in the make-up of the salmonella group.

5. Five factors seem to be operating in the increase in food-poisoning. (a) Changing food habits, taking the form of a considerable increase in the number of meals eaten outside the home in professional catering-places, where defects in hygienic control may affect large numbers of customers. (b) The extension of bulk preparation of packaged or other foods under factory conditions which inherently increase the risk of contamination with salmonellae. (c) The extensive and extending use of bulked eggs (consigned to this country frozen or in other forms) in confectionery, etc. A large number of hitherto unknown salmonella types have been introduced in this way into this country. The association of liquid egg foods with food-poisoning in Great Britain is clear-cut. (d) The extension of the reservoirs of salmonella in animals indicated in paragraph 2. (e) The increase in human carriers of salmonella organisms (mentioned under paragraph 3) supplies opportunities for specific infection of foods, particularly under the conditions set out in a and b.

6. The number of single-case salmonella incidents yearly is very large and in a material proportion is likely to be associated with other cases at present unrecognized. It would be helpful if official steps were made to define more precisely the cases to be notified as food-poisoning and to point out that prompt notification is essential as an aid for investigation. These should

be supplemented by efforts by medical officers of health to enlist the help of family doctors in giving prompt notification and co-operating in their elucidation.

7. The problem of the greatly increased and yearly increasing toll of food-poisoning may be summed up by pointing out that public health action has not kept step with the modern revolution in food habits. More and more food preparation is escaping from the domestic kitchen into the hands of the bulk commercial manufacturer, whose practices often fall below essential hygienic standards. Prepared foods such as meat pies are passing from production by the few to production on an extensive scale, with an absolute need of much higher sanitary standards of safety, which investigation of food-poisoning outbreaks shows are often not reached. The very machinery necessary in large-scale production carries and spreads the risks because of the difficulty of effective cleaning and sterilization. Methods comparatively harmless in the domestic kitchen are fraught with risk when practised in the communal kitchen. All bulk-feeding habits add to the risk, since the few infected persons may contaminate inefficiently cleaned food utensils and so spread infection.

We smile at Mrs. Beeton's direction to "take 12 eggs," but the point to us should be that they are single eggs and (except for some duck eggs) free from risk, but the mixed dry or frozen egg mixtures of to-day are far more liable not only to bacterial infection in the mixing stages but to distribution of the bacteria through the mass, probably with multiplication before usage.

These revolutionary changes in habits, with their resultant changes, are not adequately guarded against even in the latest control orders. A pathetic faith in the value of voluntary education is no adequate substitute for control based on education and exhortation with adequate reserve powers of enforcement should the will be lacking to attain to proper hygienic standards.

INHALED FOREIGN BODIES

BY

C. L. N. ROBINSON, M.D., F.R.C.S., F.R.C.S.(C).

AND

WILLIAM W. MUSHIN, M.B., F.F.A.R.C.S., D.A.

From the Sully Hospital Thoracic Centre, Glamorganshire

The problems associated with inhaled foreign bodies usually receive little attention in the medical curriculum and in textbooks. This is in contradistinction to the ingested foreign body, which is well documented at every stage of its journey. The importance of the inhaled foreign body is demonstrated by the Registrar-General's (1954) statistics for deaths in England and Wales from this cause. There were 11 due to inhalation, as compared with 29 due to ingestion (Tables I and II).

TABLE I.—Total Deaths from Foreign Bodies in England and Wales, 1954

Trachea, bronchus, and lung	11
Digestive tract	29
Pharynx and larynx	443
Genito-urinary tract	5
Ear	1
Nose	1

TABLE II.—Ages of 11 Subjects who Died From Inhaled Foreign Bodies in Trachea, Bronchi, and Lungs in England and Wales in 1954

Age:	-1	-5	-15	-25	-35	-45	-55	-65	-75	-85
No.	4	1	0	0	0	1	1	1	1	2

A foreign body may be overlooked in diagnosis for many reasons. The highest incidence is in children who are too young to give a history (Fig. 1). The typical early history of choking while eating, accompanied by dyspnoea and cyanosis, or of eating while playing and then choking, may not be known by a parent when further symptoms develop. This is particularly liable to happen if the child is on holiday or being tended by a baby-sitter when the foreign matter is inhaled (Table III, Cases 5 and 12). Again, a patient may choke and cough, and think that the object has been expelled, whereas in fact it has been inhaled from a larger sensitive tube to a smaller insensitive one (Case 8). Further, a small metallic foreign body may not cause any immediate disturbances, and only come to light years later from its pressure effects (Case 2). An object may also be inhaled when a patient is asleep, under the influence of alcohol, during an epileptic seizure, or during anaesthesia (Case 15). The foreign body is often thought to have been swallowed and that it will be passed by the bowel. Sometimes the early history is not known, and the presenting symptoms may simulate those of bronchitis, pneumonia, tumour, lung abscess, bronchiectasis (Case 6), tuberculosis, or empyema (Coope, 1948).

Protective Reflexes

The inhaled object may stimulate the laryngeal mucosa and cause adduction of the cords. The patient chokes and coughs, and may expel the object. A large object which is not dislodged will cause complete obstruction of the larynx and death from asphyxia in a few minutes.

The cough reflex is normally protective for the trachea and bronchi, but each cough is preceded by a deep inspiration, and at this time, before the burst of explosive coughing, the object may be inhaled into the trachea. From here the further passage depends on the size and sharpness of the object. The tendency is for it to be inhaled as far as its size and shape will allow it to go.

If it is large, it will remain in the trachea, causing paroxysms of coughing; as it moves up and down and strikes the glottis from below it makes an "audible slap." If the movements are forcible in the trachea they may be easily perceptible as a "thud" or, if less forcible, as a "flutter" (Jackson and Jackson, 1950).

A smaller foreign body will pass into the right bronchus more commonly than the left, because of the larger diameter and the less acute angle at which this bronchus leaves the trachea. The posterior segmental bronchi are more commonly affected than the anterior.

Pathology

The nature of the foreign body determines the degree of further reaction. Metallic foreign bodies cause very little immediate inflammation, but in the course of time they become oxidized and the edge roughens, with consequent penetration and pressure. Organic substances such as nuts and beans cause an intense inflammation with oedema, granulations, and pus due to the contained fatty acids. As the material absorbs moisture and swells it progressively blocks the lumen of the passage in which it lodges. The younger the patient the more dangerous it is.

A foreign body lodging in a bronchus may occlude it either completely or partially. Complete obstruction is followed by atelectasis of the portion of the lung supplied by that bronchus (Asherson, 1953). Subsequently the inflammatory changes may take the form of pneumonia, bronchiectasis, lung abscess, and empyema. Partial obstruction may either allow relatively easy passage of air in both directions, in which case the later effects are due to local inflammation only, or it may take the form of a ball-valve obstruction. Air enters the lungs during inspiration when the bronchus dilates, but cannot pass out in the reverse direction during expiration because the bronchial mucosa becomes approximated to the sides of the foreign body. This results in obstructive emphysema.

Occasionally, combinations of these features occur. When a foreign body causes atelectasis of a lobe the remainder of that lung may become "emphysematous" even though it is not directly affected by the object. This is a process of "compensatory emphysema."

Diagnosis

The original accident is often dramatic, accompanied by choking, prolonged coughing, cyanosis, and dyspnoea. It cannot be overemphasized that such a history should be sought repeatedly from parents, guardians, and baby-sitters. Occasionally, however, a foreign body is inhaled into a distal bronchus without setting up any reflex during its passage. The diagnosis of metallic foreign body is easy, for, although it may cause few signs apart from those of bronchitis, it is clearly seen in either a postero-anterior or lateral radiograph. The diagnosis of a non-opaque foreign body can be made from physical examination. The presence of atelectasis will be shown by diminished movement, dullness to percussion, decreased air entry, with the trachea and apex

beat perhaps displaced to the same side and the diaphragm high (Fig. 2). Obstructive emphysema is characterized by decreased movement, overexpansion of the affected part of the chest, a hyperresonant or tympanitic percussion note, and poor breath sounds, except in the early case when air is still entering in the inspiratory phase. Clinically this may be mistaken for pneumothorax, but radiographs taken in inspiration and expiration are diagnostic. A comparison of these two pictures shows the shift of the mediastinum away from the affected side on expiration, and the flattened diaphragm, with of course some lung markings in the emphysematous area (Fig. 3). The contrast in transparency of the two sides is not so evident on inspiration, for the compensatory increased movement of the sound lung fills it so well with air that there may be little difference between the translucencies of the two sides.

FIG. 2.—Case 4. Postero-anterior chest radiograph: atelectasis of left lung, with mediastinum drawn to the same side, high diaphragm, crowding of ribs, and ground-glass appearance of lung field.

FIG. 3.—Case 8. Postero-anterior chest radiograph: obstructive emphysema right lung, with mediastinum to opposite side, diaphragm depressed, and greater translucency of lung.

Differential Diagnosis

The differential diagnosis may be difficult if the history of inhalation is not obtained. Or if it is obtained and a foreign body is suspected the signs of laryngo-tracheitis *per se* will simulate those of a foreign body. This happened in a case not reported in this series:

A child went to bed sucking a boiled sweet, and was heard to cough and choke later. Although it had signs of laryngeal stridor and bronchospasm, there were none of localized obstruction radiologically. The child was prepared for bronchoscopy, but before the scope was introduced the cords were seen to be oedematous. This was thought (and proved) to be sufficient to cause the symptoms. The symptoms subsided with nursing in a steam tent and the administration of antibiotics.

Pressure on the bronchi from without, due, for example, to enlarged lymph nodes or mediastinal abscess, may give a clinical picture similar to that of inhaled foreign body. A good example is a foreign body lodged in the oesophagus, which may press on the trachea and cause partial obstruction.

If there is a reasonable likelihood of a non-opaque foreign body being in the air passages in a patient suffering from bronchiectasis, unresolved pneumonia, lung abscess, or obstructive emphysema he should have the benefit of a direct inspection of the air passages by an experienced bronchoscopist.

Treatment

The hope that a foreign body may be coughed up is unjustifiable, for this course of events occurs in only 3% of cases (Jackson and Jackson, 1950). The practice of inverting the patient and shaking him to displace the object is dangerous, for the object may move, become impacted in the glottis, and cause suffocation. It is imperative that a skilled bronchoscopist should remove the foreign body as soon as possible, under anaesthesia administered by a competent anaesthetist. There is one caution to this rule: if a child has had unsuccessful attempts at bronchoscopic removal when first seen, and is suffering from laryngeal oedema, this should be treated first and time allowed for the oedema to subside before another attempt is made (Case 3).

Anaesthesia

The importance of expertly administered anaesthesia for the successful removal of foreign bodies from the respiratory tract cannot be overemphasized. As Fig. 1 shows, the majority of our patients were infants and children, in whom it is notoriously difficult to administer safely an efficient anaesthetic for bronchoscopy. Several of our patients (Cases 1, 3, 8, 9, 11, and 15) had had previous unsuccessful attempts at removal of the object by bronchoscopy, probably necessitated by inefficient anaesthesia. Many of them suffered from anoxia of varying degree, sometimes with gross respiratory obstruction. Anaesthesia must provide the bronchoscopist with a tranquil oxygenated patient in whom all the tracheal and bronchial reflexes have been eliminated so that as much time as is needed can be spent in finding, seeing, and removing the foreign body.

We condemn as unsafe the use of relaxants to obtund respiratory tract reflexes in these circumstances. Suppression of these reflexes by this means occurs coincidentally with respiratory arrest. Unless the surgeon is interrupted continually by the need to ventilate the patient, serious and possibly fatal oxygen lack follows. We know of deaths that have occurred in this way. Surface analgesia with cocaine or, if desired, a similar but longer-lasting drug, forms the essential basis of the method of anaesthesia which we recommend. In adults unconsciousness is rarely indicated. Sedation with papaveretum and hyoscine followed by careful surface analgesia of the pharynx, larynx, and trachea is generally adequate.

Children below the age of 10 years are anaesthetized in a manner similar to that which we use for bronchography (Mushin and Lake, 1951). They are put to sleep in bed with a suitable dose of basal narcotic such as rectal bromethol.

In the theatre, anaesthesia is slowly and carefully induced with trichlorethylene and oxygen. When laryngoscopy is possible the cords and pharynx are sprayed with local analgesic, and a further 1 ml. of solution is injected through a fine catheter into the trachea.

Overdose with local analgesics is a possible danger, and is avoided by carefully limiting the dose used (Mushin and Lake, 1951). Anaesthesia is maintained with a stream of nitrous oxide, oxygen, and trichlorethylene into the side tube of the bronchoscope.

At the end of the operation, and when the bronchoscope has been removed, the child is carefully watched in case laryngeal spasm occurs. This is liable to happen when the operation has lasted longer than expected and the effect of the local analgesic is wearing off. Children are not allowed to leave the operating theatre until free respiration is present.

Bronchoscopy

Bronchoscopic removal of foreign bodies in children is specially hazardous. The patient usually has a degree of laryngospasm and bronchospasm, and if these become extreme during the procedure the bronchoscope must be immediately withdrawn as the first step in overcoming it. Needless to say, manipulations must be gentle. Because a small instrument is necessary, the grasping of the foreign body in children is always "blind"—not an easy accomplishment with an elusive object. The risk of dropping an object on which a tenuous hold is maintained is considerable: the seriousness of this accident might be imagined if an object is being removed from an atelectatic lung and it drops into the opposite main bronchus. For this reason the table should be kept tilted in a slight Trendelenburg position, and a portable x-ray machine should be available in the theatre. The instruments which have been used routinely are shown in Fig. 4.

Fig. 4.—Photograph of two instruments used for removing foreign bodies from bronchus. (Made by Thackrays from German model by H. Pfau.)

When the object has been grasped the forceps and the bronchoscope are removed simultaneously in a smooth motion, so that the object will not be dropped at the point where it may catch—the cords, the epiglottis, and the back of the tongue. Repeated attempts at removal of fragile objects—for example, nuts—may be necessary, and occasionally smaller pieces may be removed with a sucker. Sharp objects whose points are uppermost should be manipulated so that the sharp end is protected in the beak of the bronchoscope; with safety-pins the point is drawn into the scope and the "keeper" may safely trail (Fig. 5).

After removal, an x-ray film is taken on the table, and if all the material has come away the film will show a dramatic improvement in any previous obstructive emphysema or atelectasis. If there is still some slight evidence of retention of fragments the patient is encouraged to cough before

TABLE III.—Summary of Cases

Case No.	Age in Years	Sex	Duration of Symptoms	History and Examination	X-ray Findings	Findings at Bronchoscopy	Comment
1	12	M	8 days	Inhaled dressmaker's pin which he had in mouth while watching an aeroplane	Pin deeply placed in basal segment R.L.L. (Fig. 6)	Attempt to remove it bronchoscopically elsewhere failed, in spite of using magnet and obtaining "radiological" contact with pin	Right thoracotomy, attempt to remove pin by bronchotomy at basal stem bronchus failed; pin then pushed out through visceral pleura
2	25	F	12 months	Frequent chest colds with mucoid sputum. Consequently recalled swallowing or inhaling safety-pin at a party 17 years previously	Open safety-pin R.M.B. (Fig. 5)	Pin in R.L.M.B., surrounded by granulation tissue. Removed easily, keeper trailing	Cough subsided in one week
3	14	M	9 days	Definite history of inhaling foreign body. Previous bronchoscopy at another hospital unsuccessful. Considerable laryngeal stridor. T. 101° F. (38.3° C.); P. 130; R. 36	Atelectasis of basal segments R.L.L.	Two attempts at bronchoscopic removal, the second successful in extracting granite chip from R.M.B.	First bronchoscopy delayed 2 days after admission and second one for 5 days. Nursed in steam tent
4	8	F	2 "	"Swallowed" nut while running. Coughed and spluttered. Pain in upper abdomen on coughing and spontaneously. O.E., cyanosis. Atelectasis left lung; T. 100° F. (37.8° C.); P. 140; R. 30	Atelectasis and consolidation left lung (Fig. 2)	Part of nut and shell removed from L.M.B. Mucopus distal to this aspirated	Slow expansion apical segment L.L.L.; but complete in 7 days
5	9	F	24 hours	While eating raw carrot, choked, became dyspnoeic and wheezy (history obtained from "sitter" one day later). O.E., cyanosed and very dyspnoeic. Obstructive emphysema. Left lung. T. 99° F. (37.2° C.); P. 140; R. 30	Slight obstructive emphysema left lung. Cervico-dorsal scoliosis convexity to right	Piece of carrot removed from L.L.L.B.	The diaphragm regained normal position, but the mediastinum did not (owing to scoliosis). Asymptomatic 6 days
6	11	F	7 years	Pneumonia; no complications. Recurrent haemoptyses and wheezing from age 4	Bronchiectasis R.L.L.	No evidence of foreign body. Slight narrowing middle lobe orifice	Right lower lobectomy. Privet leaves found in L.L.B. Had been seen with them in her mouth when aged 4
7	4	F	1 week	Severe bouts of coughing and vomiting. Sputum purulent. Treated for "pneumonia" with some improvement	Screw in right bronchus. Atelectasis basal segments R.L.L.	Screw removed with difficulty, owing to bronchospasm, from R.L.L.B.	Good recovery
8	3	M	6 weeks	While eating peanuts, choked, went blue, and was gasping for breath. Father "coughed" him and colour improved but wheeze persisted. Bronchoscopy 9 days later at another hospital—fragments of nut removed from R.L.L.B. Initial improvement, then relapse with wheeze and stridor, pyrexia, and purulent sputum	Obstructive emphysema right lung (Fig. 3)	Several pieces of nut removed from R.L.L. and pus aspirated	Complete recovery in 12 days

TABLE III.—Summary of Cases—Contd.

Case No.	Age in Years	Sex	Duration of Symptoms	History and Examination	X-ray Findings	Findings at Bronchoscopy	Comment
9	19	F	2 months	Aspirated piece of coconut. Violent cough for 10 minutes, then pain lower chest on inspiration and tightness. Three previous bronchoscopies elsewhere, when pus and inflamed mucosa only seen	Consolidation lateral basal segment, R.L.L.	Right basal stem bronchus appeared stenosed, owing to granulation tissue; some pus	Intensive physiotherapy, postural drainage, and antibiotics—progressive improvement. Bronchogram normal 1 month later
10	3	M	5 days	While eating peanuts, fell. Bout of coughing and constant wheeze. Obstructive emphysema left lung. Bilateral rhonchi	Obstructive emphysema left lung	Mucosa of L.M.B. oedematous. No foreign body seen at first, but gentle blind instrumentation recovered 2 sizable fragments of nut	Immediate x-ray film showed mediastinum central and emphysema cleared. Complete recovery
11	6/12	M	2 "	Swallowed peanut. Coughed and developed wheeze. Attempts at disposal by holding him upside down and shaking, and suction with endotracheal catheter unsuccessful	Collapse R.L.L. and obstructive emphysema	Half shell and several fragments of nut removed from R.M.B.	Mild laryngotracheitis for 24 hours, then normal
12	2½	F	11 "	On holiday with grandmother swallowed peanuts, choked and coughed. History not known till searching inquiry. Became feverish. Given tablets prescribed by chemist. Later penicillin course. Finally, breathing distressed and cyanosed. O.E., cyanosis, left chest hyperresonant. Air entry absent. T. 99° F. (37.2° C.); P. 140; R. 50	Obstructive emphysema left lung	Nut removed from L.M.B. with difficulty due to severe bronchospasm requiring removal of scope and reinsertion	Immediate improvement in general condition and air entry left lung, then some deterioration. Bulk of foreign body thought to have been removed; nursed in steam tent and recovered completely in 7 days
13	11	M	3 "	Inhaled drawing-pin which had been held in mouth; followed by choking and pain in right upper chest on coughing. T. 100° F. (37.8° C.); P. 96; R. 24	Obstructive emphysema left lung	Pin removed by grasping edge of head (not stem). It was dropped in the pharynx and recovered by direct laryngoscopy	Some laryngeal stridor. Recovery in 5 days
14	49	M	6 "	9 teeth extracted under inhalation anaesthesia. "Swallowed" last tooth. On recovery coughed for 15 minutes, dyspnoeic, chest wheezy and tight. Pain right lower chest, worse with breathing. Sputum stained. O.E., orthopnoeic, slight cyanosis, expiratory wheeze, dullness; decreased A.E. and V.R., R.L.L.	Molar tooth in R.M.B. with consolidation lateral subsegs. of ant. and post. segs. R.U.L., R.L.L., and L.L.L., and pneumoconiosis	Tooth in R.M.B. removed easily	Complete recovery in 3 weeks
15	9	F	2 "	3 molar teeth extracted under general anaesthesia. Immediate dyspnoea and vomiting. Attempted removal at another hospital, but lost when being withdrawn. (Slipped from right to left side.) T. 100° F. (37.8° C.); P. 136; R. 26	Tooth in L.M.B. Obstructive emphysema L.L.L.	Removed from L.M.B.; was dropped during extraction. X-ray film revealed position on right side and successful removal	Cords a little oedematous. Good recovery
16	6	F	3 months 2 " 3 weeks	Inhaled tooth. Choked and coughed. Malaise Rigors	L.U.L. atelectasis and emphysema, L.L.L.	Excessive granulation tissue in L.M.B. prevented adequate view through infants' scope and tooth not removed	Postural drainage and physiotherapy; x-ray film before thoracotomy and bronchotomy 5 days later showed tooth in stomach—it was loosened by attempts at removal, was coughed up and swallowed
17	6	M	6 days	Choked on peanut. Chronic bronchitis. Coughing and febrile since. T. 100° F. (37.8° C.); signs of consolidation R.L.L. and rhonchi diffusely	Patchy atelectasis R.L.L.	Peanut removed from R.L.L.	Readmitted a month later with consolidation post. basic seg. R.L.L. Re-bronchoscopy, but no foreign body seen. Cleared with antibiotics
18	11/12	M	3 weeks	Choked while eating mouthful of peanuts. Intermittent cough and wheezing. O.E., diffuse rhonchi, hyperresonance, and absent air entry, right lower zone	Obstructive emphysema R.L.L.	Nut removed from R.L.M.B.	Good recovery
19	1	M	1 day	Swallowed piece of bath sponge. Expiratory wheeze on exertion. T. 100° F. (37.8° C.); P. 166; R. 46	Atelectasis L.L.L. with obstructive emphysema L.U.L.	Carina obscured by sponge; which obstructed L.M.B.	" "
20	1½	F	3 hours	Swallowed sugar-coated almond. Coughed and became blue. Cough and wheeze since. O.E., wheeze; decreased air entry right chest anteriorly, rales posteriorly	Atelectasis R.L.L. emphysema R.U.L.	Fragmented foreign body R.M.B., white nut and brown skin. Much oedema of mucosa	" "
21	1½	F	5 weeks	Eating apple and choked. Since then occasional cough and wheeze on exertion. O.E., T. 98° F. (36.7° C.); P. 140; R. 24	Emphysema left lung	Piece of apple size of florin removed from L.M.B.	Recovered 4 days
22	1	M	2 "	Choking and cyanosis, while eating omelette. Later developed wheeze. Temperature lower after penicillin course but wheeze remained. T. 102° F. (38.9° C.)	Triangular piece of shell impacted in upper trachea	Difficult anaesthesia and instrumentation. Cords oedematous. Piece of shell removed through glottis and several pieces removed on sucker tip. More pieces removed through bronchoscope	Some signs of laryngeal stridor immediately; one hour later extreme cyanosis and unconsciousness required tracheotomy. Tube removed 10 days; recovered in 1 month
23	11/12	M	1 week	Inhaled walnut while on bus. Choked and became blue. Intermittent cough since. O.E., obstructive emphysema right lung	Atelectasis middle lobe and obstructive emphysema R.L.L.	Piece of walnut removed from R.L.M.B. at level of middle lobe orifice	Recovery 2 weeks
24	11/12	F	7 hours	Choked on liquorice all-sort. Cough and wheeze. O.E., generalized rhonchi. Decreased air entry R.L.L.	Obstructive emphysema R.L.L.	No foreign body found. Moderate amount of purulent secretions aspirated from lower lobes	Normal x-ray film following bronchoscopy. In retrospect, liquorice had dissolved after inhalation, causing immediate intense inflammation
25	13	F	6 weeks	Accidentally inhaled small gold safety-pin. No abnormal signs	Open pin, point up, in R.L.L.B. Basal mottling	Pin below M.L. orifice, with point embedded in mucosa. Several attempts at removal unsuccessful	Thoracotomy and bronchotomy. Head of pin lying below apical seg. of R.L.L.B. It was grasped and the pin gradually removed by straightening it out. Uneventful recovery

leaving the table: a useful trick in the case of children is to blow cigarette smoke over the patient's face.

After bronchoscopy all these patients are treated on return to bed with postural drainage, physiotherapy, and a suitable antibiotic. If removal of a foreign body has failed owing to its impaction in granulation tissue the patient is sent back to bed and treated in the same way as the others. This may allow the oedema to subside and permit a better view at the next attempt. Occasionally a small object which has

FIG. 5.—Case 2. Postero-anterior chest radiograph. Open safety-pin in right main bronchus.

FIG. 6.—Case 1. Postero-anterior chest radiograph. Pin in posterior basal segment of right lower lobe.

magnetism of alloys depends on the amount of heat received during the processing. Furthermore, the power of a magnet is inversely proportional to the square of the distance from its object, and, while intervening tissues do not impair magnetism *per se*, their presence makes contact difficult. On the whole, metallic objects in main bronchi are more easily removed by direct methods, and in deeply placed situations will usually require bronchotomy.

Prevention

Loose teeth in an anaesthetized patient should always be carefully watched. Children should not be allowed to eat nuts until they have a full set of teeth, or, if they are, the nuts should be finely ground. Small objects such as pins, buttons, and coins should not be left within an infant's reach. A parent should not set a bad example for a child by holding tacks and pins in the mouth. Children should

not be allowed to play while eating, or eat too quickly without proper mastication. The adage is still true that if nothing except food was put in the mouth the inhalation of a foreign body would be a rare accident.

Summary

Experience has been gained with 25 cases of inhaled foreign body, mostly in children. The early history of an inhaled foreign body is often missed; the later results may simulate almost any chest disease. The diagnosis is made from the history and the presence on clinical examination of atelectasis or obstructive emphysema, and from chest radiography. The importance of early removal of the foreign body by a team consisting of an experienced bronchoscopist and an experienced anaesthetist is stressed. The essential part of the anaesthetic is surface analgesia of the trachea and bronchi. If removal by bronchoscopy fails, thoracotomy and bronchotomy is justified, with the sacrifice of any destroyed lung. The majority of inhalation accidents may be prevented: nuts should not be given to young children who have no molars, small objects must be kept out of an infant's reach, and care should be taken with loose teeth in an anaesthetized patient.

We should like to thank Mr. Dillwyn Thomas, consultant thoracic surgeon, Welsh Regional Hospital Board, under whose care these patients were admitted, for his stimulation, criticism, and interest in this study. Mr. W. P. Cleland has kindly given permission to publish Case 25. We are grateful to Mrs. B. Marshall for photography, Miss Juliet Hilary-Jones for secretarial assistance, and Mr. K. Hillard for drawing Fig. 1.

TRACHEOSTOMY, AND MANAGEMENT OF THE UNCONSCIOUS PATIENT

BY

JOHN ANDREW, M.B., F.R.C.S.

Senior Registrar, Department of Neurological Surgery,
St. Bartholomew's Hospital, London

In recent years the indications for tracheostomy have been extended to include the management of tetanus, respiratory paralysis, and the unconscious patient. This simple operation has gained a highly valued place in neurosurgical practice, where the problem of maintaining a clear airway in comatose patients is often encountered. In the last four years in the Department of Neurological Surgery of St. Bartholomew's Hospital 16 tracheostomies have been performed. Selected cases are reported to illustrate the varying indications for the procedure. The mechanism whereby the normal gaseous exchange in the lungs is interfered with in these cases is discussed. The technique for ensuring adequate pulmonary ventilation and a satisfactory intracranial circulation in unconscious patients is also described.

Technique of Tracheostomy

It must be emphasized that so far as is possible this operation should be carried out as an elective procedure. It may be satisfactorily performed under local

analgesia, and this is particularly desirable if consciousness and breathing are depressed. It may be carried out with the patient in bed. If necessary, oxygen may be administered through a face-mask. Good illumination is essential, and the aid of an assistant is desirable. The neck must be held straight and extended as far as possible. A vertical midline incision is made, beginning at the cricoid cartilage and extending downwards for 1 in. (2.5 cm.). If desired a transverse incision can be used, but the subsequent more difficult dissection may outweigh the slight cosmetic superiority of the scar when the tube is removed. If the deep cervical fascia is incised strictly in the midline troublesome bleeding is avoided. The sternohyoid and sternothyroid muscles are separated by blunt dissection and held apart. A high tracheostomy has the advantage that the trachea is more superficially placed, and that there is less danger of the tracheostomy tube entering a main bronchus. As damage to the first ring may result in tracheal stenosis at a later date the thyroid isthmus must be retracted downwards or divided. In the latter case it must be divided after the application of artery forceps, as there may be bleeding from anastomotic branches of the superior thyroid arteries.

The incision into the trachea is made at the level of the second or third ring, and if a large tube is to be used it will be necessary to excise a small segment of the anterior part of the tracheal wall. A very large tube should be avoided, as there is a greater risk of trauma to the tracheal mucosa. The inner tube must be of such diameter that it will not be occluded by the passage of a No. 3 or 4 (English) Jaques catheter for suction purposes. It is undesirable to allow a large negative pulmonary pressure to occur during this manoeuvre for reasons that are given later. It has been found that tracheostomy tubes of sizes between Nos. 28 and 32 have been satisfactory. If there is a likelihood of the patient retaining mucoid secretions in the nasopharynx on account of dysphagia or unconsciousness, or should he be liable to vomit, then a cuffed tracheostomy tube will be advantageous, as it will prevent aspiration of these fluids. Penicillin powder may be dusted into the wound, which is not sutured; it is covered by a tulle grass dressing.

Maintenance of an Unobstructed Respiratory Tract After Tracheostomy

Suction.—The use of a mechanical suction apparatus is essential in order to remove secretions from the trachea and bronchi. A selection of sterile fine rubber (Jaques) catheters should be available. It is important to avoid the introduction of pathogenic organisms into the bronchial tree. Additional perforations near the end of the catheter will reduce the risk of trauma to the mucosa by small segments of this being drawn into the catheter. Lubrication is supplied by sterile water or a non-greasy jelly. The frequency of suction is gauged by the speed with which secretions are formed. This may be judged by whether breathing is noisy or by auscultation of the chest. If the mucus is very viscid and difficult to remove a detergent such as "Alevaire," administered by a fine nebulizer, will make it more watery and easier to remove. If there is an established bronchitis or bronchopneumonia, resulting in cyanosis, oxygen may be given either in a tent or through a catheter placed in the tracheostomy tube.

Physiotherapy.—The patient should be turned from side to side every hour in the early days of the tracheostomy, as it is at this time that the secretions are most rapidly formed. Percussion of the chest will help to dislodge mucus retained in more peripheral bronchi, and areas of reduced air entry will indicate the site for this treatment.

Complications of Tracheostomy

A formidable number of complications have been reported by several authors. Davis *et al.* (1953) mention haemorrhage, pneumothorax, and mediastinal emphysema. Perforation of the oesophagus has also been noted. None of these complications occurred in the present series. Tracheal stenosis from damage to the first ring must be borne in mind, and might be the cause for the voice alteration in Case 6 (see below). Crampton-Smith (1955) has emphasized that the introduction of a tube into the trachea, particularly if it is made of rubber, may result in a purulent bronchitis, which in turn may cause obstruction of the bronchi. On the other hand, the management of a severe chest infection in a comatose patient is easier after the establishment of a tracheostomy. Brattström (1954) believes that acute pulmonary oedema may be precipitated by suction through a tracheostomy. He thinks that a high negative pressure may develop during this procedure and overcome the normal bronchoconstrictor control over the pulmonary alveolar pressure: a sudden lowering of the alveolar tension may cause a serous transudation into the alveoli.

Indications for Tracheal Intubation or Tracheostomy

An unobstructed airway may be maintained in comatose patients by posture—that is, by placing the patient on his side in a horizontal position to prevent the tongue falling back; secretions in the mouth and pharynx may be removed by suction. If desired, a Magill airway may be inserted into the mouth. For reasons given below, in neurosurgical practice it is often desirable to keep the patient's head and chest raised. This posture will serve to reduce cerebral congestion and to facilitate a freer respiratory excursion. If coma persists from intracranial causes, and there is difficulty in keeping the airway clear, endotracheal intubation with a rubber tube may be carried out. This has two disadvantages. Firstly, the tube should not be left in position longer than 24 hours for fear of damaging the vocal cords. Secondly, the passage of a fine catheter down the tube for suction may be difficult.

In the series of cases given below the main indications for tracheostomy were: (a) Coma persisting more than 24 hours, when frequent suction was required to remove secretions from the pharynx and trachea. Cases of severe head injury frequently come into this group: when this occurs tracheostomy has been reported by Echols (1949) to be of value; (b) Difficulty in performing tracheal intubation. (c) The development of a lower respiratory infection in stuporous patients. In connexion with this indication Pitman and Wilson (1955) have advocated tracheostomy in the treatment of acute chest infections in chronic bronchitis. (d) Shallow respiration. The total volume of air may become

Groups of Cases Requiring Tracheostomy

Groups of Cases Requiring Tracheostomy	Cases
1. Coma due to acutely raised intracranial pressure	3
2. Coma persisting or recurring in spite of relief of raised intracranial pressure	5
3. Coma following operations in close relation to the brain stem	5
4. Miscellaneous	3
(a) Lesion of cervical cord	
(b) Combined head and chest injuries	
(c) Subarachnoid haemorrhage	

dangerously low. By halving the dead space tracheostomy may give a relatively greater tidal volume (Pitman and Wilson, 1955; Mushin, 1955).

The patients requiring tracheostomy are classified into four different groups according to the varying circumstances indicating necessity for this operation (see Table). An additional indication—namely, respiratory paralysis from a cervical cord lesion—is included in this group.

Case Reports

As already stated, the cases have been grouped to emphasize the differing circumstances, whereby respiration may be depressed and consciousness altered, and when tracheostomy has been required. Tracheal intubation through the mouth or nose was either impracticable for reasons given in the histories or contraindicated because of the time the tube would have remained in place. Illustrative cases are given from each group.

Group 1

In the first group there were three patients whose respiration became depressed and obstructed as a result of brain-stem embarrassment from acutely raised intracranial pressure. Tracheostomy was carried out in the hope of improving the patient's condition by establishing a clear airway, and thus rendering him more fit for the surgical procedure required to relieve the intracranial hypertension. Two cases are briefly reported.

Case 1.—A married woman aged 50 had been suffering from headache for four months. In addition she had a troublesome smoker's cough with purulent sputum. Two nights before admission she took phenobarbitone sodium 1 gr. (65 mg.); the next morning she could not be roused. On transfer to the neurosurgical department she was stuporous, her face was congested, and she was cyanosed; the respiratory rate was 20 a minute. Breathing was stertorous, and was obstructed by secretions in the pharynx and trachea; frequent suction was required. The pulse volume was poor and its rate was 120 a minute. Cerebral angiography indicated a right frontal meningioma. A tracheostomy was performed; there was a slight but immediate improvement in the level of consciousness, the cyanosis and congestion disappeared, and the pulse became slower and of better volume. The patient had been given a more favourable chance of surviving a major operation. Six hours later a craniotomy was performed and the tumour excised. Subsequent recovery was also facilitated, as suction through the tracheostomy tube probably prevented the development of a severe pulmonary infection from retained mucopurulent secretions.

Case 2.—A married woman aged 42 had had two episodes of spontaneous intracranial haemorrhage complicated by a right-sided hemiparesis and deep stupor in the previous six days. Carotid angiography revealed an aneurysm on the left middle cerebral artery. This was exposed by craniotomy and the aneurysmal neck occluded. Two days later the patient became progressively more comatose, with slow and stertorous breathing. Frequent suction of secretions from the pharynx was required. Because it was thought that this state might persist, a tracheostomy was performed. Respirations at once became quieter and there was an improvement in the peripheral circulation. The cranial wound was explored and an extremely oedematous frontal lobe herniated through the dural opening. There was no haematoma, so an internal decompression was performed by excising the frontal lobe. The patient failed to respond to these measures and died the following day from cerebral oedema, which was unrelieved by an internal decompression or by the injection of intravenous hypertonic solutions.

Group 2

In this group of five patients coma persisted or recurred in spite of surgical relief of raised intracranial pressure.

Case 3.—A man aged 23 sustained injuries to his head and face which resulted in a fissured fracture of the cranial vault and a compound fracture of the mandible. He was concussed, but after a lucid interval in hospital he developed evidence of cerebral compression and became rapidly comatose. The prompt evacuation of an extradural haematoma was followed by a partial return of consciousness. The next day his respirations became stertorous and obstructed, and he was cyanosed and showed signs of peripheral vascular failure. Secretions rapidly accumulated in the pharynx and trachea in spite of frequent suction, and his

level of consciousness deteriorated. The mandibular injury made suction difficult. After performing a tracheostomy there was an immediate lightening of the coma and improvement in the peripheral circulation; he made an uninterrupted recovery.

Case 4.—In spite of the evacuation of a post-operative extradural haematoma, this patient, a man aged 30, remained deeply unconscious the next day. His breathing was stertorous and his pulse rate 120 a minute. Lumbar puncture revealed evidence of a pressure cone, as the pressure was only 80 mm. of water and there was no rise on jugular compression. The cone was reduced by an intrathecal saline injection; afterwards there was an immediate improvement in consciousness. He then coughed more often and more vigorously, and required frequent suction to clear his nasopharynx, as swallowing was defective. Three hours later his respirations became increasingly obstructed from acute laryngeal oedema and an attempted tracheal intubation failed; an immediate tracheostomy was performed. At once there was a further improvement of consciousness; the tube was removed six days later, after he had made a speedy recovery.

Case 5.—A man aged 31, while convalescent from a mastoid operation, became increasingly drowsy and was transferred to the department in coma. A temporal lobe abscess was tapped, but, as little improvement followed, it was excised the next day. Over the next few days he developed a purulent bronchitis, which was later complicated by a basal pneumonia. Clearance of his airway became increasingly difficult and his level of consciousness and general condition began to deteriorate. Tracheostomy was performed six days later, and this was followed by a definite improvement in consciousness. His subsequent progress was slow because of the prolonged intracranial hypertension.

There were two further cases which were similarly improved after tracheostomy.

Group 3

The third group comprised five patients in whom surgical procedures were performed in close proximity to the brain stem. Consciousness was depressed for variable periods, and in addition there was impairment of coughing, swallowing, and respiration.

Case 6.—A boy aged 5 was admitted to hospital with a history of headache, sickness, and unsteadiness of gait for 12 months. Ventriculography indicated a cerebellar tumour. At operation a cystic astrocytoma was found in the antero-superior portion of the vermis: the tumour had herniated through the tentorial opening to compress the posterior aspect of the mid-brain. The day following this operation the patient had not recovered consciousness, and maintenance of the airway became increasingly difficult because of the tongue falling back and secretions accumulating in the pharynx and trachea. There was an accompanying early failure of peripheral circulation. Tracheostomy and endotracheal suction was followed by an improvement in peripheral circulation. Consciousness began to return within an hour. The patient then made good progress, although as a later complication there is some voice alteration. It is possible that the first tracheal ring was damaged.

Case 7.—A woman aged 51 had a large acoustic neurinoma which, among other disabilities, occasioned dysphagia and dysarthria. Removal of the tumour revealed that the pons had been severely distorted. The procedure was followed by prolonged unconsciousness and by peripheral vascular collapse, which was aggravated by respiratory obstruction from an accumulation of excessive secretions in the pharynx. She developed bronchopneumonia. Tracheostomy on the fourth post-operative day tided her over, and she gradually recovered consciousness and the pneumonia resolved. The brain stem had been severely embarrassed, however, and she died from decubitus three months later.

There were four more patients in this group in whom consciousness was slow to return after operation and whose condition deteriorated as a result of respiratory obstruction and depression. Tracheostomy made it possible for two of them to recover, but in the remaining two cases the operation was performed as a terminal measure. Necropsy findings here revealed only minimal pulmonary oedema.

Group 4

Case 8: Cervical Cord Lesion.—A married woman aged 57 developed a spastic tetraparesis due to spinal cord compression at the second cervical segment. A laminectomy was performed and a meningioma was excised from this level. This procedure

was followed by an early return of power to her limbs. The patient's breathing remained shallow and diaphragmatic, however, and she could only cough weakly. She was given breathing exercises; her lung bases were cleared by postural drainage. Over the next 10 days she became increasingly cyanosed, dyspnoeic, and drowsy. Some improvement followed intermittent tracheal intubation and oxygen therapy, but the peripheral circulation began to fail, and breathing became moist. Tracheostomy was carried out terminally. Post-mortem examination of the lungs revealed collapse of both lower lobes and severe pulmonary oedema of the upper lobes. The main bronchi and trachea contained only a little fluid.

Case 9: Combined Head and Chest Injuries.—A man aged 61 sustained a fissured fracture of his skull and four broken ribs on the right side. He was transferred to the neurosurgical department on account of increasing coma following a lucid interval. Exploration of the right middle cranial fossa was carried out and an extradural haematoma was evacuated. A splint was applied over the fractured ribs, where there was paradoxical movement with respiration. The next day he was conscious enough to complain of severe chest pain, and this prevented him from coughing adequately, and caused him to breathe shallowly. He retained an increasing amount of secretion in his bronchi and became progressively more cyanosed and stuporous. There was a speedy improvement after establishing a clear airway with a tracheostomy, and his subsequent recovery was uneventful.

Case 10: Subarachnoid Haemorrhage.—A man aged 21 had two subarachnoid haemorrhages within the space of five days. A general anaesthetic was required for carotid angiography, and after this he developed stridor and was unable to cough adequately. A fine lubricated catheter was passed between his vocal cords and the secretions were aspirated. This was followed by increasing stridor and cyanosis due to acute laryngeal oedema. Consciousness deteriorated. Endotracheal intubation failed because of the laryngeal oedema; tracheostomy became urgently necessary, and after its performance consciousness began to reappear, the peripheral circulation improved, and the cyanosis disappeared. The patient then continued to improve, but he subsequently died suddenly from a third intracranial haemorrhage.

These histories demonstrate that tracheostomy was life-saving in 9 of the 16 cases in which it was performed. Of the seven patients who died, three underwent the operation in a final attempt to save life. In Case 8 it should have been performed at least three days earlier and supplemented by intermittent positive-pressure respiration. The other three patients who subsequently died were temporarily benefited by the procedure, but their deaths were inevitable owing to the nature and severity of the intracranial lesions, and were not precipitated by tracheostomy.

Discussion

Unconsciousness is frequently accompanied by respiratory depression, and there is often a single pathological process responsible for the two stages. A lesion in the medulla oblongata or pons, from whatever cause, may readily alter or depress respiration and give rise to coma by interfering with the function of the reticular formation. As a result of coma the tongue falls back as the lower jaw sags, and respiration may become obstructed as well as depressed. Additional factors in the development of obstruction are the accumulation of vomitus, blood, and secretions in the mouth and pharynx. The more severe the obstruction the more stertorous will be the breathing.

Stertor.—At this stage it will be of interest to consider the mechanism of sterter. In this condition breathing is noisy and reminiscent of loud snoring. Inspiration is laboured and accompanied by obvious contraction of the accessory muscles of respiration, and the cheeks are indrawn. Expiration is slower and probably incomplete on account of the obstruction. This results in the chest being held in a state of expansion. The face appears to be congested and the neck veins to be engorged. The noisy breathing may be due to two causes. The first is that mucus lying on the vocal cords may cause them to vibrate, as movement of the mucus occurs during the respiratory excursion. The second is that the tongue may be in close contact with the soft palate, and a number of rapid "make and break" contacts between these two structures will contribute to the noise.

Factors in Respiratory Obstruction

The factors giving rise to obstructed or depressed respirations, and leading to inadequate blood oxygenation and carbon dioxide excretion in unconscious patients, appear to fall into two categories—namely, sudden loss of consciousness and prolonged coma.

1. *Sudden Loss of Consciousness.*—The causes of coma of sudden onset that are relevant to the present discussion include head injury, cerebrovascular accidents, and pressure cones from acutely raised intracranial pressure. Respiration may be stertorous. When unobstructed respiration has been difficult to maintain by posture and by an airway inserted in the mouth, and the coma has been of severe degree, an endotracheal tube has been passed with the aid of a laryngoscope. A striking feature in these cases has been that, whereas in the nose, mouth, and pharynx there has been only a small quantity of saliva, the larynx and upper end of the trachea have been filled with white frothy tenacious fluid. The laryngeal mucosa has appeared congested. The source of this fluid is of interest. Aspirated saliva might be one source. When the mouth and pharynx have appeared relatively dry, and laryngoscopy performed within a very few minutes of the onset of coma has shown its presence, then it would appear that some other explanation is required.

In a recent case of sudden loss of consciousness in a previously fully alert patient suffering from a tumour of the fourth ventricle, active steps were taken at once to prevent aspiration of saliva until the trachea was intubated. Death followed shortly after this. Post-mortem examination revealed frothy white mucus filling the bronchial tree. Similar post-mortem findings have been demonstrated in two cases in the present series. Altschule (1954) lists acute cerebral lesions among the causes of pulmonary oedema. In the cases under consideration the lungs were not oedematous and were well aerated. The fluid was contained in the bronchi. Two possible explanations for this accumulation of fluid present themselves. The first is that there is a reflex secretion from tracheo-bronchial mucous glands, of central or brain-stem origin. The presence of subarachnoid blood in the posterior fossa of cats has been found to result in mucus secretions in the bronchial tree (J. C. Seymour, 1956, personal communication). Cameron (1948) has found that placing human thrombin and fibrin in the fourth ventricle of rabbits causes secretions to collect in the trachea and bronchi, although he attributes this to pulmonary oedema. An alternative explanation is that an abnormally high negative intrathoracic pressure in the inspiratory phase of obstructed respiration causes the ducts of these glands to discharge their secretions into the trachea and bronchi.

2. *Prolonged Coma.*—The morbid processes whereby insufficient pulmonary ventilation leads to hypoxia and hypercapnia in cases of prolonged unconsciousness are more complex than in the former group. Again there are the two primary factors of respiratory depression and obstruction. Additional factors are the loss of the cough and swallowing reflexes, and the accumulation of saliva in the mouth and pharynx, and, finally, pulmonary oedema.

Obstruction of breathing is again brought about by the tongue falling back. Over a long period of time there is a greater risk of aspiration of saliva, particularly as the swallowing reflex is often lost. The secretion of mucus into the trachea becomes less obvious and is masked by aspirated saliva and by the frequent development of a bronchopulmonary infection with the production of a copious mucopurulent sputum. The inability to cough adequately causes these fluids to be retained in the bronchi. The high negative pressure occasioned by obstructed breathing during the inspiratory phase may cause the more peripheral bronchi to become blocked. Areas of segmental pulmonary collapse ensue, and the ground is prepared for a severe pulmonary infection. In the presence of shallow breathing the tidal volume becomes dangerously lowered. The oxygen tension in the alveolar air falls, and the carbon dioxide tension rises.

It becomes apparent that the blood oxygen must fall and the blood carbon dioxide rise. After a period of respiratory stimulation, if these changes pass beyond a certain level then respiration will become depressed.

The effect of a poor respiratory excursion and obstructed respiration upon the circulation will initially be an inadequate venous return to the right side of the heart. This will cause a raised systemic venous pressure, and a particularly serious aspect will be cerebral venous congestion and perhaps cerebral oedema. Either the primary intracranial lesion may be accentuated or recovery from it delayed. It has been shown by White *et al.* (1942) that hypoxia increases cerebral intercellular fluid, and that hypercapnia causes cerebral venous congestion. These factors may inhibit brain-stem function, and by the further depression of respiration a vicious circle becomes established.

Pulmonary Oedema

Altschule (1954) and Hayward (1955) have pointed out that anoxia increases capillary permeability, and may cause pulmonary oedema. Another possible cause for this condition in cerebral cases is an abnormally high negative intrathoracic pressure accompanying the inspiratory phase when breathing is obstructed. When respiration is obstructed the pressure in the pulmonary veins and capillaries may be greater than the osmotic pressure of the blood; transudation may then occur into the pulmonary interstitial tissue and alveoli. This fluid may have a high protein content and, further, draw fluid from the blood into the alveoli.

In the present series gross pulmonary oedema was found at post-mortem examination only when coma was prolonged. In Case 8, a woman suffering from a high cervical cord lesion, respiration was shallow for a number of days, and the cough reflex was inadequate to clear her bronchi of retained secretions. Coma gradually developed, presumably from long-continued hypoxia.

From the foregoing observations it becomes clear that, in addition to maintaining a clear airway during coma, it is essential to ensure that there is a satisfactory respiratory excursion. This is necessary not only to prevent circulatory failure but also to provide for adequate gaseous exchange in the lungs. In certain cases intermittent positive-pressure respiration will be of help.

The position of the unconscious patient may tend further to diminish respiratory excursion and increase cerebral venous congestion. It is a common practice to keep the patient horizontal or even tilted head downwards to encourage secretions to drain from the lungs into the mouth, from which they can be removed by suction. Some authors believe that it is wrong to elevate the head and shoulders if the coughing mechanism is defective, for fear this position will increase pulmonary hypostasis and embarrass respiration still further. Elevation of the head and shoulders, however, has the merit of allowing a greater respiratory excursion, encouraging the return of blood to the right side of the heart from the head, and reducing cerebral venous congestion. It would be unwise to adopt this position in acute head injuries, which are often complicated by bleeding into the nasopharynx or mouth and by vomiting; there is a real danger of these fluids being aspirated. Shock would be another contraindication. Elevation of the head and shoulders becomes indicated in the group of cases with prolonged coma when these complications are often absent.

It is rare that the cough reflex is completely lost. If a tracheostomy has been established, the aspiration of secretions may be prevented by a cuffed tube. Mechanical suction, which will stimulate coughing as well, will be a more efficient means of clearing the bronchial tree than the physiologically disadvantageous position of lowering the head below the heart level.

Summary

The importance of maintaining a clear airway in comatose patients is again stressed. When consciousness

is suddenly lost this may be achieved by placing the patient in a horizontal position and inserting a Magill airway into the mouth. If this is inadequate the trachea may be intubated through the mouth or nose.

If coma is prolonged there is usually a coincidental depression of respiration and of the coughing and swallowing mechanisms. Secretions may be aspirated and retained in the smaller bronchi. The blood oxygen tension falls and carbon dioxide tension rises. Secondary circulatory changes occur, and these may lead to cerebral venous congestion and oedema, and to pulmonary oedema. Tracheostomy is of value in these cases, as it halves the dead space air and allows for ease in the mechanical suction of the trachea and bronchi. A cuffed tube is advantageous in preventing the aspiration of secretion from the pharynx. The raising of the head and shoulders allows a fuller respiratory excursion by reducing the weight of the abdominal contents on the diaphragm. Venous return to the heart is thereby improved; the danger of cerebral venous congestion is reduced.

The source of the fluid accumulations in the lungs is discussed. When consciousness is suddenly lost from acute intracranial lesions it is believed that the fluid is secreted by the tracheo-bronchial mucous glands. The possible mechanisms for this are discussed. When coma is prolonged the fluid is thought to be due to the same secretions, but additional factors are the development of a purulent broncho-pulmonary infection and, terminally, pulmonary oedema.

It is emphasized that in cases of coma tracheostomy should be an elective procedure, and its performance should not be delayed until the patient has become cyanosed or has begun to develop peripheral circulatory failure. Selected case histories are described from a series of 16 patients in whom this operation was performed.

I thank Mr. J. E. A. O'Connell for his advice during the preparation of this paper, and Dr. J. C. Seymour for permission to quote from his unpublished material.

King Edward's Hospital Fund for London Hospital Catering Advisory Service have issued a second edition of their memorandum entitled "General Hospital Diets." This is a guide to the cost of feeding patients in general hospitals based on the average wholesale and retail prices of 1955. The new edition contains a section on the extra cost of feeding maternity patients—about 3s. 6d. a week each. 36 weekly menus are given, three for each month of the year, the first set being more expensive than the other two. 662 recipes are included at the end of the book, giving ingredients for 100 portions. Copies of the booklet are obtainable from King Edward's Hospital Fund for London, 10, Old Jewry, E.C.2, price 5s., post free.

MAINTENANCE OF HIGH SICKLING RATE IN AN AFRICAN COMMUNITY

BY

H. LEHMANN, M.D., Ph.D., F.R.I.C.
St. Bartholomew's Hospital, London

AND

A. B. RAPER, M.D., M.R.C.P.
Medical Laboratory, Kampala, Uganda

It is accepted that the sickle-cell gene can cause early death if it is inherited in the homozygous state, yet in spite of this constant depletion it still exists at remarkably high frequencies in tropical Africa. Several attempts have been made to explain this. Neel (1953) gives a review of population dynamics in this connexion, and Edington and Lehmann (1956) trace the opinions that led up to Allison's (1954a, 1954b) formulations of the two hypotheses that at present hold the field. Firstly, Allison postulated greater fitness of sickle-cell heterozygotes (AS) as compared with normal homozygotes (AA) in respect of malaria, a higher death rate amongst the latter balancing the loss of S genes by deaths from sickle-cell anaemia. Secondly, he deduced from his own observations, and from reports in the literature, that about 25% of sickle-cell homozygotes (SS) survived and procreated. Each of these explanations raises problems that are briefly outlined below.

Differential Malarial Morbidity

The questions whether malarial infection is less easy to establish in sicklers as originally claimed by Allison (1954a), and whether malarial parasitaemia is less common in them than in non-sicklers, have been investigated by several workers. The evidence, some of which is contradictory, has been recently reviewed (*British Medical Journal*, 1955; Edington and Lehmann, 1956). In our opinion there is no reason to believe that the mere establishment of a *P. falciparum* infection is any more difficult in a sickling subject than in a normal person.

But from a genetic point of view these matters are of negligible importance. The crucial question is whether more sickling than sickling children die, directly or indirectly, from malaria. A relatively lower direct mortality from malaria in sickling children has recently been demonstrated (Raper, 1956), thus establishing that malaria is quite capable of acting as a selective agent. However, there has been a reluctance to believe that its effect could be powerful enough to account for the maintenance of some of the highest sickling rates observed.

For example, if the sickling gene (S) had no lethal effect, a population showing 36% of the phenotype S can be calculated to consist of 4% of the genotype SS, 32% of the genotype AS, and 64% of normal persons of genotype AA. One-fifth of the S genes are therefore carried by the sickle-cell homozygotes. If the latter were all to die before re-producing, the original S gene frequency could be restored only by the removal of one-fifth of the A genes, none from the heterozygotes, but all from the normal homozygotes. This would mean the death of 25% of the normal homozygotes from the selective agent alone. It has been difficult to imagine how malaria could account for this, especially when the total deaths may only slightly exceed this figure. We shall show below that the above calculation does not take account of all the facts; but we note here that it has contributed to the need for the second hypothesis, the survival of a proportion of the SS homozygotes.

Survival of Sickle-cell Homozygotes

There is no reliable information concerning how far the survival of sickling homozygotes contributes to the maintenance of high frequencies of the gene. It is difficult to accept statements asserting their survival to adult life unless the claim is supported by analysis of the haemoglobin. This criterion has become important since the recognition of haemolytic syndromes caused by the inheritance of certain other genes together with that for sickling, where both are in the heterozygous state; for such syndromes are generally compatible with longer life than is sickle-cell anaemia. For example, in West Africa sickle-cell-haemoglobin C disease (SC) in adults is not uncommon.

Only two published investigations refer to adult homozygous sicklers in Africa, and support the claim by haemoglobin analysis; those by Allison (1954b) and Edington and Lehmann (1955a). The latter found, in two healthy adults, a composition of haemoglobin indistinguishable from that seen in sickle-cell anaemia. Subsequent family studies showed, however, that these persons were in fact heterozygous for the sickling gene, and that they carried a thalassaemia (or thalassaemia-like) gene which suppressed the formation of haemoglobin A to such an extent that it could no longer be revealed by electrophoresis (Edington and Lehmann, 1955b). Allison's two examples showed "significant amounts of haemoglobin F together with more than 50% haemoglobin S," and he at that time reasonably accepted them as homozygotes; but in view of Edington and Lehmann's later experience his claim cannot be accepted as proved.

Nevertheless we thought it unlikely that every sickle-cell homozygote in Africa should necessarily exhibit a severe form of the disease, and die prematurely. In Uganda we have observed adolescents and young adults suffering from sickle-cell anaemia of no great severity, in whose cases haematological, chemical, and genetic studies were consistent with the view that they were homozygotes. But we have no knowledge of what proportion of such people succeed in reproducing and contribute to the stock of S genes in the next generation.

To obtain more evidence on these subjects we decided to examine a population showing a very high incidence of the sickling gene. The Baamba tribe shows the highest sickling rate in Uganda, and for this reason was chosen. Of this tribe it had been stated that "the incidence of sickling among the pygmyoid Baamba is 45%; this percentage must include homozygotes" (Lehmann, 1951). Even if only 25% of homozygotes survived to adult life there would still remain a good numerical chance of discovering them. Finally, if it could be shown that the survival of homozygotes made no contribution to the high sickling rate we should be able to observe the effect of any selective agent at its most intense.

The Baamba Tribe

The Baamba live in a region bounded on the south-east by the spurs of the Ruwenzori range, and on the north and north-west by the Semiliki river and its tributaries. The altitude is around 2,500 feet (760 metres). Baamba is a largely forested country, and the dense vegetation near the river is continuous with the Ituri forest in the Belgian Congo to the west. The people living here were effectively isolated by forest and mountain until 1938, when the completion of a mountain road from Fort Portal connected Bwamba with the rest of Uganda.

The Baamba consist of two linguistically different groups. The Babulibuli speak a language allied to some spoken in the neighbouring Congo; it is claimed that they have always occupied Bwamba, and were certainly there when the other group, the Babwizi, began to invade the country peacefully from the east, perhaps under pressure from more advanced pastoral peoples. For our present purposes, we may regard the two groups as having fused, over several centuries, into a fairly homogeneous tribe in a fixed habitat. The

neighbours of this tribe are the Bakonjo, who lead a separate existence on the mountain slopes above Bwamba; and in the forest are scattered groups of pygmies. Doubtless the Baamba miscegenate with both, but only to a very small extent.

Procedure

Blood was obtained by finger-prick from 623 Baamba. Each sample was distributed as follows: One drop was mixed immediately on a slide with a broth culture of *Bact. coli*, covered, and inspected for sickling after one to four hours (method of Singer and Robin, 1948). On another slide thick and thin blood films were made, except in the case of some of the adult subjects. The thick films were stained by Field's rapid method, and the thin films were fixed in alcohol for future reference. Finally, several drops of blood were collected in a small test-tube to be available for electrophoresis later in the day.

In all cases where the sickle-cell test proved positive, and in addition in about half of the negative samples, the haemoglobin was examined by paper electrophoresis. The method of Smith and Conley (1953) was used, electricity being provided by dry batteries.

Random samples were obtained by examining out-patients attending the Government Dispensary, catechumens attending a mission, and schoolchildren at a mission school near Bundibugyo, the main centre of population. People from a wide area came to these institutions. In this way we obtained samples of blood from 574 persons, 490 of them over the age of 5 years. To obtain more children we collected at two localities in the field, realizing that we should not obtain true random samples by this means. In fact, in one place the sickling rate was considerably higher, and in the other considerably lower, than that of the people examined at random.

In all cases location, name, sex, and, where applicable, family relationship were recorded. If the age was not known, a near estimate was made. In 463 instances we asked whether the people belonged to the Bwizi or Bulibuli section of the Baamba. It may be stated here that there was no apparent difference in sickling rate between the two.

Results

1. Sickling Rate

Table I summarizes our findings in subjects of different ages and at different localities.

TABLE I

Age Group	Locality	Total Examined	Sicklers
Adults (15 years and over)	Dispensary ..	162	56
	School and mission ..	117	47
Children (5 to 14 years)	Dispensary ..	20	8
	School and mission ..	191	72
	In the field ..	13	8
Infants (Under 5 years)	Dispensary ..	84	20
	In the field ..	36	16
Total ..		623	227

To arrive at a sickling rate for the adult population based on a random sample, certain data have to be excluded: (a) all children under 5 years, because among them it is assumed that equilibrium has not been reached; (b) those collected in the field, because the subjects consisted of families; and (c) the first-degree relations of any one subject—mostly the children of mothers at the dispensary.

Having excluded these groups, we were left with 277 adults, of whom 102 were sicklers, and 201 children aged 5 to 14, of whom 75 were sicklers; a total of 478 subjects with a sickling rate of 37.0%.

Two previous estimates of the sickling rate of the Baamba have been made. These had drawn their subjects from similar sources; Lehmann and Raper (1949) found 63 sicklers amongst 140 subjects (45%), and Allison (1954c) found 86 amongst 220 (39.1%). Calculation of χ^2 shows that each of

these three samples might, with a probability of more than 0.1, have been drawn from populations of identical sickling rate. For the purposes of calculation below, the three series have been added, giving an incidence of 39% (38.9%).

2. Electrophoretic Analysis

Altogether 435 blood samples, including those from all the 227 sicklers, were examined by paper electrophoresis. No variants of adult haemoglobin other than haemoglobin S were found.

Of the 227 sicklers, 223 were shown to possess both haemoglobin A and haemoglobin S, hence they were sickle-cell heterozygotes. These included all the adults and children, and all but four of the infants. In two sickling babies, aged 2 and 4 weeks respectively, no resolution of the haemoglobin was seen; a single spot was present in the position of foetal haemoglobin, indicating that the proportion of any other haemoglobin present was too small to allow it to be revealed by electrophoresis. Such a finding is quite usual in babies if there is a high proportion of foetal haemoglobin, and it is only at a later age, when the foetal haemoglobin has fallen, that the composition of the adult fraction of the haemoglobin can be determined. It is impossible to say whether these two babies were homozygotes or heterozygotes. In two instances (Cases 571 and 605, aged respectively 14 and 18 months) electrophoresis revealed only one component with the mobility of haemoglobin S. We concluded that these children were homozygous for the sickling gene. At the time of examination, neither had shown any clinical signs suggesting the diagnosis of sickle-cell anaemia. Examination of their thick and thin blood films gave the following results:

Case 571.—Thick film: Scanty *P. falciparum*, including gametocytes. Thin film: No leucocytosis; erythrocytes showed mild anisocytosis and a slight degree of polychromasia, a few macrocytes, no normoblasts. These findings needed no other explanation than the malaria which was present, and we cannot therefore conclude that this child was suffering from sickle-cell anaemia at the time of examination.

Case 605.—Thick film: No parasites. Thin film: There was a fully developed leuco-erythroblastic picture—numerous normoblasts and many irreversibly sickled erythrocytes were seen. There could be no doubt that this represented sickle-cell anaemia.

As we have pointed out above, analysis of the haemoglobin cannot prove beyond doubt that a subject is homozygous for the sickling gene. However, we did not think it necessary to test our diagnosis in these cases by family studies, as we should have done if the subjects had been adults.

3. Malaria

It is known that Bwamba is a highly malarious district. Its entomology and climate have been intensively studied by the staff of the Yellow Fever Institute of the Rockefeller Foundation; we are indebted to Dr. A. J. Had-dow for the information that malarial transmission occurs throughout the year. We examined thick blood films from 166 children and 186 adults. The only species found were *P. falciparum* and *P. malariae*. The crude malarial incidence at different ages is given in Table II, and will be seen to be characteristic of a hyperendemic area.

TABLE II.—Incidence of Malaria (All Species) at Various Ages in Bwamba

Years:	1	1-1	1-2	2-5	5-10	10-15	15+
Total cases	30	22	25	38	22	29	186
Malarial	16	13	19	28	18	6	9
Malaria rate ..	53%	60%	76%	73%	81%	21%	5%

A large proportion of this high incidence, however, was due to *P. malariae*. Taking all ages, the incidence of *P. falciparum* was 15% and of *P. malariae* 13%. In the 77 children under the age of 2 years (before the acquisition of immunity is well advanced) *P. falciparum* was present in 32.5% and *P. malariae* in 35%. But malarial transmission was probably less than the average for Bwamba at the time

of our study, which was just before the "long rains," and examination at such a time would tend to minimize especially the falciparum infection rate.

Discussion

Adult Sickle-cell Homozygotes

The sickling rate in Bwamba is 39%. If we assume for the moment that the previous generation had contained no sickling homozygotes, and had consisted of 39% heterozygotes and 61% normal homozygotes, the present generation must have contained at birth 3.8% sickling homozygotes. If only 25% of these survived to adult life, and if at the same time sufficient normal homozygotes died to restore the sickling rate to 39%, it can be calculated that the incidence of sickling homozygotes would become 0.98%. But this percentage would be exceeded if, instead of our original assumption, the previous generation had also contained 25% of adult homozygotes. Thus our random sample of 478 adults should have contained at the very least five sickling homozygotes. Surprisingly, none were found. From the Table for Poisson distribution of Pearson and Hartley (1954) an observed value 0 corresponds to an expected value between 0 and 3.69, with probability (confidence coefficient) 0.95, and to an expected value between 0 and 5.30 with probability 0.99. A survival rate of 25% of homozygotes is thus unlikely, and we conclude that the survival of sickle-cell homozygotes plays no significant part in the maintenance of the high sickling rate in the Baamba.

Balanced Polymorphism

Having established that selection against sickle-cell homozygotes is virtually complete, we can calculate the degree of selection against the normal homozygotes necessary to maintain a stable sickling rate of 39%. An adult population consisting of 61% normal homozygotes and 39% heterozygotes will give rise in the following generation to heterozygotes will give rise in the following generation to heterozygotes, 31.4%; sickle-cell homozygotes, 3.8%. The heterozygotes, 31.4%; sickle-cell homozygotes, 3.8%. The death of all the last-named involves the loss of 7.6 S genes out of 39, or 19.5% of all the S genes. A counterbalancing loss of 19.5% of the A genes, through the death of normal loss of 19.5% of the A genes, through the death of normal homozygotes only, would involve the death of 24.2% of homozygotes only, would involve the death of 24.2% of the latter. From this it can be calculated that the "fitness" of the normal homozygotes compared with the heterozygotes of the normal homozygotes compared with the heterozygotes of the presses the relative viability of these two elements of the population, or the final genetic equilibrium between them at the end of the process of selection that occurs between the moment of conception and the time of procreation. It gives no information concerning precisely how or when the equilibrium is brought about, and some further analysis of this is necessary.

We have no reason to believe that any selection operates in respect of mating, fertility, or foetal viability, and can assume that selection occurs between birth and reproductive age. It is postulated that the main reason why the normal homozygotes are less viable than the heterozygotes is that the former are more likely to die from falciparum malaria. But this may not be the only factor. Quite possibly the balance is a complex of several factors, some of which may actually be to advantage of the homozygotes; for instance, there have been suggestions (Lambotte-Légrand, 1951; Raper, 1956) that typhoid is a more serious disease in sicklers. However, the only effect of this kind that has been proved to exist is that exerted by malaria. So far as we can tell at present, malaria distinguishes between sicklers and non-sicklers only in that the former escape the heaviest and infections and rarely if ever succumb to cerebral malaria or the other serious forms of the disease (Raper, 1955, 1956). This distinction vanishes when immunity is acquired, a process that our observations suggest is completed soon after the fifth year in Baamba children. Before this age, malaria undoubtedly leads to ill-health, and perhaps contributes to mortality from other diseases, but we have little reason to suppose that this effect is significantly more important in

normal homozygotes than in sicklers. As a hypothesis, therefore, we may suppose that the whole process of selection in Bwamba is attributable to falciparum malaria in childhood, and that it is manifested by deaths directly due to this disease in normal homozygotes, none (or an insignificant number) occurring in heterozygotes. We have to consider whether this is a tenable hypothesis.

The question cannot be answered directly without a full knowledge of the vital statistics of Bwamba, which we do not possess. This information is difficult to obtain even in much more developed parts of Africa, and it then refers to deaths from malaria in the whole community. We must therefore examine the implications of the selective process in terms of the loss of life from malaria in the whole child population. One of the facts we shall have to take into consideration is the total loss of life from all causes in childhood, or, more accurately, before puberty; and fortunately we have a reliable estimate of this. Dr. J. McFie conducted a survey in the district in 1954, during which he carefully questioned all the women in one location about the number of live births claimed by each, and the number of their children who had died before the time of questioning. With his permission we are able to quote that 45 women of all ages claimed 189 live births, and recorded 111 deaths of their children. Thus at the time of the survey 58.8% of the children born to these mothers had died, and it is evident that to obtain the true wastage of life before puberty this percentage will have to be increased to take account of the fact that not all the children of the mothers questioned had yet reached puberty, and that some of these might still die. A conservative estimate of the loss of life before puberty in this location would be about 65%.

Accepting this estimate of the loss of life, we may envisage balanced polymorphism being achieved in Bwamba in two extreme ways. Suppose first that selection takes place before any other deaths occur; the process then is as shown

TABLE III.—Balanced Polymorphism in Bwamba: Selection Acting First

Population at Birth* (1,000)	Selective Mortality		Undifferentiated Mortality	
	Malaria Deaths	Survivors (805, AS being 39%)	Deaths (AS=AA=56.5%)	Survivors (350)
AS 314 ..	0	314	177	137
AA 648 ..	157	491	278	213

* This includes 38 sickle-cell homozygotes (SS).

in Table III. If we had been able to observe the deaths recorded in this table, we should have registered 157 deaths from malaria amongst the 648 normal homozygotes, or 24.2%, but for the whole community the loss of life from malaria would appear as 15.7%. But suppose, secondly, that selection takes place after all other causes of death have taken their toll; we should then find the results given in Table IV.

TABLE IV.—Balanced Polymorphism in Bwamba: Selection Acting After Other Causes of Death

Population at Birth* (1,000)	Undifferentiated Mortality		Selective Mortality	
	Deaths (56.5%)	Survivors (419; 33% AS)	Malaria Deaths	Survivors (350; 39% AS)
AS 314 ..	177	137	0	137
AA 648 ..	366	282	69	213

* This includes 38 sickle-cell homozygotes (SS).

Selection, now acting on a smaller population, still causes the death of 69 out of 232, or 24.2%, of the normal homozygotes at risk, but the observable loss of life from malaria for the whole community is only 6.9% of the children born. If malaria is imagined as causing deaths concurrently with other diseases, as would in fact be the case, the figures observed would lie somewhere between the limits assigned by Tables III and IV, and malaria would be credited with the removal of from 6.9 to 15.7% of the whole child popula-

tion, or of 10.6 to 24.2% of all normal homozygotes born. Since malarial deaths are likely to follow what must be a considerable proportion of the loss of child life—that in the first month or two—we may surmise that the observed figures would approximate to the lower rather than to the higher of these limits.

These considerations reduce the difficulty mentioned above, of requiring an excessively high malaria death rate to account for the maintenance of sickling rates as high as 39% ; we find that no very high malaria death rate need be recorded if the loss of life from other diseases is high, and especially if a large proportion of that loss consists of neonatal deaths. These are the conditions that prevail in Bwamba and many other parts of Africa.

Although, as we have said, we have no mortality statistics for Bwamba, we may compare it with large parts of the Belgian Congo. Duren (1951) reviewed the sources of information on malaria mortality in the Congo, and after taking due account of their inadequacy he concluded that below the age of 3 years deaths directly from malaria amounted to 14 to 22 per 1,000 per annum. Colbourne and Edington (1954) obtained a roughly similar figure, 17 per 1,000 for children under 1 year in Accra, and 10 per 1,000 for children from 1 to 5 years. The mortality in Bwamba is unlikely to be less than these estimates, which amount to a cumulative loss during childhood of about 5 to 10% of children born. This is very close to the figure, 6.9% or more, which we have shown to be required for preserving a state of balanced polymorphism in Bwamba, and we may therefore conclude that malaria could act as an effective selective agent under the primitive conditions of Bwamba, to maintain a sickling rate as high as 39%. It follows from our consideration of the mechanics of balanced polymorphism that the malaria situation in two regions might be the same in the sense that it caused the same loss of life before the age of, say, 3 or 5 years, yet in these two regions it might be the factor in maintaining two entirely different sickling rates. This could come about if the two populations differed in their mortality before the age at which the malaria mortality in each was at its greatest. Hence no simple measure of malaria morbidity or mortality even if it were the malarial mortality in normal homozygotes that could be measured, could enable one to predict accurately the sickling rate that might be maintained. The situation cannot be defined without reference to the whole infant mortality, and its relation in time to the malarial deaths.

Summary

The Baamba, an African tribe showing a high sickling rate (39%) has been examined to determine how this high rate can be maintained.

Of the 623 subjects examined, 227 were sicklers. No genetic variants of normal adult haemoglobin other than haemoglobin S were found. Amongst 191 sickling subjects over the age of 5 no homozygotes were detected; and it is concluded that the survival of sickle-cell homozygotes plays no significant part in maintaining the sickling rate of this tribe at its high level.

If selective death of non-sicklers from malaria was responsible for the maintenance of the 39% sickling rate in Bwamba, 10.6-24.2% of all normal homozygotes (or 6.9-15.7% of the whole child population) would have to die from malaria. Reasons are given for supposing that the actual death rate to be observed would approximate to the lower rather than the higher of the two limits, and that such a death rate from malaria is to be expected in Bwamba.

Our thanks for support in this investigation are due to the Director of Medical Services, Uganda, and to many members of the Administrative and Medical Services. We also wish to thank Dr. J. A. Fraser Roberts and Dr. C. A. B. Smith for advice and discussion of statistical problems. One of us (H. L.)

thanks the Colonial Medical Research Committee for a grant enabling him to visit Uganda and for defraying part of the expenses of this investigation.

FAMILIAL AGAMMAGLOBULINAEMIA

BY

R. H. ELPHINSTONE, M.B., B.Chir.

Assistant Physician, Edmonton Chest Clinic

IAN G. WICKES, M.D., M.R.C.P., D.C.H.

Paediatrician, North Middlesex Hospital

AND

A. B. ANDERSON, Ph.D., M.R.C.S., F.R.I.C.

Chemical Pathologist, St. Bartholomew's Hospital

Absence of serum gammaglobulin causing lowered resistance to infection was discovered by Bruton (1952) in a boy suffering from recurrent septic infections. More cases in boys were described by Janeway, Apt, and Gitlin (1953). The condition as it occurred in boys was thought to be primary, familial, and sex-linked.

The primary disorder was subsequently described in males and females of all ages; of 38 case histories that we have been able to obtain, 18 have been those of boys. Kulneff, Pedersen, and Waldenström (1955) describe the disease in two brothers aged 9 and 7, and in a distant male relative aged 5.

The important features of the disease are repeated septic respiratory and non-respiratory infections, lack of cutaneous responses to antigens, almost complete absence of circulatory antibodies and of gammaglobulin from the blood serum and connective tissues, diminution in the number of plasma cells in the tissues, and failure of lymphatic nodes to respond to antigenic stimuli (Janeway, 1954). In most cases isohaemagglutinins have been entirely absent from the blood. Virus exanthems usually run their normal course, but in some children they recur. Infants suffering from agammaglobulinaemia may die of intractable infections (Keidan, McCarthy, and Haworth 1953; Janeway, 1954; Hutchison, 1955). Most of the female patients have had bronchiectasis, and in most of the adults the spleen has been enlarged.

Patients who have been given repeated injections of gammaglobulin (0.1 g. per kg. body weight per month) have usually responded well. Treatment with antibiotics has been found essential to control acute infections (Janeway, 1954), and has sometimes been given continuously with good effect.

The cases here described are those of two brothers who are suffering from familial agammaglobulinaemia in its classical form.

Case 1

This patient was born in November, 1945. He had bronchopneumonia at two months. Left chronic otitis media began in 1948 and persisted until 1951, when tonsillectomy was performed; both antra were washed out, with the production of mucopus. The ear dried up, but mucopurulent discharge started again within three months.

1952.—Left cortical mastoidectomy was performed. Pus and soft granulation tissue were present in the mastoid cavity. The operation wound became septic and took five months to heal. March: Shortly after the mastoidectomy chest x-ray examination showed patchy infiltration in the right lower lobe, with enlargement of the hilar glands. April: He was Mantoux 1/100 negative; six weeks later Mantoux 1/100 positive. Guinea-pig inoculation of gastric washings showed generalized tuberculosis at necropsy. E.S.R. was 10/200 mm./hr.; white cell count, 14,200 per c.mm. (neutrophil polymorphs 75%, lymphocytes 18%, monocytes 7%). Intramuscular streptomycin was given for one month. July: Chest x-ray film showed a primary focus in the right lower lobe, with a small pleural effusion; the bronchogram was normal. His ear was still discharging and there was mucopurulent discharge from his antra. A further month of streptomycin with P.A.S. was given.

1953.—Right cortical mastoidectomy was performed. A further course of intramuscular streptomycin was given. Soon after, he developed a right upper lobe pneumonia. White cells, 5,900 per c.mm. (polymorphonuclear leucocytes 33%, lymphocytes 61%, mononuclear leucocytes 2%, eosinophil leucocytes 3%, monocytes 1%, basophils 1%). September: Chest x-ray film showed a little enlargement of the right hilar shadow only.

1954.—February and April: He had further attacks of right upper lobe pneumonia. July: Mantoux 1/10,000 positive; given intramuscular streptomycin, oral P.A.S., and oral isoniazid for one month. August: E.S.R. 5 mm.; chest x-ray film showed pleural thickening right side. October: Appeared to be well; ears dry, E.S.R. 4/200 mm. hr. Shick-positive. Bronchogram showed a small saccular dilatation of a right lower lobe segmental bronchus, but there was no other abnormality. One dose T.A.F. was given.

1955.—He had right lower lobe pneumonia in February, and bronchitis and right otitis media in March. He was seen at Edmonton Chest Clinic on June 7 suffering from right lower lobe pneumonia, and was admitted to the North Middlesex Hospital. This was his twelfth hospital admission and seventh hospital. X-ray examination showed both antra to be infected. Because of the history of recurrent infections, agammaglobulinaemia was suspected, and confirmed by agar electrophoresis of the serum proteins.

Investigations.—Paper electrophoresis: The serum was subjected to electrophoresis on paper—the paper strips were dried and stained with bromocresol green, and the protein fractions were cut out. The dye was eluted with a solution of equal parts of methanol and 10% sodium carbonate, and measured by absorptiometry. No correction was made for any difference in the dye-binding of different protein fractions. Electrophoretic pattern: Albumin, 3.71 g./100 ml.; α 1-globulin 0.67, α 2-globulin 0.84, β -globulin 0.80, γ -globulin 0.05 (normal 0.8–1.4). Re-examination of the serum in November gave a similar pattern. Zinc turbidity, 0.5 unit. Blood group A (no β -isohaemagglutinins present). Schick-positive. Mantoux 1/10,000 positive. Chest x-ray examination on August 10 showed that the pneumonia had resolved. He was discharged on August 12, taking oxytetracycline, 100 mg. four times a day. When seen on December 29 he had completed a term at school without interruption for the first time, and was well.

Case 2

Case 2
This patient, the only sibling of Case 1, was born in March, 1951. He appeared to be healthy in infancy apart from an attack of gastro-enteritis at 8 months. At 10 months he was inoculated against whooping-cough and

diphtheria. He had had measles (age unknown). At 15 months he was inoculated with B.C.G. Two months later he was Mantoux 1/100 positive, and was again positive a year later (strength unknown).

In January, 1954, he had synpneumonic empyema of staphylococcal origin; a subsequent staphylococcal infection of the nose was treated with chloramphenicol. All the polymorphs disappeared from his blood, but eventually he made a satisfactory recovery. In June he was reinoculated with B.C.G. following a negative tuberculin test (multiple puncture). In July he was examined again on receipt of the information that his brother was suffering from agammaglobulinaemia. He had had bronchitis a week before, treated by oral penicillin. On examination his general appearance was healthy, but crepitations were heard at the left base. An eschar was present at the site of inoculation, and the glands in the left axilla were enlarged. Chest x-ray examination showed nothing abnormal.

A fortnight later his nose and eyes were sticky, but there were no signs of bronchitis. Chest x-ray showed pneumonitis at left base.

Investigations.—Serum electrophoretic pattern (method as in Case 1): Albumin, 3.6 g./100 ml.; α_1 -globulin 0.7, α_2 -globulin 0.85, β -globulin 0.80, γ -globulin 0.15. Re-examination of the serum in November gave a similar pattern. Zinc turbidity, 0.5 unit. Blood group, A (no β -isohaemagglutinins present). Schick-negative.

By the middle of August he had developed a more severe cough and crepitations had returned. Chest x-ray films showed no change. The eschar was healing and the axillary glands were no longer palpable. The tuberculin test (multiple puncture) was positive. Oxytetracycline (100 mg., four times daily) was given. Apart from occasional slight attacks of diarrhoea he remained well and free of cough. He attended infant school during the autumn term.

In December he had left basal pneumonia treated by increasing dose of oxytetracycline. E.S.R. was 5/200 mm. in one hour; tuberculin jelly test positive. He was discharged well, taking oral penicillin. A fortnight later he was still well.

Investigation of Relatives

The maternal grandfather was Lithuanian. A maternal uncle was constantly ill until the age of 16 years. At the time of writing he was in good health.

Blood samples obtained from the father and mother showed a perfectly normal electrophoretic pattern and normal zinc turbidity. Samples were also obtained from the father's brother and his three sisters, and parents, and from the mother's sister and three brothers. All showed normal gammaglobulin as judged from normal zinc turbidity, and sera from the maternal relatives showed normal electrophoretic patterns.

Complete genotypes of the family were made by Dr. Dorothy Parkin, of the Lister Institute. There is no constant genetic feature in the blood groups of the family which can be related to the appearance of agammaglobulinaemia.

Discussion

The occurrence of tuberculosis in Case 1 and the behaviour of the Mantoux reaction is of interest. The disease, which developed after the symptoms of agammaglobulinaemia were established, ran its normal course, complicated by septic infections, and was cut short by the usual chemotherapy and antibiotic treatment. The boy's Mantoux reaction remained positive. The second child was first vaccinated with B.C.G. before there were any symptoms suggestive of agammaglobulinaemia and the Mantoux reaction became transiently positive. On re-vaccination the Mantoux became positive, and it has persisted for eight months. The axillary lymph node glands became enlarged, a normal consequence of B.C.G. inoculation. The patients of Kulneff *et al.* (1955) were also vaccinated with B.C.G.; the first in infancy before symptoms of agammaglobulin-

TABLE IV.—Serological Types of *E. coli* Isolated from Children Under 4 Years, and Their Seasonal Distribution (91 Cases, Together with 12 Cases of Either More than 5 Days' Duration or Having Had Treatment)

Serological Types of <i>E. coli</i>	Summer (April–September)	Winter (October–March)
O 26	25 (1)	10
O 111	9 (2)	9 (1)
O 55	4	6 (3)
O 86	1	2
O 125	2 (1)	2
O 126	1	4
O 119	0	1
O 128	5 (1)	0
O 127	1	1
O 114	2	1
Others of unclassified O group	7 (1)	10
Totals ..	57 (6)	46 (4)

Figures in parentheses denote number of cases with institutional history included in totals given.

of *E. coli* did not account for this predominance, as these organisms were found in 46 out of 485 females and in 45 out of 650 males. Identified *E. coli* infections showed no seasonal trend, except for type O 26, which, like the salmonellae, was commoner in summer than in winter. From Table IV it is apparent that the commonest *E. coli* serotypes to be encountered during the period under review were O 26, O 111, and O 55, which together accounted for nearly two-thirds of the *E. coli* infections recognized. The failure to demonstrate any constancy in the H antigens within the O groups 26, 55, and 111 suggested that many infections were not related. The serotypes of *E. coli* which most commonly cause outbreaks of gastro-enteritis—that is, types O 111, O 55, O 128, and O 119—were found to account for about one-third of all these sporadic coli infections, whereas the remaining two-thirds were infected with other specific types, especially O 26. In only a few of these infections was there evidence of a second aetiological agent also present—fat in three, *Sh. sonnei* in three, *Giardia* in three, and *Salmonella* in one. These second agents are omitted from Table I.

Shigellae.—*Sh. sonnei* was the only member of the *Shigella* group encountered. While this organism infected many children in nurseries, it was less common among young children at home. It was found in less than 7% of all cases under 24 months, but more frequently in the older age group.

Salmonellae.—These were found in 3.2% of the series. More cases occurred in summer than in winter, but there was little variation with age or sex. Of the 37 infections 32 were due to *Salm. typhi-murium*.

Proteus and Other Non-lactose-Fermenting Organisms.—The non-lactose-fermenting flora was recorded only when the growth on primary culture was profuse. Like the *E. coli* serotypes, *Proteus* strains were found more often in children under 24 months than in older children—an incidence of about 12% as compared with about 3% respectively. Most strains were *Proteus mirabilis*.

From a few children, organisms of the Providence group were isolated; in some instances they were present together with blood and pus. These organisms did not always grow reliably on deoxycholate citrate agar, but were easily isolated on MacConkey agar (Ridge and Thomas, 1955).

Fatty Diarrhoea or Epidemic Steatorrhoea

The stools from characteristic cases were very pale or putty-coloured and soft or fluid. Occasionally an aluminium sheen was evident.

A record of excess fat globules in Table I does not refer to the results of chemical analyses, which were often within the normal range for healthy children, but indicates that numerous globules of neutral fat (staining with Sudan III) of diameter 2 to 20 μ were visible in every microscopical field. Liquid paraffin had not been administered, and castor oil in three cases only, which were discounted. In normal stools at any age the only fats recognizably microscopically in quantity are soaps. While diets grossly over-supplied with

fat may disturb the balance, no oily globules were seen in the faeces of 647 healthy control children under the age of 5 years who were taking a daily dose of cod-liver oil under supervision; 133 of these healthy children were under 1 year.

Steatorrhoea in this sense appeared as an independent abnormality, not as a complication of the symptom of diarrhoea, since it was eight times commoner in the absence of other abnormalities than in their presence. In very few cases indeed was undigested starch also seen. The incidence was highest in children under 24 months old, and it showed a winter rise in prevalence.

In our experience it was not associated with giardiasis, for it was not found either in the 29 cases included in Table 1 or in a further 92 contact infections under the age of 5 years.

As is shown in Table I, fat globules were the sole abnormality in 13.1% (149 cases) of the whole series. On only 14 occasions were these globules found when known potential pathogens were also present.

Visits to the homes of affected children revealed that more often than not other persons in the household had had diarrhoea or vomiting a few days before or after the onset of symptoms in the index case. The severest illnesses were among pre-school children, who might ail for a fortnight, whereas older persons were seldom upset for more than two or three days, and it was rarer for fat globules to be seen in their stools. Examination of the urine from typical cases revealed no bile or sugar, but a gross excess of urates was often found. Two cases of coeliac disease were discovered, and were excluded from the series.

Discussion

In this survey of diarrhoea in pre-school children the proportion of cases showing certain abnormalities in the faeces has varied in a definite manner with sex, age, and season. Male cases predominated. Both in the 306 infants under 1 year old and in the whole series of 1,135 children the ratio of male to female was 1.3 to 1. This figure compares closely with the findings of Ian Taylor (1954) and of Scott (1953) in the London County Council area. The exception to this rule was a very slight female excess among the *E. coli* infections. There was a clear age trend; *Sh. sonnei* and *G. lamblia* infections rarely affected children under 1 year old, but became progressively commoner thereafter, whereas serological types of *E. coli* were identified in 11.5% of all cases of diarrhoea occurring in children under 2 years old, but in only 2.8% of those aged 2 and 3.

A form of "fatty diarrhoea" was common up to 3 years and still fairly frequent in the 3-year-old group. Indeed, this "steatorrhoea" was the most frequent single finding in the whole series, being present in 13.1% of the 1,135 cases. This finding is associated with pale stools, purging, nausea, and dehydration, and has already been described (Thomas, 1952, 1954a). It was very rare to find either cells or undigested starch in such stools.

During the acute stage, when these patients eat poorly or not at all, the percentage of fat in dried stools from representative cases has ranged from 5 to 60 g.%. In spite of the microscopical recognition of numerous globules of neutral fat, biochemical examination revealed more than half of the total fat weight to be in the split form, and gross amounts might fall within normal ranges. Some temporary failure of fat emulsification and of bile secretion, perhaps with an associated defect in absorption, appeared characteristic of this disease in young children. There was no evidence of failure to digest starch.

The brief but variable duration of the condition makes standard fat studies difficult; but a search for sequelae might be rewarding, for Sheldon (1955) suggests the possibility that coeliac disease may follow infantile gastro-enteritis. During these studies two first attacks of fatty diarrhoea were encountered in children subsequently thought to have coeliac disease.

This fatty diarrhoea may be the juvenile form of one of the "winter vomiting" group of diseases, such as types of

virus enteritis described by Gordon (1954). Its more general recognition might protect some infants from the misapplication of antibacterial drugs, which appear to be ineffective in treatment. Our experience has been that sulphonamides often provoke vomiting, but seldom control the diarrhoea.

The summer incidence of diarrhoea, as represented by the numbers of stool specimens sent to the laboratory, was lower than that in winter. Epidemic steatorrhoea was responsible for many winter cases, and such cases were often part of a household outbreak of vomiting and diarrhoea. Only salmonellae and *E. coli* O 26 showed a summer increase in prevalence, perhaps representing food-borne infection, since these organisms and O 114 have been found in animal infections (Ørskov, 1951; Charter, 1956).

Bacillary dysentery accounted for only 11.1% of all cases of diarrhoea. This and the low incidence of Boardman, infection corresponds with the experience of Boardman, Cassel, and Kahn (1955), who studied 200 African children, but contrasts with the view put by Felsen (1945) that most cases of diarrhoea were demonstrably due to shigellosis. During and after epidemics shigellae may predominate temporarily, but any aetiological picture must alter as circumstances change.

Summary

Faeces were examined from 1,135 children aged up to 4 years within five days of the onset of a diarrhoeal illness. Excess fat globules were found in 13.1% of these cases, and the significance of the finding is discussed. *Sh. sonnei* was found in 11.1%, *Salmonella* species in 3.2%, and serological types of *E. coli* in 8%. The incidence of the latter and of *Proteus* species was very much higher in those under the age of 2 years. Diarrhoea was more common in winter than in summer months, and affected more boys than girls.

We are grateful to the several laboratories which have carried out fat analyses for us. Much of the bacteriological technical work was carried out with great care and accuracy by Mr. J. H. Coward and Miss M. Kinsley, to whom our thanks are due. We are grateful to Dr. Joan Taylor, Colonel H. Bensted, and Dr. G. S. Wilson for reading the manuscript and for helpful advice.

Speaking on July 27 at Aston Hall Hospital, a mental deficiency hospital near Derby, the Minister of Health, Mr. R. H. TURTON, reviewed the problem presented by the long waiting-lists for beds in such hospitals. The position was far from satisfactory, he said. At the end of last year there were nearly 7,000 mentally deficient patients on local authorities' waiting-lists, more than half of them really urgent cases; but in spite of wars and financial difficulties, there were 51,334 patients in mental deficiency hospitals, although some of these hospitals, like Aston Hall, were very overcrowded. The Government's programmes for building "that we have at present approved or are considering," continued Mr. Turton, would provide 5,400 new beds for mental defectives. Of these beds 4,400 came into the centrally financed programme announced by his predecessor two years ago. This was building work of essential national importance. "This was recognized," said Mr. Turton, "when the Government declared that nearly alone of all building programmes, this hospital building programme should suffer neither postponement nor cut."

A FAMILY HISTORY OF UTERINE AND GASTRO-INTESTINAL CANCER

BY

DAVID SAVAGE, M.B., F.R.C.S., M.R.C.O.G.

Registrar, Charing Cross Hospital

Since Paget (1857) reported uterine cancer in a mother, daughter, and granddaughter, numerous pedigree charts showing familial occurrence of uterine cancer have been published. Atthill (1868) related that a woman of 28 years, her mother, and two sisters died of uterine cancer, and Cullen (1900) reported cancer of the uterine body in three sisters. Hutchinson (1901) details a family in which the grandmother, mother, two maternal aunts, and two sisters all died from uterine cancer.

Sir Halliday Croom (1912) recorded uterine cancer in identical twins. Both began to menstruate on the same day; both developed menorrhagia at the age of 30 years; both reached the menopause at 50. At 53 years one sister had the uterus removed; it contained a degenerating fibroid and a fundal carcinoma. Her sister died in the same year, and necropsy revealed a uterus with a degenerating fibroid and a carcinoma of the fundus.

More recently, Auvray (1927) reported cancer of the corpus uteri in a grandmother, mother, and daughter; and Purdie (1944) recorded that two sisters, one a multipara of 34 and the other a nullipara of 32 years, had cancer of the corpus, their mother having died from rectal cancer.

Warthin (1913, 1925) investigated a very comprehensive pedigree of "family G." The family consisted of 146 members, of whom 28 died from cancer. In females the cancers predominantly involved the uterus and in males the gastro-intestinal tract. The uterine cancers were all adenocarcinomas. When followed up in 1936, 174 members had reached the age of 25 years. There were 43 cancers in 41 members, and with two exceptions all involved the gastro-intestinal tract or uterus. The 23 uterine cancers were endometrial in origin, and no cancers of the cervix were found.

Cholewa (1932) published two family pedigrees showing a genetically determined localization of cancer. In one of the families the mother had cancer of the uterus and the father carcinoma of the stomach. Of the eight children, one of three sons died from gastric cancer and three of five daughters died from uterine cancer. In the other family the mother developed uterine cancer at the age of 70, unilateral breast cancer at 71, and breast cancer in the other side at 72, from which she died. Two sons were cancer-free, but of 10 daughters three have died from uterine cancer, one from ovarian cancer, and one from breast cancer.

History of "Family N"

In three generations there are 19 members of this family, and nine members have had confirmed cancers (see Family Tree). One of the four male members has had cancer and died, and of the 15 female members eight have had cancer and six have died: one had carcinoma of the rectum, one had carcinoma of the stomach, and four had carcinoma of the uterus (see Table). The two surviving females had multiple primary cancers and are still alive.

Case 9.—In November, 1949, when the patient was 48, total hysterectomy and bilateral salpingo-oophorectomy were performed and a uterus containing a small intramural fibroid and a columnar-cell papillary adenocarcinoma of the body was removed. The patient kept well until January, 1956, when a mass

FIG. 2.—A vertical radiograph and outline drawing of the same patient in 30 degrees of Trendelenburg tilt, revealing the narrow angle of vision into the pelvis and the degree to which the symphysis pubis obscures the sacrum and the pelvic viscera which must lie in front of it.

Apart from the question of encroachment of viscera it is commonly thought that better access to the pelvic cavity can be gained when the patient's head is lower than the pelvis itself. In fact, the reverse is true, for the more the patient's head is lowered in relation to the pelvis the further does the symphysis pubis move over to obscure the contents thereof (Figs. 1 and 2). In order to obtain direct vision the surgeon standing on the patient's left must then incline to his right, a tiring position to maintain for long periods. When the patient is horizontal direct vision into the pelvis can be gained, as is normally achieved for other approaches within the abdomen, by both surgeon and assistants without their recourse to bodily contortion. Nevertheless the stance and viewpoint which result from the Trendelenburg position are used routinely by the majority of pelvic surgeons, who are, indeed, conditioned to its use by their training.

Surgical access has been the prime consideration in using steep Trendelenburg tilt, but in fact such access is in most cases made more difficult by the tilt imparted to the pelvis and the inclination from vertical of the line of vision. There is therefore a surgical reason for abandoning the steep Trendelenburg position; from the anaesthetist's point of view there are more cogent reasons why such head-down tilt should be discontinued.

Disadvantages of the Tilt

Embarrassment of Respiration.—Impairment of tidal exchange with consequent reduction in minute ventilation results in inadequate expansion of the lungs—particularly the lower lobes. Such impairment may result from depressed respiration with high relaxant dosage or from "diaphragmatic splinting," when the whole of the weight of the abdominal contents lies heavily upon the under surface of the diaphragm in the Trendelenburg position. In this position the partially curarized diaphragm has to make its "descent" against the force of gravity and the weight of the abdominal viscera together with the abdominal packs used to contain them. Controlled breathing will overcome this difficulty, but it is doubtful whether it is advisable or indeed justifiable to employ controlled respiration upon all cases of this type.

Vasomotor Failure.—Vasomotor tone may become depressed during operation. Under normal conditions, with the patient horizontal, this will become manifest as a fall in blood pressure in the presence of a steady pulse rate (Inglis, 1952). When head-down tilt is adopted this type of vasomotor collapse is masked and no fall in blood pressure may be seen. In the absence of an increased pulse rate there may be no other indication of collapse until the horizontal position is resumed; a marked and dangerous fall in blood pressure may then become manifest at a time when the operation has been completed.

Venous Return.—The venous return from the lower limbs and abdomen is assisted when the Trendelenburg position is adopted. Where right-sided cardiac function is impaired the increased venous inflow can result in congestion and embarrassment of heart action.

Cerebral Circulation.—Owing in part to the same mechanism and in part to the reversal of the normal gravitational pull, the venous return from the head will be slowed down. Thus the cerebral circulation may stagnate, with an increased tendency to cerebral thrombosis.

Gastric Regurgitation.—Regurgitation of stomach contents is a very real danger, especially in emergency cases. A cuffed endotracheal tube with free drainage from the pharynx is an essential safety factor whenever the Trendelenburg position is used; without this, aspiration of gastric contents becomes a real danger with flooding of the chest when the horizontal is resumed. Respiratory secretions may also gravitate down the endotracheal tube and repeated suction become necessary.

Nerve Palsies.—Of recent years many instances of brachial plexus palsies following the use of arm-boards on anaesthetized patients have occurred. Such palsies are more prone to occur when arm-boards are used in conjunction with Trendelenburg tilt, since the force of gravity tends to increase the angle of abduction of the arm. Shoulder-rests can, if incorrectly placed, result in plexus damage from pressure in the supraclavicular fossa; indeed, elaborate and expensive devices have been described to obviate this.

Conclusions

From the anaesthetic aspect no advantages accrue from the routine use of the Trendelenburg position. It is of value as an emergency measure in collapse or in sudden vomiting; as a routine it may add to the dangers and difficulties of anaesthesia. Steep Trendelenburg position is not essential for operating within the pelvis, and its use is for the most part a relic of difficulties experienced in the past; nevertheless it continues to be employed largely as a matter of custom. With modern relaxants operative approach to the pelvis is facilitated, and the patient may be kept horizontal, a posture which invokes fewer complications than the Trendelenburg position and permits more direct vision into the pelvis.

Torsion of the Spermatic Cord: A Plea for Manipulative Reduction

The accepted treatment of torsion of the spermatic cord is operative reduction. That this is a comparatively rare surgical emergency all surgeons will readily admit. As O'Connor (1933) pointed out, however, the condition is probably much commoner than is generally realized, most cases never reaching a surgeon, and, in fact, never being diagnosed at all. They are looked upon by their doctor as cases of simple orchitis, and treated conservatively. If no attempt is made to reduce the torsion the pain will disappear after two to five days, and the swelling will disappear by the end of 10 days or a fortnight. Only if the doctor sees the case a long time afterwards, and notices that the patient has one atrophic testicle, will he have a chance of recognizing his mistake. One wonders whether it is impressed strongly enough on the young doctor that orchitis is extremely rare, while torsion of the testis is comparatively common in the young subject.

The results of operative reduction are unfortunately extremely bad, and most figures go to show that approximately 50% develop subsequent atrophy of the testis.

The reason for this is presumably the testicle's intolerance to ischaemia, and it is therefore of the utmost importance that reduction should be carried out at the earliest possible moment. The period elapsing between the consultation in the doctor's surgery and the operating table may be just sufficient to make the difference between a lost and a saved testis. If the patient has the normal complement of two testes, this may be of small importance, but it is very different if only one is present, and there is always the danger of mumps striking down the other later. Where the testis is fully descended non-operative reduction is often an exceedingly simple manoeuvre, which can be carried out by any doctor in his surgery or in the patient's home.

This non-operative treatment has not been advocated in this country on the grounds that failure to fix the testis may result in recurrence. This seems a most inadequate argument, as orchidopexy can always be performed at a later date if necessary, and, if immediate manual reduction may save the patient from a 50% chance of losing his testis, surely it is something which must be attempted.

CASE REPORT

A man aged 21 was admitted to hospital at 9.30 a.m. on April 2, 1955, with the diagnosis, by his private doctor, of torsion of the left testicle. Sudden pain had developed in the left testicle 1½ hours before admission, and had persisted. On examination there was a tender swelling in the lower end of the left inguinal canal, about the size of a grape, and the left testis was retracted up to the top of the scrotum. This appeared to be an early case of torsion of the spermatic cord in a patient with a normal scrotal testis the ideal subject for non-operative reduction. The testis was gently rocked to see which way the torsion had occurred, and then rotated in an anti-clockwise manner. The swelling and then rotated in an anti-clockwise manner. The swelling in the cord became smaller, and the pain diminished. As the testis dropped down to the bottom of the scrotum. There was no further pain, and no swelling of the testis occurred. The patient being discharged from hospital the next morning. One cannot, of course, say for certain whether or not atrophy will develop in this case, but as there had been no swelling of the testis and no hydrocele one feels that there is little doubt but that reduction was performed before any serious vascular changes had taken place.

Acute Bilateral Retrobulbar Neuritis

In June, 1954, a clergyman aged 42 complained of dimness of vision of the left eye and neuralgia over the left frontal region. Within 48 hours the left vision was limited to counting fingers. Ocular movements were full but painful, and there was tenderness on palpation over the insertion of the superior rectus muscle. The pupil reaction to light was of the typical Marcus Gunn type. The optic disk was normal. Acute retrobulbar neuritis was diagnosed. Five days later there was blurring of the disk margin, with no perception of light. Ten days later the optic disk was definitely pale. Throughout these events the right vision was 6/6 and the right eye normal.

In view of the severity of the left visual loss he was admitted to hospital. The Wassermann reaction, E.N.T. examination, blood count, x-ray film of the skull, and examination of the teeth all showed no abnormality; neurological examination revealed, apart from the ocular changes, no abnormality in the central nervous system. Eleven days after the onset of symptoms in the left eye he suddenly found that the smaller newspaper print could not be seen by the right eye. The right ocular movements were full, with no pain on movement or tenderness on palpation. The reaction of the right pupil to direct light was poorly sustained. The right optic disk and the fundus appeared normal. Within 24 hours the right vision had fallen to 6/18. The right peripheral field was temporally contracted midway to fixation point. A considerable scotoma extending to 30 degrees above and below and to the temporal side of the fixation point was present.

Corticotrophin, 10 units six-hourly, was given. After three injections the right vision recovered to 6/9. The right optic disk was slightly paler than normal, but there was no oedema of the disk or fullness of the veins. There was pallor of the left optic disk—a rather surprising finding in view of the brief history. The right visual field was full to 3/330, but on the Bjerrum screen there was a small scotoma on the temporal side only, partial to 2/1000 in a semicircle up to 6 degrees from the fixation point and complete in a further 2 degrees semicircle external to this. It was considered that the only possible diagnosis was bilateral retrobulbar neuritis of the nature of Devic's disease.

Corticotrophin, 10 units six-hourly, was continued for 10 days, after which the vision began to fail again and a further scotoma developed. Corticotrophin was increased to 50 units in 24 hours and continued at this level for 17 days. Then 20 units in 24 hours was given, and this amount was gradually lowered until corticotrophin was discontinued altogether 10 days later. By that time the right vision had recovered to 6/6 and Jaeger 1. The peripheral field was full. Only a minute partial scotoma remained in the lower temporal area. Twenty months later these findings for the right eye were unchanged. With the left eye hand movements are seen in the upper nasal field; there is no projection of light elsewhere.

At no time has there been any associated myelitis, but the two classical components of Devic's disease are by no means invariably associated. The severity of the attacks of bilateral retrobulbar neuritis, their close association in time, the response to corticotrophin therapy, and the complete absence, then or subsequently, of any other abnormal signs in the central nervous system are very strongly suggestive that this was, in fact, an incomplete form of neuromyelitis optica rather than a manifestation of other demyelinating diseases of the central nervous system, such as a multiple sclerosis.

I thank Dr. Mark Lester for watching this case and Mr. A. J. B. Goldsmith for kindly confirming the ophthalmic findings.

DORIS ROSE, M.R.C.S., D.O.M.S.,

Leukoplakia of the Bladder

Leukoplakia of the bladder, whether alone or associated with similar changes in the upper urinary tract, would appear to be rare enough to warrant comment whenever a case arises.

CASE REPORT

A man aged 59 was admitted to this hospital in April, 1950, with severe haematuria. He was anaemic-looking and had a blood pressure of 160/80 mm. Hg. The bladder was not palpable abdominally, the kidneys did not appear clinically to be enlarged, and rectal examination suggested no abnormality of prostate or seminal vesicles. Neither was any abnormality found in other systems. A provisional diagnosis of vesical neoplasm was made. As his haemoglobin was only 53% a blood transfusion was given, and this was repeated twice in the subsequent few days.

His Wassermann reaction was negative, and intravenous pyelography showed the kidneys to be normal. Ten days

after admission he developed clot retention, and suprapubic cystotomy was performed by one of us (L. M. Z.). After evacuation of many clots no evidence of vesical neoplasm could be found and a clear efflux was observed from both ureteric orifices. The bladder mucous membrane had a peculiar white appearance and was very smooth. A biopsy of the bladder wall was taken and the bladder closed round a suprapubic tube. The histological report stated: "The covering epithelium is composed entirely of

Low-power view of bladder wall. (x114.)

keratinizing epidermoid type with eleidin granules. There is subacute inflammation in the subjacent connective tissue, and beneath this is smooth muscle. The epithelium is remarkable if it comes from the bladder, as it does not at all resemble normal vesical epithelium." (See Figure.) As it did in fact come from the bladder a diagnosis of leukoplakia was made. After operation the bleeding slowly subsided and the suprapubic fistula was allowed to heal. The patient was discharged 27 days after operation, passing clear urine quite normally.

He remained symptom-free until November, 1952, when he was again admitted with fairly severe haematuria. This persisted, and as cystoscopy was unsatisfactory and it was feared that a squamous carcinoma might now have developed, the bladder was again opened. The state of affairs was exactly as before and no growth could be seen. Histological examination of a further biopsy merely confirmed the previous findings. Again the bleeding settled after the cystotomy, and he was discharged after 26 days.

Since 1952 he has had very little haemorrhage, but the suprapubic scar has broken down three times, and there has been leakage of urine. Each time, however, it has healed readily after urethral bouginage and antibiotic treatment.

Cystoscopy was last performed in December, 1954, and showed a whitish bladder mucosa with much fibrinous

debris on its walls due to superadded infection. There was no haematuria, but the urine was rather dirty and foul-smelling, and yielded a heavy growth of *Pseudomonas aeruginosa* which was insensitive to all antibiotics except polymyxin. The haemoglobin was 87% and the blood urea 30 mg. per 100 ml.

DISCUSSION

Leukoplakia of the urinary bladder was first described by Rokitsky in 1861, and has been the subject of much controversy ever since. Up to 1929 Patch could find only 123 cases in the literature, including cases where the kidneys and ureters as well as the bladder were involved. Connery (1953) found only 45 cases of proved leukoplakia of the bladder in the records of the Mayo Clinic covering the years 1915 to 1947.

Leukoplakia is a disease of undetermined aetiology involving mucous membrane. It is characterized by an epidermoid metaplasia in various stages of keratinization, and histologically the end-result closely resembles normal skin. Though the true aetiology remains obscure, most writers strongly favour chronic infection or chronic irritation as the most likely cause. Another theory is that vitamin-A deficiency may be a factor in causation, and a number of cases have been associated with a positive Wassermann reaction. It has hitherto been generally agreed that leukoplakia is a precursor of squamous carcinoma, but recent work suggests that this is incorrect, although the condition itself is still considered irreversible. Our own experience gives us no reason to suspect that the condition is pre-cancerous.

From the cases reported it appears that leukoplakia of the bladder is three times as common in the male as in the female, and is most frequent in the fifth decade of life. The usual urinary symptoms are haematuria and dysuria, but these are probably due to the superimposed chronic cystitis. Clinically the picture may be confused by such symptoms as loss of weight, fever, nausea, and vomiting. X-ray examination of the kidneys and bladder usually reveals no abnormality, so that most investigators consider that diagnosis before operation is highly improbable. However, the appearance of desquamated epithelial tissue in the urine must be considered pathognomonic. The bladder appears to be the most common site of leukoplakia in the urinary tract, and the renal pelvis to be less often affected, while it is estimated that in only 10% of cases of the latter is the bladder also involved.

Various methods of treating the condition have been suggested, including massive doses of vitamin A and a full course of antibiotic therapy, for which aureomycin is considered best. Winsbury-White (1932) reports a case of leukoplakia in which radium implanted into an ulcerated area at the base of the bladder led to the healing of a suprapubic fistula created during a diagnostic cystotomy. Ewert and Hoffman (1944) report good effect from instillation of sterile cod-liver oil into the bladder, and Helfert and Bremen (1953) claim apparent arrest of renal leukoplakia with bladder involvement following a course of A.C.T.H. As a preventive measure the thorough treatment of chronic urinary infection is emphasized, and the treatment of tertiary syphilis if this is also present.

Our thanks are due to Dr. A. J. McCall for the histological reports and to Dr. W. G. D. Caldwell for the photograph.

Reviews

ABDOMINAL SURGERY

Textbook of British Surgery. Volume I: The Abdomen. Edited by Sir Henry Souttar, C.B.E., D.M., F.R.C.S. (Pp. 547+viii; illustrated. £5 5s.) London: William Heinemann Medical Books Ltd. 1956.

Whether one likes it or not, textbooks and examinations occupy such a key position in the educational system that the appearance of a new textbook designed to meet the requirements of "candidates for the higher examinations in surgery"—in this country the final F.R.C.S.—is an important event. The present work is the first of three volumes under the editorship of Sir Henry Souttar, to which eventually forty different authors will contribute. The two questions to which one seeks answers are: Has the editor chosen his contributors well, and has he moulded their contributions into an organic whole? For a textbook should be more than a mere collection of individual contributions, and should have a general educative as well as a detailed instructional value. It will not be possible to give a final answer to the second question until all three volumes are available, particularly since the volume dealing with the main general principles of surgery will apparently be the last to appear. But the sample provided by the fourteen authors who contribute to this first volume on the abdomen should enable one to hazard a close guess to the answer to the first question.

The thing that at once impresses and refreshes is that, while all fourteen authors will from their experience and status be accepted as authoritative, almost all are distinguished by not being burdened by an excessive seniority. The general level of contributions is high, and it may be a little invidious to particularize. But perhaps special mention may be made of Mr. Rodney Smith's article on intestinal obstruction, which is surely destined to become a classic and a model of what a textbook article should be; while Mr. Lees Ferguson manages to invest his article on the now somewhat pedestrian, though still very important, subjects of appendicitis and peritonitis with an originality and literary charm which are only marred by a slightly tedious catalogue of differential diagnoses. The line drawings of Professor Goligher's excellent article on the stomach and duodenum make one regret that in other chapters similar line drawings have not replaced some of the photographs. And there are other excellent chapters that space will not allow mention of. In all the articles details of operative treatment are given in much greater measure than is usual in a textbook of surgery as opposed to a textbook of operative surgery, and this seems a very useful innovation. On the debit side, the criticism may perhaps be made that in two of the sections—those on the gall-bladder and on hernia—classification and a desire for completeness have been carried so far that it is a little difficult to see the wood for the trees. In spite of this, operative cholangiography, surprisingly enough, is not even mentioned, though Fig. 72, which is of a residual common-duct stone demonstrated in a post-operative cholangiogram, must have brought regret that the picture was not available before the abdomen was closed.

Misprints are few, but the last line of (5) on page 475 is clearly one, and there would appear to be another on coloured plate III, on which an obvious almost pure cholesterol stone is labelled "pigment." One brief, but not small, final point. Could not the title of the work be altered to "The more correct 'British Textbook of Surgery'?" A "Textbook of British Surgery" has an implication of chauvinism unworthy of the subject. Surely surgery, even more so than "le militarisme" in the well-known aphorism of Georges Wolfromm, "n'a pas de patrie."

DAVID PATEY.

VETERINARY PARASITOLOGY

Veterinary Parasitology. By Geoffrey Lapage, M.D., M.Sc., M.A., M.Inst.Biol. (Pp. 964+xvi; illustrated. 63s.) Edinburgh and London: Oliver and Boyd. 1956.

Dr. Lapage was successively lecturer in parasitology at the Universities of Exeter, Manchester, and Cambridge; subsequently he was external examiner in veterinary parasitology. His book, which is well produced and weighs 4 lb., reflects his long experience of the laboratory and classroom. In the first two chapters the general principles of parasitism and its effects upon the host are discussed. Then follow four sections, each of which is devoted to a phylum: 199 pages to the roundworms, 29 pages to the flatworms, 361 pages to the arthropods, and 152 pages to the protozoa. The systematic anatomy, life history, epidemiology, effects, and control measures of each species parasitic of domesticated animals in Britain and overseas are described fully and illustrated by 34 photographic plates and 694 text figures. A bibliography of 20 pages, which covers a wide range of specialist literature, is followed by a carefully arranged index.

The quality of some of the text figures, which have been reproduced from old publications, could be improved. The bot flies at page 524 and on Plate 22 are misspelt. The high standard of the author's work on the taxonomy is not maintained in the clinical sections. His description of pathology, symptomatology, and therapy tends to be a laboured compilation which lacks the convincing touch of the experienced veterinary clinician. The notion that the quality of an illness is measurable by the animal's age or the number of parasites in a sample of its faeces, also the confusion of tolerance with immunity, appear to be long a-dying among parasitologists.

TOM HARE.

AMERICAN ENDOCRINOLOGY

Textbook of Endocrinology. Edited by Robert H. Williams, M.D. 2nd edition. (Pp. 776+xii; illustrated. 91s.) Philadelphia and London: W. B. Saunders Company. 1955.

This is the second edition of a good textbook. The chapters on the adrenals, ovaries, pancreas, and parathyroids have been rewritten. Forsham and Thorn write on the adrenals, and Reifenshtein on the parathyroids. These two sections are the real strength of the book; in them the three authors display unrivalled experience and authority. Their work contains much information which cannot be found in any other texts; and they give an admirable account of diagnostic techniques, of operations, and of drugs which are just coming into general use in Britain. However, even this 1955 edition contains no reference to Conn's aldosterone tumour and the relation of hyperaldosteronism to the potassium-losing kidney. The chapter on laboratory diagnostic and assay procedures is a comprehensive and critical survey of techniques, both of those which are commonly employed and of those not yet generally available.

Doughaday has succeeded Newburgh as the author writing on obesity, and in consequence there has been some change of emphasis. The patient with Cushing's syndrome is now allowed to be obese, and the curious shift in fat distribution in this disorder is mentioned though not explained. Fiedgood's chapter is now less speculative, but remains an interesting account of the psychological, neurological, and biological relationships of endocrinology. The alterations in this essay and in the chapter on obesity have removed some, but not all, of the conflicting statements which marred the first edition of this book.

Adopting Trousseau's advice to the patient to "take it while it still cures," one might say to the intending student of this book, "Read it before it is out of date."

PREVENTION OF TETANUS

During the 1914-18 war the introduction of routine passive immunization for all wounded reduced the incidence of tetanus in a few months from approximately 8 to 1 per 1,000, and later this figure was lowered still further. Immunization in the civilian population had a like effect, but has never prevented tetanus entirely. The chief reasons for this partial failure are that many cases among civilians are due to wounds which are so trivial that they are not taken to a doctor, or, if taken, are considered too slight to merit antitoxin. In some cases no wound can be detected, perhaps because it is internal, or tetanus has followed conditions such as chronic ulcers, infected cavities, puerperal sepsis, and others in which its possibility is not suspected. For such reasons it is inevitable that a certain proportion slip through the net of passive immunization. A further disadvantage is that some patients are sensitive to horse serum, so that reactions when tetanus antitoxin is given are by no means rare and may be severe; very occasionally they are fatal. Further, patients who receive it are not only sensitized to further injections of horse serum but the protective effect of a second injection is less than the first.

In the 1939-45 war active immunization by toxoid was carried out on a large scale in the Allied armies, and the results were remarkably successful. In the British Army two injections of toxoid were given at an interval of not less than six weeks, with a further reinforcing dose at yearly intervals during service. If a man was wounded he was given antitoxin as soon as possible or, in the American army, a further dose of toxoid. The results of both these procedures were highly satisfactory. Reactions to toxoid were slight and rare and there were no other disadvantages.

How great was the success of active immunization is shown in a recent report of the Army Pathology Advisory Committee.¹ This summarizes the results in detail and defines precisely the indications for both active and passive immunization in Service personnel.

The committee indicates that a person is to be considered actively immunized for a period of six months if he has received two injections of toxoid, the second not less than six or more than twelve weeks after the first, and that he is to be considered immunized for a period of five years if he has received three injections of toxoid, the second not less than six weeks after the first and the third not less than six months and not more than twelve months after the second. It recommends that a dose of toxoid should be given immediately to all wounded men irrespective of whether they are actively immunized or not. In addition tetanus antitoxin should be given as soon as possible after wounding to any non-immunized person and repeated at seven-day intervals at the medical officer's discretion. In peacetime a reinforcing dose of toxoid for all actively immunized persons is recommended every five years. The evidence the committee gives suggests that thorough application of these rules would practically stamp out tetanus.

By contrast active immunization of the civilian population in Britain is casual, and apart from those who have been in the Services the majority of the population have never had it; consequently the problem of prevention for civilians is a complicated one. In a recent paper N. H. Moynihan² considers this aspect from the point of view of the casualty officer in hospital. Apart from the difficulty of deciding whether a particular wound needs antitoxin he is concerned with the frequency, inconvenience, and danger of reactions to horse serum following passive immunization, and the methods by which they may be mitigated. On inquiry at 37 hospitals in different parts of the country he found that 31 were still using the intradermal test of skin sensitivity as a guide to general or constitutional sensitivity, though this test is recognized to be unsatisfactory. This led him to investigate the practical outcome of this test on a series of 8,900 patients treated in three hospitals. It was found that, of these, 1,027 (11.5%) who were judged to need prophylaxis were not given it because the intradermal test was positive. A further 293 did not receive prophylactic antitoxin for other reasons: 140 because they had had a previous injection within a period which varied from three weeks to 18 months, and this was erroneously deemed to be sufficient protection by the doctor; 70 because of a personal or familial history of allergy; 24 because a general reaction followed a sensitivity test dose; and 59 because they refused. It is now known that effective protection following a dose of 1,500 units lasts for less than four weeks and may be as short as three days in patients who have had a previous injection. When it was found that these so-called positive skin

tests formed such a high proportion of the total, he carried out two further investigations, using physiological saline and tap water as controls against the test dose of antitoxic serum in 100 cases. The results showed that saline produced a similar reaction to antitoxin in 47% and tap water in 28%. All of the 200 patients were subsequently given the full dose of prophylactic antitoxin, and only 4.5% of these developed serum sickness and 5.5% a localized reaction at the site of injection. He emphasizes that the method of intradermal testing for sensitivity to horse serum which is at present used in so many hospitals is unreliable and should be replaced by the "trial dose" method fully described by L. J. M. Laurent and H. J. Parish.³ This consists in preliminary subcutaneous injections of a small dose of serum with a view to testing the patient's general reaction before giving a large one. Moynihan also draws attention to the important observation of G. Payling Wright and his colleagues⁴ that previous injection of a soluble antigen leads to a much faster removal from the circulating blood of a second or subsequent injections and consequently curtails the prophylactic effect. They therefore recommend that "once a person has received an injection of any horse-serum antitoxin, irrespective of the disease for which it may have been given, that person should be promptly immunized against diphtheria and tetanus with the appropriate toxoid." Moynihan points out that this recommendation was not carried out in 36 of the 37 hospitals he visited.

The excellent results obtained with active immunization in the Services contrasted with the 60 or so deaths from tetanus a year in the civilian population in England and Wales speak for themselves. Moynihan's paper also shows clearly some of the difficulties inherent in the application of passive immunization, and his recommendation that every hospital should have written rules for the guidance of house officers is a sound one. His observation that there is no valid reason why active immunization should not be practised universally is sounder still.

CO-OPERATIVE RESEARCH IN THE
COMMONWEALTH

During the early months of this year the East African and West African Councils for Medical Research held meetings, and in another part of the world an Advisory Committee for Medical Research in the British Caribbean Territories was created. These new international organizations have sprung into being during the last few years from a quickening consciousness of the need and opportunities for medi-

cal research in tropical parts of the Commonwealth; and they have been generously and wisely aided by grants from Colonial Development and Welfare Funds. They constitute an important venture, promising to benefit not only the peoples of the different tropical territories but also the progress of medical knowledge in general. The research being undertaken under the aegis of these organizations is wide in scope, and, although primarily oriented to the needs and opportunities of particular regions, it is already throwing light on problems of fundamental importance and general interest. Malaria, filariasis, and yellow fever and other virus diseases are prominent among the disorders being studied in East and West Africa; and in the Gambia, in Nigeria, and in Tanganyika the effects of persistent malaria are being unravelled. In the Caribbean region malaria forms less of a problem, and in British Guiana, where formerly it was prevalent, it has now been almost completely eradicated. Work on virus disease is, however, going on there as in the other two regions, and in each it is mutually complementary—work done in one commonly helping in the interpretation and furthering of that done elsewhere. In West Africa, for example, it has been found that, although in many areas serological surveys indicate that yellow fever is highly endemic, the disease is seldom seen clinically. Cross-immunity has, however, been demonstrated between yellow-fever virus and West Nile and Uganda S viruses isolated in East Africa; work is going on to determine whether these together with Zika and possibly other viruses are responsible for the serological changes which taken at their face value suggest previous infection with yellow fever.

In Nigeria the life cycle of the chrysops fly—which conveys the filarial infection loiasis—has been determined, although 5 or 6 years ago virtually nothing was known of it. This knowledge opens the way to means of destroying the fly and eradicating the disease it conveys. Work is also to be undertaken for the West African Council for Medical Research on onchocerciasis, a filarial infection which is responsible for much blindness among Africans. Under the East African Council detailed studies are also in progress to determine the prevalence there of filarial infections and the means whereby they may be controlled. Under the Council in Nigeria research on sweat responses to increases in body temperature has thrown much light on the aetiology of heat hyperpyrexia, hitherto little understood. This work has already benefited men working in the mines and in especially warm industrial environments in the Tropics. In Nigeria, too, investigations have shown the high nutritive value and digestibility possessed by a flour

containing 50% protein and prepared from the residue remaining when oil is expressed from ground-nuts. Work on milk substitutes made from plant proteins is in progress in Uganda. The scope of the research going on in the Caribbean was indicated by the conference held in connexion with the first meeting of the Advisory Committee for Medical Research in the British Caribbean and reported recently in this *Journal*.¹ Papers on yaws, vomiting sickness, veno-occlusive disease of the liver, and a non-nutritional neuropathic disorder were presented.

In Britain research is being carried out under the Medical Research Council and at the Schools of Tropical Medicine in London and Liverpool which both stimulates and is complementary to that going on overseas. This research also is wide in its scope, being concerned with filarial infections, schistosomiasis, nutrition, leprosy, tuberculosis, microbiology, protozoology, applied physiology, and the haemoglobinopathies. Research costs money, and the expenses of the work undertaken abroad have to date mostly been met by Governments of the territories concerned and by the Colonial Development and Welfare Fund. The function of the latter is to initiate schemes of value to the people of the Colonies, and the contribution from this source is therefore expected to be reduced in time and that from overseas Governments to increase. It is to be hoped, however, that private persons and industrial concerns overseas will feel that these efforts are worthy of their support.

These international research organizations represent a new aspect of co-operative effort within the Commonwealth. But they represent more than that: they embody recognition of a basic truth in medical progress—that medical research is indivisible and that at any time knowledge gained anywhere may be indispensable elsewhere. It reflects great credit on the Colonial Medical Research Committee, which operates under the joint auspices of the Colonial Office and the Medical Research Council, that its members have firmly grasped this truth and succeeded in giving it practical expression. Not only have they fostered the development of these overseas research bodies and organized complementary research in this country, but they have effectively linked the two together so that the free interchange of knowledge and co-operation, on which progress depends, is provided for and stimulated. The way is now open for advantage to be taken of these opportunities to advance medical knowledge, for men in this country and men in the Tropics to come together and to broaden and complement their experience to the mutual benefit of themselves and of their different

countries. Time, which changes political systems, customs, and alliances, does not alter problems of disease. The concept of these new affiliated research organizations seems, however, to be more deeply based, to rest on the requisites of medical progress itself. It is possible to hope, therefore, that they may represent the beginning of an enduring development.

ORDEAL BY SPENS

The statement issued to the press by the Ministry of Health after the meeting between the profession's representatives and the Minister on August 1 seems to have been ignored by most newspapers, with the notable exception of the *Manchester Guardian*. It appears in this week's *Supplement*. The meeting between the two has been "adjourned pending the submission by the Committee of further particulars of the legal aspects of their claim." Does this represent a modification of the attitude expressed in Sir John Hawton's letter that the Ministers do not accept the premises of the claim put forward by the Negotiating Committee? It is important that the legal implications of the Government's promises of 1946 and 1948 should be unfolded. But what the medical profession will regard as more important is the moral obligation of successive governments, in the words of the Spens Reports, to maintain "in the future the proper social and economic status of general medical practice and its power to attract a suitable type of recruit," and "the proper social and economic status of specialist practice and its power to attract a suitable type of recruit, having regard to other forms of medical practice." The examination of the legal position will take time. Parliament does not re-assemble until October. And the summer holidays have to be enjoyed in spite of the weather. The medical profession will have, therefore, to be patient in the meanwhile, but at least may gain comfort from the fact that the Minister's "No!" has had the edge taken off its sharp and emphatic note.

DIARRHOEA IN YOUNG CHILDREN

Gastro-enteritis, once a major cause of death in babies, is following the trend of some other infectious diseases and becoming less of a scourge with each succeeding year. In 1947 the total number of deaths of babies under 1 year of age in England and Wales attributed to gastro-enteritis was 4,571 (5.13 per 1,000 live births), whereas in 1954 the figure was 461 (0.68 per 1,000). Such a change, though gratifying, cannot be accepted with complacency, for many babies develop this disease, and it is still the cause of much worry to clinicians,

particularly those in charge of institutions for young children. Modern methods of treatment, with carefully controlled fluid replacement and antibiotics, have played a large part in reducing the number of deaths.

The study of juvenile diarrhoea by Dr. Mair Thomas and Miss Ruth Charter at p. 339 of the *Journal* this week is of particular interest in that it is concerned with the disease as seen in general practice, whereas most papers on this subject have described outbreaks occurring in institutions. A similar, though smaller, study has been reported by W. J. Smither.¹ Thomas and Charter find that the infecting organisms are rarely present in their material, a finding which contrasts with those of G. Ormiston and colleagues,² who investigated outbreaks in residential nurseries, where the evidence suggested that *Giardia lamblia* was of importance. In Britain *Shigella sonnei* is the most common cause of dysentery affecting the young child rather than the baby, as shown by Thomas and Charter and by A. I. Ross,³ The majority of cases occur in the winter months. The results of R. I. Hutchison⁴ suggest that spread may occur as the result of handling contaminated articles by children who are too young to understand the principles of hygiene. E. Hormaechi and colleagues,⁵ working in Uruguay, found that many different *Shigella* species affected young babies, and accept it as a major cause of diarrhoea among babies in that country, as well as in older children. It would appear that dysentery may be a major cause of diarrhoea in babies in warm climates, whereas in temperate climates it is not. In 1914 and in following years *Proteus* was regarded as the cause of infantile diarrhoea, and the careful work of D. M. Bertrand,⁶ in which strains isolated from a London outbreak were identified by serological methods, provides reasonable evidence that those views were correct. That *Proteus* is rarely found in epidemic gastro-enteritis at the present time has been noted by many workers, the only recent cases in this country which might be attributed to this cause being described by U. James and colleagues.⁷ It is doubtful if *Proteus* can be accepted at the present time as a cause of intestinal disease.

Modern investigations have related various serological types of *Escherichia coli* to enteritis in young babies. Most of this work has been done on babies in hospitals or residential nurseries in countries with temperate climates. With this background, the results are that *E. coli* infection is high as compared with salmonella and shigella infections in babies under 1 year of age. The age incidence of *E. coli* infection has been investigated by J. C. McDonald and Charter⁸ and J. Taylor and Charter in this country,⁹ and by A. Friedman in Israel.¹⁰ Thomas and Charter also find that *E. coli*

infection is most common among young babies, but rather surprisingly find that type O.26 is more frequent than others. The descriptions of institutional outbreaks have implicated many types, but usually not O.26. The source of *E. coli* serotypes has been investigated by S. Thompson,¹¹ who isolated certain serotypes from milk, cow, and chicken faeces, but there were differences between the majority of animal strains and those from humans. Nevertheless, this work, and that of H. Fey,¹² suggests that milk should be considered as a source of infection. Against this view is the fact that liquid milk is pasteurized and is rarely used as baby food, and that J. Papavassiliou has failed to isolate specific serotypes of *E. coli* from pasteurized milk in the London area. Dried cows' milk is the usual baby food, but serotypes of *E. coli* have not been isolated from dried milk powder. The evidence presented by K. B. Rogers¹³ suggests that infection is spread as the result of direct or indirect contact between sick babies and other children. The work of Taylor and Charter¹⁴ has shown that the healthy carrier may also spread infection.

Thomas and Charter describe the finding of fat globules in stools; they believe them to be an indication of an infective agent which they are unable to isolate by the usual methods of stool culture. They also suggest that this finding may indicate "winter vomiting" disease, which many workers in Britain believe may be caused by virus infection. The work of J. Gordon¹⁵ in the U.S.A. has shown that two different viruses have caused clinically similar diseases to some outbreaks of "winter vomiting" disease in Britain. Thomas and Charter state that some patients with steatorrhoea were found in household outbreaks of diarrhoea and vomiting. The suggestion that steatorrhoea may be a sign of virus diarrhoea is worth investigating in more detail.

CHRONIC ARSENIC POISONING

Arsenic, that standby of the mediaeval professional poisoner, is ubiquitous in nature and is commonly met with in industry. Arsenical compounds occur in the smelting and refining of ores, in the subliming of white arsenic, and in the manufacture of sheep dips, insecticides, weed-killers, and pharmaceutical substances, in some paints, dyes, and soaps, and in calico printing. In the past glucose, owing to arseniferous acids used in its manufacture, has conveyed arsenic into beer, confectionery, syrups, and other foodstuffs. Nevertheless, industrial processes result in relatively few cases of chronic arsenical poisoning, eight cases being reported during the years 1950 to 1954.¹

Poisoning has been reported from inhalation of dimethylarsine produced by moulds growing on wallpaper and from absorption of arsenical dusts from decorated ceilings and cornices. In a recent case before the Kensington magistrates' court,² defendants summoned for not paying rates submitted a medical report stating they had been exposed to fumes from arsenic found in the wallpaper. But the commonest cause

of arsenic poisoning may be prolonged therapy with liquor arsenicalis. In the past such therapy was so commonly given in the treatment of psoriasis that when a psoriatic subject felt unwell the physician's first thought was that arsenic might be the cause. Arsenic affects the capillary beds and may damage renal glomeruli and tubules, and it may depress the bone marrow. It may cause encephalopathy, peripheral neuritis, and cirrhosis of the liver. Early signs of poisoning consist of weakness, falling hair, brittleness of nails, conjunctival injection, oedema of lower eyelids, and catarrhal inflammation of nose, throat, and larynx simulating coryza. Nausea, vomiting, and diarrhoea sometimes alternating with constipation occur. Mental hebetude may be associated with signs of peripheral neuritis affecting the legs more than the arms. Pigmentation of skin is common; it may be local or general and "rain-drop" or diffuse in character. Epithelial hyperplasia, with formation of keratoses, chiefly on palms and soles and less commonly on trunk and head, may appear within a month after the first ingestion of arsenic or not until thirty years after medication has been discontinued; in 20% of patients with such keratoses, epitheliomata may appear either in the keratoses themselves or as superficial epitheliomata elsewhere on the body.³ More recently it has been suggested that multiple internal carcinomata may develop.⁴ Cancer of the skin from industrial processes appears to be rare but has occurred in sheep-dip workers. A relative excess of cancer of skin and respiratory tract has been found in a group of workers exposed to inorganic arsenical dust.⁵ O. Neubauer⁶ and A. N. Currie⁷ review the role of arsenic in carcinogenesis. Dusts may lead to flexural eczemas and pigmentation of head and neck, but painless perforation of the nasal septum is perhaps the most common and characteristic lesion in this group. Other industrial hazards arise from arsenuretted hydrogen, which acts as a haemolytic agent, and from organic arsenic compounds, which have vesicant as well as systemic effects.

In the treatment of arsenic poisoning dimercaprol removes the inhibition of enzymes by arsenic, but cell damage may be irreversible and H. J. Wade and E. S. Frazer⁸ found that hyperkeratoses or skin pigmentation did not improve from such treatment. In cases of chronic poisoning arsenic can be detected in urine or vomitus; it may be retained in keratin, nails, and hair for a long time after ingestion. While the estimation of small quantities of arsenic is conventionally performed by the Gutzeit method or spectographic analysis, W. A. Dewar and J. M. A. Lenihan⁹ have recently described a case of chronic arsenical poisoning in which the arsenic content of skin, hair, and nails was determined by a

radioactivation technique. The specimens were placed in a nuclear reactor; the induced radioactivity measured by Geiger counter provided an indication of the amount of the target element present in the original samples. Provided a source of sufficiently high neutron flux is available a much higher sensitivity is claimed for this method than for chemical methods.¹⁰ Analysis by radioactivation was first suggested by G. V. Hevesy and H. Levi,¹¹ but it was not a practical proposition until the advent of modern nuclear reactors, and was first applied to the estimation of arsenic in biological material by A. A. Smales and B. D. Pate.¹²

JELLY-FISH STINGS

The stings of some jelly-fish, such as *Chiropsalmus*, the Japanese "fire-medusa," and *Physalia*, the "Portuguese man-of-war," can be serious or even fatal. The latter is brought near Britain only occasionally by freak storms, and it remains to be seen whether the recent storms have swept any to our coasts. Fortunately none of the five species found regularly in British waters is so dangerous. The commonest, *Aurelia*, marked with four purple rings on the bell, and the largest, *Rhizostoma pulmo*, recognizable by the absence of marginal tentacles and its pale blue colour, are harmless. The other three, however, may cause unpleasant and sometimes alarming effects. They all have long tentacles and can most easily be identified by the colour of the bell, which is blue or yellow in the two kinds of *Cyanea* and white with brown radial striations in *Chrysaora isosceles*.

The exact nature of the poison with which they sting is unknown, but it is thought to be a mixture of proteins; there is no foundation for the old belief that it is formic acid. Experiments on small animals with various extracts from jelly-fish and allied organisms have shown a toxic effect on the central nervous system, motor nerve-endings, and the alimentary and respiratory system as well as the skin. Furthermore, repeated small doses of at least one of these extracts have been shown to produce a state of allergic hypersensitivity similar to anaphylaxis. On the other hand, examples of natural immunity are found in certain fish and crabs which exist as commensals with jelly-fish or sea-anemones, and this immunity has been transferred passively to susceptible members of the same genus. This observation might point the way to an antitoxin suitable for clinical trial. Both local and general effects have been reported in human victims. At the site of contact there is usually an immediate burning sensation followed within a few minutes to an hour by erythema, weals, or vesicles, which may be haemorrhagic and, rarely, even result in superficial necrosis with permanent scarring. Localized atrophy of subcutaneous fat has been recorded. In most cases the local symptoms and signs last only about a week, though the areas may remain hyperaesthetic for much longer. General effects may appear from one to twenty-four hours after the sting. They include erythema and urticaria, nausea, anxiety, painful cramps and clonic muscular spasms affecting chiefly the abdominal muscles and the diaphragm

and leading to respiratory distress, and a state resembling anaphylactic shock. This last phenomenon may be due to sensitization by a previous sting, which may not have been noticed or remembered.

In treatment the patient's first need is rest and careful observation for at least twenty-four hours. Application to the primary lesions of local anaesthetics such as benzocaine or antihistamine creams would probably give more relief than simpler remedies; hydrocortisone ointment might be worth a trial. Parenteral analgesia, including even morphine, may be needed. Urticaria would probably respond to antihistaminics given orally, but adrenaline should be injected promptly if severe shock develops. Muscular cramps have been relieved by either calcium gluconate or barbiturates given intravenously.

PSEUDHAEMOPHILIA

The term pseudohaemophilia has at some time been applied to almost every haemorrhagic disease of undefined aetiology. The name is now generally accepted as referring to a bleeding tendency in a patient of either sex, where the significant demonstrable abnormality is a prolongation of the bleeding time. The whole-blood coagulation time, the platelet count, and the one-stage prothrombin test are normal. The tourniquet test is positive in about half the patients.

By these criteria of diagnosis it is probable that the reported cases do not form a homogeneous group. In some of the patients a capillary defect has been shown by direct visualization of the nail-bed capillaries, which appeared distorted in shape and failed to constrict normally after injury. This was reported by R. G. Macfarlane in 1941,¹ and has been confirmed in some subsequent reports but not in others. A second view of the pathogenesis of the disease postulates a qualitative defect of the platelets. When platelets were collected from some of the patients and added to platelet-free normal plasma, they failed to induce normal retraction of clot or the utilization of prothrombin during clotting. This variety of pseudohaemophilia is sometimes called thrombocytoasthenic.² At least some of the patients reported by E. A. von Willebrand probably belonged to this group.³⁻⁵ It was he who originally stimulated interest in pseudohaemophilia, and it is still sometimes in consequence called von Willebrand's disease. He and R. Jürgens⁶ believed the disease to be due to poor agglutinability of the platelets. Of relevance also is a report from F. S. Bigelow of normal serotonin activity in the plasma of two patients believed to have pseudohaemophilia.⁶ A third group of patients have been found to have defective prothrombin consumption, indicating an abnormality in the thromboplastin system of the blood. This has been ascribed again by some as due to a functional platelet abnormality, but has also

on occasion been due to an associated deficiency of antihaemophilic globulin.⁷

The symptoms of pseudohaemophilia are very variable in intensity, but the condition usually causes less disability than severe haemophilia. Among the most frequent symptoms are epistaxis, gingival bleeding, excessive bleeding from minor cuts, and in females excessive menstrual bleeding and serious post-partum haemorrhage. Abnormal haemorrhage may follow extraction of teeth or other operative procedures. Excessive bruising can follow minor trauma. The condition is distinguished from haemophilia by its occurrence in both sexes and by the marked prolongation of the bleeding time. In haemophilia there is demonstrable deficiency of a plasma-clotting component, antihemophilic globulin, and the bleeding time is normal. A differentiation between the two conditions can usually be made on these grounds, but rare cases occur in which there is a deficiency of antihemophilic globulin associated with a prolongation of the bleeding time.⁷

No treatment is satisfactory. Blood transfusion may be indicated for anaemia, and cortisone has been reported of benefit in the control of bleeding.⁸ Local pressure to control haemorrhage can be applied in this condition, whereas it is often contraindicated in haemophilia. The hereditary pattern of the disease is difficult to determine. There is some evidence that it is a dominant sex-linked character, but the available information is not adequate to provide a final answer; the histories of most of the patients suggest that it is constitutionally determined. Pseudohaemophilia is a rare disease, but, apart from haemophilia and Christmas disease, it is probably the most common of the constitutional haemorrhagic disturbances. It has recently been well reviewed by J. C. Buchanan and B. S. Leavell.⁹

CHROMOSOME NUMBER OF MAN

It has generally been believed that the somatic cell of man contains 48 chromosomes. Now J. H. Tjio and L. Levan¹ have suggested that the number should be 46, and in support Dr. Tjio showed preparations of human chromosomes at the Congress on Human Genetics held last week at Copenhagen. Tissue cultures of fibroblasts from human embryonic lung were treated with colchicine to effect an accumulation of mitoses. Before fixation they were treated for one or two minutes with hypotonic saline solution, a method which had been used before by T. C. Hsu² to induce scattering of the chromosomes. Fixation followed in 60% acetic acid twice exchanged to wash out the salts left from the culture medium and the hypotonic saline that would otherwise have caused precipitation with orcein. Ordinary squash preparations were then made in 1% acetic orcein. Single cells were squashed under microscopical observation by slight pressure with a needle, and it was seen that no chromosomes escaped. On 22 cultures 261 chromosome counts were made, and the chromosome number was found to be 46 (2n = 46).

Effect of Fatty Meals on Blood Coagulability

SIR,—The article by Dr. G. H. Hall (*Journal*, July 28, p. 207) has naturally been of much interest to me. He seems to have shown that the accelerated clotting times after a high fat meal are not shortened when plasma rich in platelets is used. However, I find it difficult to understand the conclusions he draws from this finding. No one, I think, would presume to state dogmatically the conditions of *in vitro* clotting which most closely approximate those which hold *in vivo*. It has seemed to us that the clotting time of whole blood in silicone-coated tubes is a measure of coagulability which is less artificial than any other, and Dr. Hall's work does nothing to detract from the significance of our findings or from the tentative deductions we have drawn from them.

In addition, I would disagree strongly with Dr. Hall when he states: "It is difficult to see, however, why a change affecting the whole blood should promote the development of atheroma preferentially in certain areas—for example, the coronary arteries—and this fact argues that the initial defect is in the arterial wall and not the blood." Conditions of blood flow differ in the coronary arteries from those in any others, in that during ventricular systole there is marked reduction or cessation of flow. This factor would readily allow deposition of pre-formed fibrin on the intima of the coronary arteries, while continuous blood flow would lessen the tendency of this occurrence elsewhere. Indeed, far from agreeing with Dr. Hall's view, I would go so far as to say that the high incidence of atheroma in the coronary arteries is one of the considerations favouring the hypothesis that the initial defect in atheroma is in the blood and not in the arterial wall.—I am, etc.,

Medical Evidence at Inquests

Sir,—Thirty years ago, when I was doing my resident hospital appointments, medical evidence from one or more house officers was required by the coroner at every inquest held following a death in hospital. Whether the house officer was paid or not depended on the coroner, for fees to hospital residents were permissive but not obligatory. Curiously enough, I was a resident in an area where the coroner paid no fees when the law was altered and fees for all medical witnesses made obligatory. It was very revealing to observe the economy which the coroner exercised in his calling of medical evidence from that time on. The explanation lies in the curious anomaly that a coroner should be paid in a block grant from which all expenses, including witnesses' fees, are paid. Economy in the calling of witnesses was a direct saving to the coroner personally. I believe this is still the method used.

At that time many hospitals had no pathologist, and necropsies were done by police surgeons or hospital residents. The police surgeons were usually general practitioners. I remember the case of a Finnish seaman who was stabbed in eleven places and died on the operating table under my ministrations. I spent the greater part of one day doing a necropsy and writing a detailed report for the coroner (the police surgeon was present but played no part). On the following day I spent the morning at the inquest and the afternoon at the police court, and the sum of one guinea for the last was the only payment I received. Now the pathologist has come into his own, and all necropsies are conducted much more expertly by experienced men who devote much of their time to this work. As a consequence of this, the coroner has come to depend

more and more on the pathologist who gives precise, dogmatic, and incontrovertible evidence on the cause of death as revealed at necropsy. Secure in this knowledge, they can, and not infrequently do, ignore the clinician whose knowledge of the patient in life might have put a different complexion on the medical evidence at the inquest.

Perhaps one of the less important consequences of this practice is that house officers are never given an opportunity of attending an inquest, which should be part of their education, nor of collecting an occasional fee. More important is the building up of a clinical picture by the pathologist from his post-mortem findings, which is often widely at variance with the facts as observed by the family doctor or the hospital officer. Sometimes in evidence statements are made which are taken by the relatives to reflect on the competence of the doctor who attended the deceased, though no such reflection was intended. The object of an inquest is to arrive at the true cause of death, and post-mortem findings divorced from the clinical history are not always dependable, and may indeed give a less accurate picture than the clinical history taken by itself. I can recollect one case in which a verdict of natural causes was returned, which was, in fact, a suicide. This is a verdict which no one would wish to upset, but it could have been the other way round.

Most of us are too busy to wish to waste time at inquests, but, even though we are not called, we could sometimes give important information if requested by the coroner. We are not asked because the coroner does not wish to pay a fee and because the pathologist considers his own evidence sufficient. What is needed is a closer contact between clinician and pathologist and another method of paying coroners.—I am, etc.,

Preston

F. M. ROSE.

Vaccination Against Tuberculosis

SIR,—While agreeing with the views expressed by Dr. Kenneth Marsh (*Journal*, July 21, p. 174), one would have liked to see more emphasis laid on the last few words of his excellent letter, where he suggests extending B.C.G. vaccination to Mantoux-negative subjects over the age of 14 years.

The reasons for offering this protection to 13-year-old schoolchildren apply with equal force to all who are over this age, and such persons would seem to be more in need of B.C.G. than infants. It would be logical to offer B.C.G., with wide publicity, to all persons over the age of 13, among whom there are many thousands who are Mantoux-negative.

If the practical problem of Mantoux-testing and inoculation is too great, the scheme could be limited in the first instance to persons up to the age of 25, but with a little organization both these procedures can be done very quickly. They might perhaps be linked with mass radiography, and no doubt general practitioners and industrial medical officers would be willing to do their share if the task is too great for the resources of the local authorities and the chest clinics.—I am, etc.,

Bromsgrove, Worcs

R. B. MAYFIELD.

Apartheid in Blood Transfusions

SIR.—Dr. J. Torley's letter (*Journal*, July 21, p. 179) at first sight appears to administer firm but gentle admonition to Dr. David J. Adderley (*Journal*, June 30, p. 1546). However, on careful study it raises some very important points. Does Dr. Torley really believe that the South African Government's decision is based on scientific integrity? Would he care to suggest a "scientific" theory for the South African Government's apartheid policy in general? This is not a question of offering gratuitous advice to the profession in South Africa. There is an important moral and ethical principle at stake here, and we must not prostitute science to condone a flagrant violation of our present standards. From

his letter Dr. Torley appears to be either an apologist for South African racial doctrines or grossly ill-informed about conditions in that country. Do not let us be so naive as to imagine that this is one isolated incident in South Africa. It must be assessed against the background of apartheid in general and also the profession's attitude in that country to apartheid in science.

In 1947 an Indian doctor was appointed senior resident officer at a hospital in Capetown, and as such was responsible for supervising the work of the junior house officers and also for doing the emergency surgery—general surgical, traumatic, and gynaecological. The post also carried with it the responsibility for bleeding white blood donors for emergency transfusions at the hospital. 'Because he was non-white, the blood transfusion service in Capetown refused the senior resident permission to do this, and instead one of the white junior house officers was entrusted with this duty. The profession raised no objection to this and completely condoned the action of the blood transfusion service. It may surprise Dr. Torley to know that since 1945 non-white medical students at the University of Capetown Medical School have been forbidden to attend any class, clinic, or operation on a white patient or attend a necropsy on or dissect a white corpse. When they register at the University they are required to sign a document undertaking to abide by this. Does that meet with Dr. Torley's requirements for scientific integrity or his interpretation of the Hippocratic Oath?

Hippocratic Oath ?
Of course it is known that group A seems to be commonest in western Europe, B in south-east Asia, and O among so-called primitive groups such as Australian and American aborigines, but surely we do not suggest having separate blood banks in England, for instance, to serve the needs of the numerous racial groups living in this country. Would Dr. Torley refuse to accept a transfusion of compatible blood from a negro donor on the remote off-chance of the presence of a hypothetical injurious factor to be discovered in South Africa in the still more remote future ? No, Sir, do not let us emulate the South African ostrich and hide our heads in the sands of pseudo-science.

To the exponents of theories of racial superiority, of *Herrenvolk*, the word "blood" possesses a highly emotional content. The *Oxford Dictionary* states: "Blood is popularly treated as the typical part of the body which children inherit from their parents and ancestors; hence that of parents and children, and of the members of a family or race, is spoken of as identical and as being distinct from other families or races." Dobzhansky' says, "It is most unfortunate that the theory of 'blood,' though invalidated decades ago, still colours not merely the thinking of laymen, but finds its way, explicitly or implicitly, into textbooks." It took a world war to disclose to us the depths to which scientists could

If the medical profession in South Africa has initiated this present move, let it publish the grounds on which it bases the incompatibility of negro and white blood. On the other hand, if this is merely another political stunt of the South African Government, we hope that country's medical men will challenge it, but whatever happens we must question the integrity of a radical departure from the accepted standards and criteria of blood compatibility.—
I am, etc.,

SIR.—Dr. J. Torley (*Journal*, July 21, p. 179) in commenting upon the South African Government's (not the profession's—the head of the Medical Service is himself severely critical of it) proposed measure to segregate blood of different origin, has rather by-passed the essential objection to it. I fully support his postulate that there may be differences between such bloods, as yet unknown. This scarcely affects any individual transfusion, which would only be given after cross-matching and having taken all known precautions.

Assuming that this has been done, what objection remains? Surely, only that of a possible "taint" being acquired by the recipient, and it is that superstition to which I am opposed. This is no political theory, but an honest objection to this concept. We all deplore the introduction of politics into science, and I hope we may express our united support for the resentment against the imposition of this measure.—I am, etc.,

London, S.E.13.

DAVID J. ADDERLEY.

Diesel Oil and Lung Cancer

SIR,—The subject of the effect of exhaust fumes on public health has been discussed at length in the transport technical press, and whether by accident or design in certain cases the main issues have become confused. From this one is led to the conclusion that if the outcome of the present investigations prove that the exhaust fumes from diesel engines have a contributory effect upon the growth in the number of cases of lung cancer the establishment of this fact will have a profound effect on the transport industry, if not upon the economy of the country, bound up as we are in the use of fuel oil in all phases of transport. A doctor and friend who is much interested in the subject of diesel engine exhaust fumes and cancer has drawn my attention to the correspondence in your issue of June 2, and he has asked my opinion about the catalytic exhaust filter mentioned by Dr. Handley Howell (p. 1297).

The researches of Dr. Handley Howell and others, which some of us have had the benefit of studying, show that means of counteracting the noxious and/or poisonous fumes are available in the catalytic exhaust filter, which is extensively used in the United States of America, and no doubt transport operators will be ready to give this equipment a thorough trial. It would appear, however, that the catalyst is not effective until a fairly high temperature is reached, which is not attained until a diesel engine is running at 60% of full load or more. When running below such load conditions the catalytic reaction may not be fully effective, but with 60% of full load it has been stated that 60%-85% of the noxious ingredients in the exhaust gases are eliminated.

Thus it may be easy to obtain ideal conditions for using catalytic filters with stationary engines, but with motor-bus engines, idling for much of the time at stops or while the vehicles are running at low speed, the effectiveness of the equipment must be questioned. One can only trust that more information can be made known, as this seems to offer hope, quite apart from the fact that the exhaust from diesel engines is unpleasant anyway and creates a further discomfort in the streets and congested areas of towns to-day.—I am, etc.,

Southwick, Hants.

B. R. MILLER.

Personality and Cancer

SIR.—At least since 1930, when Le Gros Clark and his colleagues¹ outlined the link between the emotional thalamic drive and the endocrines, and Engels² extended the work from the endocrines to cancer, the clinician has had rational support for his experience that worry of the type your annotation (*Journal*, June 30, p. 1537) describes does in fact often precede cancer. The link is not more generally recognized because, in the words of your annotation, "many of the workers found what they were looking for . . . their observations were in part determined by their preoccupations." The suggestion here is that to search for confirmation of a hypothesis is somehow intellectually inferior to detached observation of what an experiment yields and what answer a statistical computer provides.

This latter attitude has been challenged very recently by both Carl Jung³ and Professor R. A. Kapp.⁴ In his *Interpretation of Nature and the Psyche* the former says, "The experiment imposes limiting conditions on Nature, for its aims are to force her to give answers to questions devised by man. Every answer of Nature is therefore more or less influenced by the kind of questions asked and the result

is always a hybrid product. The so-called 'scientific view of the world' based on this can hardly be anything more than a psychologically biased partial view which misses out all those by no means unimportant aspects which cannot be grasped statistically."

Kapp's criticism is no less formidable: "If the laws of physics do not preclude any events that are logically possible, those of biology seem nevertheless to do so. For there is evidence that the laws of biology lead to specified order whereas the laws of physics do not." In other words, the current subordination of the medical mind to the statistical and experimental methods excludes the logically possible. This is a reversal of the teaching of Osler and Horder. Clinical observation is the fact, the hypothesis is the logically possible, hence Horder's insistence on the mastery of *Jevons's Elements of Logic*.⁶

My object in writing this is to invite attention to the fact that no section of any of our learned societies and no section of our professional press is devoted to study of the logically possible, and the R.S.M. apparently has no committee able to initiate such a study. Your annotation again expresses the prevailing opinion: "Evidence that [personality] plays a part in the aetiology of cancer can be satisfactorily derived only from controlled studies." Some of us in *ad hoc* committees have found it impossible to devise experiments involving personality. It is, on the other hand, logically possible to express a rational evolution of structure and function from such a basic presupposition as, for example, monism, and I venture to plead for a subsection within organized academic medicine dedicated to this end.—I am, etc.,

Caernarvon.

Increase in Lung Cancer Deaths

SIR,—Following the correspondence which questions whether the increase in the number of deaths from lung cancer is real or purely apparent and due to better diagnostic facilities, attendance at x-ray departments, etc., and the increased facilities at hospitals following the advent of the National Health Service Act in 1948, might I ask Dr. Jane M. Fullerton (*Journal*, May 26, p. 1238) and Dr. John S. Willmann and Dr. E. Gallop (*Journal*, June 30, p. 1543) to consult the Registrar-General's *Statistical Review for 1952* (published 1955), page 149? Diagram 12 illustrates the incidence per million living of deaths from cancer of the lung from 1936 to 1952.

It can be seen that, for men over 40, there has been a steady increase of this condition since 1935, and the graphs, from ages 55 to 70 in particular, approximate to a straight line. There is therefore no evidence that rate of increase of the diagnosis of cancer of the lung has changed since 1948, and, indeed, the reverse appears to be the case with a falling off of the increase since 1946 in the age groups 40 to 50. If better hospital facilities were the sole cause of this increase then surely during the war years, with the shortage of medical practitioners and extreme pressure on existing facilities, there would at least have been a halt in the increase, but this is not the case.

Dr. Fullerton's figures suggest that at St. Olave's Hospital, at least in the years 1950-2, approximately 50% of the actual cases were being diagnosed "ante-mortem," so that undoubtedly extension of pathological services will lead to an apparent increased incidence of pulmonary carcinoma, but nevertheless in addition to this fact it is likely that there has been an increase in the true incidence of carcinoma of the lung.

Might I refer your correspondent Dr. P. H. Cummins (*Journal*, July 7, p. 43), who has questioned the role of cigarette paper, to a recent paper by Cardon and Alvord to the American Association of the Advancement of Science

(abridged in the *Chemical Engineering News*, January 16, 1956, volume 34, p. 224) which shows that when cigarette smoke was drawn through acetone by a smoking machine and analysed the average packet produced 2½ µg. of 3-4-benzpyrene, of which 25% came from the paper and 75% came from the tobacco?—I am, etc.,

Stafford.

H. BINYSH.

Cigarette Smoking

SIR,—While one cannot fail to applaud the representatives of the B.M.A. in their efforts to maintain the health of the nation, one does not agree that cigarette-smoking should be banned, unless it is excessive and involves inhalation.

I do not think we have had any *proof* that the habit is a cause of disease. If nicotine is to be noted as an instance of a drug which is to be banned, what is to be done about tannin? Surely excessive tea-drinking can be quoted as harmful also? The deep and frequent potations of the hard-working charlady if abolished or curtailed would produce severe psychical results, however beneficial to the physical well-being of this valuable worker.

What is the alternative to cigarette-smoking? Chewing-gum? Heaven forbid!—I am, etc.,

London, W.1.

J. HAMILTON MCILROY.

SIR,—In speaking of the evils of heavy smoking, cancer of the lung seems to occupy the stage, but there are other evils of great importance rarely, if ever, mentioned.

I was a heavy smoker for over 50 years, and stopped 4½ years ago at the age of 67 years. I found the following changes for the better: (1) A great improvement in my mental processes, most marked by an ability to make an immediate decision after looking at a matter in all its angles, especially marked in financial matters such as buying and selling stock. (2) An immediate improvement in the state of my digestive tract, which for years had been affected with pains and wind-eructations and at last vomiting every few days of a light green bitter fluid, often about a pint to 1½ pints (0.6 to 0.9 litres) in volume. Indeed, it was the immediate improvement in my digestive system with lack of pain and a revival of appreciation of the taste of food with gain of weight and feeling of general well-being that enabled me to break off the habit at once permanently. (3) At times a feeling of vertigo, especially after morning smoking on an empty stomach. (4) I was fully 35 lb. (16 kg.) underweight for many years and regained it when I stopped. (5) An immediate improvement in my chronic bronchial cough with sputum. But this took about three years to be completely relieved.

Finally, now that they are investigating smoking and its evils in Britain, I feel that all these bad effects and many more (effect on arteries, heart, etc.) should be looked into at the same time.—I am, etc.,

Montreal, Canada.

A. E. BOTSFORD DENOUAN.

Staggered Dumping and Sugar Tolerance

SIR,—In my article (*Journal*, March 31, p. 714) I reported on the radiological signs in a series of patients with dyspepsia referable to distension of the terminal oesophagus and of the pyloric antrum. Common to all was the helical pattern of the mucosal relief observed especially in the second and third parts of the duodenum and in jejunal loops. The appearances on the screen of the meal's passage through the pyloric canal, the duodenum, and the jejunum were compared to loopwise discontinuous cascades and described as "staggered dumping." In conjunction, the observations suggested that the muscularis mucosae acted in these segments as a co-ordinated peristaltic organ, propelling the meal by means of successive and adjoining helical springs. It was further suggested that intermittent mucosal prolapse—into the duodenal cap at the pylorus and upwards into the diaphragmatic part of the oesophagus—could readily be explained as mechanically conditioned side-effects of the helical spring peristalsis at the natural straits of the digestive canal.

To verify the physiological affinity between dumping *en bloc* (post-gastrectomy syndrome) and "staggered dumping" it was decided to determine the sugar tolerance in patients exhibiting the latter syndrome, but no significant deviation from the normal rate of gastric emptying *in toto*. This was done, so far, in six patients, and it was already available in a seventh. Jejunal and duodenal motility was "normal"—according to current radiological standards—except in Cases 1 and 2, in which the rapid filling of the ileum was commented on.

Minutes After Taking 50 g. Glucose	Blood Sugar (mg.%) in Seven Patients with "Staggered Dumping" (1-7)						
	1	2	3	4	5	6	7
0	92	79	85	103	95	80	79
30	134	153	167	360	155	145	127
60	888	231	185	190	190	175	120
90	76	213	124	108	145	135	105
120	76	147	91	90	95	115	57
150	64	102	75		70	75	86
180	64	94	79		60	75	78
210							
240	66						
300	70						
360	64						

The fasting blood sugar was normal in all patients. Hyperglycaemia and glycosuria occurred in four (2, 3, 4, and 5). The occurrence of hyperglycaemia was made probable in another (6) between 30 and 60 minutes (blood presence of sugar in the urine passed at 60 minutes (blood sugar 175 mg.%) but not in the other specimens. In six patients (2, 3, 4, 5, 6, and 7) there was a lag in the return to fasting level. Hypoglycaemia was demonstrated in five patients (1, 3, 5, 6, and 7). One (1) exhibited typical and diurnal hypoglycaemic symptoms between 4 and 7 p.m. The hypoglycaemia was not established in this case by the standard two-hour tolerance test, but it became apparent when Dr. William T. Foley, of New York, carried the test—in keeping with the timing of the patient's symptoms—to 6 hours.

The patient whose blood sugar rose from the fasting 103 to 360 in the first half-hour (4) had had for 30 years, since the age of 20, attacks of sudden faintness with extreme muscular weakness and carried the diagnostic label "Familial periodic paralysis." The major attacks occurred as a rule during a spell characterized by daily episodes of minor degrees of the same symptoms. Some kind of periodic dumping was suggested, apart from the cited tolerance curve and its variability at different times, by the patient's observation that major attacks were usually preceded by gurgling epigastric distension and their passing heralded by gurgling in the abdomen; this, however, and "snake-pit activity" in the lesser degree of weakness which was soon followed by a lesser degree of weakness which would last for several hours and was due, presumably, to would last for several hours and was due, presumably, to reactive hypoglycaemia. I had the chance of seeing him in an acute attack; it came on about ½ hour after a meal, in a blood taken from the cubital vein contained 450 mg.% blood taken from the cubital vein contained 450 mg.% sugar, while sugar was absent in a specimen of urine passed only approximately 8 minutes before.

On preliminary impression, the sugar tolerance in patients with staggered dumping is comparable to the findings in the early and the delayed type of the post-gastrectomy syndrome as reviewed and analysed by W. M. Capper.¹—I am, etc.,

London, W.1.

Treatment of Measles

SIR,—For the past three years I have been in the habit of administering sulphonamides as a routine prophylactic measure in the treatment of measles. I have treated approximately 200 cases in this way and have had no complications. After reading the recent report by the study group of the College of General Practitioners¹ I began to administer antibiotics or sulphonamides only to selected cases with the

indications mentioned in the report. Of the 12 cases treated since reading the report, three were mild cases with no indications and therefore were not given the usual prophylactic sulphonamide (sulphadimidine). Two developed otitis media and the third a residual catarrhal bronchitis. The other nine cases treated as usual with sulphadimidine were uncomplicated.

I realize that my figures would not stand up to examination by a statistician, but I feel that in future I shall be reverting to my old practice of the routine use of a prophylactic measure.—I am, etc.,

Harold Wood, Essex.

C. R. LYNN.

Atypical Weil's Disease

SIR,—Dr. H. R. Miller's letter (*Journal*, July 14, p. 100) raises some interesting points. I agree with him that toxic confusional states are not a rarity in leptospirosis. I can recall several cases occurring in soldiers occupationally exposed in Malaya during the period 1951 to 1954. In these cases it was probably related to severe physical exertion and unavoidable delay in evacuation to hospital. Toxaemia and meningeal irritation aided by anaemia in severe infections might well be the precipitating factors. With regard to jaundice, Trimble¹ states that it only occurred in 3% of cases at that time.

Weil's disease as such was relatively rare. Broom² carried out a serological survey of 200 cases and only found *L. haemorrhagiae* in less than 1%. Over 90% were due to *L. autumnalis* and *L. hebdomadis*.

However, there may still be a case for retaining Weil's name. As Dr. Miller stated, *L. haemorrhagiae* was the first leptospira to be discovered. It may well be that this particular species was the original prototype, and the multiplicity of species and strains now catalogued may have evolved from it. Until this theory is disproved I still have a regard for the term Weil's disease, and, anyway, old names, though not strictly scientifically accurate perhaps, have an affectionate familiar sound. Such names die hard.—I am, etc.,

Taunton.

Abdominal Migraine

SIR,—Regarding the letters recently appearing in the *Journal* on the above subject, may I suggest that the derivation and/or nomenclature of migraine are not clinically important? In fact, they might easily be misleading, or at least be unhelpful in diagnosis.

Sir John Parsons, in a letter to the *Journal* (October 29, 1949, p. 980) replying to a suggestion that migraine might cause permanent scotomata, strongly emphasized that migraine is a symptomatic syndrome, and that the syndrome when complete is unmistakable, but in mild forms only parts may occur. He considered scintillating scotomata the most frequent symptom and doubted a diagnosis without them. I wrote in the *Journal* (November 19, 1949, p. 1177) that, after a great many years' interest in the condition, I did not consider the scintillating scotomata the most frequent sign, but that the bad headaches, feeling of sickness, photophobia, and wishing to rest in a darkened room were the most symptomatic. After seven more years' experience I am convinced that after the headaches the abdominal symptoms are the most pathognomonic of the syndrome, and without any history of such I would be slow in diagnosing migraine. I therefore see every reason to be grateful to Dr. H. G. Farquhar for his able study (*Journal*, May 12, p. 1082).

Two years ago an architect patient of mine found himself away from home in the Midlands one week-end. He had been cured of migraine for 18 months before this. On the Saturday afternoon he was taken suddenly ill with acute abdominal pain, sickness, and prostration. He was rushed

Medical Education

SIR,—Some of Professor G. W. Pickering's remarks (*Journal*, July 21, p. 113) are very disturbing. First, the implication that the introduction of the compulsory year of residence might justify substantial change in the teaching of the students. Does this mean reduction of his clinical teaching?

Even before the pre-registration year was introduced a very large number of the newly qualified did one or two resident appointments, so that a reduction in, for example, dressing and clerking now would mean that for the majority there would in fact be less clinical teaching before a man left the shelter of a hospital appointment. Further, it is almost certainly true that the best students get the best resident appointments in their own hospitals, and the weaker ones have to be content with perhaps appointments in special departments and perhaps with appointments in non-teaching hospitals, in which, at any rate in my experience many years ago, there was practically no instruction.

Those of us who consider it perhaps our highest honour that we are able to be teachers in a medical school have no confusion of mind as to what we are trying to do, nor do we think that our methods differ in principle from those of our forebears. In teaching a man to be a doctor, of course, we teach him about the implications of what he is doing. If he is instructed on how to pass a catheter he can scarcely escape being instructed on what the result may be, and why, and how. I can remember my teacher, the late Dr. James Russell, sitting on the bed of a patient and setting fire to our curiosity and interest in a way that few who have been taught by him have forgotten (1920). It is upsetting that medical scientists joining a medical school to-day should suddenly imagine that these elementary principles of thinking and understanding are something quite new in a medical school. I notice also some confusion of thought in that the arts department in the university considers the medical school badly educated, and the science department thinks that a medical student must be taught how to think.

When I was a student I could not fail to see among my teachers men who were humane, devoted, reliable, and in every way a pattern of what a doctor should be, and I think that there is scarcely any finer education than to work with such men. If I were to suggest a change in the medical curriculum, it would be that we would protect ourselves from it becoming a pure faculty of medical science, and that perhaps we should find a place—as, for example, instead of botany—for some general philosophical instruction, so that a young man might be encouraged to think about his place among his fellow men and in eternity. I am sure that in the world as it exists to-day the thing of the greatest importance is the preservation of the morale of the medical profession.

As to what we propose to produce as a basic doctor, there cannot be much argument about this. It is governed by an Act of Parliament through the General Medical Council, and it is a clinician.—I am, etc.,

Birmingham.

H. DONOVAN.

Artificial Respiration

SIR,—Following a recent visit to England, I am not surprised at the contents of the letter (*Journal*, May 26, p. 1239) by Dr. R. E. W. Fisher concerning artificial respiration in a moving ambulance. The advice he offers on behalf of the chief medical officers of the area gas boards only befits an obsolete state of affairs in relation to ambulance equipment in England.

Several years ago all the civil ambulances throughout the state of Victoria were equipped by the Hospitals and Charities Commission with oxygen resuscitators and suction apparatus. The oxygen resuscitator, known as the "R.M. resuscitator," is a modification of the Oxford inflator with certain improvements. The suction apparatus is worked by simply connecting it to the intake manifold of the engine of the ambulance. So successful has been this type of apparatus that its use by the ambulance crew, apart from any more skilled medical help that may be available, is

now taken for granted, and a long list of impressive "saves" have accumulated over the years. The lives saved have been due either to the apparatus in the ambulance entirely or to the maintenance of life during an asphyxial episode while the patient is being conveyed to hospital in order to receive specialized treatment in the hands of anaesthetists, such as emergency bronchoscopy, etc.

To me it is a paradox that a country like England, which has contributed so much to anaesthetic progress and to whom I am indebted for my own training, should be so backward as regards the installation of suitable oxygen resuscitators and suction apparatus in ambulances.—I am, etc.,

Victoria, Australia.

NORMAN R. JAMES.

Radiation Hazard

SIR,—The holiday season is with us, and during this period many people will, as usual, sustain injuries requiring hospital treatment at long distances from their homes. Many of these will obtain primary treatment at the local hospitals wherever they happen to be, and will be referred back for continuation of treatment in the accident services of the hospitals in the main population centres where they reside.

May I address through your columns an urgent plea to casualty officers, who deal with these cases in the first place, to take the greatest possible care that sufficient and accurate information is transmitted to the hospitals that will be responsible for further treatment? This particularly applies to relevant x-ray films, which should always accompany the patient.

Although the early transmission of x-ray films, which may sometimes have to be sent in the custody of the patient, may give rise to considerable administrative inconvenience, it is surely of primary importance that they should be made available without delay to the surgeon responsible for the care of the case. A very substantial number of x-ray exposures could be avoided if patients' previous x-ray films were always available when they first attend the accident services in their home towns.—I am, etc.,

Rotherham.

H. L. McMULLEN.

Blindness

SIR,—In your annotation (*Journal*, July 21, p. 146) you state: "The largest single cause of blindness is still senile cataract, and this is *par excellence* a remediable condition; yet of those so registered 82% have received no treatment, though some 50% are considered to be amenable to surgical relief."

I have found in many of these old patients that the deterrent is a fear of hospital and not a fear of operation. This fear of hospital would appear to arise in the main from three causes: (1) fear of the unknown; (2) fear of entering an institution where relatives, friends, and neighbours of the same age group have died within the past year or two; (3) fear of losing the home or the room occupied by the patient in the home. In this last case the fear is often justifiable, and I have on many occasions had difficulty in persuading younger relatives to have the older patients back home after a short stay in hospital.

It occurred to me that it might be feasible to take cataract surgery to the patient in cases where the patient refused to come to hospital. Most of the homes are not suitable to operate in, but I thought that a mobile surgical truck could be taken to the patient's home and the operation performed there. I realized that collaboration between the patient, the family doctor, the district nurse, the Institute for the Blind, and the hospital service would have to exist, and I suggested an outline for this scheme to the Institute for the Blind and the regional hospital board in the first place. It is interesting to note the different reactions of these two bodies to the suggestion.

The superintendent of the Institute for the Blind agreed with me. He thought the idea of a mobile surgical theatre was a good one, and in wishing me success in my efforts he said that I could rely upon the utmost co-operation from him. The senior medical administrative officer of the regional hospital board said that the scheme would be

quite unacceptable to the board for many reasons, and that there was no possibility of such a scheme being adopted. I showed this letter to the superintendent of the Institute for the Blind, who expressed great surprise at the general tone of it. He noted that no reasons were given, and he thought that it was very discouraging and frustrating to have a useful proposal turned down in such a summary fashion.

I myself thought that any suggestion which was made to deal with so serious a problem would have received the serious attention of one's medical colleagues at the regional hospital board.—I am, etc.,

Dudley.

L. H. G. MOORE.

Wound Healing

SIR,—I was interested to read the report of the 8th Quarterly Clinical Forum of the Ciba Foundation on wound healing (*Journal*, May 19, p. 1167), particularly in reference to the mechanism of "wound contracture" presented by Mr. M. Abercrombie. In a previous article¹ I have presented quantitative experimental data dealing with restorative processes in mammalian wound healing, with particular reference to contraction in wounds, and it is gratifying to find my conclusions supported by Mr. Abercrombie. It is indeed remarkable that the phenomenon of contraction in wounds receives such passing attention and faulty descriptions in current textbooks of pathology and surgery.

In 1876 Sir James Paget² clearly recognized contraction as a dominant restorative mechanism in the healing of wounds with tissue loss. Paget's descriptions of the healing of external wounds compares more than favourably with current textbooks, and it appears that many of the fallacies underlying current descriptions stem from results on wound healing obtained by an analysis of physical factors involved in the tensile strength of artificially closed wounds. Perhaps the time is ripe to stress that a biological approach to growth mechanisms involved in wound healing demands recognition of a wound as a traumatic loss of tissue, and the basic conception of healing to be a restitution of the spatial deficit with living tissues.

In reference to the mechanism of "wound contracture," Mr. Abercrombie indicates that contracture is "due to the activity of the cellular components of granulation tissue," and again that "contractility—was probably a property common to many members of the fibroblast family of cells." While I am essentially in agreement with the former proposition, experiences based on radiobiological investigations on contraction and other aspects of wound healing fail to support the latter hypothesis. It is well known that cells which undergo active shortening to create tensile forces as an essential physiological function are extremely radio-resistant—for example, smooth, cardiac, and voluntary muscle—and, indeed, huge doses of irradiation require to be administered to interfere with this physiological mechanism. In the rabbit, arterial and arteriolar smooth muscle obliterated *in vivo* in Sandison Clark type ear chambers will tolerate single tissue doses of x or γ rays in excess of 6,000 r without apparent alteration in shortening induced by lished observations). However, I have shown that single doses of irradiation as low as 200 r significantly lengthen the latent period in wound contraction, and decrease the linear rate of contraction in wounds in the rabbit.¹ It has been found that the relationship between the rate of contraction and the dose of irradiation follows an exponential curve (unpublished observations). I have suggested that the mechanism responsible for contraction in wounds is essentially similar to that for growth in general—viz., cell movement or migration—and that the processes of granulation tissue formation and contraction essentially follow the patterns of regenerative growth in lower animals—viz., epimorphosis and morphallaxis respectively. Both of these processes are essentially similar, involving the tactical mechanism of cell movement and reorientation, but differ on a regional basis, depending on the development of axial symmetry in organs

and organisms together with the limitations placed on re-orientation of cell groups and tissues, *en masse*, by exoskeletal and endo-skeletal structures.

It is considered that the spatial reorientation of a cell in growth processes in embryonic and regenerative mechanisms should not be confused with the physiological mechanism of cellular contractility. The changes in protein structure involved in the two processes, based on observed changes in the ultra structure of protoplasmic constituents, show marked differences, and indeed this difference is paralleled by the profound differences in behaviour to tensile gradients and with certain other physical agents, particularly ionizing radiations.—I am, etc.,

Melbourne, Australia.

No Doctor at Sea

SIR,—May I use a little of your space to explain to Dr. R. D. MacLean (*Journal*, May 19, p. 1175) that I omitted all reference to the *International Code of Signals* in my original letter (*Journal*, April 28, p. 981) because I believe it to be, for all practical purposes, defunct. The G.P.O. tells me that the case-stating section of it is never, or hardly ever, used by ships requiring medical advice. The *International Code* was originally intended to overcome language difficulties in international communication, not as a means of abbreviation. For the latter purpose, indeed, it is hardly suitable. My objections to it would occupy too much space to be detailed here, but I have communicated them to the G.P.O., and they say they may consider the matter again.

I agree with the suggestion contained in Dr. MacLean's final paragraph that messages should be dealt with by someone with seafaring experience, but foresee difficulty in arranging this. The volume of traffic is insufficient to support a full-time appointment, and it is unlikely to be easy to arrange 24-hour coverage by local practitioners with the necessary background. Perhaps the easiest solution would be to refer medical advice messages to the nearest naval hospital.

The *Ship Captain's Medical Guide* is already available to the hospitals at present concerned; there would be little point in providing also the *International Code* until shipmasters can be induced to make use of it.—I am, etc.,

Victoria, Australia.

S. J. LLOYD.

Fluoroscopy for Children

SIR,—It is the common experience of most radiologists, as well as physicians, including the paediatricians, that children scream and create trouble during fluoroscopy, however they may be reassured by kind words. Even if the mothers are allowed to stand by the side of their children, it does not allay their fears, as the room becomes dark.

Recently I have tried out the following simple method, and since adopting it the crying of children during fluoroscopy has practically vanished from my hospital practice. It consists in simply asking the child to close its eyes and to open them when commanded by me. The lights of the room are switched off after the child closes the eyes, and are switched on before the child opens them. I think children are afraid of darkness, as well as strange objects and strange persons. As soon as they close their eyes they become oblivious of their surroundings, and immediately become patient and co-operative. I think this method can be employed while taking x-ray pictures of the children.

I am sure this procedure has not been described by any radiologist nor is it mentioned in any works on radiology, including standard works like *Textbook of X-ray Diagnosis* by British authors.¹ It will be interesting to know if any of your readers have had a similar experience.—I am, etc.,

Bombay, India.

M. V. CHOKSI.

Obituary

R. J. McCONNELL, M.Ch.

Mr. R. J. McConnell, consulting surgeon to the Royal Victoria Hospital and to the Ulster Hospital for Women and Children, Belfast, died at his home at Belfast on July 22. By his death the Belfast Medical School has lost one of its best-known and most popular consultants. He was 72 years of age.

Owing to the early death of both his parents, Robert John McConnell was brought up with the family of his uncle, Mr. (later, Sir) Thomas McConnell, and was educated at Bedford Grammar School and Queen's University, Belfast. After graduating M.B., B.Ch. in 1912, he became demonstrator in anatomy under Professor Johnson Symington and passed the primary examination for the Fellowship of the Royal College of Surgeons of England at the first attempt. While he was working in the anatomy department he made a special study of the gall-bladder and bile ducts and read a paper on the subject at the meeting of the British Anatomical Society in Glasgow.

The first world war interrupted McConnell's studies, and with his friends, S. R. Foster and Harry Malcolm, he joined the R.A.M.C. and served in France with the 59th North Midland Territorial Division. In 1916 he was invalided home with trench fever and was sent as a patient to the Ulster Volunteer Force Hospital, Belfast, and on discharge from the hospital became its house-surgeon for the later years of the war. But he never completely overcame the war legacy of illness. After demobilization he returned to the serious study of surgery and by obtaining the degree of M.Ch., with distinction, qualified himself for a hospital appointment in Northern Ireland. A period of service as clinical assistant in the Ulster and the Royal Victoria hospitals was soon followed by appointments to the surgical staffs of both these hospitals, and to both of them he gave faithful service till the age of retirement. A member of the British Medical Association for nearly forty years, he served as a vice-president of the Section of Orthopaedics, Including Treatment of Fractures, when the Association held its Annual Meeting at Belfast in 1937.

Mr. S. T. IRWIN writes: R. J. McConnell began his consultant work at a time when it was still considered respectable to be a general surgeon, and so, although perhaps he paid most attention to the abdomen, he had a wide acquaintance with the surgery of the other regions. When the British Orthopaedic Association met in Belfast in 1927 he made a considerable contribution to the meeting on the subject of club foot. In both his hospital appointments he gave much time to teaching and his classes soon became popular, especially with final-year students. He was at his best with a small class around the bed or when discussing a case with his assistants over a cup of tea. He disliked large audiences and could rarely be persuaded to speak at public meetings. This reticence prevented him from accepting the presidency of several medical societies which he was offered, and he refused to become chairman of staff in either of his hospitals. He had a wide and accurate knowledge of surgical literature. His retentive memory, coupled with his dexterity and power of anticipation, made him an invaluable surgical assistant in his earlier years. No apology need be made for recording his gallantry in the devastating air raid of May 4, 1941. On that particular night he was on duty at the Ulster Hospital when it was almost completely demolished by explosive and incendiary bombs. He

worked with the casualties throughout the night in the midst of fires and falling masonry, and in the morning drove members of the nursing staff to the homes of friends through streets littered with debris. He received an official commendation for his brave conduct. He was most at home in his own unit in the Royal Victoria Hospital. This unit was perhaps the happiest and certainly the most attractive to resident pupils, house-surgeons, and nurses, to whom he showed the greatest consideration at all times. He was adored by all his patients, whether they were children in the Ulster Hospital or adults in the Royal. To him the interest of the patient was always of prime importance. In his student days and for some years after he was a keen sportsman. He rode in point-to-point races, played golf and Rugby football. But when he gave these up he adopted photography as his hobby, an art in which he made himself an expert. When cine-films in colour were introduced he became interested in this aspect of photography, and had a very considerable collection. These included weddings in the families of his friends, operations, and foreign scenes, but perhaps his best-known film was an amusing skit on the Smith-Petersen operation. This was indeed a masterpiece, and has been widely shown to visiting medical societies in Belfast. Apart from his professional work, perhaps his greatest interest was in reading. He was a voracious reader, and his nightlight was rarely extinguished before 2 a.m. He had an extensive library, mainly historical and biographical, and almost to the end of his days he remained the student. It would be true to say that for a period of 30 years no member of the Belfast Medical School enjoyed to a greater extent than "Bobby John," as he was known to colleagues and students alike, the confidence of the general practitioners of the province or was more beloved by successive generations of medical students.

DORIS GORDON, M.B.E., M.B., F.R.C.S.Ed., D.P.H.

Dr. Doris Gordon, who did much to stimulate public opinion on the progress of obstetrics, particularly in New Zealand, died recently at Stratford, Taranaki, New Zealand. She was 65 years of age.

Doris Clifton Jolly, the daughter of Mr. Alfred Jolly, general manager of the National Bank of New Zealand, was born in Victoria, Australia, but went to New Zealand with her family in 1894. She was educated at Otago University, graduating M.B., Ch.B. from the University of New Zealand in 1916. Later she obtained the D.P.H. After graduation she held an appointment on the medical staff of Dunedin Hospital, and was lecturer in bacteriology in 1916-17. In the latter year she married Dr. W. P. P. Gordon, and in 1918 they set up in practice at Stratford.

Dr. Doris Gordon devoted the whole of her professional life to the problems of maternity and child welfare. The arguments she used in a thesis written in 1924 helped to form the basis of the New Zealand Government's maternity service scheme. Under the scheme every primigravida became entitled to a fortnight in hospital free of charge, together with the best available medical attention and the use of analgesia in childbirth. She was always a staunch advocate of the use of chloroform, about which she had many differences of opinion with her professional colleagues, including the late Sir Truby King. She was director of the Maternal and Infant Welfare Health Department in New Zealand from 1946 to 1948.

In 1925 Dr. Gordon became the first woman from Australasia to obtain a Fellowship in any Royal College. In that year she was elected F.R.C.S.Ed., her husband being admitted to the Fellowship also at the same ceremony. When the British (now Royal) College of

Obstetricians and Gynaecologists was founded in 1929 she was elected a founder Member, becoming a Fellow in 1937. On the occasion of the silver jubilee celebrations of the College in 1954 she was awarded honorary Fellowship in recognition of her distinguished services to obstetrics and gynaecology in her own country, and in particular for being instrumental in obtaining funds for the endowment of a chair at Dunedin. She organized an appeal in 1930 which produced over £30,000. She was also responsible for the foundation in 1927 of the New Zealand Obstetrical and Gynaecological Society. She was appointed M.B.E. in 1935. Her autobiography, *Backblocks Baby Doctor*, was published last year. Dr. Gordon is survived by her husband and the three sons and one daughter of the marriage.

W. POINTON DICK, M.R.C.S., L.R.C.P.

The obituary of Dr. W. Pointon Dick was printed in the *Journal* of August 4 (p. 305).

Dr. A. J. HAWE writes from Kumasi, Gold Coast: W. Pointon Dick's decision in 1952 to accept the post of tuberculosis specialist in the Gold Coast was probably influenced by the knowledge that his father, Dr. W. B. Dick, had practised medicine there some decades earlier. Pointon Dick found the disease to be widespread and dreaded by patients and relatives alike. The condition had earned such an evil reputation that fear and often panic followed its diagnosis. He was the best possible choice for the task of combating tuberculosis in the Gold Coast and threw himself into the work with great energy. By establishing treatment centres and using mass radiography and tuberculin surveys he was able to bring help to those areas where it was most needed. The work was very strenuous and demanded great physical exertion and much travelling. His friendly attitude and kindness to his patients soon won him popularity, and his success in the treatment of patients—often with advanced disease—established his reputation and raised the morale of the population. It is largely due to his work that patients in the Gold Coast no longer regard the diagnosis of tuberculosis as tantamount to a sentence of death. His passing will be mourned all over the extensive territories where he laboured so hard. It is pleasing to know that the Prime Minister of the Gold Coast has requested that the tuberculosis wards in the Gold Coast Hospital shall be named "The Pointon Dick Memorial Wards," and so help to perpetuate his name.

Dr. D. F. WHITAKER died suddenly at his home at Guildford on August 1 at the age of 56. Donald Faraday Whitaker was born on July 17, 1900, the son of the late Sir James Smith Whitaker, the first Medical Secretary of the British Medical Association. Receiving his medical education at University College Hospital, he qualified M.R.C.S., L.R.C.P. in 1926, and then held the appointments of house-surgeon at Hampstead General Hospital and house-physician at the Seamen's Hospital, Greenwich, before he settled in general practice at Guildford early in 1929. For a time he was also assistant anaesthetist to the Royal Surrey County Hospital, and later became out-patients medical officer to the physiotherapy department of the hospital. In his home life as a youth Dr. Whitaker must have heard many references to the British Medical Association, of which his father was Medical Secretary from 1902 to 1912. A member of the Association since 1930, he came to prominence in the affairs of the B.M.A., both centrally and locally, immediately before the outbreak of the second world war. He was honorary secretary of the Guildford Division from 1938 to 1944; its representative at the Annual Representative Meeting on several occasions from 1938 to 1954; and its chairman in 1951-2. It was perhaps appropriate that in 1953 Dr. Whitaker should become a member of the Constitu-

tion Committee of the Association, which was set up in that year to review the Association's constitution, because his father was a member of the Constitution Committee appointed by the B.M.A. in 1900, the establishment of Divisions within the Branches of the B.M.A. being among the recommendations of that committee. Dr. Whitaker also served on a number of other B.M.A. committees, including the General Medical Services Committee, the Joint Formulary Committee, the Central Ethical Committee, and the Protection of Practices Committee. During the second world war he acted as emergency officer for Guildford and was honorary secretary of the local medical war committee. Since the introduction of the National Health Service he had served on the Surrey Executive Council and on the Surrey Local Medical Committee, of which he had been chairman since 1953, having become vice-chairman in 1951.

Dr. NOEL E. WATERFIELD writes: The news of the sudden death of Donald Whitaker from coronary thrombosis has been received by his colleagues with profound sorrow and regret. For many years while engaged in a very busy practice he gave up a considerable part of his leisure time to the service of his colleagues in the profession. We in Surrey have particular grounds for gratitude for his work as chairman of the Surrey Local Medical Committee. He filled this post with conspicuous success, and by his wise interventions kept members to the point, soothed ruffled tempers, and helped the committee to arrive at wise decisions. His presence on the Surrey Executive Council and its many committees, where he was equally respected, did much to maintain friendly relations between the practitioners in Surrey and the council. Many of us have lost a good friend and the profession generally a wise counsellor.

Dr. M. K. JOHNSTON died in Yardley Green Hospital, Birmingham, on July 19 at the age of 53. Munro Kennedy Johnston was born on September 18, 1902, the third of four sons of the Rev. William Johnston, of Troon, Ayrshire. After graduating M.B., Ch.B. from Glasgow University in 1930, he began his career as a psychiatrist at Stoneyetts Mental Hospital, Glasgow. He then held an appointment at the Mansfield and District Hospital from 1931 to 1933. In 1935 he became medical officer at Brookwood Hospital, Surrey, where later he was promoted to deputy medical superintendent. He obtained the D.P.M. of the English Royal Colleges in 1936. Joining the R.A.M.C. in 1939, he served throughout the second world war until 1945, attaining the rank of major, and for some time was in charge of Rudolf Hess, from whom he elicited valuable information about the German war effort. After the war he was appointed consulting psychiatrist to the Staffordshire County Council, but in 1947 he contracted pulmonary tuberculosis, from which he died after a prolonged illness. Dr. Johnston's friendliness and modesty and his keen sense of humour made him a charming companion. He is survived by his widow and three daughters. One of his brothers is Dr. Lennox Johnston, of Wallasey.

Dr. T. B. COSTELLO, one of the oldest medical practitioners in Ireland, died at Tuam, Co. Galway, on July 14 at the age of 92. Thomas Bodkin Costello was born at Tuam in January, 1864. After leaving the local school of the Christian Brothers, he was apprenticed to his uncle, Dr. Nicholas Mahon, of Galway, and later studied medicine at the former Queen's College, Galway, and the Carmichael Medical School, Dublin. He graduated M.D. from the old Royal University of Ireland in 1888, and took the D.P.H. of the Irish Royal Colleges in 1906. Shortly after graduation he became dispensary medical officer on the island of Lettermore, Co. Galway, where he was the only doctor for many miles around. With no qualified nurses or midwives to help him and with the nearest hospital and dentist both 40 miles away, his early life as a doctor called for physical strength and endurance almost as much as it did for professional skill. His area included a number of islands off the coast of Galway, and to reach them he used a currach, in all weathers. He left Lettermore to

Sir Francis Fraser has been elected a representative of the University on the governing body of Queen Elizabeth College.

Professor M. A. Rushton, M.D., F.D.S.R.C.S., and Professor F. C. Wilkinson, M.D., F.D.S.R.C.S., have been appointed representatives of the University on the General Dental Council set up under the Dentists' Act, 1956.

Professor W. J. Hamilton has been appointed representative of the University on the governing body of Charing Cross Hospital, in place of Sir John Stewart-Wallace.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

CH.M.—H. Bolton.
FINAL M.B., CH.B.—R. Abendstern, M. B. Bailey, J. H. E. Baines, A. T. Battle, J. R. D. Bedford, K. Boothby, R. Brown, A. J. Burkhardt, K. N. Butteriss, D. H. Carroll, G. E. Clews, M. J. Conway, A. J. Cook, F. B. Cookson, R. Crowther, Janet M. Dawson, J. M. Dickey, Hazel M. Fearn, S. B. Foulds, Elisabeth D. Hahn, T. M. Hardiker, A. Harris, Mary Heald, G. D. Hunt, Barbara Y. Hutchinson, Maureen P. Kenmare, J. A. Lee, J. D. Lece, A. H. Levy, J. B. Lynch, J. D. McLean, I. W. Manson, C. S. Mellor, R. Michaels, R. Millon, Elizabeth A. M. Parkes, P. B. Parnaby, B. L. Poston, A. J. Ralston, Jean Rowley, Felicity H. Sambrook, G. B. Seddon, Jean Shackleton, D. Smith, Rita Smith (distinction in surgery), Patricia V. Sutcliffe, Margaret M. Sutherland, W. R. Swinburn, W. F. White.
DIPLOMA IN PUBLIC HEALTH.—F. R. Calvert, Marjorie T. Dare, Mary S. Gilbody, Katie Keane, G. A. Levell, Joan M. MacCarthy, L. G. Nicol, Geraldine T. O'Carroll, J. D. Willis.

UNIVERSITY OF WALES

The following candidates at the Welsh National School of Medicine have been approved at the examination indicated:

M.B., B.Ch.—Hannah M. Beddow, June M. Birch, D. H. Blackall, B. K. Bondzi-Simpson, P. Coy, D. Daley, D. E. Davies, I. A. Davies, J. A. Dodge, J. G. Elias, A. G. Evans, D. H. Evans, D. J. Griffiths, M. F. Holding, D. S. B. James, Enid P. Jarvis, R. A. C. Jones, W. J. Jones, Sheila B. Kidd, G. S. Lodwig, W. S. B. Loosmore, R. G. Penn, G. A. D. Rees, G. E. Roberts, Marise E. Roch, Joan M. Summerell, W. G. Thomas, G. L. Williams, J. M. Williams, Margaret D. Wyatt.
With distinction in pathology and bacteriology. With distinction in social medicine and public health. With distinction in surgery. With distinction in forensic medicine and toxicology. With distinction in medicine (including psychological medicine) and child health.

UNIVERSITY OF BIRMINGHAM

Professor A. B. MacGregor, F.D.S.R.C.S., M.B., B.Chir., has been appointed representative of the University on the General Dental Council set up under the Dentists' Act, 1956.

The title of the Department of Pharmacology and Therapeutics has been changed to the Department of Medical Biochemistry and Pharmacology.

The title of the post held by Dr. C. R. Lowe has been changed from Lecturer in Public Health to Lecturer in Social Medicine.

The title of University Research Fellow in Medicine has been given to Dr. H. A. V. Muth and in Surgery to Dr. J. F. Nunn, both holders of research posts financed from the Teaching Hospital Endowment Research Fund.

Dr. F. Letemendia has been appointed Research Fellow in the Department of Experimental Psychiatry.

In Congregation on June 30 the following degrees were conferred:

M.D.—J. M. Bishop, R. H. Gosling, J. A. Litchfield.
Ph.D.—In the Faculty of Medicine: J. S. Knight, H. J. Yardley.
M.B., CH.B.—G. Cumming, Margaret J. Darch, C. T. Dollery, W. A. Lishman, M. E. Abrams, W. W. Alderman, R. M. Baddeley, Lavinia J. Bailey, N. C. Bhandari, M. H. Bletcher, V. A. W. Blunt, D. G. Boddington, P. H. Boyle, A. R. Brathwaite, A. Brickman, Mary Burman, Cecilia H. Butt, Margaret A. Calver, D. Carling, Kathleen M. Cash, G. W. Chance, J. Cockin, M. A. Cole, T. L. D. V. Dhupa, T. C. Dixon, D. Evans, C. J. Garrett, J. Gelson, P. H. D. G. W. Hollands, Barbara L. Hooker, J. S. Horner, R. P. Jordan, R. A. Margat, J. Kelly, Maria J. Kielbinka, M. R. Landeg, A. J. Lyne, A. N. Mitra, J. P. Neasham, R. I. Patel, G. Phillips, F. J. Pickworth, Jennifer M. Radford, J. M. Rolfe, P. A. Roxburgh, S. O. Schandorf, H. G. Schroeder, P. R. Seed, E. M. Skinner, B. S. Smith, Jacqueline J. Speake, P. A. J. Starr, J. Steinert, D. A. Stephens, Gillian H. Stillwell, J. R. Taylor, A. L. Thomas, I. D. Thompson, R. O. Walker, J. W. D. Windsor, H. O. Wooller, A. Wootton, D. Wright.
With honours. With second-class honours. Distinction in surgery. Distinction in medicine. Distinction in pharmacology and therapeutics. Distinction in social medicine. Distinction in pathology and bacteriology. Distinction in obstetrics and gynaecology. Distinction in paediatrics and child health. Distinction in forensic medicine and toxicology.

The following scholarships, etc., were awarded in the Faculty of Medicine: *Queen's Scholarships*.—Final year, G. Cumming; Fifth year, Marigold J. Parsons; Third year, J. Herbert. *Ingleby Scholarships*, W. A. Lishman (obstetrics and gynaecology), R. O. Walker (paediatrics and child health). *Special Undergraduate Scholarships*, I. A. O. D. Brodie, E. F. Evans, D. Gompertz, J. D. Hamer, J. Herbert, J. A. Hickman, P. H. W. Rayner, A. G. Ringer, B. Stone, N. R. Whiting. *Arthur Foxwell Memorial Prize in Clinical Medicine*, Sampson Gamgee Memorial Prize

in Surgery, Beckwith Whitehouse Prize in Obstetrics and Gynaecology, and Douglas Marsh Ear, Nose, and Throat Prize. G. Cumming. *Joseph Sankey Prize in Clinical Surgery*, J. Cockin and Margaret J. Darch (divided). *Queen's Hospital Joseph Sampson Gamgee Prize in Surgery*, A. D. Barnes. *Cyril Raison Prize in Surgical Diseases in Children*, H. G. Schroeder. *Russell Memorial Prize in Nervous Diseases*, W. A. Lishman. *Priestley Smith Prize in Ophthalmology*, G. S. Willetts. *Leith-Newman Prize in Pathology (Medical)*, Marigold J. Parsons. *Bostock Hill Memorial Prize in Social Medicine*, Edwina E. Rogerson. *Peter Thompson Prize in Anatomy*, P. Hicken.

In Congregation on June 30 the following degrees were conferred:

M.D.—J. M. Bishop, R. H. Gosling, J. A. Litchfield.
Ph.D.—In the Faculty of Medicine: J. S. Knight, H. J. Yardley, H. Saha (in absentia).
M.B., CH.B.—G. Cumming, Margaret J. Darch, C. T. Dollery, W. A. Lishman, M. E. Abrams, W. W. Alderman, R. M. Baddeley, Lavinia J. Bailey, N. C. Bhandari, M. H. Bletcher, V. A. W. Blunt, D. G. Boddington, P. H. Boyle, A. R. Brathwaite, A. Brickman, Mary Burman, Cecilia H. Butt, Margaret A. Calver, D. Carling, Kathleen M. Cash, G. W. Chance, J. Cockin, M. A. Cole, T. L. Cooksey, D. R. Cowman, M. D. Cox, D. R. Cumpsty, B. W. Davis, D. V. Dhupa, T. C. Dixon, D. Evans, C. J. Garrett, J. Gelson, P. H. Grant, C. P. Gray, P. M. Green, I. F. G. Haddow, Ethel J. Harris, D. G. W. Hollands, Barbara L. Hooker, J. S. Horner, R. P. Jordan, R. A. Jupe, J. J. Kelly, Maria J. Kielbinka, M. R. Landeg, A. J. Lyne, Margaret J. McBroom, F. E. McGuinness, N. M. C. Mayne, S. Mesbah, A. N. Mitra, J. P. Neasham, R. I. Patel, G. Phillips, F. J. Pickworth, Jennifer M. Radford, T. M. Rolfe, P. A. Roxburgh, S. O. Schandorf, H. G. Schroeder, P. R. Seed, E. M. Skinner, B. S. Smith, Jacqueline J. Speake, P. A. J. Starr, J. Steinert, D. A. Stephens, Gillian H. Stillwell, J. R. Taylor, A. L. Thomas, I. D. Thompson, R. O. Walker, J. W. Warburton, G. S. Willetts, C. W. O. Windsor, H. O. Wooller, A. Wootton, D. Wright.

With honours. With second-class honours. Distinction in medicine. Distinction in surgery. Distinction in pharmacology and therapeutics. Distinction in social medicine. Distinction in pathology and bacteriology. Distinction in obstetrics and gynaecology. Distinction in paediatrics and child health. Distinction in forensic medicine and toxicology.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—D. J. B. Ashley, K. Baker, D. B. Mossman, W. R. Parkes, R. H. Roberts, J. Winter, V. Wright.
M.B., CH.B.—R. D. Gartside (with second-class honours and distinction in surgery), V. S. D. Logan (with second-class honours and distinction in obstetrics and gynaecology), D. J. Weatherall (with second-class honours and distinction in surgery), J. M. Abbott, Erika M. Adler, E. O. O. Arbener, J. S. Bamforth, T. J. Barnett, R. F. Beckett, H. Bodsworth, P. Boggiano, B. F. Bracewell, Pauline M. Carruthers, R. Carruthers, M. D. B. Clarke, M. C. Crocker, N. Dale, H. Dinnick, W. Durrant, I. R. Entwistle, D. G. Evans, Jean M. Fell, C. Gallagher, Patricia E. Gaughan, A. F. Gilbertson, Sheila M. Griffin, Mary C. Hardicker, A. A. M. Hardy, Margaret O. Harrison, B. J. Hawe, G. Hughes, I. W. Hughes, Jarvis, Doris Johnson, Doreen E. Jones, K. Jones, Marjorie, V. Jukes, J. Kelly, A. Kennedy, A. Kirby, Margaret A. W. Kneale, P. C. Lawson, Shirley A. Leslie, K. Longstaff, B. W. McGuinness, D. P. Manning, T. W. Murphy, June Nelson, Nora M. Norris, Heather B. Nunnerley, Margaret M. O'Kane, T. A. O'Malley, Pauline M. B. Park, D. Parker, A. Patterson, G. W. Pennington, Ruth M. Poland, D. J. Pollock, Shona H. Russell, Dorothy E. M. Speed, D. Sykes, C. A. Veys, B. A. Walker, R. A. Walmsley, R. S. Walton, D. S. Williams, Marguerite J. Williams, N. E. Williams, R. D. Williams, J. G. Winwick (with distinction in obstetrics and gynaecology), P. Worthington, J. E. Wright, Ann C. Young.
DIPLOMA IN PUBLIC HEALTH.—H. P. Burrows, D. M. Cameron, B. Didsbury, Mary P. Haran, E. M. Hughes, D. L. Lewis, T. F. McElligott, A. McGregor, Mary A. R. Marshall, L. A. Nettleton, C. W. R. Pyne, Esther M. E. Ramsay, Myfanwy R. H. Roberts, K. P. Sivam, T. D. Thomas, Sheila M. Tyrrell, Megan E. Wilkinson.

DIPLOMA IN RADIOLOGY.—Radiodiagnosis: H. J. J. Beyleveld, R. S. Miller, V. Rogers, M. C. Winter. Radiotherapy: B. Lall, S. H. M. Zaidi.

UNIVERSITY OF SHEFFIELD

The following full-time appointments are announced: Dr. G. Weber, Senior Lecturer in Biochemistry; Dr. G. C. Bates, Demonstrator in Anatomy.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on July 12 Professors and Lecturers for the ensuing year were appointed as follows:

Hunterian Professorships.—Sir Hugh Poate, one lecture; Dr. Raymond Greene, one lecture on the diagnosis, pathology, and treatment of discrete nodules in the thyroid gland; Mr. D. F. Ellison Nash, one lecture on congenital spinal palsy—the management of incontinence; Mr. Robert Cox, one lecture on the management of dysphagia due to malignant disease of the thoracic and abdominal oesophagus; Mr. J. I. P. James, one lecture on paralytic scoliosis; Mr. Myer Makin, one lecture on the surgical management of Friedreich's ataxia; Mr. F. J. Gillingham, one lecture on the management of ruptured intracranial aneurysm; Mr. Edwin Haigh, one lecture on the acute abdomen in neonates;

Professor A. K. Saha, one lecture on zero-position of gleno-humeral joint—its recognition and clinical importance; Mr. A. A. Jefferson, one lecture on pituitary chromophobe adenomata and Rathke pouch cysts; Mr. H. J. Shaw, one lecture on radical surgery in laryngopharyngeal cancer—some problems in perspective; Mr. R. T. Turner-Warwick, one lecture on the lymphatics of the breast in relation to the spread of carcinoma and its treatment.

Arris and Gale Lectureships.—Professor G. W. Causey, one lecture on cytological investigations with the electron microscope; Mr. P. P. Rickham, one lecture on the metabolic response to neonatal surgery; Mr. D. G. Walker, one lecture on facial development.

Erasmus Wilson Demonstratorships.—Dr. G. T. Allen, Dr. F. C. Chesterman, Dr. L. W. Proger, Dr. A. J. M. Reese, Dr. H. G. H. Richards, and Dr. J. B. Walter, one demonstration each.

Arnott Demonstratorships.—Miss Jessie Dobson, Mr. B. E. Greenfield, Professor R. J. Last, Dr. R. McP. Livingstone, Dr. Frank Stansfield, and Dr. B. D. Wyke, one demonstration each.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on July 24, with the President, Sir Stanley Davidson, in the chair, the following were elected Members of the College:

J. A. W. McCluskie, E. G. Oastler, J. B. Rennie, I. Gordon, S. A. A. Sabry, G. K. Laxton, C. Freed, H. Singh, W. Davies, B. J. Kelly, K. K. Sinha, A. P. Poole, H. T. W. Jayasekara, D. O'Brien, J. C. Little, B. O. Mulvihill, L. G. Young, B. Dhar, H. Samy, F. Bakir, E. N. Coleman, B. W. Subhivah, J. Ghosh, C. F. H. Vickers, J. Crooks, R. G. Brackenridge, S. E. Levin, J. F. L. Aldridge, I. R. Ferguson, S. M. Rab, H. M. S. Hamidi, G. P. Crean.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on July 11, with Sir Walter Mercer, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

M. M. Abu-Sittah, R. B. Baluch, M. L. Blaggana, W. G. Bowes, M. N. Ellis, R. M. Gibson, J. D. Green, B. Hammar, A. A. Hooper, D. W. H. Hurley, W. F. Kerr, W. G. Lucas, K. A. McCluskey, I. McKechnie, I. K. Mikhail, R. B. Patil, H. Roberts, D. E. Rothery, R. Shanon, D. T. Thompson, W. G. Thomson, J. C. Wardill, G. I. Young.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the College held on June 6, Dr. A. M. Cantor was admitted to the Membership and Henry K. Takyi was admitted to the Licence of Medicine and Midwifery.

The following candidates were duly admitted Licentiates in Medicine and Midwifery on June 25, having passed the final examination in medicine, surgery, and midwifery of the Conjoint Board of Ireland:

R. Allaye, Mary C. I. Brady, D. S. T. Breen, H. A. A. Brown, S. Collins, R. T. W. L. Conroy, P. I. Coyle, M. M. Davies, V. R. Devan, Columba Devlin, J. E. Dignan, G. E. Edwards, R. A. Falkiewicz, R. K. Gilbert, A. L. Greenburgh, T. M. Griffin, C. L. Huang, G. C. Inerfield, Agnes E. Jackson, G. Kay, Orla M. Kiernan, S. Lal, Ann Leahy, Phyllis M. May, C. L. Mootoo, Eileen J. Mulligan, Moira T. M. McMahon, Deirdre M. O'Phelan, T. J. Quinn, K. A. Rahimulila, L. Raymond, J. R. Harper-Smith, A. H. Smithen, J. Szeps, R. Weinberg.

ROYAL COLLEGE OF SURGEONS IN IRELAND

On July 6 J. O. M. C. Craig was conferred with the Fellowship of the College and H. K. Takyi was conferred with the Licence of the College.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have satisfied the examiners at the examination for the Diploma in Industrial Health:

S. K. Biswas, A. J. de Villiers, P. S. Edgecombe, D. I. C. Finlayson, J. R. Glover, A. S. Sethi, M. Zeville.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on July 28 the following officers were re-elected: *Honorary Librarian*, Mr. A. J. McNair; *Honorary Curator of the Museum*, Mr. R. A. Brews; *Honorary Treasurer, Australian Regional Council*, Mr. J. N. Chesterman; *Honorary Treasurer, Canadian Regional Council*, Mr. G. A. Simpson; *Honorary Treasurer, New Zealand Regional Council*, Mr. J. E. Giesen.

The following were admitted to the Membership: Margaret B. Malloch, C. F. Macdonald.

The following candidates were elected to the Membership:

L. A. Aller, A. Bates, R. G. Blair, Tara B. Borker, G. L. Bourne, Nancy I. Cardno, E. Cassar, W. Chanen, P. A. Deck, J. N. De Villiers, J. A. G. Dunlop, J. P. Hendrickse, B. M. Hibbard, R. A. St. C. Hoyte, Elsie S. Jaikaran, P. J. Joubert, A. M. Kelso, A. W. Laughland, D. W. Leslie, Cecilia M. Liggins, G. C. Liggins, E. M. Little, J. D. O. Loudon, P. C. McAuliffe, Clara J. McFarlane, Marion C. Miller, S. Nan, W. J. O'Sullivan, S. W. Page, J. K. P. Perera, N. A. Regan, Kathleen J. Rennie, P. Rhodes, D. W. T. Roberts, I. D. Ronayne, A. O. Sankey, H. H. A. Sauer, T. Schneider, J. S. Skipper, T. S. Train, N. W. F. Weir, A. J. Woolf, Janet W. Worling.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examination, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glasg.:

M. N. Birsell, Cho-Man Chung, J. F. Corr, A. Dasen, R. G. FitzPatrick, E. T. T. Hu, P. Jago, J. P. King, G. M. Lorde, I. F. Lundy, K. S. Pauw.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

In the list of new Members of the College, printed in the *Journal* of August 4 (p. 311), the name of Dr. I. J. McKelvie, of Queensland, was mis-spelt "McGelvie."

ROYAL AUSTRALASIAN COLLEGE OF SURGEONS

The following, having satisfied the Court of Examiners, were admitted to Fellowship of the College by the Council on June 23:

E. L. G. Beavis, J. H. Brown, J. K. Clarebrough, D. S. Cole, T. A. R. Dinning, W. G. Doig, P. C. Grayson, G. L. Grigg, I. A. Harris, L. L. Hoare, L. C. Hudson, G. R. Jones, N. W. Kinny, J. M. Langham, W. J. McCann, H. K. McComb, T. P. Nash, R. K. Newing, E. D. Smith, A. A. Tye, G. W. Westlake, R. F. Zacharin.

Vital Statistics

Week Ending July 28

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 573, whooping-cough 2,388, diphtheria 3, measles 3,270, acute poliomyelitis 160, dysentery 843, paratyphoid fever 25, and typhoid fever 4.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations of the infectious diseases in England and Wales in the week ending July 21 were a rise of 154 for whooping-cough from 2,404 to 2,558, and a fall of 179 for dysentery from 1,149 to 970. Measles notifications fell by 25 from 3,276 to 3,251, and scarlet fever rose by 16 from 514 to 530. Notifications of acute pneumonia rose by 11, from 210 to 221.

Notifications of whooping-cough rose by 20 in Cheshire from 58 to 78, by 32 in Essex from 174 to 206, by 20 in Kent from 70 to 90, by 51 in Lancashire from 357 to 408, by 26 in Nottingham from 74 to 100, and by 25 in Surrey from 44 to 69; they fell by 31 in Derby from 76 to 45 and by 22 in Durham from 90 to 68. Notifications of measles increased by 51 in Cornwall from 124 to 175, by 70 in Lancashire from 435 to 505, by 22 in Oxford from 44 to 66, and by 38 in Southampton County from 73 to 111; they fell by 42 in London from 329 to 287, by 32 in Essex from 213 to 181, and by 54 in Norfolk from 162 to 108.

The main centres of dysentery were Lancashire 104 (Salford C.B. 11), Leicester 67 (Market Harborough U.D. 22), London 138 (Lambeth 16), Rutland 18 (Uppingham R.D. 18), Staffordshire 55 (Smethwick C.B. 27), Warwickshire 77 (Coventry C.B. 63), and Yorkshire West Riding 158 (Leeds C.B. 39).

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 21 (No. 29) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

B.M.A. Visit to Russia.—The B.M.A. delegation which is visiting Russia at the invitation of the president of the U.S.S.R. Academy of Sciences (see *Journal*, July 7, p. 53) left London Airport on August 4 on their journey to Moscow.

Chairs of Surgery at Edinburgh.—Appointments are announced to both the Regius Chair of Clinical Surgery and the Chair of Surgery at Edinburgh University. Both are at present combined in the person of Sir JAMES LEARMONTH, who is due to retire on September 30. The QUEEN has appointed Mr. JOHN BRUCE, vice-president of the Royal College of Surgeons of Edinburgh, to the Regius Chair of Clinical Surgery, and the University announces the appointment of Professor M. F. A. WOODRUFF, Ralph Barnet Professor of Surgery at Otago University, New Zealand, to the University Chair of Surgery, which is to be renamed the Chair of Surgical Science. Mr. BRUCE graduated, with honours, at Edinburgh in 1928, and held a succession of surgical appointments at Leith Hospital and the Royal Hospital for Sick Children and the Royal Infirmary, Edinburgh. He served with distinction in the R.A.M.C. during the second world war, being mentioned in dispatches twice in the campaigns in Norway and Burma, and being awarded the C.B.E. while acting as consulting surgeon to the 14th Army. Mr. Bruce's present appointments include those of lecturer in surgery and applied anatomy at Edinburgh University, and surgeon-in-charge of the general surgical and gastro-intestinal units at the Western General Hospital. He is also president of the section of surgery of the Royal Society of Medicine, and author of numerous papers on surgery. Professor WOODRUFF, who emigrated from London to Australia at an early age, began by graduating in electrical engineering, with first-class honours, at Melbourne University. He then abandoned engineering for medicine, graduating M.B., B.S. at Melbourne in 1937 and later proceeding M.D. and M.S. During the world war he served with the Australian Army Medical Corps in Malaya, being a prisoner of war for most of the time. After his release he wrote an account of deficiency diseases in Japanese prison camps which the Medical Research Council printed in its *Special Report Series* (No. 274). He then returned for a short time to Australia, being first assistant at the Royal Melbourne Hospital. In 1946 he was appointed a tutor in surgery at Sheffield University, and two years later he became senior lecturer in surgery at Aberdeen University. During his tenure of the latter post he was awarded a W.H.O. travelling fellowship and a Hunterian professorship of the Royal College of Surgeons of England. In 1952 he was appointed to his present chair at Otago University. Sir JAMES LEARMONTH became professor of surgery at Edinburgh in 1939 and regius professor of clinical surgery in 1946.

Manufacture of Poliomyelitis Vaccine.—Extremely detailed requirements for the manufacture and testing of inactivated poliomyelitis vaccine came into operation on August 1 under the Therapeutic Substances Amendment Regulations, 1956 (S.I. No. 1131 of 1956, H.M.S.O., price 3d.). The provisions, which deal among other matters with the inspection of manufacturers' records, ingredients to be used or avoided in making the vaccine, preservatives, antibiotic content, methods of inactivation and its testing, sampling and safety tests, certification, and labelling, are given in a Schedule of 16 paragraphs. The last of these reads: "Poliomyelitis vaccine shall not be issued for sale combined with any other material without the consent of the licensing authority."

Radon from Coal.—Two workers from the physics department of the Institute of Cancer Research report in the July 28 issue of *Nature* (p. 203) the results of their

analysis of 10 samples of coal from different coalfields in Britain for their radium content. They find that the radium contents of the coals are in a "narrow range of values," and conclude that "the absence of levels of a higher order suggests that the contribution of radon from this source does not represent a significant addition to the total atmospheric level."

Demand for Cleaner Air.—The Chief Inspector of Alkali (and other) Works records in his annual report for 1955 (H.M.S.O., price 2s.) an increased number of complaints against registered works. This was not due to deteriorated conditions, he states, "but to a greater public awareness of the desirability for cleaner air due to the publicity this has received." During the year there were 21 occasions when "escapes" in excess of the statutory limits were recorded, and a further 27 "infractions related to failure to 'use best practicable means.'" In every case notification of an infraction was followed by appropriate steps being taken to abate the nuisance. Inspectors carried out 3,894 visits and inspections during the year. The report includes a section by the chief inspector for Scotland. Among the industrial processes discussed in the report are coke and gas production, metallurgical processes, lime burning, alkali production, cement making, smelting, production of sulphuric and nitric acids, manufacture of chemical manures, and processes involving lead.

Local Authorities and B.C.G.—Not all local authorities have yet taken power to offer B.C.G. vaccination to 13-year-old schoolchildren, it is stated in a circular letter from the Ministry of Health to local authorities, dated July 27. The letter draws attention to the fact that the first report of the Medical Research Council's committee on tuberculosis vaccines (see *Journal*, February 25, p. 413) "shows that vaccination offers a substantial degree of protection when given to children of this age," and goes on to recommend those authorities which have not already done so to take the necessary powers to vaccinate school-leavers. Those authorities which have not so far used these powers to the full are urged to intensify their efforts. A model form of proposal which would provide for the extension of B.C.G. vaccination to others besides the school-leavers is suggested to authorities in the circular. It reads: "The council will also make arrangements to offer B.C.G. vaccination to any other classes of person as may be approved from time to time by the Minister of Health."

Admission of the Press.—Among the public bodies included in the schedule of the Public Bodies (Admission of the Press to Meetings) Bill are regional hospital boards and executive councils. The Bill, which was introduced in the House of Commons on August 1 under the 10-minute rule by Mr. J. E. S. SIMON, Conservative M.P. for Middlesbrough West, provides for the admission of the press to the meetings of certain bodies exercising public functions. It retains the right of such bodies, on a majority vote, to exclude the press temporarily if the public discussion of an item of business is deemed not to be in the public interest. The Bill also provides for the supply to the press of documents concerning meetings "not later than the document is sent to the members of such public body," with again a saving clause in the case of documents whose public disclosure is considered inadvisable. Another section empowers the Government, after consultation with the interested parties, to extend the provisions of the Bill to bodies not already scheduled. Apart from Mr. Simon, the sponsors of the Bill include six Conservatives, four Labour members, and one Liberal.

British Team for Latin America.—A British cardiac surgery team, consisting of a surgeon, a cardiologist, and an anaesthetist, left for Latin America on August 8 under the auspices of the British Council, where they will give demonstrations and lectures to medical audiences in Brazil, Uruguay, Chile, and Colombia. The members of the team are Mr. T. HOLMES SELLORS (Middlesex Hospital),

To answer the specific questions: (1) A routine chest radiograph will detect at a very early stage a carcinoma starting peripherally in the lung, especially if there is a previous radiograph available for comparison. Rare exceptions to this rule may be encountered, if the growth starts in a part of the lung not visible in the commonly used radiological projections—for example, in the posterior costophrenic sulcus, behind the hilar shadows, and in the medial part of the left lower lobe behind the heart shadow. Carcinomata starting in the main bronchi give rise to no radiological shadows until they cause sufficient bronchial obstruction to lead to changes in the lung beyond the obstruction. These may take the form of atelectasis if the obstruction is complete, or of inflammatory consolidation, either massive or patchy, if the obstruction is partial. In order to detect a carcinoma of a large bronchus, not yet causing complete obstruction, bronchoscopy is necessary; and even this can give no information about certain inaccessible bronchi. In the left upper lobe, only its division into upper and lower divisions can be seen and none of the segmental orifices of the upper division are visible in any circumstances; and in the right upper lobe only the actual

orifices of the segmental bronchi are visible. It is difficult to assess the probable value of routine chest radiographs. Certainly symptoms may appear before x-ray shadows are evident, and in many cases where the disease has come to light as the result of routine radiography careful inquiry will show that there have in fact been some suspicious symptoms.

(2) If routine radiography is to be relied upon for a really early diagnosis of bronchial carcinoma, frequent examinations will be necessary. It would be futile to suggest examinations at intervals of more than three months, for in three months a rapidly growing carcinoma can become inoperable. For a complete survey, right and left oblique and lateral views would be desirable.

(3) The only other way of detecting early lung cancer is bronchoscopy; and this should be regarded as complementary, rather than alternative, to radiography. Perhaps the prospect of three-monthly bronchoscopy might be used to discourage the desire to continue smoking.

Diaphoretics in Paediatrics

Q.—What place have diaphoretics in the treatment of infants and small children? Are they ever indicated in the ordinary febrile complaints of infancy and childhood? What preparations are advised for those infants and children who vomit preparations containing aspirin?

A.—Diaphoretics seem to have disappeared entirely from use in the modern treatment of children's diseases, as a result presumably of the effectiveness of antibiotic and chemotherapeutic drugs in those conditions where prolonged high fever used to occur. It may safely be said that diaphoretics are never required in the treatment of ordinary febrile complaints, but that if some drug is required to lower the temperature then aspirin is the first choice. It is now available as calcium aspirin in so many non-irritating preparations that it is worth trying a different preparation if a child vomits ordinary aspirin.

Strangulated Hernia on Board Ship

Q.—How should a ship surgeon, with limited equipment and surgical experience and no skilled assistance, treat a case of strangulated hernia?

A.—If the hernia has been strangulated for less than six hours an attempt at reduction by taxis should be made. The patient should be laid down with the feet raised and after half an hour reduction should be attempted. If reduction is impossible operation must be undertaken. This would best be done under local analgesia, the essential point being to relieve the strangulation.

In an inguinal hernia the constriction may be at the external inguinal ring or at the neck of the sac. In the former instance reduction will occur as soon as the external oblique is incised from the external abdominal ring and the sac need not be opened. If the constriction is higher, the whole length of the inguinal canal must be opened up, the sac opened, and the constricting neck incised by a pair of scissors, the operator making sure that the vessels of the spermatic cord are pushed aside. The external oblique should be repaired and the skin wound closed.

In the case of a femoral hernia the strangulation is nearly always caused by the rigid margins of the femoral ring. By blunt dissection the medial margin of the sac should be followed up until the reflected portion of the inguinal ligament (Gimbernat's ligament) can be felt. With a small scalpel this can be nicked, care being taken to avoid the sac. The sac should then be opened and its contents reduced. Occasionally a tight neck of the sac requires cutting with scissors. After reduction the sac should be ligated at its base and cut off, and the skin sutured.

A short course of penicillin should be given, and the patient advised to have a radical repair when circumstances permit.

NOTES AND COMMENTS

Prolonged Constipation in Children.—Mr. H. REID, F.R.C.S. (Liverpool), writes: Your expert gave a very clear and adequate account of the treatment of constipation in children ("Any Questions?" May 19, p. 1187). His opinion on the use of the proprietary form of standardized senna which he mentioned is in conformity with an increasing number of members of the medical profession. When, however, liquid paraffin is recommended, we are uneasy. As long ago as 1942, a leading article in the *Lancet*¹ made four important points: (1) A considerable amount of liquid paraffin finds its way from the intestine to the liver and viscera. (2) Liquid paraffin renders the recto-sigmoidal "valve" incompetent, and permits continual leakage of a mixture of oil and faeces into the rectum. (3) In patients with rectal lesions... healing is more rapid when liquid paraffin is avoided. (4) Liquid paraffin in the bowel may interfere with absorption in the small intestine both by hurrying the food along and by coating the mucosa. Since then other writers of eminence have written about the way in which liquid paraffin interferes with absorption of vitamins. A recent annotation in the *Journal*,² on the treatment of constipation, incriminates liquid paraffin as a cause of lipid pneumonia and as an obstacle to the absorption of fat-soluble substances such as carotene and to the healing of wounds. In these days of economy in prescribing, I should like to make one other point—namely, that the biologically standardized form of senna which you mention is cheaper by half than paraffin, is far easier to dispense, and there is no wastage of storage space.

REFERENCES

- ¹ *Lancet*, 1942, 1, 656.
² *British Medical Journal*, 1956, 2, 36.

OUR EXPERT replies: Liquid paraffin is certainly feeling the swing of the pendulum, and, like many useful and comparatively harmless drugs, is being brought into disfavour by being prescribed too frequently and in too large a dosage. Mr. Reid's comments certainly apply to paraffin when given in excessive amounts and in surgical conditions; but, if prescribed with discrimination and in small quantities, it seems completely harmless and to be of value. The neostigmine mixture recommended in my answer has been in use for many years, and over long periods, with no ill effects. The actual cost of two drams (7 ml.) of liquid paraffin daily, and of a tablet of the biologically standardized preparation of senna ("senokot") daily, is about one penny a week in either case.

Intragastric Oxygen for Asphyxia Neonatorum.—Dr. D. MORRIS (London) writes: Could I bring to your notice an omission in your answer to the use of intragastric oxygen for asphyxia neonatorum ("Any Questions?" July 7, p. 55)? In answer to the specific question, "What apparatus is advised for use in general practice?" we have designed and described¹ a small portable apparatus for use in general practice, and it is now being used by district midwives and general practitioners.

REFERENCE

- ¹ Waller H. K., and Morris, D., *Lancet*, 1953, 2, 951.

OUR EXPERT replies: I owe Dr. David Morris an apology for forgetting his adaptation of the Sparklet apparatus, made by Messrs. Sparklets, at a price of six guineas, for supplying intragastric oxygen. It sounds as if this should be a very handy apparatus for giving intragastric oxygen. The apparatus is one that is now used by many general practitioners and midwives for supplying oxygen to the mother or baby through a face mask. To adapt it for giving intragastric oxygen, all that is required is a special connecting piece, costing 2s., the catheters, and tubing.

Correction.—In a news paragraph (July 21, p. 185) which mentioned a forthcoming conference at the National Physical Laboratory on the "Direction of Research Establishments" it was wrongly stated that Sir Harold Himsworth, F.R.S., would be among the speakers.

HYPOTHALAMIC SYNDROMES*

BY

I. S. WECHSLER, M.D.

Clinical Professor of Neurology, Columbia University, New York

My interest in clinical manifestations of coma dates back to the epidemics of encephalitis, then called lethargic, which accompanied and followed the world-wide epidemic of influenza after the first world war. Among the varied clinical expressions of the encephalitides was a peculiar type of coma then called vigil. It usually set in fairly acutely and persisted unaltered for days or weeks and even months, sometimes ending in death, at others in seeming recovery only to be followed in certain instances months or years later by a Parkinson syndrome. The coma differed from the usual type. The eyes were frequently open, the eyeballs wandered and gave the erroneous impression that the individual was in contact with his environment. He might turn his head from side to side as if in response to sounds which he evidently did not hear. There were no signs of paralysis of the limbs. Characteristic in many cases was such profuse perspiration, often oily, as to require frequent change of bedclothes. Calling the coma vigil was the usual way of giving classical names to conditions which escaped explanation, in the vain belief that to coin a word or phrase is to create a scientific fact.

Case 1.—A few years after the acute epidemics had spent themselves a girl of 18 was admitted to the Montefiore Hospital with the complaint of obesity, of inversion of the sleep mechanism, and of grave sexual moral lapses. There was a history of acute encephalitis. Previously normal in her behaviour, she now began to show symptoms of nymphomania. She would immodestly accost men and overtly express uncontrollable sexual urge, entirely out of keeping with her previous moral and ethical behaviour. The diagnosis of pituitary obesity was made but never proved. The suspicion of a hypothalamic syndrome, which could now be entertained in retrospect, was not even considered at that time. All we knew then was that in the diencephalon there was a corpus Luysi and a mammillo-thalamic bundle of Vicq d'Azyr.

Case 2.—Also in the early 1920's a man was admitted to the hospital with the main complaint of hypothermia. His temperature fell as low as 94° F. (34.4° C.) and persisted unchanged for several weeks. One day it rose to 99° F. (37.2° C.). The acute rise of 5° F. (2.8° C.), the local signs, and the leucocytosis led to the diagnosis of acute mastoiditis. A mastoidectomy was done, and the temperature fell back to 94° F. (34.4° C.) as he made a comparatively rapid recovery. He died some time afterwards. At post-mortem examination a middle-fossa tumour was found impinging on the interbrain area.

Case 3.—At about the same time I saw a man at the Mount Sinai Hospital in the terminal stages of general

*Lecture delivered at the National Hospital, Queen Square, London, on May 31, 1956.

paresis. Several weeks before his death he developed severe polydipsia and polyuria, taking in and putting out many litres of water daily. Obviously an intercurrent diabetes insipidus. At post-mortem examination, in addition to the typical pathology of paresis, a discrete gumma was found perching on the tuber cinereum. The diabetes insipidus apparently was the result of the gumma.

Case 4.—Some years later I saw in the hospital a young woman with diabetes insipidus who was taking in six litres of water daily and putting out as many. She responded neither to pitressin nor to other treatment. A review of the history showed that for some time before the onset of the polydipsia she was treated for severe ethmoiditis and sphenoiditis. The question arose whether she might not have had secondary to the infection of the sinuses a basilar pachymeningitis which impinged on the interbrain region and pressed on the tuber cinereum. This was a purely clinical impression or guess based on the observation of the diabetes insipidus in the paretic and the gumma found on the tuber cinereum. Since it is known that radiation by means of deep x rays can have a beneficial effect on chronic inflammatory tissue, the radiation was directed from both sides of the skull to the interbrain area. After a few treatments, and no medication, the diabetes began to lessen and finally cleared completely.

On rare occasions a comatose patient would be seen with the diagnosis of a cerebral ictus the result of vascular thrombosis or haemorrhage. The history was generally of an acute onset in an individual with marked hypertension and evidence of arteriosclerosis. The coma was not like the usual type. There would be striking pallor, unexplained rise in temperature, and frequent perspiration. The patient would lie quietly, sometimes with eyes open, but there was no hemiplegia or other sign of regional involvement of the brain. There was no difference in response to pin-prick on the two sides. The fundi would be normal, except for evidence of sclerosis of the retinal arteries. The rise in temperature would be unaccompanied by the usual parallel rise in pulse rate. Very characteristic would be a sharp drop in the systolic blood pressure from, say, 200 systolic or higher to as low as 100, the pressure remaining low throughout the course of the illness. Generally the coma would deepen and the patient would die within days or weeks. The fever would be unaccompanied by leucocytosis and heightened sedimentation rate. If, as occasionally happened, the patient recovered there would remain no residual paralysis, sensory disturbances, visual field defects, or aphasia.

It is of interest that a sharp drop in blood pressure is often seen in apoplexies obviously the result of closure or rupture of a large cerebral vessel. The pressure

might continue low for a considerable period of time or rapidly return to the pre-ictal level. As time went on the conjecture approached conviction that the type of coma, the variation in blood pressure, the pallor, the sweating, the unexplained fever, and the absence of signs of paralysis all pointed to the hypothalamic region.

Case 5.—In 1938 I reported two cases diagnosed as epilepsy (a word which I should like to see discarded or very strictly limited) with grand-mal and petit-mal seizures (Wechsler, 1938). One was that of a middle-aged woman who sustained a fracture of the base of the skull when thrown from a speeding automobile. She recovered from the acute injury in a comparatively short time but then began to have typical grand-mal seizures. These were controlled by phenobarbitone. At the same time minor seizures, occurring twenty and more times daily, and showing the following characteristics, began to appear. They set in with a feeling of apprehension and a fleeting loss or orientation; she became extremely pale and complained of palpitation; her blood pressure dropped from 150 systolic to 90, and the pulse rose from 80 to 120 and as high as 150 beats a minute. Every seizure was marked by very slight impairment of consciousness, the pallor, the drop in pressure and increase in pulse rate, and would last one to three minutes. They failed to respond to treatment. Based on Penfield's description in 1929 of diencephalic autonomic epilepsy, the thought occurred that the woman's seizures reflected diencephalic features. In Penfield's case there was suffusion and rise in pressure as opposed to the pallor and fall in pressure, also with little impairment of consciousness. Reasoning that pallor and suffusion and rise and fall in pressure and variation in pulse rate are opposite manifestations of the regulatory mechanisms, the conclusion seemed justified that the woman also suffered from diencephalic seizures. Recalling too that catalepsy, which probably is hypothalamic in nature, responds favourably to ephedrine or amphetamine, the former was prescribed. She promptly ceased to have the seizures and remained free till her death several years later from an unrelated cause. Of interest is the fact that a stimulating drug was effective where the depressant drugs usually prescribed in convulsive states had no effect. This observation of both clinical and pharmacological importance in the treatment of certain petit-mal seizures was confirmed by Lennox in 1945.

Case 6.—The other case, in brief, was that of a woman of 24 who suffered from grand-mal seizures and from bizarre minor seizures up to twenty times by day and night. The minor spells were characterized by a sudden cry, waxy pallor, a drop in blood pressure, a rise in pulse rate, and loss of consciousness. Each seizure lasted one to two minutes. They set in one year before she came under observation in 1937 with irregularity of menstruation and loss of libido. Occasionally a spell would begin with sudden rigidity, momentary fall, and no loss of consciousness, reminiscent somewhat of catalepsy and cataplexy. There was a history of loss of consciousness sustained in an automobile accident at the age of 6 and of influenza (possibly encephalitis) the year before the onset of the present illness. She failed to respond to all the usual sedative drugs. Ephedrine promptly brought about marked improvement. The attacks did not cease altogether, but were reduced in intensity and in number from twenty a day to three or four. Interestingly, the libido returned.

Before proceeding with further description of cases, some of which have been previously reported, and cautiously correlating the clinical manifestations with hypothalamic dysfunction, it may be well to discuss briefly the anatomy, physiology, and pathology of the diencephalon.

Anatomical Considerations (Wechsler, 1953)

The very small hypothalamus, estimated by LeGros Clark (1938) to weigh about 4 g., presumably integrates directly and

indirectly a great many vital functions: pulse and respiratory rate, temperature and blood-pressure regulation, vasomotor control, water and possibly sugar and fat metabolism, sleep and abnormal states of consciousness, sex function, and states of elation and depression. The following, taken from Ingram, is a brief description of the nuclear organization and chief connexions of the primate hypothalamus:

I. Afferent Connexions.—(1) The median forebrain bundle probably from the frontal lobe. (2) Thalamo-hypothalamic fibres: (a) thalamo-mammillary fibres, (b) relay of somatic and visceral sensory impulses of the hypothalamus. (3) The fornix, from the hippocampus to the mammillary and other nuclei. (4) The stria terminalis from the amygdala. (5) The supraoptic commissure. (6) Pallido-hypothalamic fibres. (7) Subthalamo-hypothalamic connexions, including presumed cortical fibres of undetermined pathways via the thalamus.

II. Efferent Connexions.—(1) Hypothalamo-thalamic fibres, including the mammillo-thalamic tract. (2) Mammillo-tegmental. (3) Paraventricular system. (4) Hypothalamo-hypophyseal connexions: (a) supraoptic hypophyseal, (b) paraventricular-hypophyseal, and (c) tubero-hypophyseal.

III. Intrathalamic Connexions.—There is considerable evidence, some of it inferential and some direct, that just as the hypothalamus activates other parts of the brain so do brain and brain-stem regions activate the diencephalon, among them the ascending activating reticular system described by Magoun (1952), the centrifugal projections to the brain stem (Jasper, Ajmone-Marsan, and Stoll, 1952), and the centrencephalic system of Penfield (1952).

IV. Arterial Supply of the Hypothalamus.—Small branches from the anterior cerebral artery as it comes off the internal carotid at its junction with the anterior communicating artery go to the paraventricular nuclei and the preoptic and supraoptic regions. Branches from these arteries, from the internal carotid, and from the posterior communicating artery supply the tuber cinereum. Small branches from the posterior cerebral arteries supply the mammillary bodies.

Physiological Considerations

That the hypothalamus integrates or correlates or possibly controls so many metabolic and visceral functions and has to do with sleep, with emotional expressions, and with states of consciousness is one of the most interesting aspects of cerebral physiology. That such a small structure directly or indirectly regulates water, fat, and sugar metabolism, vasomotor activity, blood pressure, pulse and respiratory rate, and sex function is of great clinical importance. In this region apparently are locked secrets which when fully revealed will help to solve many as yet obscure problems in clinical medicine.

Ranson and Magoun have shown that the hypothalamus influences *cardiovascular activity*. Electrical stimulation caused rise in blood pressure, depending on the location of the electrode and the frequency of stimuli. The hypothalamus, it seems, does not control or regulate the circulatory system but can modify it, as can a chemical agent, an emotional reaction, and environmental stimulus, or a temperature variation.

There is ample evidence, both clinical and experimental, that the hypothalamus has to do with *temperature regulation*. In the cat, the monkey, and man, lesions in the neighbourhood of the anterior commissure are likely to produce transient hyperthermia, while lesions in the caudal part of the hypothalamus are apt to cause hypothermia. It has been shown that all of the brain in front of the hypothalamus can be removed without seriously affecting the nervous regulation of temperature. *Sweating*, too, appears to be regulated by the hypothalamus. It apparently influences *pilomotor* activity with other manifestations of fear, rage, and sexual excitement, all also under the control of the

cerebral cortex. Barbour concluded that injury to cats by transection of the posterior hypothalamus, caudal to the tuber cinereum, deprives them of the power of regulating body temperature against cold. Destruction of the mammillary bodies and the mammillo-thalamic tracts results in hypothermia and bradycardia, whereas lesions in the mid-portion of the upper mammillary tract result in hyperthermia, tachycardia, and pilo-erection. Davison, Zimmerman, and Alpers have adduced clinico-pathological evidence of disturbance of temperature regulation by lesions in or near the hypothalamus. In 1943 Beaton and his co-workers discussed neurogenic hyperthermia, often euphemistically labelled as fever of unknown origin. This fever is not accompanied by signs of infection, is not characterized by sweating, leucocytosis, or heightened sedimentation rate and rapid pulse, and does not respond to antipyretics but may to barbiturates, particularly sodium thiopentone, which presumably have effect on the hypothalamus. This type of fever, often very high, is occasionally seen post-operatively in brain tumours and may lead to a fatal termination.

While regulation of *carbohydrate metabolism* is essentially the result of the activity of the anterior pituitary, the result of the activity of the pancreas, there is evidence of hypothalamic control. Indeed, the paraventricular nuclei have been considered as "centres" of carbohydrate metabolism. Ingram (1946) found hypoglycaemia as the result of lesions in the anterior hypothalamus and destruction of the paraventricular nuclei. The hypothalamus has been related functionally to the thyrotropic and gonadotropic activities of the adenohypophysis.

Water and Fat Metabolism and Sex Regulation as Functions of the Hypothalamus

Diabetes insipidus has been produced by destruction of the supraoptic hypophyseal system. While polydipsia is a consequence of polyuria, which is dependent on the absence of diuretic substance, puncture of the hypothalamus has been shown to cause polyuria. Obesity (and genital atrophy) have been reported as the result of trauma to the diencephalon. An adiposo-genital syndrome has been produced in a dog by a lesion in the hypothalamic area. There is clinical and experimental evidence that bilateral lesions in the hypothalamus and the tuber cinereum, without injury to the hypophysis, may result either in obesity or in emaciation. The two recorded clinical cases of diabetes insipidus were, in retrospect, correctly attributed to involvement of the tuber cinereum.

Though sex function is regulated essentially by hormonal activity, there is evidence of influence on gonadotropic hormones via cortico-thalamic-hypothalamic pathways. There is also some evidence that section of the diencephalon may exert influence on the capacity of female cats to display sexual excitement. However, full pattern of oestral behaviour can be obtained in cats after complete destruction of the middle or caudal portions of the hypothalamus. The nymphomania of the girl with obesity previously described becomes understandable in the light of present knowledge. As for other regions, there is the report of uncontrollable sexual desire in a woman of 60 as one of the symptoms of a paracentral lobe meningioma, and that of a religious young woman who displayed uninhibited ardent sexual urge as one manifestation of a large frontal meningioma. Both were relieved of their ardour after successful removal of the brain tumours.

Gastro-intestinal activity apparently is in part a function of the lateral and mammillary regions of the hypothalamus. Stimulation of those regions can inhibit peristalsis. In 1934 Watts and Fulton reported the occurrence of intussusception on ablation of the cortex in monkeys. They thought that the impulses travelled via the hypothalamus may cause gastro-tumours injuring the hypothalamus may cause gastro-intestinal haemorrhages and perforating ulcers. I have observed abdominal syndromes simulating appendicitis, renal colic, and duodenal ulcer as manifestations of brain tumours (Wechsler, 1935).

Sleep

Sleep and its relation to the hypothalamus has been the subject of numerous investigations which brought understanding as well as confusion. The impression has gained currency that the diencephalon is the centre of sleep and the seat of consciousness. One may seriously question the first and successfully contest the second (Wechsler, 1952). At best the diencephalon is one important relay station where states of consciousness are integrated and lesions of which can bring about in varying degrees alterations of a negative state called unconsciousness. Sleep is a negative not a positive state; it is absence of consciousness. We are not dealing with entities or faculties or specific localizations, but with relative states expressive of varying degrees of impairment of integration.

Normal sleep is believed to be the result of decreased activity of the hypothalamus, hypersomnia of depression of function, and insomnia and excitement of increased activity. The regions implicated are the paraventricular nuclei, the floor of the third ventricle, and the tuber cinereum. Apathy and unresponsiveness, akinesia, and catalepsy have been attributed to lesions of the mammillary bodies and the hypothalamic portions of the mammillo-thalamic tracts. Rasmussen and his co-workers have produced catalepsy and somnolence by damaging structures in the neighbourhood of the mammillary bodies. Ranson observed that bilateral destruction of the lateral hypothalamic areas in monkeys caused somnolence. Hess (1944, 1947) described adynamia on stimulation of the lateral and anterior regions of the hypothalamus. Patton, Ruch, and Walker (1944) found that lesions in the ventral postero-medial nucleus of the thalamus resulted in immobility, catalepsy, and somnolence. The electroencephalographic changes induced by lesions in the upper mammillo-thalamic tract paralleled sleep records.

Whereas the posterior portion of the human hypothalamus causes somnolence, stimulation of the anterior portion causes restlessness, euphoria, excitement, and mania. Penfield induced manic excitement during operation for tumours in the region of the hypothalamus. While tumours of the third ventricle frequently cause somnolence and stupor, psychotic manifestations can also occur. I once saw a young patient with conduct and behaviour disorders as the outstanding manifestation of a craniopharyngioma, and complete recovery following its removal. Akinetic mutism, a state of inertia with the eyes open, has been described by Cairns, Oldfield, Pennybacker, and Whitteridge (1941).

Manifestations of the Syndromes

Before summarizing the clinical hypothalamic syndromes a brief description of a few cases showing the variety of manifestations may be of interest.

Case 7.—A man in the early fifties who suffered from hypertension suddenly complained of loss of vision in that he could not recognize what he saw. Within a few minutes he lost consciousness and was promptly admitted to hospital. There he lay quietly, pale, eyes open, the eyeballs wandering. There was no evidence of paralysis of the limbs; the cranial nerves appeared normal, and so were the fundi and the spinal fluid. He lingered practically unchanged for weeks, life being maintained first by tube then by intravenous feeding. Death resulted from starvation. The onset of cortical blindness pointed to basilar artery thrombosis at its bifurcation into the posterior cerebrals, the coma vigil to hypothalamic involvement by occlusion of the branches from the posterior cerebrals to the hypothalamus.

Case 8.—A man aged 61, a known hypertensive, suddenly went into coma in March, 1944. Seen three days after the ictus, he lay quietly, pale, eyes open, pulse normal, temperature elevated; he gave no responses, showed no hemiplegia or other signs of focal involvement; the spinal fluid was normal, and the blood pressure had dropped to normal from 180 systolic and 110 diastolic. He regained consciousness in a few days and rapidly recovered without residual

signs and symptoms. Except for the return of his hypertension he was well and working up to the time of his death in 1946 from acute coronary occlusion. The type of coma, the absence of focal signs, the drop in blood pressure, the rise in temperature without corresponding rise in pulse rate, the pallor, and the complete recovery without residua, suggested hypothalamic involvement on a vascular basis.

Case 9.—A woman of 62 with a history of controlled diabetes and moderate hypertension rapidly went into coma without premonitory symptoms. She lay with eyes open, was restless, looked very pale, and perspired profusely; the blood pressure was low, the pulse 120 a minute, the temperature 98° F. (36.7° C.). There were no signs of paralysis. She died two weeks after the acute onset. The type of coma, the marked pallor, the subnormal temperature, the drop in blood pressure, the rise in pulse, the profuse perspiration, the restlessness, and the total absence of paralysis all pointed to hypothalamic localization.

Case 10.—A man aged 50 developed, quite rapidly, fever which ranged from 103.6 to 104.8° F. (39.8 to 40.5° C.). He became disoriented, then comatose, restless, and incontinent. He was extremely pale; the blood pressure dropped from 138 systolic and 70 diastolic to 116 and 50 respectively; the spinal fluid showed 50 mononuclear cells. On one occasion the urine contained 3% sugar and the blood 158 mg. per 100 ml. He showed marked variation in temperature uncorrelated with equally marked variations in pulse and respiration, and perspired so profusely as to require frequent daily changes of pyjamas and bed sheets. There were no gross signs of regional involvement of the brain or brain stem, and he recovered in four weeks. The high fever, the variations in pulse rate and respiration without parallelism, the type of coma, the restlessness, the pallor, the temporary glycosuria and hyperglycaemia, the profuse sweating, the absence of paralysis, and the recovery without residua pointed to hypothalamic involvement in the course of encephalitis.

Case 11.—In 1946 Gross and I reported the case of a boy of 10, first seen in 1944, who showed repeated paroxysmal attacks of hypothalamic dysfunction, with intervals of comparative well-being, since the age of 2 (Wechsler and Gross, 1946). They were generally ushered in by loss of appetite, vomiting, rise in blood pressure to as high as 170 systolic and 130 diastolic, rise in temperature to 104° F. (40° C.) and fall to 94° F. (34.4° C.), lethargy, excessive salivation, vasomotor imbalance, profuse perspiration, and absence of lacrimation. The attacks generally lasted several days. During an interval of comparative well-being he suddenly died at home and permission for necropsy was not obtained. Engel and Aring (1945) reported a very similar case with necropsy findings showing hypothalamic involvement.

Summary

In summarizing the conclusions a word of warning against hasty interpretation is necessary because much of our present knowledge of the structure and function of the hypothalamic region is derived from experimentally induced lesions. The various structures and their connexions are not yet precisely defined. While experimental lesions can be more or less accurately placed, pathological lesions the result of brain tumours, vascular disease, or inflammatory processes are rarely sufficiently circumscribed to permit accurate correlation. Too many contiguous structures may be affected and distant connexions impaired to warrant positive conclusions. Furthermore, most of the physiological experiments and the anatomical studies deal with lower animals, and it is a little hazardous to apply the conclusions, however carefully drawn, to more complex human structures and human functions. Some of the objections have been met by experiments on primates and more recently by accurate studies and direct observations on humans.

There is also the pressing need to bear in mind the injunction of Hughlings Jackson, so often violated, not to draw false conclusions from negative evidence or from symptoms attributed to destroyed structures. A word of avowal of ignorance, really a defensive confession and apology, is in place to meet the just criticism of drawing clinical conclusions in the absence of positive evidence furnished by careful studies of pathological lesions. This communication is merely an attempt to suggest the correlation of clinical symptoms with disturbance of function with such anatomy and physiology of the hypothalamus as we know to-day.

In summary, the hypothalamic coma differs from the usual coma in that there is no evidence of paralysis or of other signs of regional involvement of the brain and brain stem. It may rapidly end fatally or persist unchanged for long periods of time. Generally it terminates in death, but if recovery takes place no residua are present. Among the symptoms observed may be mentioned a sharp drop in blood pressure in known hypertensives and temporary fluctuation in either direction where no previous hypertension existed. With the coma may alternate restlessness, excitement, and unconscious sexual manifestations. Excessive perspiration may occur in the absence of fever. There may be quickening or slowing of the pulse for no apparent reason. Fever, often high, of cerebral origin, may be seen in the absence of infection and without parallel rise of pulse rate. In other words, there is dissociation between fever, pulse rate, and blood pressure. The fever is not accompanied by its usual manifestations of leucocytosis, sweating, and heightened sedimentation rate, and does not respond to the usual antipyretics. It may respond to barbiturates, especially sodium thiopentone, which appear to have some selective affinity for the diencephalon. Polydipsia and polyuria—that is, transient or persistent diabetes insipidus—may occur from involvement of the tuber cinereum. Transient glycosuria or hyperglycaemia may occur in non-diabetics. Occasional petit-mal autonomic diencephalic seizures and, more rarely, grand-mal attacks may also occur.

The prognosis varies with the underlying cause. Generally it is very grave. In vascular disease it is poor, but recovery may take place. In tumours in or near the interbrain the outlook depends on the possibility of surgical removal; generally it is hopeless. In inflammatory conditions—namely, encephalitis—recovery may take place after weeks and weeks provided excitement can be controlled and nutrition maintained.

COARCTATION OF THE AORTA

BY

W. P. CLELAND, F.R.C.S., M.R.C.P.

T. B. COUNIHAN, M.D., M.R.C.P.

J. F. GOODWIN, M.D., M.R.C.P.

AND

R. E. STEINER, M.B., F.F.R.

From the Departments of Surgery, Medicine, and Radiology of the Postgraduate Medical School of London and Hammersmith Hospital

Since the introduction of radical surgical treatment for coarctation of the aortic arch by Crafoord and Nylin (1945) and by Gross (1945), the operation has been widely performed and in experienced hands the mortality of the operation has been reduced to below 10%.

We have carried out a survey of 52 patients (34 males, 18 female) with coarctation who have been under the care of one or other of us, paying particular attention to the natural history of the disease and to the effect of resection upon its various features in 40 of them.

The Clinical Series

The patients' ages ranged from 1 to 55 years (Tables I and II). Of the 40 patients who had resection (see also Diagram) all were aged under 40, and no fewer than 25 were 15 years or older. Of the 12 patients who did not have surgery, 6 were aged over 40 when last seen, but 3 of these have died, the oldest at the age of 55 (Table I).

Mode of Discovery

It is well known that coarctation is often remarkably symptomless (Lewis, 1933; Bramwell, 1947), and 43 of our cases were diagnosed during medical examinations carried out for reasons unrelated to the coarctation. Nine patients presented with symptoms referable to the coarctation. In two of these symptoms were due to dissecting aneurysm of the aorta. Two others had general symptoms due to subacute bacterial infection, and another presented with nephritis (probably focal-embolic, as vegetations were later found at the site of

In all cases the operative procedure was excision with end-to-end anastomosis, except where grafts are indicated.
Average reduction of blood pressure = 32/16 (excluding Case 40—too recent).
* Freeze-dried aortic homograft inserted.
Note.—(1) The brachial blood-pressure figures are average values. The femorals are simple measurements, usually at last visit. (2) The size of the anastomosis is compared with that of the aorta between the anastomosis and the subclavian artery and presented as a percentage of the latter. No figure is given in cases in which detailed measurements were not made.

coarctation). Three developed cerebrovascular accidents; and, finally, one patient with auricular fibrillation, mitral stenosis, and aortic incompetence was admitted in congestive cardiac failure.

The presenting symptoms of these nine patients, who had been previously well, were manifestly due to serious complications. Equally important complications, however, occurred silently in other cases and were unexpectedly found at operation. The dramatic onset of these complications is illustrated particularly by those who suffered vascular accidents. A labourer aged 47, for example, enjoyed perfect health until his sudden collapse at work from a dissecting aneurysm, which proved fatal in a few days.

Discovery of Symptomless Cases

In several instances the cardiovascular system became suspect many years before the correct diagnosis was reached. Four patients, for example, had been diagnosed in childhood as having rheumatic heart disease on discovery of a cardiac murmur. In fact, an unexpectedly high incidence of rheumatic fever has been reported in patients with coarctation, and three of our cases gave histories of it. One further patient had the signs of valvular disease, possibly rheumatic, with mitral stenosis, aortic incompetence, and auricular fibrillation, in addition to coarctation.

The initial findings that eventually led to the diagnosis of coarctation in these 43 patients were heart murmurs

Acellular fibrin deposits on the intima were recognized in several other cases, but their macroscopic and histo-

logical appearances were distinctly different. These are the so-called "jet lesions" described by Edwards *et al.* (1948).

Among Abbott's (1928) 200 cases of coarctation were 14 instances of infective endoaortitis. Four of these had resulted in rupture of the aorta. The silence of the infection is sinister, therefore, in that disaster may happen before the complication is recognized and before antibiotic therapy is indicated.

Dissecting Aneurysm of the Aorta

The calamity of dissecting aneurysm of the aorta was encountered twice. The sudden onset and the rapidly fatal issue in one case have been mentioned:

Case L.—A labourer (Table I) aged 47, previously in excellent health, collapsed at his work. Comatose on admission to hospital, he remained in coma until he died on the fourth day. Necropsy showed coarctation with a dissecting aneurysm of the

FIG. 2.—Six-foot (1.8 m.) postero-anterior radiograph of chest in Case 19, showing the aneurysm of the arch and descending aorta.

FIG. 3.—Six-foot (1.8 m.) postero-anterior radiograph of chest in Case 19 after resection of the aneurysm and insertion of aortic graft.

aorta. The initial tear was a short distance above the aortic valve, and thrombus formation here had resulted in embolism of the brain and kidneys before final aortic rupture into the pericardial sac caused death from tamponade.

The second was of slower tempo, and an attempt was made to deal with it surgically.

Case 19.—A woman who had led an active life with good health had tonsillitis in September, 1952 (aged 35), followed three weeks later by severe interscapular pain radiating down the back. (B.P. 170/100). The femoral pulses were feeble and delayed. X-ray examination revealed an aortic aneurysm (Figs. 2 and 3) and a retrograde aortogram showed a dilated aorta with a double lumen. In March, 1953, she had a further attack of interscapular pain. A diagnosis of dissecting aneurysm was made. In October, 1953, thoracotomy revealed coarctation below the origin of the left subclavian artery with dissection of the aorta below, giving entrance to a large aneurysm; there was a double lumen down the entire length of the thoracic aorta extending into the abdominal aorta for an undetermined distance (Fig. 4). The thoracic aorta from the subclavian artery to the diaphragm was resected and replaced by a freeze-dried graft. The specimen showed that the initial tear was 2 cm. below the coarctation. There were no vegetations on the excised specimen. The patient made a good recovery, but in the convalescent home, six weeks after operation, a massive fatal haematemesis occurred. Necropsy revealed that the dissecting aneurysm had extended throughout the abdominal aorta to the bifurcation and had ruptured into the stomach. There was gross mucoid change of the media with corresponding loss of muscle in the aorta proximal to the graft and in the subclavian artery.

FIG. 4.—Excised aneurysmal sac in Case 19 viewed from below. The double lumen is well shown, the false channel being the larger, above, and the true lumen the smaller, below.

The operation was a desperate expedient in the hope that success might attend replacement with a graft if the dissection was favourably limited. This type of dissecting aneurysm must be regarded as one of the direct complications of coarctation.

Non-dissecting Aortic Aneurysm

Saccular aortic aneurysms were recognized radiologically and found at thoracotomy in two cases. In each the aneurysm lay immediately beyond the coarctation. One of the patients (Case 26) had subacute bacterial infection and has been described; the other (Case 13) did not have an infective lesion.

Case 13.—The diagnosis of coarctation was made by Dr. W. Brigden in this boy aged 7, who had pains in his limbs, thought at first to be rheumatic. X-ray films showed a large shadow just below the aortic arch, and its aneurysmal nature was confirmed by angiocardiology (Fig. 5). At thoracotomy, a saccular aneurysm, 35 mm. in diameter, began 20 mm. below the left subclavian artery. The main mass of the aneurysm extended deeply behind the hilum of the lung, and the wall was quite firmly attached to the spine and firmly blended with the oesophagus. The muscular layer of the oesophagus had been eroded and only oesophageal mucosa covered the thin wall of the aneurysm at this point. The aneurysm was mobilized, excised, and replaced by a 35-mm. aortic graft. In the specimen a coarctation with a 1-mm. orifice led eccentrically into the aneurysm, which had a large distal opening. During the three years of follow-up the patient had remained very well. The angiocardiology, 20 months after resection, showed a normal aorta (Fig. 6).

Such aneurysms can be resected, although their presence adds to the risks of the operation. But the degree of

erosion and thinning found in Case 13 indicates that its initial manifestation might easily have been fatal rupture into the oesophagus. Although their tempo is slower than that of dissecting aneurysms, their silence makes their timely discovery so much a matter of chance that they are scarcely less hazardous to life.

Post-stenotic dilatations were common. At operation they added to the difficulties of obtaining a uniform calibre of the reconstituted aorta.

FIG. 5.—Angiocardiology, left lateral projection in Case 13. The aneurysm is clearly shown in the upper portion of the descending aorta. There is no filling defect within the sac, and the coarctation is hidden by the aneurysm. (Film reproduced by courtesy of Dr. Wallace Brigden.)

FIG. 6.—Post-operative angiocardiology of Case 13: left lateral projection. No aneurysm is present, and there is good filling of the aorta with minimal constriction of the lumen.

Intercoastal Aneurysms

Small saccular aneurysms occurred even more frequently on the intercoastal arteries just below the coarctation, most commonly close to their origin from the aorta (Fig. 7). They were found at operation in six of our cases (Nos. 10, 20, 25, 34, 36, and 37), and their walls were so delicate that blood could be seen swirling inside them. We were surprised to find no record of their rupture in the literature, but such an event might be mistaken for rupture of the aorta itself. Dr. Norah Schuster (1955, personal communication), who noted them intact in two cases of coarctation at necropsy, was of the opinion that they might very easily be overlooked. Their common incidence at operation and the hazard they constitute are attested by Gross (1953).

These intercoastal aneurysms have all been clinically silent. Furthermore, they were not evident on x-ray examination, except in two of our cases where they indented the barium-filled oesophagus (Fig. 8). Angiocardiology also failed to outline them. In short, they are part of the occult threat of fatal vascular rupture that besets persons with coarctation.

FIG. 7.—Photograph of resected aorta in Case 20. A thin-walled saccular aneurysm can be seen at the junction of an intercoastal artery with the aorta just below the coarctation on the right-hand side of the picture. The coarctation can be seen at the upper end of the specimen.

FIG. 8.—Chest radiograph with barium swallow (left lateral projection) in Case 10. The upper part of the oesophagus is displaced forward by the post-stenotic dilatation of the aorta immediately below the coarctation. Below this is another more sharply localized indentation of the oesophagus produced by an intercoastal aneurysm.

Intracranial Vascular Lesions

Cerebrovascular accidents occurred in three of our patients.

Case 2.—Male. Cardiac abnormality discovered at birth. 1944 (aged 25): complained of frontal headaches. 1947: "stroke" with hemiplegia, with almost complete recovery; coarctation diagnosed. 1949: resection of coarctation; before resection, average brachial blood pressure was 237/109; after resection average brachial pressure, during six years follow-up, was 180/103. No further cerebrovascular accidents.

Case 8.—Male. 1950 (aged 12): sudden onset of headache when diving into swimming-pool; meningism and impaired consciousness followed; brachial blood pressure 168/104; subarachnoid haemorrhage confirmed by lumbar puncture; good recovery. 1951: resection of coarctation. Followed up for five years—remained very well. Average brachial blood pressure: pre-operative, 165/105; post-operative, 138/75.

Case 22.—Male. 1953 (aged 17): classical spontaneous subarachnoid haemorrhage; slow recovery; resection of coarctation. During two years' post-operative observation remained well. Average brachial blood pressure: pre-operative, 203/111; post-operative, 145/82.

The brachial blood pressure in these three patients was higher relative to their age than in most of our cases, and doubtless was a factor in the aetiology of the intracranial lesions.

Hypertension

In all our cases the brachial blood pressure was elevated for the individual's age and sex above the average value expected in the general population (Stocks and Karn, 1924; Hamilton *et al.*, 1954). The elevation affected both the systolic and the diastolic pressure, except where the latter was lowered by aortic incompetence. The hypertension was usually moderate in degree, and it increased with age after the fashion of the blood pressure in the population generally (Hamilton *et al.*, 1954), but at a somewhat accelerated pace. Rapid rises in pressure or rapid deterioration of the patient from increasing hypertension were observed in only one patient (Case 7), a girl who, whilst under observation, developed papilloedema in association with unusually high levels of blood pressure.

Case 7.—In 1948, when aged 12, this girl was suspected of having rheumatic fever with carditis. Coarctation was discovered, but it was possible that active rheumatism was also present. Later, tuberculous gingivitis and cervical adenitis developed. In November, 1949, she could not see the blackboard at school. Bilateral papilloedema and one superficial retinal haemorrhage were present with arteriovenous nipping. Brachial blood pressure 200/125. Femoral pulses barely palpable, and femoral blood pressure not obtainable. September, 1950, retinopathy had not progressed. Blood pressure 190/130. Clinical urine tests normal. Effective renal plasma flow 278 and 415, and glomerular filtration rate 132 and 157 ml. a minute (duplicate measurements). Resection of coarctation with direct anastomosis carried out. Papilloedema subsided. Remained well during five and a half years' post-operative observation. Albuminuria noted in October, 1953, but not subsequently. **Present assessment:** Condition of optic disks consistent with healed papilloedema; no retinopathy; no albuminuria; renal plasma flow 268 and 344, and glomerular filtration rate 41 and 60 ml. a minute; no delay in femoral pulse peak; no palpable collateral vessels; average brachial blood pressure after operation 175/100 (before operation 190/130). The change in renal clearances suggests deterioration of renal function.

So far as we know, papilloedema has not previously been described in coarctation, and the hypertension existing in the upper parts of the body has not been reported to enter a malignant phase. Case 7 seems to be a unique exception.

The probable part played by hypertension in the production of intracranial vascular lesions in three of our patients has been mentioned, and this point and the aetiological role of hypertension in dissecting aneurysms are more fully discussed below. Apart from this, the hypertension of coarctation was remarkably well tolerated. Uraemia did not occur, and heart failure was found only in association with valvular defects of the heart.

Heart Failure

Congestive heart failure occurred in only two patients, but caused death in both.

Case F.—Male (Table I). Congenital heart disease was diagnosed at school, but he lived an active life until the age of 33, when dyspnoea and recurrent bronchitis began. He continued to work intermittently until aged 40, when nocturnal dyspnoea and oedema of the legs set in. Auricular fibrillation was then present and the heart was enlarged. The first heart sound was accentuated and there was an apical diastolic rumble; a systolic murmur with thrill was present at the base of the heart and an early diastolic murmur along the left sternal border. Blood pressure was 160/100, and the usual signs of coarctation were present. E.C.G. showed left bundle-branch block. He died at home (aged 41) a year later. No necropsy was performed. Clinical diagnosis: coarctation of aorta; aortic incompetence and probably aortic and mitral stenosis.

Case K.—Male. Heart disease known since childhood. There had always been some dyspnoea of effort. Pneumonia 1949 and 1952. On examination (1952, aged 55) gross cardiac enlargement, chiefly left ventricle. Loud systolic murmur at base; early diastolic murmur at left sternal edge; apical mid-diastolic murmur. Blood pressure 170/60. X-ray film showed calcified aortic valve and dilated ascending aorta. E.C.G. left ventricular hypertrophy. Heart failure imminent. Died at home

two months later. No necropsy. Clinical diagnosis—coarctation of aorta; aortic stenosis and incompetence.

Severe valvular lesions were present in both these patients, and presumably accounted for failure of the heart. Hypertension was not severe in either at the time of observation.

Natural History of Coarctation

The high incidence of serious events and ominous operative findings in our patients is in line with what is known of the natural history of coarctation. Necropsy series indicate that the majority of patients with the "adult type" of coarctation die before the fifth decade of life. Seventy-four per cent. of Abbott's (1928) collected cases (200 cases, including none under 3 years of age) and 61% of 104 additional cases collected by Reifstein *et al.* (1947) had not survived the 40th year of life. Such statistics, being derived from necropsies, may give an unduly gloomy impression; but, unfortunately, available clinical studies which should give a truer perspective are much less extensive.

Lewis (1933), Bramwell (1947), Campbell and Suzman (1947), Newman (1948), and Shapiro (1949) give clinical accounts of a total of 94 cases of coarctation, of which 27 were fatal. When death was from cardiovascular causes (excluding two patients who died after surgical operation), the average age at death was 33 years, and only seven had passed the 40th year. Where the ages of the remaining subjects were given, only six were recorded to have passed the 40th year of life.

The evidence is clear that many if not most patients with coarctation die before middle age.

Causes of Death

Although they may have no symptoms persons with coarctation live in danger. Vascular complications are often sudden and overwhelming, and may preclude effective treatment when they have set in; they challenge resection to prove itself prophylactic as well as anatomically corrective. The vascular complications are sometimes remote from the coarctation, and analysis of the mode of death, in its relationship to coarctation as the basic lesion, is of great importance.

The region of the coarctation itself is sometimes the seat of fatal lesions. In our cases, actually or potentially infective vegetations were found eight times. Excision of the coarctation should abolish the risks from this complication. However, infective endocarditis is more common than infective endoaortitis in coarctation. Of the 23 cases of one or other in the series of Reifstein *et al.* (1947), only six had endoaortitis without endocarditis, and the large majority of cases of the latter lesion had infection of bicuspid aortic valves. Since the same authors found bicuspid aortic valves in 42% of all cases of coarctation, it is obvious that a considerable part of the hazard from infection resides in this lesion alone, which would not be expected to be diminished by resection of the coarctation.

The other local lesion in reference to coarctation is aneurysm formation, which was found twice in the post-stenotic aorta and six times in the intercostals entering below the stenosis in our cases. One further case had a dissecting aneurysm with the initial tear just below the coarctation. In 5 of the 104 cases of Reifstein *et al.* (1947) rupture of the aorta had taken place beyond the coarctation. Abbott (1928) also found rupture in direct relation to the stricture in 5 of her 200 cases. Prevention of this complication may also reasonably be expected from resection and reconstitution of a full lumen.

Other vascular lesions are more remote from the coarctation. The initial tear in our other patient with dissecting aneurysm was located just above the aortic valve. It was situated in the ascending aorta in 19 of the cases of Reifstein *et al.* and in 33 of those of Abbott. The aortic valve was bicuspid in no fewer than 17 of the 33 cases reported by Abbott, and it is noteworthy that Gore (1953) found bicuspid aortic valves in 9 out of 32 cases of dissecting aneurysm in persons aged under 40 (in these it was asso-

ciated with coarctation only once). The initial tear was in the ascending aorta in the great majority. By contrast with coarctation Gore found that hypertension was exceptional in cases of dissection under the age of 40 though the rule after that age, and concluded that the elevated blood pressure exploits the weakness of primarily diseased or abnormal vessels, though it might also aggravate the degeneration of the media which underlies dissection.

Intracranial vascular lesions occurred in three of our cases. Subarachnoid haemorrhage was proved in one. The high incidence of intracranial aneurysms of the congenital type is well recognized in coarctation (Abbott, 1928), and rupture of these appears to constitute the main hazard from intracranial lesions, though cerebral thrombosis may also occur. Reifstein *et al.* (1947), reporting 11 cases of intracranial lesions among their 104 necropsied cases, found no instance of cerebral haemorrhage that had not originated in an aneurysm, either "congenital" or mycotic. Hypertension is provocative of rupture of these aneurysms, but rupture may occur also in normotensive persons (Taylor and Whitfield, 1936; Magee, 1943; Walton, 1952; Stehbens, 1954).

Hypertensive heart failure did not occur in our cases, although hypertension, by adding to the load placed on the left ventricle by aortic valve disease, may well aggravate failure. The great majority of the patients of Reifstein *et al.* and of Abbott who had heart failure also had other cardiac lesions, but Abbott remarked that there was a relatively small group in which coarctation and the relatively small changes in the circulation that arise from it had secondary changes in the circulation that arise from it had apparently been the essential factors in the cardiac strain. It is in early childhood, possibly before the collateral circulation is well developed, that the heart most often fails from the hypertension of coarctation (Mustard *et al.*, 1955), although even at this time there are often associated lesions such as persistent ductus arteriosus and endocardial fibrosis. Reduction of the blood pressure can be expected to prevent some of the complications that occur at a distance from the coarctation, and this reduction is one of the chief aims of resection.

Pregnancy

The risk of rupture of the aorta in patients with coarctation is commonly believed to be increased by pregnancy. Mendelson (1940), reviewing the literature, cited 31 cases of pregnancy in patients with coarctation; dissecting aneurysm had occurred in two patients. Ten of our patients had one or more pregnancies, and their obstetrical histories were of interest. Three of these patients did not have surgical treatment; one had had five and another had had four full-term deliveries without incident; the third patient had two pregnancies, both terminated at term by elective caesarean section. Six patients had had pregnancies before being referred for surgery—two had had one pregnancy; three had had two pregnancies, and one had had three full-term normal deliveries before resection.

The indications for therapeutic abortion were the fear of rupture of the aorta rather than actual deterioration of the patient. Blood-pressure measurements showed a lowering of the pressures in the middle trimester; there was usually a rise of pressure in late pregnancy and during parturition. This corresponds with the findings of Dixon and Hartley (1955).

Our experience of pregnancy in coarctation is too slight to permit conclusions of a general character; but clearly, while great care in management is required, pregnancy can be brought to a successful conclusion in many cases. Two of our patients have had normal pregnancies and deliveries following resection of the aorta.

Physical Signs

Some of the most important signs in the assessment of patients may be mentioned.

Habitus.—The development of stature was retarded in many cases. The lower limbs were underdeveloped, the

pubis-to-ground measurement was short, whilst the upper parts of the body were particularly well developed and sturdy, and span exceeded height—in one case by as much as 5 in. (12.5 cm.). Disproportion was most pronounced in two patients in whom the aorta was completely interrupted by an imperforate diaphragm.

"Carotid Swell."—The augmented carotid pulsation was very characteristic, and of itself suggested the diagnosis. A sustained systolic arterial wave or "swell" appears in the suprasternal fossa and travels outwards along the subclavian arteries and up the carotids, where it is best observed.

Collateral Arteries.—These were most often found around the scapulae, but examination of the intercostal spaces, the axillae, and the posterior triangle of the neck sometimes revealed them. Such enlarged anastomotic arteries were found in 42 of our cases. They were absent in 10 patients, whose ages were 3, 5 (two cases), 7, 10, 18, 19, 25, 30, and 36 years. Thus their absence was not explicable by youth of the patients, nor did it correlate with the disproportion in habitus.

Murmurs

Systolic murmurs are a feature of coarctation. The precordial systolic murmur was often nondescript, but a characteristic murmur occurred in many cases: loudest at the sternal borders, its onset separated from the first heart sound by a brief silent interval, it slowly reached maximum intensity and declined through the second heart sound into early diastole. Distinct from this, in nine cases which came to surgery there was a loud rough systolic murmur at the base, accompanied by a basal systolic thrill in six. In the other three, a thrill was not palpable over the praecordium but only over the carotid arteries. These murmurs suggested aortic stenosis, but for lack of corroboratory signs in the other seven this diagnosis was made in only two cases. The systolic gradient across the aortic valve was measured in these two cases; in one it was 20 mm. and in the other 10 mm. These gradients suggested mild stenosis, and aortic valvotomy was not attempted. Post-operatively, their murmurs were unchanged. Of the remaining seven cases, one came to necropsy and the aortic valve was bicuspid with somewhat thickened leaflets; three others had no murmurs at the base of the heart after operation, and three had fainter murmurs without thrills. It will be recalled that in one patient, who did not have surgery, a clinical diagnosis of aortic stenosis was made and calcification of the aortic valve was seen on x-ray examination.

Subaortic stenosis is known to occur in association with coarctation (6% of Abbott's cases), but our experience here indicates caution in making this diagnosis from the precordial signs alone. From the post-mortem findings in one case it is tempting to ascribe these rough basal systolic murmurs to bicuspid aortic valves, but their diminution after operation seems to indicate that they had included a component from the coarctation or the collateral arteries. We would therefore prefer to underline the difficulty of their interpretation (Smith and Matthews, 1955). One patient (Case 27) had a loud pansystolic murmur maximal in the third left intercostal space, thought to be due to a ventricular septal defect.

Over the upper dorsal spine, and sometimes widely conducted up and down, there was a prolonged murmur, again of late onset with reference to the first heart sound and continuing well into cardiac diastole. A murmur of similar character and timing could occasionally be traced to its origin in a superficial anastomotic artery and be caused to disappear by digital occlusion of this vessel.

The delayed dorsal interscapular systolic murmur may arise in the coarctation itself or in dilated and tortuous intercostal and anastomotic vessels. In one instance a thrill felt at operation on a patient with a complete stenosis appeared to be caused by blood entering the distal aorta from the intercostal arteries. These murmurs are heard in the majority, and their site is a rough guide to the site of the coarctation. When the coarctation is at the usual site the murmur is loudest between the scapulae in the

Operative Findings

In all cases the coarctation was of the classical "adult" type. Dissecting aneurysm of the aorta was present in one case, non-dissecting post-stenotic aneurysm of the aorta in two cases, and berry aneurysms of the intercostals in six cases. These last usually lay at the origin of the first or second pair of intercostal arteries beyond the coarctation, but occasionally were seen more peripherally. They were very thin-walled and easily damaged. Their origin from the aorta was often unusually large, in some cases measuring 2-3 mm. in diameter. Histologically the walls of these dilated intercostals were often deficient in muscle and elastic tissue, and in places were composed solely of intima and adventitia. They were dealt with either by ligation or by suture at their point of origin from the aorta. The ductus arteriosus was patent in five cases (Nos. 1, 17, 26, 29, and 31), widely in two and admitting only a fine probe in the others; in all it entered just above the coarctation. The left subclavian artery entered the narrow segment in one patient; at its point of entry its lumen measured 4 mm. and the artery was narrow from aorta to its first branch, where it abruptly widened to normal size. (The pre-operative brachial blood pressure was 210/105 in the right arm and 170/115 in the left arm.) In one patient the left subclavian artery arose so close to the coarctation that the origin of the artery was included in the anastomosis (see diagram, page 380). Vegetations as previously described were found on the interior of the resected aorta in eight cases.

Post-operative Course

The immediate post-operative course was uneventful in most cases. The death of one patient six hours after operation from rupture of a suture has been mentioned. Post-operative haemorrhage of severe degree occurred in two other cases but stopped spontaneously after transfusion.

In the majority of cases the blood pressure in the arms was near pre-operative levels in the immediate post-operative period for about 24 hours; it showed marked fluctuations, but gradually fell during the subsequent week or so to a lower and more stable level. Hypertensive crises have not been encountered. Cases with aortic valve lesions did not behave differently from the others.

In five cases abdominal pain in the post-operative period was severe enough to cause concern. In two cases it began on the fifth and in two others on the eighth post-operative day, was severe and colicky, and referred to the mid-abdomen but without localizing signs. In all four the pain subsided after several days. In the fifth case the pain was accompanied by a massive ascitic effusion. Resolution rapidly followed the removal of 2 litres of clear fluid. Price Thomas (1955, personal communication) has had similar experiences, and the signs demanded a laparotomy in an early case; the only abnormality seen was a little free fluid, mesenteric adenitis, and marked engorgement of the mesenteric vessels. Bowel function had not been disturbed in any of our patients, nor has there been any evidence of intestinal haemorrhage. There has been no evidence to suggest that the condition is due to mesenteric embolism.

Chylous fluid continued to drain from the left chest in one patient for several days after operation. The thoracic duct bears a close anatomical relationship to the aorta, and was doubtless damaged in the dissection. Cardiac tamponade occurred about a week after operation in one case in which the pericardium had been opened and pressure readings recorded from the left ventricle. Repeated aspiration of the pericardium was necessary for a few days, but the condition then subsided.

There have been no late complications in this series, but it has been our practice to delay ambulation for three weeks after operation and to restrict activities generally during the first six months.

Results of Operation

Mortality.—Three patients died. Two of these have already been noted: Case 19 had a dissecting aneurysm of the aorta, and the operation was advised as a desperate resort. In Case 6 death occurred six hours after operation from haemorrhage from the aorta due to rupture of the suture line. The third death, that of a woman aged 30 (Case 5), occurred suddenly five weeks after operation while she was in a convalescent home. At necropsy it was found that the suture line had parted and haemorrhage had taken place through the aperture in the aorta. Histologically, the aorta showed a cellular infiltration which suggested a low-grade infective process. These last-mentioned cases were the fifth and sixth of our series. It is well known that the mortality rates in any one clinic decrease with experience, and a mortality rate of less than 10% may now be anticipated in practised hands.

Follow-up.—The remaining 37 cases have been followed up after operation for periods ranging from three months to eight years, and all have remained in good physical health. Those patients who had symptoms from organic complications before operation have had no recurrences. Symptoms of cardiac anxiety states were alleviated in most of the cases in which they had been present pre-operatively, but were unchanged in three cases and worse in two. Both the latter had long-established neuroses, and one was a long-standing case of hysteria. Those patients who had syncopal attacks before operation had no recurrences after, but one patient developed occasional episodes for the first time post-operatively. No organic cause for them could be found.

Physical Findings During Follow-up.—The arterial pulsation in the neck always diminished. The femoral pulse increased in volume to within normal limits in all cases. The peak of the femoral pulse wave was reached either before or synchronously with the peak of the radial pulse in all but two cases. These findings were checked by arterial pulse records in 10 cases. Collateral arteries were no longer palpable. The murmurs were altered in all patients. The systolic murmur over the upper dorsal spine became fainter, but in only one case did it disappear completely. Its genesis and the significance of its persistence have been discussed above; it continued to be heard in cases that gave eminently satisfactory results on all other counts, and it could not therefore be used to assess the adequacy of aortic reconstruction. Otherwise the alterations in murmurs were as would be expected: the precordial systolic murmurs became faint, the early diastolic murmurs of aortic incompetence generally did not alter, and the mid-diastolic murmurs were less frequent. Only the apparent evolution *de novo* of aortic diastolic murmurs after operation in two cases was noteworthy.

Blood Pressure

The brachial blood pressure was reduced by the operation. The change was studied in detail in the first 20 patients in our hospital series, who were followed for three months or more after operation, and has been separately reported (Counihan, 1956). Both pre-operatively and post-operatively the brachial blood pressure fluctuated considerably, but the average of the post-operative pressures was lower by 32 mm. systolic and 16 mm. diastolic than the average of the pre-operative ones for the group. Statistically this fall is highly significant, the probability of its occurrence by chance being less than 1 in 1,000. However, the post-operative average brachial pressures were higher than the expected average pressures for the age and sex—that is, the pressures remained higher than normal.

No relationship was found directly between the amount of fall of pressure and the diameter of the aorta measured at the site of anastomosis. However, the amount by which the post-operative brachial pressure exceeded the expected average for the normal individual was apparently related

to the degree of deviation from uniformity in calibre of the reconstructed aorta, so far as systolic pressure was concerned, but not diastolic. The greater the restriction of the aortic diameter the more abnormal the systolic pressure. But even when uniformity was attained in the diameters of the reconstructed aorta the blood pressure remained higher than the expected normal.

The evidence that the residual hypertension was not due to the incomplete restoration of the aortic lumen in the cases studied is, first, all collateral vessels disappeared; secondly, the delay in the femoral pulse peak was abolished; and, finally, the femoral systolic blood pressure was at least as high as the brachial. The measurement of the femoral as high as the brachial. The measurement of the femoral blood pressure by auscultation may be open to some inaccuracy, but from our figures after operation the femoral pressure, like the brachial, was above normal.

Many authors have found a generalized increase in the peripheral vascular resistance in coarctation. Furthermore, the fact that post-operative brachial pressures remained above the expected average for age is in harmony with the persistence of long-established hypertension after removal of a phaeochromocytoma or a diseased kidney. When a hypertensive agent has been acting for a sufficiently long time it appears that the blood pressure may become permanently set at high levels. We noted a tendency to a greater fall in the younger subjects than in the older; and, of course, the percentage fall has been greater in young subjects because their initial pressures were lower.

The three patients who had cerebrovascular accidents have had no recurrence and are in excellent health after a post-operative follow-up of 6½, 4½, and 2 years. The average post-operative blood pressure was in each case lower than the average pressure before operation. The reductions in the average pressure were 54 mm. systolic and 5 mm. diastolic in one case, 20 systolic and 25 diastolic in another, and in one case, 20 systolic and 29 diastolic in the third, leaving these subjects with average pressures close to but somewhat above the expected average for their respective ages. In the one patient in whom papilloedema had been present it regressed after resection.

The Cardiogram.—When the cardiogram had shown evidence of left ventricular hypertrophy it was exceptional for it to return to normal; it did so in only three cases and showed a change towards normal in one other.

X-ray Appearances

The size of the left ventricle was unaltered in almost all cases. It appeared smaller in four but larger in one. The aortic arch retained a double contour in four, but was smaller in one of these. Aortic dilatation regressed except in one case in which the arch remained prominent. Where noted before operation, posterior oesophageal displacement disappeared except in two cases in which it remained substantially unchanged.

Rib-notching usually remained unchanged, although in one youth (Case 22) there has been marked regression.

Angiocardiography has been carried out post-operatively in only two cases, 9 and 20 months respectively after operation. One patient (Case 13) had an eroding post-stenotic aneurysm excised and grafted. The pre- and post-operative angiograms are shown in Figs. 5 and 6. In both of them the appearances of the aorta were satisfactory. The angiograms of these two patients indicate that the reconstructed aortic lumen remains fully patent.

Discussion

Full assessment of the place of resection awaits a longer follow-up than is possible at present, but the encouraging results, so far, make a discussion of policy fruitful.

It has been shown that when organic symptoms occur in a person with coarctation serious complications have probably already developed. These may be remote from the coarctation (such as subarachnoid haemorrhage) or they

may occur locally (post-stenotic or intercostal aneurysms) and clearly indicate resection.

More often, however, the coarctation is accidentally discovered in a symptomless person, in whom the indications for surgery are less clearly defined. Investigations may reveal that trouble is afoot and that resection is desirable. But the finding of unsuspected vegetations and of thin-walled intercostal aneurysms at operation forbids complacency when investigations have been negative. Watching and waiting may end in disaster, with the occurrence of a vascular catastrophe. Alternatively, anxiety states are prone to develop during the waiting period. We believe that it is advisable to come to a decision without undue delay.

The menace from lesions in the neighbourhood of the coarctation has been successfully dealt with by resection in our cases. The occurrence of some of the more distant complications has been shown in this paper to depend, at least in part, on the hypertension. The reduction of this by resection has been demonstrated by detailed analysis of our first consecutive 20 cases that have been followed up for three months or more after operation. Our cases suggest that closest approximation to normal pressures is obtained in those patients in whom a uniform aortic lumen has been achieved, even though these pressures still remain above normal levels. It must be the surgical aim, therefore, to reconstruct the aorta with the maximum possible diameter. Marked residual constriction should be avoided by the use of grafts. The demonstrated fall in pressure does not seem to be large, but it should be noted that the figures refer to the average values of many pressure measurements taken at rest. They both reflect a constant lowering of the pressures and reveal the possibility that greater reductions have occurred in the blood pressure during daily activity as compared with levels obtaining before operation, since the blood pressure is said to rise excessively on effort in unresected coarctation (Gross, 1953).

Our three patients who had suffered from intracranial vascular accidents before resection had no recurrences afterwards. In the one in whom hypertensive neuroretinopathy had appeared, it regressed after operation.

Conclusion

The mortality of the operation is now small and the results have been satisfactory. The brachial blood pressure has been lowered towards normal. Post-operative cerebrovascular accidents, bacterial infection, aortic aneurysm, and heart failure have neither occurred nor recurred.

These are reasons for confidence that the bad prognosis for life carried by coarctations has been improved by operation, though this will be proved only by long follow-up.

The pros and cons of operation may be summarized as follows:—In favour: (1) the improbability of surviving past middle age; (2) the insidious or sudden nature of serious or fatal complications, such as aneurysms, endoarteritis, and cerebrovascular accident; (3) the reduction of blood pressure after operation; and (4) the low operative mortality. Against: (1) the difficulty of judging the risks to life in any individual patient; (2) the uncertainty that resection will prevent the onset of serious complications; and (3) the reluctance to submit a symptomless individual to a major operation of a prophylactic nature.

Serious consideration of this difficult problem has led us to believe that the pros outweigh the cons. Consequently we have recommended resection in all our cases below the age of 40 unless contraindicated by the presence of severe associated cardiovascular anomalies unlikely to be affected by the resection.

The ideal time for operation is before adolescence, because then the vessels are healthier and local vascular complications are less common. In addition, the likelihood of obtaining normal post-operative blood pressures is probably greater in the younger individual. Also, thoracotomy is

tolerated better by the young and anxiety states are unusual at this age. We believe, too, that a relatively serious operation of election should be carried out before the individual has acquired responsibilities and dependants.

Summary

Fifty-two cases of aortic coarctation have been studied.

A review of the literature and of our 12 unoperated cases emphasizes the poor prognosis in the untreated case.

Forty patients were submitted to operation.

Symptoms and physical and radiological signs have been evaluated before and after operation.

A surprisingly high incidence of unexpected local complications was encountered at operation, owing possibly to the preponderance of adults.

Three deaths occurred in the surgical series.

Satisfactory clinical results were obtained in the surviving patients, who have been followed up for from three months to eight years.

The brachial blood pressures have been reduced in all cases.

The factors influencing the post-operative blood-pressure levels have been discussed.

The indications for operation have been evaluated.

We are grateful to the many physicians who have so kindly referred cases to us, and especially to Dr. Paul Wood and Dr. Terence East for allowing us to quote patients who have been under their care before and after operation; to Dr. Wallace Bridgen, who most kindly allowed us to reproduce the pre-operative angiogram of Case 13; and to Professor J. McMichael, who gave valuable advice and criticism. We are also indebted to Mr. L. L. Bromley for permission to quote his operative findings in three patients. Finally, we must record our indebtedness to Sisters Anderson, Bowtle, and Prior for their invaluable and unstinted work in the wards and theatre.

SURGICAL TREATMENT OF CHILDREN WITH COARCTATION OF THE AORTA

BY

A. L. d'ABREU, O.B.E., Ch.M., F.R.C.S.

AND

CLIFFORD PARSONS, M.D., F.R.C.P.

From the United Birmingham Hospitals

Each advance in cardiovascular surgery increases the need for careful selection of patients suitable for operation. It is particularly difficult to come to a correct decision about cases of aortic coarctation because the disorder is compatible with a long and active life. Moreover, operation is not without risk, it does not always relieve hypertension, and even when the result seems at first to be successful an aneurysm may form at the line of anastomosis.

The difficulty is aggravated because when coarctation is first diagnosed it is usually impossible to predict the course of the disease, and, although undoubtedly some patients may be destined to attain a ripe old age, others will die before their due time. Sometimes death is sudden and without warning when the aorta or some smaller artery, such as one of those at the base of the brain, bursts under the strain; at other times death comes slowly when the heart fails or superimposed subacute bacterial infection proves resistant to treatment.

It might be possible to get a better idea of the likely outcome for the individual if the natural course of the untreated condition could be studied in a sufficiently large group of patients. But this again presents a problem, for during life the disorder must sometimes elude discovery, and after death, unless this occurs in hospital or is reported to the coroner, the body is unlikely to be examined by a pathologist. Probably many people with aortic coarctation die at home and are certified as having had hypertensive heart disease, myocardial infarction, or apoplexy. We recognize that these factors must make figures inaccurate and may lead to false conclusions. Nevertheless the selection of patients for operation will depend on criteria determined by experience, and we therefore record our experience of coarctation at the Birmingham Children's Hospital between July, 1950, and July, 1955.

Mortality

During these five years 30 infants (16 girls, 14 boys) died more or less directly as a result of coarctation, 17 within a week of birth, 8 within a month, and 5 within six months. Cases grossly complicated by associated defects have been excluded from this series. There was no record of a death from coarctation in an older child up to the age of 14, but we know of two deaths amongst adolescents with the disease. In this same period we saw at the hospital 22 children (14 boys, 8 girls) with coarctation, 21 of whom still survive.

It is impossible not to be impressed by the proportion of deaths occurring in infancy, especially in the first month. Fig. 1 (left-hand open column and solid columns marked A) shows that more than a third of Blackford's (1928) series of 323 cases of coarctation died in infancy. Most of these early deaths are associated with the infantile type of coarctation, but this is by no means invariable, and in our series one of the infants who died and one of the babies who have been operated on had the adult type of disease. Further, the infantile type of coarctation does not necessarily cause early death: four of the older children had a long narrow segment of aorta proximal to the origin of the ductus

arteriosus, and in three of these the ductus remained patent. Moreover, it is quite possible to operate successfully in these cases. For these reasons we shall not regard our patients as belonging to two entirely different anatomical groups.

There are reports of three large series of cases in which coarctation was found at necropsy. Blackford (1928) includes both the infantile and the adult varieties in his review;

of material make it difficult to compare the three series. However, if infant deaths are excluded from Blackford's series it can be assumed that almost all the remainder are examples of the adult type of coarctation. In Fig. 1 deaths in each decade are recorded as a percentage of all cases in the particular series—A, B, or C. Deaths occurring in infancy are represented in the single open column on the left of the figure. The remaining five triple columns form a pattern which gives an impression of the outlook for older individuals with coarctation.

If columns A and B are compared with columns C the figure shows that the prognosis has improved since antibiotics reduced the mortality of endocarditis and pneumonia. Nevertheless the general trend remains much the same now as it was in 1928. If a child with coarctation survives the perils of the first 12 months he is unlikely to die before he is 10, but he has a poor (1:3) chance of reaching his forties; indeed, he cannot lightly dismiss the possibility of dying before the age of 20. The figure does not show that only about 25% of these patients succumb to incidental illnesses, of which the most important is pneumonia, a condition to which these patients seem to be particularly susceptible. For most of the remaining 75% death, no matter when it comes, is likely to be the result, directly or indirectly, of hypertension.

Diagnosis

Uncomplicated hypertension is usually regarded as a disease without symptoms, and it is not surprising that children with coarctation should be unaware of a handicap. Yet parents are unanimous about the change wrought by successful operation. This may be because a patient who has gone through a serious operation does not like to admit that he has failed to benefit, or it may be that symptoms are recognized only after they have disappeared. Five children spoke of relief from headache, and this had been severe enough to prevent one athletic boy from playing rugby. Eight children found that they were not so easily exhausted, and this increase of energy was readily measured in two children who before operation had been regarded as lazy because they so easily gave up trying, but afterwards were able to compete successfully with an unaffected twin. In three children chest pain disappeared. The presenting symptom in 7 of the 22 children was pulmonary, and 14 had had repeated attacks of really severe bronchitis or pneumonia.

The diagnosis was seldom in doubt. A small, absent, or delayed femoral pulse was the most valuable sign of coarctation; there was great difficulty in recording the leg pressure by auscultation. The collateral circulation was

less obvious in children, and rib notching, though once doubtfully present in an infant, could not usually be recognized with certainty until about the age of 6. Murmurs could always be heard, and it was this which first brought nine of the children under observation. Most commonly, murmurs were systolic and loudest high in the chest; sometimes an aortic diastolic murmur could be heard. Murmurs could often be heard close to the spine, and no fewer than six children had systolic and mid-diastolic murmurs at the apex of the heart. These apical murmurs tended to persist after operation, and, as most of the children were too young to have acquired mitral stenosis, the sign may have been evidence of associated endocardial fibrosis of the mitral valve. There was no recognizable enlargement of the left atrium. All showed arterial pulsation in the suprasternal area.

Electrocardiographic findings varied considerably. Minor degrees of left ventricular preponderance were seen, but more usually were absent, and one child of 10, with an adult type of coarctation, had right ventricular preponderance. Several children had an increased pulmonary artery pressure, possibly secondary to bronchitis.

X-ray screening often provided confirmatory evidence of coarctation, but without doubt angiocardiology provided the most valuable information. In children good results are obtained from both intravenous and retrograde aortic injections, making it possible to study not only the position and nature of the coarctation but also the anatomy of the aortic branches and the collateral circulation, as well of the ductus arteriosus if it is patent.

From the technical point of view only one case was unsuitable for operation—a 6-year-old boy whose coarctation lay between the innominate and left common carotid arteries. The infantile type of coarctation was not considered unsuitable.

Surgical Considerations

In the period under review most of our experience was with older patients, and the chance to operate on 11 children under the age of 14 provided an opportunity to contrast the technical problems in the two groups. The resection of an adult type of coarctation in children is a far simpler problem than it is in adults; the collateral circulation is less formidable, so that entry into the thorax is easier; the exposure is better because of the ease of rib-spreading and the more elastic nature of young tissue generally. The aortic wall is free of sclerosis, and troublesome berry aneurysms have not yet formed on the intercostal vessels; we have seen these aneurysms in patients as young as 15. Once the coarcted area has been excised there is rarely difficulty in approximating the proximal and distal ends of the aorta prior to suturing. Except in one instance the ease of surgery has been notable.

Type of Anastomosis

Undoubtedly the best operation is an end-to-end anastomosis following an adequate resection of the coarcted area, so that a really wide channel exists, approaching or equalling the calibre of a normal aorta. The technique of the operation has been notably simplified by the invention by Dr. Potts of a multi-toothed, narrow-bladed aortic clamp. Had these clamps been available it is probable that one of the two subclavian aortic anastomoses mentioned below would not have been substituted for an end-to-end anastomosis. In all the patients the lower segment was wider in calibre than the upper segment—the post-stenotic dilatation so well described by Holman. To overcome this disparity in size the upper segment was cut obliquely so that its lumen approximated in calibre to that of the lower one.

Subclavian aortic anastomosis had to be used in two patients; but, clearly, the operation should be regarded only as a substitute for the better end-to-end anastomosis.

In the first case, after a long and difficult dissection and end-to-end anastomosis, the lower aortic segment developed a linear tear an inch (2.5 cm.) in length. This was repaired, but further severe bleeding from the anastomosis required

a rapid suture of both ends. The boy's condition became critical and the operation was abandoned. Three weeks after this disaster the blood pressure was 240/170 and he complained of intractable headache; the chest was reopened and a large subclavian artery was divided, turned down, and anastomosed end-to-end to the lower aortic segment. Recovery was rapid, and five years later he was well, with a normal blood pressure.

In the second case the stenosed area reached so high up to the arch that only an aortic graft or a subclavian aortic anastomosis would have been possible. Grafts were not available at that time and the subclavian artery was therefore used: the result has been perfect.

It may be said here that, though aortic homografts may be essential in adults, their use in children may not be without future danger, because of the risk of calcification and failure to grow with the child.

When there was a persistent ductus arteriosus in addition to aortic coarctation it proved possible to excise the coarctation, to close the ductus opening into the pulmonary artery, and to obtain a good end-to-end aortic anastomosis (Fig. 2).

FIG. 2.—Coarctation and persistent ductus arteriosus. The tapes are round the aorta above and below the ductus. The aorta shows post-stenotic dilatation.

In assessing the results there can be little doubt that the bigger the calibre of the anastomosis the quicker and more outstanding is the effect on the blood pressure in the upper and lower limbs.

Results of Operation

Whilst eight children have benefited from operation, one infant died, another improved only temporarily, and an older boy has deteriorated after operation.

The published figures and our experience agree that if a baby with coarctation develops symptoms of heart failure before the age of 6 months and fails to respond rapidly to treatment he is unlikely to survive more than a few weeks. In view of this we decided to operate on two infants, one of whom died shortly afterwards.

A male infant aged 2 weeks was admitted to hospital with convulsions and found to have pneumonia with coarctation and congestive heart failure. Blood pressure: arms, 150/90; legs, 0. An enlarged heart, a loud systolic murmur, large pulmonary arteries, and congested lungs suggested associated septal defect. The diagnosis was confirmed by venous angiogram and retrograde aortogram. Oedema, hepatic enlargement, and tachycardia persisted after treatment of pneumonia. The condition deteriorated. Operation: Age 7 weeks; adult type of coarctation resected and end-to-end anastomosis performed. Ductus arteriosus found to be closed. Post-operative respiratory failure with pulmonary oedema, attacks of cyanosis, and convulsions. Death occurred during attack of vomiting 36 hours after opera-

tion. Necropsy: Heart large (56 g.); hypertrophy of both ventricles, small ventricular septal defect, dilated pulmonary artery. Aortic anastomosis satisfactory. Trachea and main bronchi contained vomitus.

The second infant also developed symptoms of heart failure.

A baby girl aged 7 months was admitted with bronchitis and with deformities suggestive of Turner's syndrome. Blood pressure: arms, 160/90; legs, 0. Heart enlarged. Faint basal systolic murmur. Coarctation of the aorta of adult type confirmed

FIG. 3.—Aortogram showing post-operative stricture formation.

by angiography. Operation: Age 9 months; because of increasing oedema and hepatic enlargement. Resection and end-to-end anastomosis. Resected segment showed pin-hole opening and post-stenotic dilatation. Post-operatively, arterial pulse felt at groin, but blood pressure did not fall. In next few weeks femoral pulse gradually faded and disappeared. Retrograde aortography two months after resection showed that stenosis had recurred (Fig. 3). Blood pressure in arm five months after operation, 200/120 (dotted lines, Fig. 4).

FIG. 4.—Blood-pressure records before operation and at time of discharge from hospital after operation.

A boy aged 10 years. Coarctation of the adult type. Delayed femoral pulse. Blood pressure: arms, 165/100; legs, 140/110. No history of nephritis. Blood urea 80.6 mg. per 100 ml.; renal function—slightly impaired ability to concentrate (1020) and dilute (1004). Urine: no albumin or casts. As blood pressure was rising it was suggested that operative treatment might be followed by at least a partial improvement. Operation: Resection of adult type coarctation; end-to-end anastomosis. Post-operative condition satisfactory with good femoral pulse, but no influence on blood pressure. Follow-up: Blood urea fell to normal, but arm blood pressure rose steadily to 190/128 (dashed lines, Fig. 4).

The renal condition did not appear to be responsible for this failure because, in spite of the pre-operative findings, blood urea and urine became normal. The collateral circulation was well developed, and the femoral pulse was easily felt, though delayed, both before and after operation. An angiogram showed that there was some narrowing of the aorta at the operation site, and direct brachial and femoral artery blood-pressure readings show that the hypertension is confined to the upper part of the body. This boy has been operated upon again using a human graft.

The remaining eight children improved. This was demonstrated by the comments of the parents. Increase in exercise tolerance was pronounced, and one child climbed Snowdon within a year of operation, a feat which she could not previously have attempted. Her greater capacity for exertion was due in part to easier breathing, but more to a greater power in her legs. As her mother put it, "Her legs are twice the size." Four children noticed that their feet were no longer cold, and three of them were relieved of cramps.

The most readily measurable criterion is the effect on blood pressure. Before operation the 11 children showed only slight fluctuations in blood pressure, and 11 controls (identical except that they had not been treated surgically) have shown a slight increase of pressure during the period of observation. The effect of resection is shown in Fig. 4, where immediate pre-operative pressure is compared with the post-operative pressure. The two cases treated by subclavian aortic anastomosis showed improvement in every way comparable to that from an end-to-end aortic junction.

In successful cases the blood pressure not only fell immediately but continued to fall for some weeks after operation. This can be demonstrated by comparing the blood pressure at the time of discharge with that recorded when the patients were last seen (Fig. 5). The finding encourages the hope that improvement may be permanent in most of these children.

What happens at the site of anastomosis is uncertain, but the continued fall of blood pressure is presumptive evidence that in older children the junction usually grows with the child. We have not seen an aneurysm develop, and we imagine that it is less likely to happen in the relatively healthy tissues of a child's aorta than in the degenerated vessels of an adult. On the other hand, post-operative stricture has occurred in two patients. In one of them, an infant, the stenosis formed quickly and completely after an entirely satisfactory re-

FIG. 5.—Blood-pressure records at time of discharge from hospital and when last seen.

section and a good anastomosis. It is difficult to avoid the impression that some inherent quality of the infant's aortic tissue played a part in the recurrence. In the older child stenosis was less severe and developed less rapidly.

The cause of the hypertension in coarctation remains a matter of controversy. When circumstances made it necessary to occlude the descending aorta for several days in a child who had well-developed collateral channels, the blood pressure in the arms rose from 145/110 to 240/170. It fell again immediately after a successful operation ten days later. The blood pressure remained high in both patients who developed post-operative stenosis. These observations suggest that a purely mechanical factor plays a considerable part in the hypertension, but the progressive, less spectacular, fall of blood pressure which follows the immediate improvement points to a gradual reduction of vascular tone, and perhaps may be due to a falling concentration of pressor substances in the circulating blood.

Impressions

Coarctation seems to be potentially a dangerous disease, and for any individual patient it is difficult to predict the future. When a baby with coarctation has symptoms of heart failure, and when this failure shows no response to a medical treatment, he is unlikely to survive more than a few months unless treated surgically: the only post-operative death in this series occurred in an infant previously in heart failure. During the rest of the first decade a child with coarctation appears to be comparatively safe, but the hazard

to life seems to increase greatly after puberty. Operation has seemed to us to be easier and safer in children than in adult subjects, and has usually been followed by a fall of blood pressure which has been progressive over a period of several weeks. Stricture formation may follow operative treatment; it is likely to have more serious consequences in infancy, and on present evidence, therefore, we feel that the best age for operating on cases of coarctation is the second half of the first decade. Earlier operation may be essential when there have been symptoms of heart failure or of subarachnoid haemorrhage.

Summary

Evidence is presented to show the prognosis of coarctation of the aorta. If a baby has coarctation and symptoms of heart failure, and if the failure is slow to respond to medical treatment, death is probable within the course of a few months unless treated surgically.

During a period of five years at the Children's Hospital, Birmingham, 30 infants died from coarctation within six months of birth. During the rest of the first decade a child with coarctation appears to be comparatively safe, but the hazard to life increases again at puberty and the chances of reaching the age of 40 are poor. Operation has proved easier and safer in children than in adult subjects, and has usually been followed by a fall of blood pressure which has been progressive for a period of several weeks. Stricture formation may follow operative treatment: two examples of this are given. We believe that the second half of the first decade is the best time to operate on cases of coarctation.

We thank our colleagues for referring patients to us, Dr. H. S. Baar for post-mortem reports, and Dr. Roy Astley for his constant help.

OUTBREAK OF FOOD-POISONING FROM BREAD MADE OF CHEMICALLY CONTAMINATED FLOUR

BY

G. M. DAVIES, M.B., Ch.B., D.P.H.

Medical Officer of Health, Pontardawe Rural District Council

AND

IEUAN LEWIS, M.B.E., F.S.I.A.

Senior Sanitary Inspector, Pontardawe Rural District Council

The outbreak of food-poisoning here reported upon is characterized by two factors: the widespread nature of the inquiry, and the unusual nature of the contaminant. The extensive inquiry was necessary in that, contamination during transport being suspected, it was essential to establish the full facts in order to prevent recurrence. The unusual nature of the contaminant, endrin, is indicated by the fact that no previous record has been found of endrin-poisoning since the insecticide became generally available in March, 1954. It is of interest, therefore, to report on the means by which the contaminant was identified and to provide clinical details of endrin poisoning.

Description and Location of Area.—The Rural District of Pontardawe is situated in Glamorgan some seven

miles to the north-east of Swansea. It has a population of 32,520 and an acreage of 35,000. The main centre of population is in the Swansea Valley, which runs through the area from south-west to north-east, with the town of Pontardawe at its centre. The principal industries of the area are coal-mining, steel and tinplate manufacture, and nickel refining. The outbreak was entirely confined to the lower portion of the valley, which embraces the six miles between Clydach and Godregraig.

Inquiry into Outbreak

At 4 p.m. on May 2 the public health department was informed by telephone that 10 men at a local works had been taken violently ill during the course of the day. Immediate inquiry showed that their places of work and illness so differed that gas and fume escape could be eliminated; food-poisoning was therefore suspected. Of the 10 men, seven had been sent home, one had remained at work, while two had been admitted to hospital.

Further inquiries were immediately made at the homes of the persons concerned and details taken of the food eaten at the works that day. It was found that in every case the only common factor was white bread rolls, and in most cases such rolls and a cup of tea had provided the only meal before the illness. This fact was established at 7 p.m. the same evening, and a visit was paid at once to the bakery where these rolls had been manufactured. The baker was asked to provide details of his bakings for that day's consumption, and it was found that the works rolls were manufactured from white patent flour while his bread was manufactured from national flour.

He had during the morning of May 2 returned two sacks of national flour to his suppliers because of an indefinable odour. It should be noted that at this time the only commodities implicated were white bread rolls, and the illnesses were confined to persons working in the local works. At 11.30 p.m., however, a medical practitioner telephoned that a person having no connexion with the works and not having consumed rolls from the works supplies but from the same bakery had collapsed in similar circumstances to the other cases. Inquiries were therefore pursued through the night in order to ascertain whether or not there was sufficient prima facie evidence to warrant a B.B.C. warning being given to the public the following morning, May 3.

By 6 a.m. on May 3 it was considered that a broadcast warning was necessary, and the police were asked to transmit a message through the appropriate channels. This message, which was broadcast on the 8 a.m. and 9 a.m. news, instructed all persons who might have purchased white bread rolls in the Pontardawe area on May 2 to destroy them as it was possible that some might have been chemically contaminated. That the warning was justified was apparent during the course of that day, May 3, when 47 cases were notified among the general public. In every case it was established that bread manufactured at the same bakery on May 2 had been consumed by the patients.

It is estimated that the amount of contaminated bread available for consumption in the area placed approximately 1,500 persons under risk. The word "destroyed" was used advisedly in the broadcast, as it was thought that the public might otherwise dispose of the bread in unsatisfactory circumstances. It is known that in one instance the bread was fed to 12 chickens, all of which died.

Inquiries were complicated by the fact that the 10 persons ill on May 2 at the works had eaten white bread rolls made from white patent flour, while the 47 people taken ill on May 3 had eaten bread manufactured from national flour. A number of samples were obtained of the actual bread, and the Welsh Board of Health, with whom the local health department was in close contact, made arrangements for analysis of the bread samples by the Department of the Government Chemist, London. On Monday, May 7, the wooden floor of the bakery storeroom was closely examined and found to be giving off an aromatic odour at a point

where the baker indicated a sack of national flour to have rested. This section of the floor, some six inches (15 cm.) square, was thoroughly scraped with a wire brush and the dust obtained also forwarded to the Government Chemist through the Welsh Board of Health.

The two sacks returned by the baker were traced to a depot at Swansea, and on examination one was found to have some aromatic odour at the bottom of the sack. Samples of this sacking and the flour immediately below were again sent for analysis. The depot foreman of the flour company was able through his invoices to trace that this flour was loaded into a rail wagon at Cardiff on April 21, discharged at the Swansea depot on the 25th, and delivered immediately to the baker.

The number of the rail van was passed to the transporters and they were asked to trace both its present location and its movements and contents prior to April 21. On May 14 a report was received from the Government Chemist that after a long and difficult analysis the contaminant had been identified as endrin, a chemical used in horticultural sprays against various pests. It was also found that this chemical was manufactured only in the U.S.A. and that only one firm imported it into this country. The firm concerned was given the number of the rail wagon and asked to trace whether it had ever been used by them, and, in addition, whether they had received any complaints that endrin products had leaked during transit.

On May 22 the transporters reported that the rail wagon had been found near Cambridge, and it was later learned that it would be brought to London under seal for further examination. On May 28 representatives of the public health department, the flour firm, the chemical importers, and the transporters discussed the question in London, when it was found that leakage of endrin during transit had occurred on February 20, 1956, and that further inquiry had shown the wagon in which the spillage had occurred to be the same as that in which the contaminated flour was later transported.

It was stated that endrin was dissolved in xylene for normal spraying purposes and that the spillage into the wagon had occurred at a concentration some 800 to 1,600 times higher than that at which it was sprayed in the field. It was appreciated that under normal conditions xylene evaporates fairly quickly and that some two months had elapsed between spillage and suspected contamination of the flour, but it is felt, however, that the problem of non-evaporation is of less significance than the fact that endrin was spilled in a wagon which subsequently carried flour found on analysis to contain endrin. It was arranged at this meeting that the wagon floor be sectioned and scraped and the scrapings analysed for the presence of endrin. The laboratory reports of endrin content of the various samples are shown in the Table.

Symptoms

As a result of the episode described previously 59 persons were notified by local general practitioners as suffering from food-poisoning, and it is probable that at least a hundred more felt unwell but did not call in their doctor. All the illnesses followed the eating of bread rolls, "batches," or loaves made from flour now known to have been contaminated with endrin.

The main symptoms were in every case suggestive of a disturbance of the central nervous system. The severity of the attack appears to have been related directly to the amount of bread eaten: about three or four slices or two or three rolls were usually sufficient to produce a convulsion. The time of onset was somewhat variable. In most cases symptoms occurred about three hours after ingestion. Where the interval was only half to one hour it was usually found that some of the bread had also been eaten at an earlier meal as well.

Approximately 30 of those affected suffered from a convulsion of sudden onset. With no warning, they fell to the ground unconscious wherever they happened to be, and

Tabulated Results, with Comments, of Samples Analysed by the Department of the Government Chemist, London

Sample	Date	Description	Origin	Endrin Content		Remarks
				%	p.p.m.	
1	5/5/56	White patent flour	Shaken from empty sack "A" at bakery	Nil	Nil	Probably contaminated by storeroom contact with national flour sacks (sample 8 below)
2	5/5/56	" " "	Shaken from empty sack "B" at bakery	0.02	200	
3	5/5/56	" " "	From sack in current use	0.05	500	
4	5/5/56	Floor scrapings	Wooden floor of bakery flour storeroom	0.96	9,600	Scraped from place where used sack of national flour had rested from 25/4/56 to 2/5/56
5	7/5/56	" " "	" " "	" " "	" " "	Remaining portion of loaf which had caused illness to one person
6	7/5/56	Loaf	Mix "A" May 2	0.015	150	These samples were taken from two full sacks of national flour returned to flour depot by the baker on May 2, and sampled there
7	8/5/56	National flour	Taken from top of Sack 1, returned full by baker	Nil	Nil	
8	8/5/56	" " "	Taken from bottom of Sack 1, returned full by baker	0.55	5,500	
9	8/5/56	Sacking	Cut from bottom of Sack 1	0.15	1,500	Traces of endrin in five other flour samples of same wagon. Presence of wheat starch in all samples
10	8/5/56	National flour	Taken from Sack 2, returned full by baker	Nil	Nil	
11	8/6/56	Floor scrapings	Scraped from bottom of wagon	11.6	116,000	

several injured themselves in so doing. Eyewitnesses, including local doctors, have recorded that the convulsions were epileptiform in character, with frothing at the mouth, facial congestion, and very violent convulsive movements of the limbs, sometimes accompanied by an arching of the vertebral column. Two persons suffered from a shoulder dislocation during a convulsion. After a period of several minutes the patient became quiet but remained semi-conscious in most instances for a further 15 to 30 minutes. Three of those affected had more than one convulsion, and in one case, that of a young farm hand who had eaten almost a whole loaf, convulsions followed one another in quick succession for about an hour.

Symptoms also followed a definite pattern in the less acute cases. These patients first noticed that they were becoming dizzy, with weakness in the legs, abdominal discomfort, and nausea. Few actually vomited, but those who did, whether spontaneously or after being given a salt-and-water emetic, recovered more rapidly. In many cases the feeling of weakness increased; the patient became disorientated and felt as if he were falling forward. There was considerable confusion of thought and some actually imagined at the time that they were "going mad." At this stage some of them became a little aggressive; one or two said that the top half of their head felt as if it was solid. Several noticed that they became temporarily deaf.

Recovery was comparatively rapid even in cases where there had been a convulsion, and by the following day most of those affected felt fairly well. However, a few complained of weakness, insomnia, and loss of appetite for several days. A small minority remained away from work for two to four weeks complaining of headaches, lethargy, weakness, and anorexia, but the symptoms of some of this latter group may have been psychological in origin.

Often the whole family became ill after eating the bread, but in some cases, although all had eaten the bread, only one person became ill. It is interesting to note that very few children were affected. Among the notified cases there were only three children of 10 years of age or younger, the youngest being a girl of 8½. In all, 17 persons were sent to hospital, the majority of whom had practically recovered by the time they were admitted. Case histories show that in no cases were abnormal neurological signs discovered with the exception of some abnormal findings in the seven patients who were examined electroencephalographically. The electroencephalograms are now being repeated in some of these cases.

Case 1.—A steelworker aged 21 ate some of a contaminated batch for supper on May 2. After he had gone to bed he felt a little dizzy and could not sleep during the night. Next morning he ate more of the batch for breakfast and felt weak and giddy during the morning. At midday he had his lunch, eating four slices of the same batch. He then went to work feeling dizzy and thirsty, and having

an unpleasant taste in his mouth, with a certain amount of nausea. At 4 p.m. he suddenly fell down unconscious and remained so for about 15 minutes. He was admitted to Morriston Hospital at 6 p.m., having dislocated his left shoulder during the convulsion. On arrival at hospital he was quite conscious and there were no abnormal, neurological, or other signs. He remained in hospital three days and was discharged apparently quite well. An electroencephalogram taken four and a half hours after the convulsion suggested a paroxysmally unstable element, finding expression chiefly in the right posterior area and temporal or central areas.

Case 2.—A male member of the steelworks maintenance staff aged 28 ate three white rolls at 8 a.m. on May 2. He felt perfectly well during the morning, but while out for a walk on the road outside the works at about 11.15 a.m. he fell in a "fit" and was unconscious for approximately 20 minutes. He was brought home and went to bed feeling giddy and suffering from nausea. He slept well that night and felt no ill effects. At 12.30 p.m. on May 3, however, he ate four slices from a contaminated batch, and three hours later felt ill, weak, and dizzy once more. He returned to bed, and at 6 p.m. had a further convulsion, after which he remembered very little for about two hours. He again slept well and awoke fully recovered on the morning of May 4, except that for some days afterwards he suffered from vertigo on lying down. He returned to work on May 7. Five weeks after his illness he stated that he still felt a little vertigo on lying down.

Case 3.—A male clerk aged 50 ate three slices from a contaminated batch at about 1 p.m. on May 2. At 4 p.m. he found he could not concentrate, and at 5 o'clock he returned home from the office with a slight feeling of nausea. When he reached home he became confused in thought and felt very irritable and was perhaps a little aggressive. He felt unbalanced, and described the symptoms as feeling as if he was "going mad." He suffered from lack of orientation. The top of his head felt like a stone, and he noticed a feeling as of insects crawling on his left arm. His legs became very weak and felt heavy, and on looking in the mirror he noticed that his pupils were widely dilated. These symptoms continued during the early part of the evening, and at 8 p.m. he went to bed. From 10 p.m. until 3 a.m. he was unable to sleep, only dozing fitfully. By 3 a.m. he felt much better and slept well until 6 a.m. He got up and ate a good breakfast. About 10 o'clock, while at the office, he noticed a slight recurrence of mental confusion and disorientation, but this lasted only for about 15 minutes. He was off colour and weak for a further 72 hours. He stated that in spite of his mental confusion he was able by a great effort to collect his thoughts from time to time.

Case 4.—A man aged 24, a clerk at the steelworks, ate two white bread rolls in the works canteen at 10.45 a.m. on

May 2. Two hours later he felt "hot" and not very well, and walked to the top of the stairs to get some fresh air. He apparently had a convulsion and remembers nothing for 30 minutes. He fell downstairs, severely bruising the area around his right eye. He went home and soon felt much better, but was off his food for several days. He remained away from work for eight days.

Case 5.—A pharmaceutical chemist, aged 46, ate five slices, at 1 p.m. on May 2, of a contaminated batch which had been quite recently baked. Two hours later he felt hazy and could not concentrate. He had some flatulent discomfort but did not vomit. He became giddy and was stated to be a little aggressive and to be blinking his eyes frequently. He gradually improved but did not feel quite well. At 7.15 p.m. he ate a further five slices from the contaminated batch, and, although he still did not feel well, he attended a meeting where he was chairman. He found that he could not concentrate again, and at 8 p.m. he suddenly became rigid and fell unconscious. He bruised his nose and cut his scalp in falling and there was considerable bleeding. During the convulsion his arms and legs were jerking. He was unconscious for about 15 minutes and was removed to hospital. He thinks that he vomited before he arrived. It is stated that he was fully conscious on arrival at the hospital and there were no abnormal neurological signs. However, he still felt hazy and very restless that night, sleeping badly. Next day he felt much better. An electroencephalogram was taken approximately 20 hours after the fit. It was reported to be abnormal and suggestive of some irritative condition or mild unstable element finding expression chiefly to the right of midline in central and also to some extent in temporal areas. A further electroencephalogram was taken four days after the convulsion and was reported as showing considerable improvement, but still not typically normal, being reminiscent of persons experiencing a state of tension or anxiety.

Case 6.—A tinplate worker aged 47 ate half a loaf from a contaminated batch for supper on May 2. He felt peculiar during the night and could not sleep. At 9 a.m. he ate a further half loaf for breakfast. He did not feel like going to work, and by midday he was feeling very ill. He felt numb from the waist down, was dizzy, and had considerable confusion of thought. At 2 p.m. he had a convulsion and fell. He was noticed to be black in the face and frothing at the mouth, and his limbs were jerking. The convulsion lasted three or four minutes, and he remembers nothing for about half an hour afterwards. He was sent to hospital, where on admission his condition was satisfactory and a clinical examination was negative. He was in hospital for two days and had no after-effects.

Case 7.—A housewife aged 46 ate two slices of a contaminated batch at about 10 p.m. on May 2. She awoke at 2 a.m. feeling ill, trembling all over, perspiring, and very weak. She vomited and felt much better afterwards. At 9 o'clock the following morning she ate three further slices from the contaminated batch. She did not feel very well during the morning, and by midday she was again trembling with weakness and had abdominal discomfort and nausea. There was considerable confusion of thought. She was disoriented, was deaf, and her eyes were slightly dim. She was admitted to hospital. On the way down in the ambulance she vomited and felt slightly better afterwards. On arrival at the hospital her condition was good and clinical examination was negative. She remained in hospital for two days and had no after-effects.

Case 8.—A schoolgirl aged 16 ate four or five slices from a contaminated batch for supper on May 2. She awoke at 3 a.m. and could not sleep for the rest of the night, feeling weak and having a sensation of nausea. She felt much better next morning but did not go to school. At 9 a.m. she ate a further four slices from the batch. At 11 a.m. she felt ill and was noticed to be extremely pale. She lay down, and at 11.30 she had a convulsion, becoming unconscious. She was black in the face, frothing at the mouth, and remained unconscious for about 20 minutes.

She came round and felt weak and drowsy. Half an hour later she had a second convulsion and was again out for 15 to 20 minutes. Whilst in the ambulance she had a third similar convulsion, after which she vomited. On admission to hospital she was pale and drowsy. Nothing else abnormal was recorded. She remained in hospital for two days with apparently no after-effects.

Case 9.—A schoolgirl aged 8½ ate three slices of a contaminated loaf at 5 p.m. on May 2, but felt quite well. For breakfast on May 3 she ate a further two or three slices of the loaf with no ill effect. However, by 5 p.m., she felt "funny in her tummy," had a headache, and looked heavy about the eyes, but ate her tea, at which meal she consumed a further three slices of the bread. She played during the evening but was not quite well. She went to bed at 8 p.m., and about 8.30 p.m. her father called upstairs to tell her to keep one of the other children quiet. He received no reply, and, on going up to investigate, found the child lying on the floor in a dazed condition. She stated that she did not know where she was. He picked her up and placed her on the bed, whereupon she had a convulsion, with considerable jerking of her arms and legs, and fell off the bed again. She was semi-conscious for about half an hour; then she vomited a little and felt much better. She slept well during the night and was quite all right next day.

Case 10.—This patient, a blind man aged 55, attends an occupational centre. At 1 p.m. on May 3 he ate four slices of bread from a contaminated batch. These formed part of his lunch, which he ate as sandwiches whilst away for the day at the blind institute. About 4 p.m. he felt dizzy, "off his balance," and felt as if he was falling forward. He returned home, and at 5.15 ate two more slices of bread from the same contaminated batch. About an hour later he fell in a convulsion, cutting the top of his head. He was removed to hospital and remained there for two days; it was noted on admission that he was shocked but fully conscious. He had a laceration over the right parietal bone but no bony injury. He felt weak for several days after his return from hospital.

Case 11.—A male clerk aged 18 ate three slices from a contaminated batch for his lunch on May 3. He felt quite well, and at 5 p.m. ate a further four or five slices from the same batch. Again he felt no ill effects, but at 6.30 he fell in a sudden convulsion and was removed to hospital. On arrival he was conscious but feeling dazed. His condition was stated to be satisfactory. He felt dizzy for a further two days after his return home and remained away from work for five days.

Case 12.—This patient, a woman aged 22, was a chemist's assistant. At about 8 a.m. on May 3 she ate one round of toast made from a contaminated batch. At 11 a.m., while working in the chemist's shop, she began to feel sick and dizzy, and says that she saw double for a while. She came home at 1 p.m. suffering from nausea and feeling as if she was going to fall. She vomited a little and spent the afternoon in bed. She felt somewhat better, and at 4.30 p.m. had tea, eating three slices from the contaminated batch. She was feeling much better during the evening, but at 8 o'clock suddenly had a convulsion and became unconscious. She remembered nothing for about an hour afterwards. On admission to hospital she was stated to be quite well, with no abnormal signs. An electroencephalogram taken 19 hours after the convulsion was reported to be outside normal variation, suggesting a non-specific unstable element finding expression in the central and posterior areas generally. She remained in hospital for a week. She stated that she slept badly for a further week after return home and that her appetite was still rather poor. She was off work for five weeks.

Case 13.—A farmer aged 33 consumed four or five slices from a contaminated batch at about 1 p.m. on May 3. He continued his work and felt quite well during the afternoon. About 5 p.m., whilst he was driving a tractor in a

field which he was harrowing, he fell and remembers nothing until he found himself lying on the ground, the tractor having continued on its course and run into a hedge. He got up and returned home, and for about an hour he felt ill, with some confusion. At 6 p.m. he vomited and went to bed. He slept well and felt much better the following morning, but was a little weak during that day. There were apparently no after-effects.

Case 14.—A farm hand aged 18 ate the greater part of a contaminated loaf at 10 a.m. on May 3. About two hours later he had a fit while driving cattle on the road. He fell unconscious and was noticed to be purple in the face and frothing in the mouth; his arms and legs were jerking. He became partially conscious after three or four minutes, and then had a second fit. During the next hour he had a series of similar fits each lasting a few minutes with a period of semiconsciousness between them. He was removed to hospital, and on admission was said to be drowsy and comatose. There were no abnormal neurological signs, and he recovered within a few hours. An electroencephalogram taken 48 hours after the convulsion was reported as being abnormal, but the possibility of underlying behaviour disorder was suggested in this case. This boy is at an approved school and is boarded out with local farmers. On discharge from hospital five days later he did not return to the farm where he was working, but went back to the farm school from which he originally came.

Chemistry of Endrin

The word "endrin" is a coined common name for a pure chemical with the following structural formula:

Endrin is the newest member of a triumvirate of insecticides, the others being "aldrin" and "dieldrin." All are closely related both structurally and in that all three have their origin in dicyclopentadiene, a hydrocarbon found in small quantities in distillates from "cracked" petroleum or coal-tar. Endrin, however, is the most versatile insecticide because in addition to the range of insects killed by dieldrin it also gives control of many caterpillar and aphid pests.

At present endrin is produced at the Shell plant at Denver, Colorado, U.S.A., but will soon be produced also at the new insecticide plant of the Royal Dutch Shell Group at Pernis, Rotterdam.

Endrin is soluble in aromatic hydrocarbons and ketones, sparingly soluble in alcohols and paraffin hydrocarbons, and insoluble in water. As marketed for formulation purposes, it is a pale buff granular product containing 90-95% of endrin, is easily ground, and has a faint "medicinal" smell. It became available for field evaluation outside the U.S.A. towards the end of 1952 and was generally available in March, 1954.

Formerly known as compound 269, this new insecticide has been found extremely useful in the field, exercising control over cotton and tobacco pests, borers of cane, rice, and coffee, moths, caterpillars, and aphides. In this country its main use to date has been in the fruit-growing industry for control of apple aphid, apple sucker, winter moth caterpillar, tortrix caterpillar, and apple saw-fly.

The manufacturers recommend sensible precautions with regard to endrin, while emphasizing its toxicity to be of a lower order than that exhibited by the older anticholinesterase or phosphate insecticides or by arsenic compounds.

This insecticide is comparatively new, and present information must necessarily be regarded as interim.

Toxicity of Aldrin, Dieldrin, and Endrin

So far as is known no previous cases of endrin poisoning have been reported in human beings, but cases have occurred of poisoning by aldrin and dieldrin (Princi, 1952), which are chlorinated hydrocarbons similar to endrin, and are also used as pesticides.

Endrin is an isomer of dieldrin. In these cases the early symptoms are reported as being headache, nausea, vomiting, general malaise, and dizziness. Where the amount of intoxicant which had been absorbed was small further symptoms rarely developed. However, when larger doses were taken central nervous symptoms occurred. These were characterized by convulsions which were clonic and tonic in character. If the dose was excessively large, the central nervous symptoms occurred without any other premonitory symptoms. The convulsions were sometimes followed by coma. Hyperexcitability and hyperirritability were common. Thus it is seen that the symptoms of poisoning by these substances are very similar to those caused by endrin in the outbreak at present under review.

One case of aldrin poisoning which occurred in 1951 has been described in considerable detail (Spiotta, 1951). It refers to a 23-year-old farmer in the United States of America who intentionally drank from a coca-cola bottle containing an aldrin mixture. He was estimated to have ingested 25.6 mg. of aldrin per kg. of body weight. In spite of gastric lavage generalized convulsions began within 20 minutes and persisted until large amounts of barbiturate had been given. During one of these convulsions he dislocated a shoulder. Later an electroencephalogram revealed generalized cerebral dysrhythmia. The rhythm did not become essentially normal until five months had elapsed. Haematuria and albuminuria appeared on the second day and persisted for 18 days. Although symptoms in this case persisted for 12 days complete recovery ensued and there appeared to have been no permanent kidney or liver damage. In addition no permanent organic brain changes were found either by means of electroencephalographic tracings or by psychometric testing.

Data concerning the management and treatment of aldrin and dieldrin poisoning are available, and it would appear that the treatment of endrin poisoning is on similar lines. It is recommended that if aldrin or dieldrin has been ingested in any form the stomach should be washed out as quickly as possible, and that later adequate quantities of magnesium sulphate should be given in order that the ingested material may be purged rapidly. The patient should be closely watched for 72 hours, and at the first suggestion of involvement of the nervous system barbiturate therapy should be instituted. Barbiturates may be employed in the form of either sodium phenobarbitone or sodium amylbarbitone. Glucose may be administered intravenously, care being taken that not so much parenteral fluid is given as to encourage the production of pulmonary oedema. In cases either of acute or chronic intoxication a high-protein therapy may be advantageous, since liver damage may be produced by this type of poisoning. For this purpose the intravenous administration of amino-acids is recommended. The use of morphine is definitely contraindicated. Because this type of poisoning may in very severe cases result in the production of pulmonary oedema it may be necessary to institute oxygen therapy. In acute intoxications kidney damage may be manifested by the presence of haemolysed blood in the urine, therefore the benzidine test may be positive in the absence of red cells in the urine.

Although there is apparently no literature concerning human endrin poisoning, details of the mammalian toxicity of this substance have been published (Cole, 1955). It is stated that the acute oral toxicity of endrin to small laboratory animals is greater than that of aldrin or dieldrin, the LD₅₀ to male rats being approximately 35 mg. per kg., and to female rats about half of this figure.

Summary

The investigation has established that a consignment of endrin dispatched on February 20, 1956, leaked 3 gallons (13.6 litres) into the conveying wagon in transit. The same wagon, which was used for the conveyance of empties between February 20 and April 25, was on the latter date loaded with sacks of flour at Cardiff and dispatched to Swansea. Of the 100 sacks carried in the wagon it was proved that two absorbed endrin from the vehicle floor, and both these sacks were delivered to one bakery as part of the weekly consignment. One of these sacks was returned, and endrin was found to be present in some parts of the flour to the extent of 5,500 parts per million. The other sack was used by the baker to manufacture loaves which caused 49 people to be ill enough to require medical treatment. Endrin was recovered from some parts of the bread consumed to the extent of 150 parts per million. It was further established that while in the bakery the empty contaminated sack which had contained national flour came into contact with dough made from patent white flour which, having been used to make white bread rolls, caused 10 men to become ill at a local works after consuming them.

Samples taken from the wagon floor and analysed on June 8 showed endrin still to be present in one section of the wagon to the extent of 116,000 parts per million.

The successful result of the inquiry would not have been achieved had the public health department not received the fullest assistance and co-operation from all the firms and organizations involved. It is desired to acknowledge the assistance provided by the Department of the Government Chemist, London, and the Glamorgan County Public Health Laboratory. The information on case histories was readily provided by Dr. Duncan Davies, medical superintendent, Morriston Hospital; Dr. Idwal Pugh, medical superintendent, Hill House Isolation Hospital, Swansea; and Mr. B. J. Baker, department of electroencephalography, Morriston Hospital.

TREATMENT OF MEGALOBlastic ANAEMIA OF PREGNANCY AND THE PUERPERIUM WITH VITAMIN B₁₂

BY

E. B. ADAMS, M.B., B.Sc., M.R.C.P.

Professor of Medicine, University of Natal, Durban

Early reports from temperate climates indicated that treatment of megaloblastic anaemia of pregnancy and the puerperium with vitamin B₁₂ was usually ineffective (Bethell *et al.*, 1948; Day *et al.*, 1949; Furman *et al.*, 1950; Ginsberg *et al.*, 1950; Ungley and Thompson, 1950; Clark, 1952). Total dosage did not exceed 120 µg. in the cases described. Later, however, a case was treated successfully in Holland with only 45 µg. (Nieweg, 1952), and recently in Dublin satisfactory responses followed the use of massive doses ranging from 900 to 5,000 µg. in 13 patients out of a series of 17 (Moore *et al.*, 1955). In warmer climates response to vitamin B₁₂ in small amounts was often satisfactory (Patel and Kocher, 1950; Chaudhuri, 1951), and good results sometimes followed the use of larger doses (Cohen, 1953; Adams and Wilmot, 1953; Tasker, 1954; Berry 1955).

Kothari and Bhende (1949) believed that the disease commonly seen in India and the Tropics was the same as that described in Britain by Callender (1944). Diagnosis depended on the presence of megaloblasts of Ehrlich in the peripheral blood or bone marrow. Cases reported from most parts of the world usually responded well to treatment with folic acid, and there were clinical similarities. Differences in response to vitamin B₁₂, however, supported the views of Thompson and Ungley (1951) and others that there are several varieties of the condition, while the work of Foy *et al.* (1952a, 1952b) in East Africa showed differences in the appearance of the bone marrow.

This paper records the results of a clinical trial using large doses of vitamin B₁₂ in 10 cases of the type of megaloblastic anaemia associated with pregnancy or the puerperium seen in Durban. The appearance of the bone marrow is briefly described.

Clinical Features

From a series of 34 patients with severe megaloblastic anaemia associated with pregnancy or the puerperium, 10 who were not dangerously ill were chosen for the trial. Two patients were African and eight Indian. Their ages and parity are indicated in Table I, which also shows the main findings in the blood on admission to hospital, and the results of gastric analysis after stimulation with histamine. Clinical features were similar to those previously described in our cases (Adams and Wilmot, 1953). These will not be discussed further except as regards infections and other factors which might be expected to retard recovery after treatment. Pyrexia was present in seven patients, all of whom were investigated for sources of infection. There was mild pyelitis in two (Cases 2 and 6); two others had com-

plained of diarrhoea before admission, but no cause was found on stool examination. X-ray examination of the chest in nine patients revealed no abnormality. One patient had evidence of puerperal sepsis, which was not severe (Case 9), but pyrexia persisted after this had been cleared up. Full investigations revealed no cause, other than severe anaemia for this pyrexia, which settled when the blood count rose. In their series Badenoch *et al.* (1955) record a high incidence of other complications such as vomiting and haemorrhage, but these were absent from my cases. In the whole series of 34 cases there was no clinical evidence of steatorrhoea, an uncommon disease in South Africa; faecal fats estimated in 21 (six of the present trial series), were always within the normal range. It thus seems unlikely that infections or other factors have obscured the results of treatment in this trial.

Diet

Dietary histories are difficult to obtain and are not very reliable. Family incomes of all were low, and carbohydrate intake tended to be high. Protein was very low in seven, and apparently adequate in one (Case 6). One patient is of particular interest in view of the suggestion of Badenoch

and his colleagues that resistance to haemopoietic factors may develop during pregnancy.

Case 4.—An Indian woman had been under my care during the seventh and eighth months of pregnancy for severe chorea gravidarum. As she was thin she had received soured milk and an egg daily in addition to hospital diet. On admission haemoglobin was 8.6 g. per 100 ml., mean corpuscular haemoglobin concentration 29%, sedimentation rate 51 mm. in one hour (Wintrobe). Treatment consisted of bed rest, salicylates, sedation with barbiturates, and ferrous sulphate. The bone marrow was not examined. Leaving hospital against advice, she delivered a stillborn infant at home two weeks later. Severe chorea recurred immediately and she was readmitted. Examination of the blood and bone marrow revealed the presence of megaloblastic anaemia, haemoglobin being 5.6 g. per 100 ml.

Bone Marrow

Diagnosis depended on examination of the bone marrow in all cases. My experience has been somewhat similar to that of Foy *et al.* (1952a), who described two groups of macrocytic or normocytic anaemia in East Africa. In one are giant metamyelocytes in the bone marrow with erythroblasts, macronormoblasts, and megaloblasts in various stages of development; in the other, giant metamyelocytes are present without megaloblasts. I have observed similar bone-marrow changes in some cases of kwashiorkor (Adams, 1954), and Berry describes them as a feature of some of the cases of anaemia of pregnancy in Lagos. Giant metamyelocytes were seen in all 10 of the present series, while in six there were megaloblasts of Ehrlich as well as cells of intermediate type similar to those described by Dacie and White (1949). Intermediate cells were present in the marrow in four, but megaloblasts were not observed (Cases 5, 7, 8, and 10). Differentiation from true megaloblasts is sometimes difficult. For the purposes of this trial a bone marrow was reported as megaloblastic if it contained true megaloblasts or intermediate cells as well as giant metamyelocytes.

Clinical Trial with Vitamin B₁₂

Before treatment with vitamin B₁₂ was started, all cases were observed over a control period—four days in Case 6, and five to seven days in the remainder. During this control period and throughout the trial which followed, progress was determined by daily reticulocyte counts, and by haemoglobin (Hb) and the volume of packed cells (P.C.V.), both estimated in duplicate every five days. Seven patients

had previously received no treatment and two had been treated with penicillin because of pyrexia (Cases 2 and 7). Significant blood changes did not occur in any of these during the control periods. Case 5 had been treated with penicillin and streptomycin seven days before vitamin B₁₂ was given. During this time a slight rise occurred in P.C.V., while the reticulocytes rose to 12.1% but dropped again to their previous level. No change occurred in the Hb, however, and examination of the bone marrow at the end of the control period showed well-marked megaloblastic erythropoiesis. She was therefore included in the series.

Vitamin B₁₂ was administered by the intramuscular route in doses ranging from 100 µg., given in one injection, to 1,400 µg. in daily injections of 100 µg. The results are analysed in Table II, which also shows the subsequent course of each patient.

It will be seen that seven responded to vitamin B₁₂. Response was good in six, but only moderate in the seventh. In four of these the bone marrow was re-examined during the trial, and in all erythropoiesis was then normoblastic, although in one some giant metamyelocytes were still present (Case 5). Three of these patients received only 100 µg. during the trial. As a group, response appeared to be as good as that of the other four who were given 1,000 µg. of vitamin B₁₂ or more. After the trial two received folic acid (10 mg. thrice daily); there was no second reticulocytosis in one of them on whom repeated reticulocyte counts were done. Three patients later showed signs of iron deficiency, for which ferrous sulphate was given.

Vitamin B₁₂ was judged to be ineffective in two patients (Cases 8 and 10). A false reticulocytosis of 20.9% occurred in Case 8, but the Hb failed to rise in both, while the bone marrow remained megaloblastic (examined on the fifteenth and seventh days respectively). The trial in Case 9 was inconclusive. Hb and P.C.V. dropped considerably and there was no rise in reticulocytes after five days, so folic acid therapy was started; but on this day partial change in erythropoiesis was observed in the bone marrow.

Discussion

In this small series satisfactory responses followed treatment with vitamin B₁₂ in all seven cases seen after delivery, 100 µg. apparently being as effective as larger doses. There was an average daily Hb rise during the trial of 0.16 g. per 100 ml. Better response followed treatment with folic acid in 14 other post-partum cases (mean daily Hb rise 0.23 g. per

TABLE II.—Analysis of Results

Case No.	Diagnosis of Anaemia	Vitamin B ₁₂ Dosage (µg.)	Hb Before Treatment (g./100 ml.)	Response to Treatment	Subsequent Course	Result of Vitamin B ₁₂ Trial
1	14 weeks post partum	1,000 (100 × 10)	4.3	13.5% reticulocytosis on 5th day, Hb 5.9 g./100 ml. on 10th day; bone marrow then normoblastic	Slow rise on further B ₁₂ , folic acid, and iron to 12.5 g. Hb/100 ml.	Good
2	8 weeks post partum	100	3.3	34.3% reticulocytosis on 5th day; Hb 5.4 g./100 ml. on 15th day	Continued rise on further B ₁₂ and later iron to 11.6 g. Hb/100 ml.	"
3	2 weeks post partum	100	3.2	28.3% reticulocytosis on 6th day; Hb 5.4 g./100 ml. on 15th day	Continued rise on further B ₁₂ to 9.8 g. Hb/100 ml.*	"
4	2 weeks post partum	1,400 (100 × 14)	5.4	12.6% reticulocytosis on 6th day; Hb 8.4 g./100 ml. on 15th day, marrow then normoblastic	Changed to folic acid with continued rise of Hb to 11.9 g./100 ml. No second reticulocytosis	"
5	2 weeks post partum	1,000 (100 × 10)	3.3	26.5% reticulocytosis on 6th day, Hb 6.9 g./100 ml. on 14th day; marrow normoblastic on 7th day, with some giant metamyelocytes	Continued rise on further B ₁₂ and later iron to 15.6 g. Hb/100 ml.	"
6	At term	1,000 (100 × 10)	6.0†	31.3% reticulocytosis on 6th day; Hb 7.7 g./100 ml. on 15th day, marrow then normoblastic	Continued rise on further B ₁₂ to 11.6 g. Hb/100 ml.	"
7	" "	100	6.5	10.1% reticulocytosis on 5th day; Hb 7.8 g./100 ml. on 15th day	Continued rise on further B ₁₂ to 13.3 g. Hb/100 ml.	Moderate
8	4 weeks ante partum	100	4.6	20.9% reticulocytosis on 8th day; no rise in Hb by 15th day, marrow then still megaloblastic	10.3% reticulocytosis on 4th day after folic acid, Hb 6 g./100 ml. 15 days later. Marrow then normoblastic. After delivery and iron Hb rose to 12.3 g./100 ml.	Reticulocyte rise only
9	4 weeks ante partum	200	6.8	No rise in reticulocytes by 5th day; Hb then 5 g./100 ml., but marrow more nearly normoblastic	22.8% reticulocytes on 7th day after folic acid, but slow rise with iron to 9.8 g. Hb/100 ml.*	Partial marrow change only
10	10 weeks ante partum	700 (100 × 7)	3.8	No rise in reticulocytes by 7th day, Hb then 3.2 g./100 ml., and marrow megaloblastic	33.1% reticulocytosis on 5th day after folic acid, Hb 5.1 g./100 ml. on 11th day. Continued rise to 8.6 g. Hb/100 ml.*	None

* Left hospital against advice. † Transfused before trial.

100 ml.), but these two groups are not strictly comparable, since the folic acid cases were usually more anaemic before treatment and could not be observed over preliminary control periods. The addition of folic acid to treatment did not seem to alter the subsequent course in two of the trial cases, while in four others who were followed long enough blood counts reached normal values on vitamin B₁₂ (with added iron in two).

Very poor results followed treatment with vitamin B₁₂ in all three cases seen during pregnancy. From Table I it is seen that total proteins and serum albumin levels were lowest in these three cases, so that, besides pregnancy, protein malnutrition might be a factor inhibiting response to treatment. This seems unlikely from my experience with folic acid series. In six cases, four treated with folic acid at term and two post partum, serum albumin was less than 3 g. per 100 ml. (range 1.6 to 2.8 g.), and in three of these the total protein was less than 6 g.; yet five responded well, including one with only 4.9 g. total protein and 2.5 g. albumin.

A similar distinction between cases treated before and after delivery is found by analysing the details of the trial reported by Moore *et al.* Ten of their 12 post-partum cases responded to the large doses they used, but in some there were only small increments in Hb in the first two weeks. Only three out of their five ante-partum cases responded to vitamin B₁₂, and in all three the average daily Hb rises were very low. On the other hand, seven of Berry's nine cases treated during pregnancy responded to vitamin B₁₂, although normal Hb levels were not reached. Like Das Gupta *et al.* (1953), who treated nutritional macrocytic anaemia with vitamin B₁₂, Berry believes that additional folic acid may be necessary for complete remission. Foy *et al.* (1955) suggest that there are two types of non-pernicious megaloblastic anaemias in Africans—classified on response to treatment—including cases seen in pregnancy. One type responds completely to penicillin (in specified doses) or to vitamin B₁₂ by mouth, and serum vitamin B₁₂ levels are very low before treatment. The other (with normal serum vitamin B₁₂ levels) responds to folic acid but not to penicillin or vitamin B₁₂.

In Durban the bone marrow differs from that described in megaloblastic anaemia seen in temperate climates. Giant metamyelocytes are always present, but erythropoiesis may be either megaloblastic or of the intermediate variety. Similar appearances are seen elsewhere in Africa. Dacie and White, who observed red-cell precursors of intermediate type in cases of pernicious anaemia not severely anaemic, ascribed the changes to minor deficiencies in haemopoietic factors. In my cases, however, as in those of Foy *et al.* (1952a) and Berry, this intermediate type of megaloblastic change may be seen when anaemia is severe.

It seems likely that there are several varieties of megaloblastic anaemia associated with pregnancy because of these differences in the appearance of the bone marrow and in response to treatment. Despite this, however, cases reported from many parts of the world have much in common. They tend to occur in the last three months of pregnancy or in the puerperium; sometimes the onset is rapid; the peripheral blood picture is inconstant; spontaneous remission may occur after delivery; and dietary deficiencies do not appear to be the only cause, although diets are often poor. The common factor among them all may well be the development of resistance to the action of haemopoietic substances during pregnancy, as Badenoch and his colleagues have suggested, rather than to absolute deficiencies.

Summary

The results of a clinical trial using vitamin B₁₂ in 10 patients with megaloblastic anaemia of pregnancy are recorded. The appearance of the bone marrow is briefly described.

Response was satisfactory in all seven treated after delivery. It appeared to be as good with doses of 100 µg.

as it was when 1,000 µg. or more was given, but better results are usually obtained with folic acid.

Three patients treated before delivery responded poorly.

Because of differences in the appearance of the bone marrow and in response to treatment, it seems likely that there are several varieties of megaloblastic anaemia associated with pregnancy.

I wish to thank the medical superintendent of King Edward VIII Hospital, Dr. S. Disler, for permission to publish, and Drs. Kelman Drummond and N. A. Rossiter for access to cases under their care.

OPERATIVE PARATHYROID ARTERIOGRAPHY FOR LOCATION OF PARATHYROID TUMOUR

BY

R. E. STEINER, M.B., F.F.R.

Lecturer in Medical Radiology

RUSSELL FRASER, M.D., F.R.C.P.

Reader in Medicine

AND

IAN AIRD, Ch.M., F.R.C.S.

Professor of Surgery

Postgraduate Medical School of London, Hammersmith
Hospital

The operative discovery of a parathyroid tumour which lies at a distance from the thyroid gland, and especially of a parathyroid tumour in the superior mediastinum, can still be a difficult surgical exercise, and any procedure which locates such a tumour is of advantage. It has been found possible, at least on some occasions, to outline a parathyroid tumour by passing an arterial catheter disto-proximally into the arch of the aorta so that its tip lies at the orifice of the subclavian artery and radio-opaque material injected by way of the catheter can enter that artery, and pass by the inferior thyroid trunk to the thyroid gland and parathyroid tumour; but filling of the vertebral artery by this technique may give cerebral complications (Seldinger, 1954). The parathyroid tumour is so vascular that it may be

outlined. It occurred to one of us (R.F.) that more direct arteriography might be undertaken during the operation.

Procedure

Inferior thyroid arteriography was done during the exploration of the neck of a woman who had parathyroid osteodystrophy and investigation of whom had proved that she suffered from parathyroid overaction. Clinical examination did not expose any asymmetry of the neck, a plain x-ray film of the neck and barium swallow did not demonstrate any displacement of trachea or oesophagus, and before operation the location of the parathyroid tumour was not known.

The initial steps of the operation followed the usual pattern. The patient was placed carefully on the operating-table with the shoulders symmetrically raised on a pillow and the chin pointing directly forwards. A low collar incision was made, the infrahyoid muscles were separated in the midline and transected, and the thyroid gland was exposed. Close inspection failed to reveal any asymmetry, except the normal degree of displacement of the pyramidal lobe a little to the right of the midline. As in the case of at least one previous parathyroidectomy, the thyroid gland lay at a rather higher level than usual, the upper border of the isthmus being situated slightly above the level of the cricoid cartilage. The superior thyroid vessels, which were symmetrical on the two sides, were divided as in thyroidectomy, and the middle and inferior thyroid veins were divided also. The upper and lower borders of the isthmus and the gland were defined, as also were the medial borders of the upper poles of the lateral lobes. Then, on each side, of the upper poles of the lateral lobes. Then, on each side, the stay sutures were inserted into the lateral borders of the lateral lobes, and these were retracted while the carotid sheath was drawn laterally. Search in the areolar tissue between the thyroid gland and the carotid sheath failed to reveal a tumour, nor could a tumour be seen on close inspection of the borders of the oesophagus and the grooves between trachea and oesophagus. The fascia over the inferior thyroid artery on each side was now opened and

both inferior thyroid arteries were exposed. The right inferior thyroid artery was distinctly greater in girth than the left—a useful indication of the side of a parathyroid tumour.

It was decided to perform inferior thyroid arteriography on the right side, the side of the larger vessel. A "record" syringe containing 10 ml. of 50% diodone was connected by "polythene" tube with a hypodermic needle. The right inferior thyroid artery was elevated on a thread support at the point of its emergence from under cover of the carotid sheath, with just enough tension to stop the flow in it. The needle was then inserted into the lumen of the artery just distal to the point of its occlusion, and the radio-opaque material was rapidly injected. With the aid of a cassette placed under the patient's neck three antero-posterior films were taken, one towards the end of the injection and two immediately after the completion of the injection. They were developed and examined wet; the first of the two films is here reproduced. This shows the right lateral lobe of the thyroid gland clearly outlined by opaque material, while below it and rather lateral to it the outline of the responsible parathyroid tumour is observed.

Comment

This film shows clearly that a parathyroid tumour can be outlined by inferior thyroid arteriography. The character of the shadows suggests that if the parathyroid tumour had lain on the side of the trachea, or in the groove between the trachea and oesophagus, the shadows of the thyroid gland and parathyroid tumour would not have been separately distinguishable. A tumour in such a situation, however, should offer no great difficulty of operative dissection. It would seem that it is precisely on those occasions when the parathyroid tumour lies at a distance from the thyroid gland that it is most easily delineated radiologically. On this occasion the tumour did in fact occupy the situation in which radiology showed it to be—in the connective tissue of the neck below and lateral to the lateral thyroid lobe, and at a distance of about 2 cm. from the lower border of that lobe. Had we failed to outline the parathyroid tumour by right inferior thyroid arteriography, we should have had recourse to arteriography on the opposite side in the hope of outlining a left parathyroid tumour. If the disparity in size had been not between the inferior but between the superior thyroid arteries the larger superior thyroid vessel would have been chosen for the injection.

Research into "river blindness" and plans for the control of the Simulium flies which carry the filarial worm causing the disease (onchocerciasis) are described in the annual report of the British Empire Society for the Blind. An ophthalmic team, under Dr. F. C. Rodger, has been assessing the extent of river blindness. In the worst endemic areas of the Northern Gold Coast, among the million African inhabitants, 600,000 have onchocerciasis and at least 30,000 are blind. In some villages one-tenth of the population and one-fifth of the adult males are blind. Dr. Geoffrey Crisp, leader of the entomological team, has prepared a plan to control the fly at a cost of only £66,000. This plan, worked out with the help of the London School of Hygiene and Tropical Medicine, recommends a three-year campaign by six teams of African workers supervised by an entomologist. The report explains: "Each of these teams, using a simple routine and inexpensive equipment, would treat a section of the main endemic areas, at specified points, during the vital phases of the flies' life cycle. The total effect should be rapidly to clear some of the most heavily infected points and, over the main endemic area, gradually to reduce the number of flies to manageable proportions so they can subsequently be controlled by a permanent routine." Apart from the plans being made to prevent infestation, research has been carried out into the effect of new drugs in preventing an already infested person from going blind.

MACROGLOBULINAEMIA OF WALDENSTRÖM

BY

D. G. FERRIMAN, D.M., M.R.C.P.

Physician, North Middlesex Hospital

AND

A. B. ANDERSON, Ph.D., M.R.C.S., F.R.I.C.

Chemical Pathologist, St. Bartholomew's Hospital

In 1944 Waldenström described two cases of macroglobulinaemia. A similar case is here presented, with a brief review of the literature.

Case Report

A man aged 60 was referred to one of us in November, 1954, by Dr. D. R. Daniel, with a history of deteriorating vision for the previous two years. Apart from this he had little in the way of symptoms, but occasional mild epistaxes followed admission.

The only physical sign of note was a retinitis, but this presented striking and unusual features, the retinal veins

Case of macroglobulinaemia: retinal drawing.

being visibly distended and somewhat tortuous, and the fundi showing many scattered haemorrhages (see Fig.). Vision was reduced to 6/60 in both eyes. Slightly enlarged glands were present in both axillae. Anaemia was not apparent. There was no purpura, no enlargement of the liver or spleen, and no fever. Slight albuminuria appeared on occasion.

Investigation revealed a hypochromic microcytic anaemia with a haemoglobin of 31%. White counts varied between 4,000 and 6,400 per c.mm., with lymphocytes ranging from 22 to 54%, and an occasional lymphoblast. Rouleaux formation was marked. The E.S.R. was greatly elevated, ranging from 130 to 170 mm. in the first hour (Westergren). Marrow smears showed a lymphocyte preponderance, with lympho-

blasts more in evidence than in the peripheral blood (Dr. A. H. T. Robb-Smith). Liver biopsy (followed by bleeding) revealed minimal lymphocytic periportal infiltration (Dr. J. F. Heggie).

The serum was remarkably viscous, but did not gel in the cold. Total plasma proteins were 9.9 g.% (albumin 2.5 g.; globulin 7.4 g.). Paper electrophoresis showed an abnormal globulin with a mobility lying between the β and γ fractions, proportions of the various constituents being albumin 2.3 g.%, α_1 globulin 0.46 g.%, α_2 globulin 1.01 g.%, abnormal globulin 3.26 g.%, γ globulin 1.47 g.%; the figure for the abnormal globulin includes β globulin, as there was no clear line of demarcation. A paper electrophoresis after treatment showed only slight changes in pattern, but a clear demarcation appeared between the abnormal and the β globulins (abnormal globulin 2.82 g.%, β globulin 0.61 g.%). The main abnormal features of this protein pattern are the decreased amount of albumin and the very large amount of abnormal globulin present. The formol-gel test was strongly positive. Ultracentrifugation produced a sedimentation constant for the abnormal globulin of 18, indicating a molecular weight of over one million (Dr. A. S. McFarlane).

Bleeding, clotting, and prothrombin times, platelet count, and serum fibrinogen were within normal limits. X-ray pictures of the lumbar spine, pelvis, and skull showed no abnormality. Blood W.R. and Kahn were negative.

He was treated with blood transfusions initially, iron, cortisone, and tri-(2-chloro-ethyl)-amine. A slow but steady improvement took place. Vision recovered to 6/9 in both eyes, and retinal haemorrhages largely disappeared. The haemoglobin rose to 100%. A significant part of the recovery seemed to follow use of the nitrogen mustard. The man was well and at work 18 months after first being seen.

Discussion

Some important features of 16 similar cases studied, and of our own case, are shown in the Table.

Clinical Features.—The condition has been reported more often in men than in women, and usually in the older age groups. It seems to be only slowly progressive, the illnesses having lasted up to 14 years. Anaemia has been usual. A slight-to-moderate lymphadenopathy and enlargement of the liver and spleen have been reported. A haemorrhagic tendency has been usual, epistaxes and bleeding from the gums being the common manifestations. A haemorrhagic retinitis has been reported in five cases besides our own. Bone pains are not a feature, and x-ray films have been normal or have shown diffuse osteoporosis, contrasting with the findings in classical multiple myelomatosis.

Clinical Pathology.—The blood has been strikingly viscous, and the E.S.R. unusually high (in the region of 150 mm. in the first hour—Westergren). An absolute or relative lymphocytosis in the peripheral blood has been usual. Various disturbances of the bleeding mechanism have been reported, but as often as not the cause of bleeding has not been explained. Hyperglobulinaemia due to the presence of a macroglobulin has been present. Bence Jones proteinuria has been observed in five cases.

Macroglobulinaemia.—The distinguishing characteristic of a macroglobulin is, as the name suggests, the large size of the molecule. The molecular weights are all in the region of 1,000,000, while that of normal serum albumin is 65,000 and of the α , β , and γ globulins 150,000 to 300,000. Other abnormal proteins may be found in the serum or elsewhere,

MACROGLOBULINAEMIA OF WALDENSTRÖM

We wish to thank Dr. J. F. Heggie for laboratory facilities; Dr. A. H. T. Robb-Smith for a report on the bone-marrow smears and for advice on pathological aspects of these cases; Dr. A. S. McFarlane for the ultracentrifuge study; Mr. J. H. Dobree for ophthalmological reports; Mr. T. R. Tarrant, of the Institute of Ophthalmology, for the retinal drawing; and Dr. R. G. Macfarlane and Professor N. H. Martin for assistance.

such as the Bence Jones proteins, which have molecular weights of the order of 25,000 to 75,000. Cryoglobulins—weights of the order of 25,000 to 75,000. Cryoglobulins—weights of the order of 25,000 to 75,000. Cryoglobulins—weights of the order of 25,000 to 75,000. Cryoglobulins—weights of the order of 25,000 to 75,000.

Pathogenesis.—The presence of an excess of globulin and of abnormal globulins is characteristic of various disorders involving the reticulo-endothelial system. The similarity of the 17 cases here discussed suggests that a clinical entity is being described, but its nature remains uncertain. The lymphocytosis in the peripheral blood is paralleled by lymphoid hyperplasia in bone-marrow smears, but an excess of plasma cells has also been found in the latter on occasion. Lymphoid or plasma-cell hyperplasia, or both, have been observed in sections from lymph nodes, spleen, bone marrow, and other organs obtained on biopsy or at necropsy. The condition therefore has affinities with both lymphatic leukaemia and multiple myelomatosis, but final elucidation of its nature must await further evidence. In any event, it is unlikely that macroglobulinaemia will be found confined to any one disease, any more than Bence Jones proteinuria is exclusively associated with multiple myelomatosis. The second case reported by Schaub (1952) may be a case in point.

Treatment.—Cortisone, amidines, urethane, and nitrogen mustard have been used by others without seeming effect on the underlying process, though the last-mentioned drug appeared to be of value in our case.

Summary

Summary
A case of macroglobulinaemia is described. The rather characteristic features of this and similar cases from the literature are reviewed.

Medical Memoranda

Anterior Tibial Syndrome after Acute Arterial Occlusion, Treated by Decompression

In his report of instances of an anterior tibial syndrome following arterial embolism, Watson (1955) suggests that surgical decompression of the ischaemic muscles should be attempted. The present communication reports the successful use of this treatment in a case of acute arterial occlusion which was probably due to arterial thrombosis rather than embolism (Jepson, 1955).

CASE REPORT

A man aged 68 was admitted as an emergency case at 11.15 p.m. on July 20, 1955. Five hours previously he had experienced a sudden severe pain in his right leg, which rapidly became cold, numb, and paralysed. For several months before admission he had suffered from angina of effort and intermittent claudication.

On examination his general condition was good and his temperature normal. A loud blowing systolic murmur was heard all over the praecordium, maximal at the aortic area, but there was no other evidence of cardiac disease. The left lower limb appeared healthy and the usual pulses could be felt in it. The right was pale, and felt cold from a level just above the knee. No pulsation could be felt distal to the femoral artery. Voluntary movements of the ankle were absent and there was complete sensory loss distal to the knee.

Medical treatment for arterial embolism was instituted with tolazoline, papaverine, heparin, and phenindione. Within 24 hours the whole limb, except the outer side of the foot, felt as warm as the left. No pulses had returned, but motor and sensory functions had greatly improved.

On the next morning the patient complained of pain down the front of the right leg. The pain increased during the day, and could be controlled only by morphine. By the evening the antero-lateral part of the leg was swollen and the skin over it reddened. Dilated veins could be seen here, and the maximum calf circumference was $\frac{1}{2}$ in. (1.3 cm.) more than on the left side. Sensory loss was demonstrable in this area and in that corresponding with the cutaneous distribution of the anterior tibial nerve. In view of the patient's good general state and severe pain, the anterior tibial compartment was explored.

Under general anaesthesia, a linear incision some 8 in. (20 cm.) long was made over the reddened skin area. When the deep fascia was incised the anterior tibial muscles bulged outwards and were seen to have a well-marked patchy yellowish discoloration. This faded during the next five minutes, and the muscles by that time appeared normal.

KEEPING UP WITH THE TIMES

This country has built up its reputation in the world by virtue of its belief in the sanctity of treaties and contracts, and indeed in what have been known as "gentlemen's agreements." The medical profession as a small part of this country was, we are sure, astonished to read in *The Times* of August 9 a leading article aimed, it would appear, at extricating the present Government from the pledges given to it in the reports of the two Spens Committees of 1946 and 1948. "What was unexpected," the leading article states, "was that the Government, hard-pressed to get the Health Service launched, should have solemnly promised to carry out all the proposals of the two mutually incompatible Spens Reports. That pledge has haunted Parliament ever since." Does *The Times* wish to imply that the Government of the day regarded the recommendations of the two Spens Reports just as bribes to get a reluctant profession into a State health service so that, as Mr. Bevan put it on one occasion, the fruit could be plucked when it was ripe? Who, it may be asked, regarded the proposals of the two Spens Reports as "mutually incompatible"? Was it the Government of the day? If so, its spokesmen did not say so. Was it the medical profession, who would be most likely to have divergent views on differentials? But the medical profession as well as the Government accepted the recommendations of the two Spens Committees. *The Times* states that the Consultant Spens Report "contradicted this aim," the aim, namely, of the G.P. Spens recommendations "to induce able men to prefer general to specialist practice." But this was not the view of the policy-making body of the B.M.A., the Representative Body. At the Cardiff meeting in 1953 the R.B. unanimously carried the following motion moved by a general practitioner¹: "That this meeting is of the opinion that an adequate betterment factor should now be accorded to the consultants and specialists in conformity with the intention of the Spens Report accepted by the Government and profession and

already implemented in the case of general practitioners by the Danckwerts Award." When the Representatives met in the following year at Glasgow it was again a general practitioner who voiced disquiet that the consultants had had to accept an award that was in fact not an implementation of the Spens recommendations, and the Representative Body agreed with him. In these two declarations of policy the R.B. thus backed to the full the view expressed at Cardiff in 1953 by the then chairman of the Central Consultants and Specialists Committee²: "The Spens Report not only involved adjusting remuneration to the postwar value of money, but defined the different grades of doctors serving in the hospital service and their relation to each other. It might suit the dictates of political expediency to regard the report as obsolete, but that was something to which the representatives of the profession would never agree."

The Times considers the Spens recommendations as unrealistic and asks how long the pledge given can be "regarded as binding on future Governments who have no responsibility for what their predecessors did in the wildly optimistic days of 1946 and 1948." This wild optimism must be a figment of the imagination of *The Times* leader writer, for the medical profession during that time was profoundly pessimistic and ever since has found it difficult even to be mildly optimistic over the position in which the medical profession now finds itself as a result of nationalization. Does *The Times* really seriously assert that a pledge given by one Government can be cynically disregarded by one of its successors? If the Government follows a lead thus so conveniently given to it the medical profession will then be justified, and even perhaps compelled, to review all those other conditions it accepted by entering the National Health Service in 1948. General practitioners, for example, finally and with much reluctance agreed to forgo their cherished custom of buying and selling the goodwill of general practices. They regarded this as a custom which would give them some degree of freedom and independence in a State-provided medical service. They surrendered this on compensation terms which with the subsequent devaluation of the pound have become completely unrealistic. If compensation had been paid outright at the time it would have been a different matter; but it was not. By entering the National Health Service the whole profession agreed to the profound alteration in the relationship between patient and doctor brought about by the intervention of the State as a third party. Consultants and general practitioners treating patients in the Health Service forwent the customary practice

of professional men of making private arrangements for the payment of fees. In doing this they made it impossible for themselves to make those private adjustments to the prevailing economy which members of Mr. R. H. Turton's profession, the Law, are still able to do. With much misgiving about the consequences, a misgiving which found its expression in the two plebiscites of 1948, they abandoned all these and other safeguards, because of the acceptance by the Government of its responsibility to see that in return for these sacrifices by the profession its relative economic position and social status would be preserved.

Of course the Government wants to agree with *The Times*, "that the Spens reports are outmoded." Perhaps the Health Service itself is outmoded. How the outmoded in many respects was described in the presidential address given to the Metropolitan Counties Branch of the B.M.A. in July, 1951.³ The planners of medicine⁴ have invariably singled out doctors as the principal obstacle in the way of their administrative dreams. But the planners and the politicians will never admit they may be wrong. They blandly assume that the N.H.S. is the best medical service in the world. A fatuous insularity of outlook helps them to ignore that other countries may be bold enough to doubt this. The World Medical Association, published in 1952 a valuable statement⁵ on medical services under social security which should act as a corrective to assumptions too easily accepted in this country. Quite apart from the present controversy over Spens, the time is opportune to have a fresh look at the various provisions of the N.H.S. in the light of the experience of other countries—for example in Sweden, Denmark, France, Australia, New Zealand. There are those who see that payment by capitation fee plus restriction of lists may lead to the whole-time salaried service which even a Labour Party spokesman⁶ agreed would be incompatible with free choice of doctor. But there are other alternatives successfully in operation in other countries. Why do not our politicians have a look at the Australian pharmaceutical scheme, or at the same realistic approach of other countries to this problem? Are they really blind to the undermining of individual responsibility that is always inseparable from any public system of giving something for (apparently) nothing? The old virtues of thrift, initiative, independence, personal responsibility for decision and action, are now in the discard, and rival political parties feverishly search for methods of bribing the voter, and do not hesitate to use Medicine in this unholy game. The professional classes as a whole are being squeezed

out of decent existence in the process, as numerous articles in the national press have shown during the past year or so. And it is not only their economic position which is at stake, but a way of life that with all its faults was a powerful force for good in the country. By standing up for its rights the medical profession will be doing something more than an act of enlightened self-interest; it must do it *pour encourager les autres*. We must learn the lesson with which *The Times* concluded a leading article on Suez early this month, when it quoted F. S. Oliver thus: "If a country will not stand up for its rights, it will surely lose them. The spirit of giving in is the most fatal disease to which nations are subject, and it is apt to attack them, like a cancer, when they have arrived at the meridian." A country, it might have been added, will be able to do this only so long as the individuals in it live up to this sturdy doctrine.

ATTENUATED POLIOMYELITIS VIRUSES

Prevention of poliomyelitis presents many problems. One of the most prominent at the present time, especially in countries where mass immunization is being carried out, is to know how long the protective effect of a formalized vaccine will last. Whatever may be the mechanism for persistence of antibody in poliomyelitis, there can be no doubt that its presence following natural clinical and sub-clinical infection is directly concerned in the prevention of subsequent infection of the nervous system. J. E. Salk has shown that antibody levels, comparable to those encountered in the natural disease, can be produced with a formalized vaccine, provided the vaccine itself is potent and the injections are correctly spaced.¹⁻³ In his opinion there also exists a hyper-reactive state, which results in an accelerated antibody response on subsequent injection of vaccine. What is not clear at present is whether the same type of booster response will follow natural reinfection. If it does the outlook is encouraging. A. B. Sabin, on the other hand, failed to demonstrate an accelerated response in a small number of human volunteers with minimal antibody levels given attenuated viruses by mouth.⁴ This is but one of many problems waiting to be clarified. In the meantime research on the development of modified strains of poliomyelitis continues.

Though there are important differences in the method of attenuation they are all based on the same principle, which is to produce an asymptomatic infection of the alimentary tract with the subsequent formation of antibody.⁵⁻⁷ Four years ago H. Koprowski and his associates made a preliminary report on the effect of feeding an attenuated type 2 virus (T.N. strain) to a number of young children.⁸ All remained well, and alimentary infection, with formation of antibody, resulted. Since then the work has developed in many directions. Two strains have now been modified by serial passage in small rodents, a type 1 (S.M.) strain and an even more attenuated type 2 (T.N.) strain.⁹ Both have the same general properties of greatly reduced virulence for the nervous system and are immunogenic when given by mouth.⁹ No attenuated type 3 strain of this type is yet available. In a recent paper Koprowski and his colleagues report on further clinical investigations with these two attenuated strains, in which much of their experience of the last five years is summarized.¹⁰ The trial was carried out in a State institution for mentally defective children. Special arrangements were made for clinical observation, organization of medical and nursing staffs, isolation, and detailed laboratory investigations. The type 1 (S.M.) strain was given in a gelatin capsule and the type 2 in a milk-shake. In accordance with the actual amount of virus present, the type 1 regularly produced alimentary infection and neutralizing antibody. With the type 2 strain alimentary infection was sporadic, but antibody developed, though not quite as promptly as with type 1. As to contagiousness, the type 2 strain is almost non-contagious, since it appears only sporadically in the faeces. Special arrangements were made to determine the contagiousness of the type 1 strain by exposing non-immune subjects to conditions of very close contact and to conditions which might prevail in an ordinary hospital ward. Five out of 15 contacts became alimentary carriers of type 1 virus, but the social behaviour of some of those participating was far from normal, and was conducive to transmission of infection by the faecal-oral routes. On the other hand, 7 out of 9 nurses, who at the start of the trial had no antibody to type 1, still had no antibody several months later.

Dr. Koprowski and his co-workers had earlier shown that, if both type 1 and type 2 strains were fed together, virus "interference" resulted, which usually meant that the type 1 got the upper hand unless a much larger dose of type 2 was given. Their recent findings suggest that this can be overcome by feeding the type 2 virus several weeks after the type 1. They were also able to show that immune serum globulin

given simultaneously with virus did not prevent alimentary infection, the duration of the intestinal carrier state, or the development of antibody. This is an important observation, for it has been suggested that previous immunization with a formalized vaccine might, by virtue of the antibody present, nullify the subsequent use of an attenuated vaccine, should that be necessary. It also indicates that it may be possible in future to immunize children under cover of maternal antibody or gamma globulin.¹¹ In spite of the many difficulties encountered in this type of work great progress has been made since the original report four years ago.⁸ But as an alternative method of immunization this work is still unquestionably in the experimental stage. In the present state of our knowledge a vaccine to afford complete protection should contain all three immunological types of virus, and special problems of its safety arise on which much more information is needed. So far as they go these results are encouraging and present yet another step "in an attempt to transfer results obtained in the laboratory to actual field observations."⁸

PULMONARY EMBOLISM BY AMNIOTIC FLUID

Although pulmonary embolism due to amniotic fluid was first described in 1941 as a possible cause of shock in obstetrics,¹ published accounts of the condition were still very few some ten years later when this entity was discussed in these columns.² In what is apparently only the fourth report of this condition in British journals, H. D. Attwood has recently described a fatal case.³ The clinical picture was typical in that the victim was an elderly multipara in strong labour, with the symptoms beginning soon after rupture of the membranes disclosed meconium-stained liquor. However, the infusion of liquor amnii into the maternal circulation may begin before there is clinical evidence of rupture of the membranes, and exceptionally the symptoms precede the onset of labour or, less uncommonly, follow its conclusion. In Attwood's case there followed in rapid succession profound shock, unconsciousness, dyspnoea, and cyanosis, and the patient died within five minutes. Necropsy showed an asphyxial type of cyanosis and a greatly dilated right heart. The characteristic histological findings are shown with uncommon clarity in accompanying photomicrographs. In the

⁸ Scott, J. S., *British Medical Journal*, 1955, 2, 290.

pulmonary arteries and arterioles and alveolar capillaries can be seen epithelial squames, mucin with enmeshed polymorphs, fat, lanugo hairs, and bile. Squames and mucin are also present in the uterine venous sinuses and in the glomerular and peritubular capillaries of the kidneys. Several strands of mucin with related polymorphs are seen in a cerebral capillary and one squame in a capillary deep in the myocardium.

The emboli thus consist of the particulate matter of amniotic fluid and meconium, and indeed P. E. Steiner and C. C. Lushbaugh¹ produced similar clinical and pathological signs in dogs and rabbits by the intravenous injection of unfiltered liquor and meconium; the injection of filtered liquor was without effect. Attwood was unable in his case to demonstrate the possible site of entry of the liquor into the maternal circulation, but in every case some abnormal communication must presumably exist through which the liquor is forced by the strong uterine contractions while the foetal head plugs the outlet. Indeed, in more than half of the previously reported cases obvious tears into the myometrium from the interior of the uterus or gross lesions at the placental site were found. This high incidence of associated pathological conditions, notably intrapartum haemorrhage and uterine rupture, is an important factor in the high mortality rate. Non-fatal forms of the disease have been recognized clinically,^{4,5} but probably in most cases with survival the diagnosis of amniotic embolism is either not suspected or not proved. The frequent accompaniment of haemorrhage, especially when death was not immediate, led D. E. Reid and his colleagues⁶ to suggest that the infusion of amniotic fluid into the maternal circulation might produce intravascular clotting and subsequent defibrination of the maternal blood, with consequent haemorrhage from the genital tract. However, C. L. Schneider⁷ concludes that, important as fibrin deposits causing pulmonary vascular occlusions may be in severe accidental haemorrhage, there is not yet any evidence that coagulation of fibrin contributes much to the circulatory embarrassment of amniotic embolism. He regards it as unnecessary to postulate that the process of circulatory obstruction after amniotic infusion is one of intravascular coagulation, because the widely disseminated pulmonary embolism of amniotic debris provides an adequate cause. Attwood confirmed in his case the enormous extent of the plugging of the maternal pulmonary vessels; and he believes that the use of special staining methods such as he used may show that the proportion of deaths in labour due to the infusion of liquor

amni is higher than present figures suggest. When the pathogenesis is considered, it is not surprising that this particular complication of labour does occur; rather is it surprising that it apparently occurs so infrequently, especially at a time when pitocin is widely, if not always wisely, given to enhance uterine contractions.

Since clinical recognition is far from easy and the frequency of immediate death high, the likelihood of being able to give specific treatment is small. However, when amniotic embolism is suspected—and especially when shock in labour is accompanied by cyanosis—the administration of oxygen is indicated, and Attwood suggests that the application of venous tourniquets would lessen the strain on the right ventricle. If the patient survives the immediate threat to life, the possibility of hypofibrinogenemia must be borne in mind and tested for by a simple technique such as that described by J. S. Scott.⁸

CRYOGLOBULINAEMIA AND MACROGLOBULINAEMIA

In 1933 M. M. Wintrobe and M. V. Buell¹ described, from a case of multiple myeloma, the presence in the serum of a protein which precipitated on cooling. Some twenty reports on the presence of such proteins in multiple myelomatosis have appeared since. C. G. Holmberg and A. Gronwall² found them in a patient with rheumatoid arthritis, and D. H. Atlas and his colleagues³ in liver disease. E. Wertheimer and his colleagues⁴ found cold-precipitable protein in kala-azar, bacterial endocarditis, malaria, chronic nephritis, and periarteritis nodosa. A. B. Lerner and C. J. Watson⁵ in 1947 coined the term cryoglobulinaemia for all those conditions in which cold-precipitable proteins are found (*κρυός* meaning cold). At that time they reviewed fourteen earlier reports on the subject, and some twenty-five have appeared since. Though one case has recently been described in which cryoglobulinaemia and a high titre for cold agglutinins were associated,⁷ the two are usually not found together. Cold agglutinins are found in virus pneumonia, mumps, infectious mononucleosis, tropical eosinophilia, and trypanosomiasis. Cryoglobulinaemia, on the other hand, is often seen in bacterial endocarditis, multiple myeloma, chronic lymphatic

leukaemia, and polyarteritis nodosa; it can also be found sometimes in cases of coronary disease, asthma, urticaria, gout, malaria, and brucellosis. There have been three cases in which extensive investigation before and after death failed to reveal an underlying cause; these conditions were named "essential" cryoglobulinaemia by Volpé and his colleagues.⁸ Biochemical examination of the serum shows that the cryoglobulin moves with the gamma globulin fraction on electrophoresis; gamma globulin increases in accordance with the degree of the cryoglobulinaemia. On exposure to cold the protein may be deposited intravascularly. Gelatinous material may be seen in the retinal vessels *in vivo* and has been demonstrated in other vessels *post mortem*. Partial occlusion of blood vessels with viscous protein may lead to stasis, and this may give rise to a variety of conditions ranging from simple urticaria with subsequent purpura to a fully developed Raynaud's syndrome, even with subsequent necrosis and gangrenous ulceration. Cryoglobulinaemia is worth bearing in mind when a patient is unduly sensitive to cold. An unexpected reddening of an area exposed to draught is often the first indication of the state.

It has generally been held that not much could be done for the patient apart from treating the conditions which may be associated with cryoglobulinaemia. The only effective measure was care in avoiding exposure to cooling, since this would prevent any further damage due to occlusion of vessels by sludges of viscous cryoglobulin. But Volpé and his collaborators have suggested that tissue reaction may be a factor in the pathogenesis of the lesions. The patient's own precipitating cryoglobulins might act as a foreign protein, stimulating a tissue response with associated rigors and fever, and resulting in purpura. In support of this thesis they report favourable results of treatment with A.C.T.H., without significant decrease in the concentration of the cryoglobulin. On the other hand, Z. T. Wirtschaffler and colleagues⁹ treated a patient with cortisone and found that the cryoglobulin disappeared from the plasma and that the patient no longer reacted abnormally to cold. The possible therapeutic role of A.C.T.H. and cortisone in cryoglobulinaemia will clearly have to be more widely explored.

Another pathological "globulinaemia" is a condition in which part of the globulin fraction consists of very large molecules. J. Waldenström, the first to describe it, in 1944, named it macroglobulinaemia¹⁰ and a case is reported at p. 402 of the *Journal* this week by Drs. D. G. Ferriman and A. B. Anderson. The first indication in the laboratory may be a raised erythrocyte sedimentation rate, but the large molecular weight of the protein can be identified only by ultracentrifugation. Unlike the cryoglobulins, which on electrophoresis are found in the gamma globulin fraction, the macroglobulins move on electrophoresis with the beta globulins, or between the beta and the gamma globulins. Patients with Waldenström's macroglobulinaemia suffer from lassitude, shortness of breath, and bleeding mucous membranes. The liver is usually enlarged and the lymph nodes painlessly swollen. Often, though

not invariably, numerous lymphocyte-like cells are found in the bone marrow. Ferriman and Anderson's patient presented with a history of deteriorating vision for two years, due to an unusual type of retinitis. Waldenström's patient had a low concentration of fibrinogen, and it is likely that the macroglobulins interfere with the formation of fibrin itself. H. Braunsteiner and colleagues¹¹ have shown by means of electron microscopy that the formation of pseudopodia and the adhesiveness of platelets are inhibited. Adsorption of coagulation factors on the macroglobulins may further increase the tendency to bleeding.

Macroglobulinaemia has to be distinguished from purpura hyperglobulinaemia, another condition described by Waldenström.¹² Purpura hyperglobulinaemia is associated with a hypergammaglobulinaemia, and in addition to the difference in the electrophoretic pattern there is no increase in molecular weight in this condition. Electrophoretically myelomatosis cannot be differentiated from macroglobulinaemia; the only way to arrive at a definite diagnosis (in the absence of a clear-cut clinical picture) is to test the serum for macromolecules by ultracentrifugation. I. R. Mackay and colleagues¹³ have pointed out that it appears probable that many atypical cases of lymphosarcoma and lymphatic leukaemia may in fact be cases of macroglobulinaemia. In all three are found infiltration of bone marrow and lymph nodes with small atypical lymphocytes, as well as lymphadenopathy and hepatosplenomegaly.

SPREAD OF BACILLARY DYSENTERY

Although the unprecedented numbers of notifications of Sonne dysentery in recent years are attributable in part to improved diagnostic facilities, this infection seems now to be unduly widespread, particularly in primary schools and nurseries. Dr. R. Irene Hutchinson, of the Public Health Laboratory, Southampton, has made an extensive study of the distribution of the organism in infected environments which goes far to explain how the infection may be spread.¹ Of many possible contaminated objects cultivated in homes or institutions where cases were occurring, water-closet seats, floor dust collected near them, and bedding and toys used by cases yielded the only positive results, and attention was concentrated on the first of these. Dye tests showed that the seat was splashed by flushing, and the organism could be cultivated from the seat after a liquid infected stool had been flushed away, although not after the disposal of smaller quantities of solid faeces. This finding, though the author does not say so, seems to invite an inquiry into the design of water closets with a view to preventing contamination of the seat. Observation was then kept on small children using water closets: 17 out of 37 "handled the seat with one or both hands while settling themselves upon it," and 6 of the 17 "then handled the face and mouth . . . or sucked their fingers." Though they all washed after leaving the closet,

¹ Hutchinson, I. R., *Monthly Bull. Minst. Hlth (Lond.)*, 1956, 15, 110.

transmission could already have occurred. The survival of *Sh. sonnei* outside the body, on water-closet seats and under other conditions, was also studied and found to be favoured, as would be expected, by poor illumination, low temperature, and high humidity. That these are just the conditions which exist in the average water closet was verified by observations of temperature and humidity in several of them.

It was also shown—not for the first time—that faecal bacteria readily pass through two layers of toilet paper: these experiments were done with five different makes, two containing disinfectants. Two questions therefore arise: Has anyone ever shown that the incorporation of a disinfectant in toilet paper has any hygienic value, and, Is it beyond the wit of man to devise a material for this purpose which is not freely permeable by bacteria? The finding of *Sh. sonnei* on children's hands is presumably thought to be explicable mainly in this way. The results of such tests were somewhat erratic. At a primary school and three day nurseries where outbreaks were in progress the numbers of positives were 2/118, 0/25, 0/50, and 17/35. These swabs were taken after the children "had visited the toilet for the purpose of micturition and before hand washing"; the results for boys and girls are not separately stated. It was also found that *Sh. sonnei* applied as a broth culture will survive on the fingers for three hours.

Unfortunately preventive measures based on these findings do not readily suggest themselves. That water closets should be in "a brightly lighted, warm and sunny position" is a counsel of perfection, and if it reduced the survival of *Sh. sonnei* on the closet seat from 17 days to as many hours the risk would still be there. It is an interesting thought that the most primitive provision for defaecation, such as squatting over a hole above a pit, would obviate a hazard now shown to be involved in the use of a civilized appliance, although admittedly primitive methods of sewage disposal have other and sometimes graver drawbacks.

RADIOLOGICAL PROTECTION

The public has heard or read many official and semi-official statements on radiation hazards and protective measures during recent months. But the report of the International Commission on Radiological Protection is in a special category inasmuch as this committee of experts has had the subject under review for almost thirty years, and its membership has always been drawn from many nations. Reporting last week to the 8th International Congress of Radiology meeting in Mexico City, the Commission made no drastic changes in its recommendations about permissible levels for occupational exposure, but some ambiguities were removed and new detailed recommendations made on specific matters. Sir Ernest Rock Carling comments on the report in our correspondence columns this week (p. 416). In the Commission's last report¹ there was a recommendation that "in the case of the prolonged exposure of a large population the maximum permissible levels should be reduced by a factor of 10 below those accepted for occupational

exposure." In some quarters this was taken to mean that the whole population could safely be subjected to one-tenth of the level permitted for occupational exposure. The Commission denies this interpretation and states that the recommendation was, and is, intended to ensure that if large numbers of people live near a nuclear energy establishment it shall not be considered safe to expose them to the same dose as may be received by the smaller number who actually work in the establishment. This safety factor was presumably introduced on genetic grounds, and the Commission has now recognized its responsibility to assess the larger genetic hazard which could arise from the exposure of the whole population as a result of widespread use of nuclear energy as a source of power. It promises a quicker study of this problem and in the meantime holds that it would be "prudent to limit the dose of radiation received by gametes from all sources additional to the natural background to an amount of the order of the natural background in presently inhabited regions of the earth." The recent M.R.C. report on radiation hazards² estimated that in Britain the average dose to the gonads from diagnostic radiology alone was 22% of the natural background dose, and the corresponding American report³ estimated that the diagnostic dose in the U.S.A. was about equal to the natural background dose. These figures emphasize again the narrow margin between present practice and present estimates of the "safe" genetic dose.

The committee considering very high energy x rays and heavy particles has this year supplemented its recommendations with a number of practical appendices on the properties of high-energy radiations, their attenuation in different materials, and the danger from secondary neutrons and protons when very high energy rays are used. In view of the increasing number of research institutions where cyclotrons or other high-energy accelerators are in use, the I.C.R.P. has wisely given thought to the problems of induced activities and stray radiations from such machines. When the Commission's last report was published in 1955 the committee on the handling of radioactive isotopes and the disposal of radioactive waste had not yet reported. This committee has now issued a long report touching on all aspects of these two subjects. It emphasizes the need for continuing study of the many problems entailed in large-scale disposal of waste and promises more detailed consideration of this topic in subsequent reports.

It is good that the traditions of caution and of international co-operation between experts without governmental interference, which were built up by the I.C.R.P. long before the subject of radiological protection had assumed any political significance, are still being maintained so well, and its recommendations should be given the greatest weight. The Commission has been recognized by W.H.O. as a non-governmental organization, and it is to be hoped that this link will facilitate the work of the Commission and make it more widely known without restricting its freedom in any way.

FIRST INTERNATIONAL CONGRESS
OF HUMAN GENETICS

[FROM SPECIAL CORRESPONDENTS]

For many years students of human genetics have played an active part at the International Genetics Congresses. Now for various reasons it has become desirable that a congress of purely human genetics should take place. The interest of medical men in genetics has been increasing with the development of genetic clinics to which doctors may refer their patients; in addition, great strides have been made in the development of serological genetics. Much anxiety is felt too about the genetic effects of nuclear energy, even when put to peaceful use. The obvious country for the first meeting was Denmark, which, under the inspiring leadership of Professor TAGE KEMP, is genetically the most thoroughly investigated country in Europe. Thus during August 1-6 the First International Congress of Human Genetics was held at Copenhagen. Over 250 papers, demonstrations, or films were given there, and it is only possible to report those that were novel or of general interest.

Radiation and Mutation

The possible effect of radiation in increasing human mutation has been fully evaluated recently in the Medical Research Council's report on *The Hazards to Man of Nuclear and Allied Radiations* and the report of the National Academy of Sciences from the U.S.A.¹ Accordingly there was little more to be said on this apart from additional information given at the Congress by Professor J. V. NEEL, of Ann Arbor, U.S.A. He reported that the apparent alteration in the sex ratio of children born to irradiated mothers, earlier reported, no longer existed now that additional children had been brought into the series. There were, in fact, now no clear indications that radiation of parents had affected their later-born children except in the few cases where the mother was already pregnant at the time of the exposure.

There was considerable discussion on the amount of deleterious mutations already current in human populations and the effect on this load of, for example, doubling the mutation rate. There were here two contrasting viewpoints. Professor H. J. MULLER, of Bloomington, U.S.A., argued that the load was already very considerable and would be proportionately increased by any increase in mutation rate. In human beings, he said, a number of different lines of reasoning suggested that the average mutation rate per gene locus was about 1/100,000 and that the total mutation rate at all gene loci was of the order of 1/10. Accordingly the chance that a newly conceived child would receive a fresh mutation was about 1/5. Nearly all mutations, he suggested, were partially "dominant" and they exerted some effect in the heterozygote—that is, when present on only one member of a chromosome pair with a normal corresponding gene on the paired chromosome. This meant that to balance the new mutations constantly arising in each generation it was necessary that about one individual in five should suffer a genetically determined death. Only a minority of this elimination could occur, he thought, from intrauterine death. Clearly, then, a doubling of the mutation rate would be a most serious matter.

Professor L. S. PENROSE, of London, thought that current estimates of mutation rates were all rather high; that with dominant mutations, for example, what appeared to be a single pathological entity was often caused by several alternative mutant genes, each individual gene having a mutation rate several lower than that required if all cases were due to mutation at the same gene locus. More important, he considered that many genes which caused serious diseases in the homozygous state—that is, when present on both members of a chromosome pair—had been kept relatively common by a selective advantage of the

gene in the heterozygote. This selective advantage might occur only in certain environmental circumstances; for example, some high frequencies of deleterious mutations in the population to-day might be there because of advantage in relation to major epidemic diseases now eliminated. In this situation a doubling of the mutation rate would have little effect on the frequency in the population of a deleterious mutation. The selective advantage of the heterozygote had brought the frequency of the disorder present in the homozygotes much above the level which would be maintained by the mutation rate alone. It was possible, he thought, that an alteration in environmental circumstances—for example, the elimination of a serious infectious disease—might reduce the frequency of some genetic disorders in spite of a rise in the mutation rate for the genes responsible.

Dr. T. C. CARTER, of Harwell, England, made the point that, since there were a considerable number of genes which were undoubtedly disadvantageous in the heterozygous state and under almost any conceivable circumstances, an increase in mutation rate was undesirable.

Cousin Marriage

One way of estimating the frequency in the population of deleterious genes which are recessive—that is, genes that are readily detectable only when homozygous—is to study the offspring of cousin marriages. If a man marries a first cousin there is a 1/8 chance that she will carry any particular genetic factor he has himself, and so with rare genes the risk is much increased that a child will receive the same abnormal recessive gene from each parent. No large-scale studies of cousin marriages are yet available. Professor J. A. BÖÖK, of Uppsala, Sweden, reported an interesting small-scale, but thorough, study of all first-cousin marriages in an isolated area of Northern Sweden. There were 34 such unions, with 218 live-born children, and their experience was compared with a similar number of random control families. The fertility of the parents and the number of abortions and stillbirths in the cousin marriages was much the same as in those of the controls. But more intellectually defective children were found in the offspring of the cousin marriages, and Professor Bök calculated that the total risk of hereditary disorder to children of these marriages was as high as 16%, as compared with 4% in the control marriages. He estimated tentatively that the average individual in this area was heterozygous for three recessive genes which would cause major illness in homozygotes and that in the whole district there were from 150 to 450 such deleterious recessive genes current in the population.

Others present reported cousin marriage studies contemplated or already begun—for example, Professor A. C. STEVENSON, of Belfast, and Dr. J. MOHR, of Oslo. Much the biggest, however, will be that in Japan, where a very large number of cousin marriages have been ascertained in the Hiroshima and Nagasaki surveys.

Another use of cousin marriages was illustrated by Dr. ELIOT SLATER, of London. The investigator starting with a series of individuals who have a rare recessively determined disorder finds that a considerable proportion are the children of parents who were cousins or otherwise blood relations. Dr. Slater reported a study of 242 patients with psychotic illnesses whose parents were related and 242 controls with psychotic illness whose parents were not related. The one type of mental illness significantly more frequent in the first group was schizophrenia, and Dr. Slater showed that one might tentatively estimate that if a single recessive gene was responsible for this excess in the group of cousin marriages it would account for about one-fifth of all cases of schizophrenia.

Twinning

Twins have been important in the study of human genetics since Francis Galton first pointed out in the last century that twins were of two types, now called "identical" and "fraternal," or better "monozygous" and "dizygous." Professor P. J. WAARDENBURG, of Leyden, Holland, and Dr.

N. F. WALKER, of Toronto, outlined the development since then of the methods available for distinguishing the two types of twins. Over 25 years ago it was established that by no means all monozygous twins were monochorionic; they might have entirely distinct placentas and membranes. The methods now used were mainly blood-group determination and analysis of finger-prints. Dr. WALKER stressed the value of the recent discovery by Smithies of the haptoglobulins in blood plasma and the demonstration by Smithies and herself that there were three types simply inherited on the basis of two allelomorphous genes, the heterozygotes being distinguishable from either homozygote. The addition of these plasma types to the blood groups based on red-cell antigens meant that 94% of dizygous twins could be distinguished by sex and blood alone. Professor WAARDENBURG noted that inter-pair differences between monozygous twins gave an idea of the range within which a given genetic constitution might be modified by the environment. The comparison of the degree of resemblance of monozygous and dizygous pairs was useful in estimating the role of heredity in determining conditions which were difficult to study by the family method—for example, senile conditions—but, he added, the shortcomings of the method must constantly be borne in mind.

A number of speakers described important twin studies now being contemplated or already under way. Notable among these is a scheme in Denmark to ascertain every twin born between 1870 and 1910. Some preliminary reports of this Danish study were given. The importance of complete ascertainment in this way was well illustrated in a paper from Dr. B. SIMONDS, of London, showing how in her own survey the apparent resemblance of twin pairs for pulmonary tuberculosis was much affected by the way in which, and the completeness with which, the twins were ascertained.

Detection of the Carrier

Genetic analysis and the reliability of genetic advice to parents who are referred by their general practitioners to genetic counselling clinics is made much simpler when it is possible to pick out the carriers of the gene. These carriers may be heterozygotes for recessive genes or, in the case of women, for sex-linked recessive genes. Dr. D. Y. HSIA, of Harvard, U.S.A., reported that the heterozygotes for the recessive gene responsible for phenylpyruvic amentia could be distinguished by a high plasma level of phenylalanine following a test dose of 0.1 g. per kg. body weight, though there might be overlap in individual cases. Dr. C. O. CARTER and Dr. M. J. SIMPKISS, of London, reported that women heterozygous for the sex-linked recessive gene for nephrogenic diabetes insipidus could be distinguished in most instances by a simple urine concentration test. Carriers may also be those with a dominant gene who are themselves apparently unaffected. Professor A. CODOUNIS, of Athens, reported that some individuals possessing the dominant gene responsible for hereditary methaemoglobinemia, although the amount was below the level which produces clinical cyanosis.

Antenatal Sexing and Blood Grouping

Dr. F. FUCHS and his co-workers, of Hellerup, Denmark, gave an account of sexing the human foetus as early as the fourth month from amniotic fluid cells, and of the determination of the ABO group of the foetus late in pregnancy. Dr. L. SACHS and his co-workers, of Jerusalem, gave a similar account of the possibility of early antenatal sexing.

Man's Chromosome Number

Man's chromosome number of 48 has gone unchallenged for more than 20 years, but Dr. J. H. TJO, from Spain, had a demonstration of slides prepared from tissue culture of cells from three-months human embryos showing that the true number was 46.² Dr. C. E. FORD and Dr. J. L. HAMERTON, of Harwell, England, showed photomicrographs of cells

from three human testes confirming that the true number was 46, and estimating that the total length of the human chromosomes was 27 morgan units, half as long again as those of the mouse.

Specialist sessions were held on internal medicine, neurology, ophthalmology, psychiatry, and odontology. The part played by genetic factors in the first three specialties is well known, but two excellent papers in the dental section, by Dr. C. J. WITKOP, of Bethesda, U.S.A., and Dr. C. SCHULZER, of Göttingen, Germany, were noteworthy for putting genetic studies for the first time firmly on the map in this specialty.

Recent research on abnormal haemoglobins was described by two British workers, Dr. H. LEHMANN (London) and Dr. A. C. ALLISON (Oxford).

Blood Groups and Disease

The section entitled "Population Genetics—Anthropology—Blood Groups" accounted for about one-third of all the papers presented at the congress, and a great majority of these, about 28 papers, dealt with some aspect of the blood groups—clear evidence of the vitality of research in this field. A subject which was almost for the first time introduced on an international platform was the relation between blood groups and the incidence of various diseases. The outstanding previous paper which initiated the present rapid development of the subject was that of I. AIRD, H. H. BENTALL, and J. A. FRASER ROBERTS,³ who early in 1953 showed a highly significant excess of group A subjects among sufferers from carcinoma of the stomach. At this congress the introductory paper was given by Sir RONALD FISHER (Great Britain), who showed how a new science was being created by the coming together of demography, biometry, and physical anthropology under the aegis of the blood groups. One among many stimulating ideas put forward was that of evolutionary modification of blood group frequencies under environmental influences. This was taken up by Dr. A. E. MOURANT (Great Britain), who showed that the present distribution of the ABO groups was such as to suggest that it was the effect of such influences; he stated that the recently observed disturbances of frequencies of the ABO groups among sufferers from certain diseases showed that the environment was indeed favouring the survival of certain groups at the expense of the others. Dr. J. A. FRASER ROBERTS (Great Britain) summarized the knowledge won in the last three years on altered ABO blood group frequencies in carcinoma of the stomach, duodenal and gastric ulcer, and diabetes mellitus, while the frequencies were essentially unaltered in several other diseases.

In a subsequent session it was a striking experience to hear speaker after speaker bring forward either new correlations between blood groups in disease or important confirmations from one country of correlations previously observed in another. Such confirmations are important, since they tend to show that the correlations observed are direct rather than accidental by-products of stratification of the population of a particular country. Mr. H. H. BENTALL (Great Britain) reported a collaborative investigation which for the first time demonstrated unmistakably the previously suspected excess of group A persons among patients with pernicious anaemia. Dr. J. A. BUCKWALTER (U.S.A.) showed that in Iowa the trends in gastric and duodenal ulcer and in gastric carcinoma are similar to those found in Great Britain. Dr. C. A. CLARKE (Great Britain), in collaboration with Dr. P. M. SHEPHERD, showed that the association in the general population between Group A and duodenal ulcer did not extend to sibships (that is, sibships including persons with and without ulcers—some siblings being of group A and others of group O). Possible explanations are that the population is indeed stratified, or that the ulcer diathesis depends not directly on the patient's own blood group but on that of his or her mother. Dr. R. B. MCCONNELL (Great Britain), again with the collaboration of Dr. SHEPHERD, showed that patients with duodenal ulcer include an excess of non-secretors of the ABO antigens, not only in the population as a whole, but in sibships.

³ Ibid., 1953, 1, 799.¹ British Medical Journal, 1956, 1, 1418; 1472.² British Medical Journal, 1956, 2, 353.

It would thus appear that ulceration is more directly related to secretion than to blood group.

Dr. E. MAYR (U.S.A.) reported an investigation in collaboration with Drs. L. K. DIAMOND, P. LEVINE, and M. MAYR on blood group frequencies in a variety of diseases of the central nervous system and associated structures. The numbers were inadequate to prove definite correlations, but two observations were highly suggestive—an association of chromophobe adenoma of the pituitary with group O and one of glioblastoma multiforme with Rh-positiveness. Dr. I. ZEYINOGLU (Switzerland) did not confirm the previously demonstrated association of diabetes mellitus with group A. He did, however, find such an association with the Kimmelstiel-Wilson syndrome and, less markedly, with diabetic retinitis. The impression left by these papers was that a field of great promise first fully opened up by British workers is now being cultivated by investigators from many different countries.

Somatic Mosaicism

Only a few of the many other papers on blood groups can be selected for mention. Dr. C. W. COTTERMAN described somatic mosaicism leading to a mixture of A₂ and O red cells in a single individual. He found the character of blood-group mosaicism to be inherited. Rather surprisingly, therefore, the person in whom the character was first observed showed also a striking eye-colour mosaicism. Possibly related to the A₂-O mosaicism is the Bw group described by Dr. P. LEVINE (U.S.A.); in these cases the individual has mainly red cells with group O properties, together with a very small minority of B cells, anti-B being absent from the serum.

The biochemical action of the A and B blood-group genes was considered by Dr. WINIFRED M. WATKINS and Professor W. T. J. MORGAN (Great Britain), who showed that in the ovarian cyst fluid of heterozygous AB women most if not all of the mucopolysaccharide molecules possessed both A and B activity. In A₂ women, on the other hand, it was in some cases possible to precipitate the molecules having A activity, leaving molecules in the supernatant which had H but no A activity. This accords well with other evidence suggesting that the H substance is not, as has been supposed, a product of the O gene but is a basic substance which the A and B genes are able to "stamp" with their own characteristic antigenic properties.

Dr. R. GRUBB (Sweden) announced his discovery of a hereditary character involving human serum. When human red cells are sensitized with an incomplete antibody (e.g., D-positive cells with incomplete anti-D) the cells are not agglutinated when suspended in saline. They can be caused to agglutinate by certain reagents such as Coombs reagent (anti-human-globulin serum). It has now been shown that they are also agglutinated by certain empirically selected sera from cases of rheumatoid arthritis. Agglutination so produced is inhibited by many human sera. The inhibiting component is a γ -globulin, the product of a single gene to which the symbol Gm^a has been given. Among Swedes 60% are inhibitors, but among Greenland Eskimos 95%. This character, readily investigated by the techniques of blood-group serology, promises to be of considerable interest and importance.

Blood-group Anthropology

Among many interesting papers on the application of blood groups and other genetical characters to anthropology we can mention only two. Dr. R. SINGER (South Africa), in collaboration with Dr. P. BRAIN, showed that, in Madagascar, though the culture and language are derived from South-east Asia, the blood groups and the high frequency of the sickle-cell trait indicate that most of the tribes are far more African than Asiatic. Dr. L. SACHS (Israel), working with Dr. M. BAT-MIRIAM, has used fingerprint patterns as a valuable addition to blood-group data in investigating the affinities of Jews in Israel.

Dr. P. HÖSLI (Switzerland), who has collaborated with Dr. A. HÄSSIG and Professor A. FRANCESCHETTI, announced a new example of linkage between two sets of genes in man—those for the MNSs blood groups and those determining the presence or absence of congenital ptosis. Outside the sex chromosomes only three examples of linkage were previously known in the human species, all involving blood groups. The study of the blood groups is thus proving indispensable in the mapping of the human chromosomes, as was foreseen many years ago by Sir Ronald Fisher.

At the end of the meeting it was generally agreed that this first human genetics congress was a great success, for which much credit must go to the admirable efficiency of the Danish organizing committee, and that further congresses on human genetics could be held perhaps at five-yearly intervals without prejudicing the activities of the International Genetics Organization.

INTERNATIONAL CONGRESS OF PHYSIOLOGY

MEETING IN BRUSSELS

[FROM A SPECIAL CORRESPONDENT]

The 20th International Physiological Congress was held in Brussels from July 30 to August 4, under the presidency of Professor C. HEYMANS. Over 2,600 members from 43 different countries were present, and the opening ceremony was graced by the presence of Her Majesty QUEEN ELIZABETH OF BELGIUM. Professor C. H. BEST, F.R.S. (Canada), took advantage of the occasion to review briefly the activities of the International Union of Physiological Sciences, which was formed at the previous International Congress held in Montreal in 1953 and of which he is president. He also announced that Professor B. A. HOUSSAY's invitation to hold the 21st International Congress in the Argentine had been accepted.

At the scientific sessions a wealth of material was presented. Fifteen lecture theatres were used simultaneously during the four morning sessions, when papers were read, and four for the symposia held on the three afternoons. In addition there were numerous demonstrations and films. A few of the more "applied" subjects discussed at the meeting are here noted.

Gastric Secretion

Professor B. K. M. UVNÄS (Sweden) reviewed the nervous and humoral control of gastric secretion. He was definite that gastrin released from the antrum was not histamine; gastrin was a protein material. He discussed the hypothesis that gastrin stimulates the gastric glands by releasing the histamine which is so abundant in the body of the stomach, but thought the evidence was far from complete. He suggested on the basis of experimental evidence in animals that the antral mucosa contained mechano- and chemo-receptors which generated impulses in afferent nerves, and that these impulses were relayed via local synapses to efferent cholinergic fibres which in turn stimulated the gastric glands to produce gastrin. Further, the pH in the antrum influenced the release of gastrin, an increased acidity depressing gastrin secretion and vice versa. In dogs, if the antral region were excluded from the acid-secreting areas, both the resting secretion and that produced in response to food and insulin hypoglycaemia were greatly increased. This often caused death of the animals from bleeding or perforation secondary to ulcer. Uvnäs described observations by Noring on human subjects before and after resection of the pyloric antrum, which accorded with his experimental observations.

Mr. A. P. MCE. FORREST (Britain) reported that the formation of an innervated antrum-pouch provoked a profound hypersecretion in all dogs. Denervation of the pouch decreased their secretion.

These findings, if they prove applicable to man, may require some reevaluation of the operation of gastro-enterostomy, as protection of the antrum from contact with the acid content of the stomach might seem liable to increase the acid secretion from the fundus; perhaps, however, denervation might decrease this effect.

Hypothermia

Dr. E. NEIL (Britain) reviewed the metabolic, circulatory, and respiratory changes in animals and man during hypothermia, dealing at length with the acid-base changes. In addition to a respiratory acidosis due to the reduction in spontaneous respiration, there was also a reversible metabolic acidosis. If circulatory arrest was superimposed upon hypothermia it became more difficult to reverse the metabolic acidosis, as in intracardiac surgery. Dr. Neil produced evidence that this effect was associated with congestion and damage to the liver. The latter could be avoided by removing blood from the systemic veins and reinfusing it into the arterial system, a procedure which prevented the marked rise in venous pressure otherwise seen.

Thirst and Appetite

Dr. B. ANDERSSON (Sweden) reviewed the role of the hypothalamus in the control of water intake. He described the evidence for the existence of a thirst centre in the hypothalamus of the goat, and showed a film of the goat's behaviour when this centre was stimulated electrically by behaviour when this centre was stimulated electrically by indwelling electrodes. After a latent period as short as five seconds, the animal sought out the bowl of water provided and drank until stimulation was discontinued. A goat could be induced in this way to drink water up to 40% of its body weight within a short period of time, with resulting haemolysis and haemoglobinuria. Destruction of this region of the hypothalamus resulted in hypodipsia (or this region of the hypothalamus resulting in hypodipsia) lasting for a variable time. The centre was near and somewhat overlapping the centre controlling the neurohypophysis.

Professor J. R. BROBECK (U.S.A.) described the concept of two hypothalamic "centres" associated with food intake—a medial part concerned with satiety, and a lateral part with appetite. Lesions of the medial part in man led to obesity. The sense of satiety was mediated, Professor Brobeck suggested, by the temperature changes associated with the specific dynamic action of the foods consumed, but he produced little evidence in support of this hypothesis.

Dr. JEAN MAYER (U.S.A.) reviewed the evidence for the role of glucose as a regulator of appetite. He described the hyperphagia resulting from the administration of aurothioglucose which selectively destroys cells in the ventromedial region of the hypothalamus. (It is suggested that this region normally exerts an inhibitory influence on food intake and that its activity is dependent upon the local concentration of glucose.)

Renal Studies

Professor K. J. FRANKLIN, F.R.S., and Dr. M. WISE (England) reported that in animals the effusion of blood on to the endometrium, peritoneum, pericardium, or pleura, or into the myometrium resulted in a rapid reflex renal cortical constriction which could be prevented by denervation of the kidney. These findings clearly may have important implications for the cortical necrosis which occurs clinically in such conditions as concealed accidental uterine haemorrhage.

Dr. A. GROLLMAN (U.S.A.) put forward the hypothesis that hypertension is due to the lack of a substance normally produced by the kidney which lowers the blood pressure in animals and in man. He claimed that renal extracts when administered orally lowered the blood pressure with-

out harm to the experimental animal or to the human patient. He also claimed that he had been able to detect this substance in the blood of normal subjects, and that it was decreased in the blood of animals with renal hypertension. If this is correct, as Grollman pointed out, it suggests a way to a more rational approach to the control of this disease than is at present available.

Alcoholic Nystagmus

Dr. L. GOLDBERG (Sweden) studied positional nystagmus before and after the intake of 40–300 ml. of whisky. He described two phases. The first came on 30 minutes after ingestion of the whisky, and lasted for about three hours. It occurred when the blood alcohol level was about 0.038% and consisted in jerking with the rapid phase to the right on looking to the right and to the left on looking to the left. The second phase was characterized by the rapid phases occurring in the opposite direction. It began about 5½ hours after the consumption of the alcohol and lasted on the average for 11 hours. It persisted for 5–6 hours after all the alcohol had left the body. He suggested that the manifestations of the second phase—and those of the hangover—were due to secondary metabolites rather than the alcohol itself. These observations should obviously be borne in mind when assessing the significance of an isolated finding of nystagmus.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Freudian Concepts and Brain Physiology

SIR,—One cannot but admire the several able addresses and papers which have combined to celebrate the centenary of Sigmund Freud. Yet many must feel that an atmosphere of unreality surrounds the thoughts of his disciples, for they seem to make no serious attempt to correlate their studies with current knowledge of brain physiology. Thus if we take Freud's so-called "discovery of the unconscious," it has now become pretty certain that the thousands of millions of nerve cells in the brain are in constant activity. This supports the view that nearly all thought is unconscious, and that the mechanisms which operate when we are actually aware of what we are thinking constitute only a minute fraction of general cerebral activity. The "unconscious" repression of a thought is from the physiological point of view a different matter, as also is the individual's ignorance of the remote influences and behaviour patterns which to a large extent determine his present reactions. Or, again, the conception of the super-ego is no doubt convenient as a means for explaining human doubts and hesitations, but what happens to this mechanism when the frontal lobes are seriously damaged? Further, the Freudian ideas about memory and forgetting appear grossly inadequate in relation to clinical studies of the various amnesic states.

Freudians should not evade these and other issues, for it seems reasonable to suppose that the only psychoanalytical conceptions which will survive will be those that are at least compatible with modern studies of the brain in health and disease.—I am, etc.,

Oxford.

W. RITCHIE RUSSELL.

Gas Gangrene Risks

SIR,—Publicity has recently been given to a case at the South Devon and East Cornwall Hospital in which gas gangrene following a leg amputation is said to have been attributable to defects in the operating theatre (see *Journal*, August 4, p. 309). May I suggest that details of this case

and its surrounding circumstances should be published so that others may form their opinions on it and have the benefit of such lessons as are to be learned from it?

The architecture and ventilation system of perhaps a majority of operating theatres are such that particles of floor dust liable and indeed likely to contain spores of pathogenic *Clostridia* must sometimes pollute their atmosphere, yet gas gangrene and tetanus are fortunately very rare. This is because these spores cannot germinate in tissue oxygenated by a normal blood supply. It may be significant that the Plymouth patient was aged 71. I have within the past two years twice seen gas gangrene follow an amputation necessitated by obliterating arterial disease, a condition in which the oxygen tension even in the tissues above the line of amputation is liable to be abnormally low. Each of these was an amputation through the thigh, and this involves an additional factor. The skin in the neighbourhood of the anus is contaminated with intestinal bacteria to a greater distance than is generally supposed: these bacteria include *Cl. welchii*, the spores of which are not destroyed by ordinary methods of skin disinfection. The infection in gas gangrene following a thigh amputation may therefore be autogenous, however polluted the atmosphere in which the operation takes place.

Whatever the circumstances of the Plymouth case, I feel it should be more widely recognized that amputations either for obliterating arterial disease or through the upper part of the thigh—and particularly when both factors exist—involves an exceptional risk of gas gangrene. Such operations afford one of the few imperative indications for full penicillin cover.—I am, etc.,

London, E.C.1.

LAWRENCE P. GARROD.

Radiological Protection

SIR,—A preliminary report of the April meeting of the International Commission on Radiological Protection was presented to the Eighth International Congress of Radiology in Mexico City on July 28. I am informed by a member who was present that there was widespread desire for information as to the exact figures likely to appear as emendations of the 1954 publication which had world-wide circulation.

Pending the issue of the full text of the report, as to which there must be some delay, it may be stated in the meantime that as regards persons occupationally exposed to ionizing radiations it is proposed that the maximum permissible levels continue to be represented by weekly doses of 300 mrems (milli-roentgen equivalent medical) in the blood-forming organs, the gonads, and the lenses of the eyes, and 600 mrems in the skin. In exceptional circumstances, in which it is necessary for a person to receive in one week more than the basic permissible weekly organ doses, the unit of time may be extended to 13 weeks ($\frac{1}{4}$ year), provided that the total dose in any organ accumulated in a period of 13 weeks does not exceed ten times the respective basic permissible weekly doses.

Whilst the possible bodily injury manifestable in the lifetime of an individual exposed at the present permissible levels would be very slight or difficult to detect, the Commission has given consideration to the possible limitation of the total dose accumulated during a lifetime, since certain effects, such as shortening of life-span, might become significant when large groups are examined statistically. Accordingly the Commission feels that it would be prudent to limit the accumulated doses to 50 rems by the age of 30, and beyond that age to average doses of 50 rems per decade. Thus by the age of 60 no one should have received more than 200 rems (200 rems by age 60 is the figure subsequently adopted by the committee which produced the White Paper). In practice it has been found that in order not to exceed the recommended maximum permissible weekly doses, and to comply with the general recommendation of the Commission "that exposure to radiation be kept at the lowest practicable level in all cases," a considerable factor of safety must be allowed in the design of protective devices and operating pro-

cedures. Therefore, under present conditions, it is expected that the average yearly dose actually received by an occupationally exposed person would be about 5 rems and the accumulated dose in the employment period up to 30 years of age would be about 50 rems. Accordingly the Commission recommends continuation of the present conservative practice as regards doses received by occupationally exposed persons to keep the accumulated doses as low as possible, especially up to age 30.

Since doubt has been expressed, it should be stressed that there is no carry-over from one decade to the next: for example, if a man starts work at 35, he must get no more than 50 rems by age 45.—I am, etc.,

London, W.1.

International Commission on Radiological Protection

Diesel Oil and Lung Cancer

SIR,—While many of us may feel that the increased use of diesel fuel may have some bearing on the increasing lung cancer rate, I found it difficult to swallow Dr. F. F. Waddy's "fact" (*Journal*, July 7, p. 44) that "the dirtiest and blackest oil is issued from these vehicles by bad driving." His subsequent exposition left me in still further doubt as to the accuracy of his statements. Before rushing into print, I took the precaution of consulting my friend, Mr. L. Cohen, M.I.M.I., A.M.I.M.E., who was kind enough to produce the following authoritative information.

"The writer, Dr. Waddy, appears not to be a motorist, in view of his implication that it is not necessary to 'put his foot down' when driving a petrol engine at a hill or uphill. The correspondent is under the misapprehension of the method of control and governing applied to all diesel vehicles in this country. For this reason the theory which he puts forward, to explain why some vehicles emit more smoke than others, is entirely erroneous. The control of all diesel road vehicles is by means of a pneumatic, hydraulic, or mechanical governor, connected to the engine fuel pump. The function of the governor is primarily to control speed and to limit the maximum speed of the engine. In addition to the governor proper there is a fuel control which is so set by the makers to permit the injection of no more fuel than can be satisfactorily burned without the production of excessive smoke however the vehicle may be driven. This fuel control is usually sealed at the manufacturer's works. The production of smoke from an engine which has the makers' original fuel setting can occur only after deterioration of fuel pumps or injectors—i.e., as a result of lack of maintenance. An also not infrequent cause of smoke is the tampering with the maximum fuel stop, by drivers and others, to permit increased fuel, in an attempt to get more power from the engine."

The emission of excessive smoke from road vehicles is at best a nuisance and at worst a danger to health, but this is already a punishable offence under the Road Traffic Act, 1930 (Construction and Use Regulations, 1955). If and when diesel fumes are finally proved to have some relationship to lung cancer, it is to be hoped that the police will enforce the existing law more strictly.—I am, etc.,

London, S.E.17.

E. K. PRITCHARD.

Air Pollution, Smoking, and Lung Cancer

SIR,—The report by Dr. Percy Stocks and Dr. John M. Campbell on the relation of air pollution to lung cancer (*Journal*, October 15, 1955, p. 923) concludes that the urban/rural ratio is 9 to 1 among non-smokers for this disease. This conclusion is based on the assumption that fewer than 4% of the male population of the city of Liverpool, aged 45 to 75, are non-smokers. 3.9% of the "control" group in Liverpool hospitals were non-smokers. But if the non-hospital or the total male population, aged 45 to 75, of Liverpool were polled as to smoking history, it would probably be found—as in London—that about 10% or 12% were non-smokers. Thus table III of Doll and Hill¹ shows only 4.5% non-smokers among male non-cancer patients in London hospitals, while their table XXI shows 12.1% non-smokers among males (of corresponding ages) in the general population of London. It is of interest that the

figure of 3.9% for Liverpool hospital patients who are non-smokers corresponds closely with 4.5% for the London group. Calculations based on a 10% non-smoking Liverpool male population show that 100 instead of the actual 539 Liverpool deaths would occur if no one smoked—an 81% decrease.

As there is mounting evidence that smoking increases the incidence of diseases other than lung cancer, it is to be expected that a "control" group consisting of hospitalized men will contain a lower proportion of non-smokers than the general male population of a city. Therefore one must question the logic of comparing lung cancer patients with other hospitalized patients rather than with the general population (of same age and sex) in regard to smoking habits.

I agree with those who conclude that air pollution, both general and special—that is, in specific occupations—significantly increases the incidence of lung cancer. But complete eradication of such pollution could at the most reduce the lung cancer death rate among men in urban areas by about 40%, according to the data of Stocks and Campbell (315 expected deaths instead of 539 actual deaths in Liverpool).—I am, etc.,

WALTER MENAKER.

Rauwolfia Serpentina in Psoriasis

SIR,—In view of the favourable report about the use of rauwolfia serpentina for psoriasis by Dr. G. Leslie (*Journal*, June 11, 1955, p. 1428), we have carried out a short pilot investigation on a series of twenty patients. These were taken at random from patients attending the skin department at Huddersfield Royal Infirmary and by coincidence the series was equally divided between the sexes. Their ages ranged from 20 to 70 years and they all showed characteristic forms of psoriasis. In addition, one had rheumatoid arthritis and seven showed some degree of hypertension.

Messrs. Squibb and Co. very kindly provided "raudixin" in 50-mg. tablets and at the same time provided the control in 50-mg. tablets. Alternate patients were treated with raudixin A and tablets. Alternate patients were treated with raudixin B and no one in the hospital knew which was the dummy tablet. Treatment was continued over a period of two months and no patient showed any intolerance. The results were reviewed at the end of this time and in the control series one patient cleared initially but relapsed, five improved, one very markedly, one remained stationary, and one became worse. Amongst those receiving raudixin, one cleared completely, one cleared at first but relapsed, three improved slightly, four remained stationary, and one became worse. Of the seven patients showing some degree of hypertension, two received raudixin and the patient whose psoriasis cleared was one of these; the other showed no improvement. One of the five hypertensive cases receiving the control tablet, however, also improved, almost to the point of clearing, and another also showed considerable improvement.

The natural history of psoriasis varies so widely that it is of necessity difficult to draw any conclusions from such a small series as this. It is however felt that raudixin treatment are not significant enough to suggest that raudixin appreciably modifies the course of psoriasis or to merit a larger investigation.—We are, etc.,

Early Management of Poliomyelitis

SIR,—Dr. E. G. Brewis's article (*Journal*, June 30, p. 1539) counselling the treatment of all but a few cases of poliomyelitis in the home must have alarmed all those who have extensive experience both of the unpredictable nature of the disease in the first few days and of the end results of inadequate care even in the most mildly affected cases. Dr. G. E. Breen (*Journal*, July 21, p. 175) has already made the necessary comment so far as the acute phase of the

disease is concerned, and there is little to add to his criticisms, except that if lumbar puncture is not routinely carried out it is only a matter of time before a case of bacterial meningitis is unnecessarily left for several days without treatment.

Dr. Brewis's article contains many *ex cathedra* statements which our experience does not support. I would, however, like to lay especial emphasis on the danger of inadequate physical control and treatment, even in children who show only moderate paralysis, and indeed in those who have "muscle tightness" without any actual paralysis at all. The poliomyelitis unit at Queen Mary's Hospital for Children, Carshalton, has in recent years always contained between 50 and 130 cases of poliomyelitis, about half of which are admitted in the acute phase, the other half being transferred later in the course of the disease. Our routine treatment, which has recently been described in detail,¹ is, very briefly, as follows: (1) Rest, in carefully controlled positions requiring constant nursing supervision. (2) Hot-packing of muscle groups showing "tightness," at frequent intervals throughout the day. (3) Early passive movements to the extent that tightness, as partially liberated by hot-packing, will allow. (4) Later a carefully controlled re-educative process carried out in the physiotherapy department, which is different for each child and which varies from week to week. Much of this process is directed towards limiting a child's spontaneous activity to that which he has already learnt to do well. If he is stimulated or even allowed to "run before he can walk" he will develop fixed pathological patterns of movement, dictated not only by differential paralysis, but also by tightness spontaneously developing into fixed contractures.

If this process, and it is a most laborious one for all concerned, including the child, is not conservatively and rigorously carried out, the child will be left with much needless deformity and disability. It cannot be too strongly emphasized that much of the residual disability of poliomyelitis is due not only to actual paralysis but to the uncontrolled progress of tightness into contracture. We have ample proof of this in our experience of comparing the residual disabilities of children who have been carefully handled from the start with those who have been transferred to us after weeks of pure passivity or of inexperienced physiotherapeutic management. This kind of treatment could not possibly be carried out in the home, but can only be done effectively in a fully equipped hospital with a specialized physiotherapeutic and nursing team working in the closest co-operation and, so far as children are concerned, in a hospital which can provide a full range of educational services during the long periods of in-patient treatment which are essential.

In short, there is no doubt that the course which Dr. Brewis advocates will lead to unnecessary deaths in the acute stage, to the failure to treat bacterial meningitis in children, especially during a poliomyelitis epidemic, and to a very large amount of avoidable disability and deformity in the survivors.—I am, etc.,

Carshalton, Surrey.

Progressive Massive Fibrosis

SIR,—In their paper on progressive massive fibrosis (*Journal*, May 26, p. 1193) Dr. A. L. Cochrane and co-workers discuss the various theories of causation. I am prompted to make some remarks on one of the theories according to which progressive massive fibrosis (P.M.F.) develops only in a tuberculous site. The authors state that "most people believe that tuberculosis plays some part in the aetiology of P.M.F., but many fewer believe it to be the only factor (in addition to coal dust)." Those who hold these views, especially the latter, base their contention on the morbid anatomy in P.M.F. in coal-miners. The question arises whether P.M.F. always supervenes in a tuberculous lung in other or all types of pneumoconiosis. I would draw attention to graphite workers' pneumoconiosis,

first described by *de* in Hull, and later confirmed by others elsewhere in the U.K., Italy, and Germany. P.M.F. often occurs in graphite pneumoconiosis. Hitherto, in the cases that have come to necropsy, careful examination of the lungs has failed to detect histological evidence of tuberculosis either in this country or abroad. In others of these workers whom I have followed up, no instance of later onset of clinical pulmonary tuberculosis so far has been seen, in contrast with the relatively high incidence of tuberculosis which is well known in other types of pneumoconiosis—for example, coal-miners, grain-dockers. From the morbid histological findings in graphite pneumoconiosis one may conclude that tuberculosis is not necessarily a prerequisite in the development of P.M.F.

Among cases I have published² occurring in graphite workers were some where the x-ray pattern was at first of "snowstorm lungs"; later a proportion of these cases developed P.M.F. by local conglomeration of separate nodular lesions. I must add, however, that I have as yet been unable to obtain post-mortem examination in any of this small group, so that all I can say is that clinical evidence of pulmonary tuberculosis was absent and sputum bacteriology in the men examined by me was negative.—I am, etc.,

Hull.

Nystagmus in Alcoholic Intoxication

SIR,—I have read with great interest Dr. D. E. Howells's article on nystagmus in alcoholic intoxication (*Journal*, June 16, p. 1405). May I suggest—as a lawyer for the defence in an impaired driving case might—that there is a little vagueness as to quantities? Dr. Howell says, "The majority required from 0.7 to 1 ml. of absolute alcohol per kg. body weight," etc. Later he says, "Alcohol when given in approximately the same quantities in the form of whisky or gin produced the same effects" (my italics). And again, "can be produced in experimental subjects by giving ethyl alcohol, whisky, or gin."

The question is, does that mean an ounce of ethyl alcohol, or of whisky, or of gin? Or does it mean an ounce of absolute alcohol, or the amount of whisky or gin required to give one ounce of absolute alcohol? My presumption would be the latter, but the lawyer for the defence could lodge a doubt in the jurors' minds.

The value, to my mind, of the test is that it proved every driver tested showing nystagmus as a result of taking alcohol had his driving impaired anywhere from 4.3% to 40.5%. I should be grateful to Dr. Howells if he would make the point I raise clear.—I am, etc.,

St. John's, Newfoundland.

CLUNY MACPHERSON.

C-reactive Protein

SIR,—Your recent annotation on C-reactive protein (*Journal*, July 21, p. 145) gave a misleading indication of the nature of this substance, since no mention was made of two important and comparatively recent investigations.

Wood, McCarty, and Slater¹ isolated crystalline C-reactive protein by a modification of the technique used by McCarty,² and reported that it was located in the fast component of the gamma globulin when subjected to zone electrophoresis in a starch-supporting medium. It was also detected in this position after a similar analysis of an acute-phase human serum. In free solution, on the other hand, the crystalline preparation migrated as a beta globulin, and they pointed out that this was in agreement with its behaviour on ammonium sulphate precipitation. Brattsten³ showed that C-reactive protein occurred in the gamma globulin after continuous electrophoresis in a starch medium.

The technique of immuno-electrophoresis⁴ now enables a direct confirmation to be made of the electrophoretic mobility of the C-reactive protein of acute-phase serum under conditions approximating closely to those of free

Photographed by dark-ground illumination. Positions of protein fractions obtained by taking a filter-paper print from the surface of the gel.

solution. The result of such an investigation is shown in the illustration (immuno-electrophoretic analysis at pH 8.2 of acute phase serum; C₁ and C₂, canals containing C-reactive protein anti-serum), where the arcs of precipitate clearly occur in the position of the beta globulin fraction. It is also interesting to note that it appears to be associated with the chylomicrons, which migrate as a sharp band under these conditions.—We are, etc.,

London, N.W.3.

Sulphonamides in Aetiology of Lupus Erythematosus

SIR,—We read with interest the report on a case of systemic lupus erythematosus presenting with sulphonamide hypersensitivity reaction, by Dr. Michael Honey (*Journal*, June 2, p. 1272), but do not agree that the exhibition of the sulphonamide was an aetiological factor. The pre-existing pleurisy and haematuria were possibly all part of the lupus erythematosus syndrome. The degree of leucopenia on admission to hospital and the morbilliform rash point to the existence of the syndrome before the sulphonamide was exhibited.

We believe that hypersensitivity reactions to sulphonamides, penicillin, gold, mepacrine, and chloroquine are simply another manifestation of the already present disease and that in all cases of acute reactions to drugs the possibility of systemic lupus erythematosus should be considered.—We are, etc.,

Newcastle, N.S.W., Australia.

Treatment of Hypertension

SIR,—The recent article by Dr. S. Locket (*Journal*, July 21, p. 116) underlines once more the importance of developing satisfactory hypotension-maintaining drugs. From the case material presented it would appear that the two new drugs described are capable of producing very profound and lasting falls in blood pressure.

Whether it is desirable to produce extreme blood-pressure reduction in patients with advanced arteriosclerotic disease is a matter of debate. This is but one of the questions that can only be answered after prolonged use of hypotensive agents. Among others, we require to know more about the long-term effect of blood-pressure reduction by whatsoever means, on the patient's symptoms, on cardiac function, and on the cerebral, renal, and other complications of hypertension. Perhaps the most important question of all is when, if ever, hypotensive treatment may be omitted.

I would submit, Sir, that the answers to these and to many other questions on this important subject will come

from the field of general practice. The general practitioner has unique opportunities for the follow-up of these patients, opportunities which are denied to the hospital physician. The general practitioner is able to supervise his patients' treatment more closely over longer periods than can be possible with long-interval out-patient appointments. His blood-pressure readings are likely to reflect more realistically the patient's everyday levels. Indeed, the many published hospital reports on this subject illustrate the extremes of misinterpretation liable to arise owing to the methods employed. Thus at one end of the scale we have studies on patients kept at rest in bed over long periods. This regime results in the achievement of optimistically low readings when applied to the subsequent exigencies of everyday life. On the other hand the tension of out-patient sessions is liable to induce higher readings than are found in the atmosphere of the consulting room, as a recent study has shown.¹ Similarly, treatment by self-administered injection at home is in the main impracticable. Indeed, 20% of Dr. Locket's patients omitted treatment of their own accord, with disastrous results in one.

In short, the conditions of hospital practice are not the most suitable for a long-term study of hypotensive treatment. It is duly appreciated that without preliminary hospital studies on the actions of the drugs employed, such as that described by Dr. Locket, effective hypotensive treatment probably would not be available at all. I feel that we now require information from general practitioners on their practical experience of hypotensive therapy over the past few years. We require, too, a means of continuing such reporting over the years to come. Such an investigation would provide information of incomparable value on this subject.—I am, etc.,

Twickenham, Middlesex.

Pregnancy Test

SIR,—It is with dismay that I have received this morning a brochure from a drug firm describing a test for differentiating between pregnancy and amenorrhoea by the administration of a mixture of synthetic hormones, and the induction of withdrawal bleeding in those with amenorrhoea. There must be few cases in which it is necessary, either from the point of view of the patient or the doctor, for an immediate diagnosis to be made. In those few cases where an early differentiation is desired there are adequate tests available of a high degree of reliability, and which do not require the administration of drugs to the patient.

The test would presumably be used in the first few weeks of pregnancy, at a time when the main structures are being laid down in the embryo, and when the embryo is most susceptible to noxious influences. It seems a shocking thing to administer drugs which will upset the delicate hormonal balance of the mother and the foetus at this stage. So-called tests of the safety of this procedure are condemned by their only too obvious crudity; a continued pregnancy and an apparently normal child is no guarantee that no harm is being done.—I am, etc.,

London, N.W.8.

Hibernation in Shocked Patients

SIR,—Dr. Sheila Kenny's experiences with the use of chlorpromazine in severely shocked cases (*Journal*, July 28, p. 211) lead me, in the absence of our consultant anaesthetist, Dr. E. K. Gardner, to mention briefly a similar technique we use at Whipp's Cross Hospital. The emphasis is on autonomic block, and we have made no attempt to record the lowering of body temperature before or after induction of anaesthesia, or to prolong the hypothermia. To this end we have used hexamethonium in conjunction with chlorpromazine.

The principal points are: (1) intravenous injection of chlorpromazine ("largactil") 25 mg. in 20 ml. on arrival in the anaesthetic room; (2) adoption of 10 degrees head-down

tilt and liberal oxygenation throughout induction and operation; (3) anaesthesia by the standard sequence thiopentone-pethidine-nitrous oxide-oxygen-curare, though with greatly reduced dosage; (4) replacement of sufficient blood to restore the blood pressure to 80–100 systolic; thereafter the rate of the drip is slowed and hexamethonium used to lower the systolic pressure to 60–65 mm. Hg throughout operation.

I have recently used this technique with signal success in anaesthetizing four severely shocked patients when attempts to raise the blood pressure by the usual methods had failed. Operations lasting up to 2½ hours have been performed calmly in an almost bloodless field, and with little anxiety to the anaesthetist. We wonder if we are right in restricting this technique to the very poor risk patient and whether other milder cases might not also benefit.—I am, etc.,

London, E.11.

A. S. GARDINER.

Preparation for Marriage

SIR,—We are grateful to Dr. G. de M. Rudolf (*Journal*, July 28, p. 244) for drawing attention to the part played by Catholics in the field of marriage guidance. To avoid confusion, however, may I point out that our correct name is the Catholic Marriage Advisory Council? We shall be pleased to give further information about our work to any doctor who may have Catholic patients with marital problems.—I am, etc.,

STEPHEN ACKROYD,
Acting General Secretary,
Catholic Marriage Advisory Council.

London, S.W.1.

The Chart in General Practice

SIR,—In many cases of ill-health there are three measurements which can and should be made with reasonable accuracy: the temperature of the body, the rates of the pulse, and respiration. In hospital practice it was always useful, if not essential, to have the patient's chart at hand when considering diagnosis and progress. Yet after several years in N.H.S. general practice I have found no trace of a suitable chart for recording these observations. The introduction of yet another form must be approached with great trepidation, and the specimen shown has been produced only after a lengthy period of gestation.

So often in my practice I am meeting brief (and less often more prolonged) fevers whose aetiology is not really quite as clear as one would like to think. The pattern of the illness is all too often lost when irregular "T.P.R." recordings are jotted down anywhere but where they belong—on a simple chart. It is hoped that the simple ruling should allow the facts to be recorded by parents or other attendants in many cases, and that the chart will be of real value. The cost of charts works out at about one penny each, and they are printed for me from my own block by Messrs. H. K. Lewis.—I am, etc.,

Andover.

JOHN W. EVANS.

Practice in the U.S.S.R.

SIR,—Three weeks ago I went to the Soviet Union as a tourist. I was given an opportunity to visit a polyclinic and a children's hospital and also to have a chat with doctors about general medical services in Russia. The main unit for general medical services is a polyclinic, which is like a hospital out-patients run by G.P.s. Each district has its own polyclinic, to which go all the families living in that district. The clinic has a large staff of doctors, including specialists and nurses. Patients are seen by appointment, which may be for the same day or the following day. There are no waiting-lists.

In the first place, I was told that medical care in the Soviet Union was completely free. But further questions elicited the fact that it was not so. All consultations and treatment at the clinic (including injections, dressings, drugs) are free, but drugs, appliances, injections, etc., for use at home have to be paid for. I was told that one injection of streptomycin would cost about 10 roubles (about 19s. at the present rate of exchange), ordinary drugs from 1 to 6 roubles. If a person wishes to have doctors or specialists of his own choice he can attend one of the paying clinics, where he has to pay for consultation and treatment. There is no free treatment for temporary residents. There are special clinics for them where they have to pay for consultation and treatment. Tourists from abroad, however, are treated free, but they have to pay for their drugs like the Soviet citizens.

Polyclinics have special emergency departments which are open for treatment day and night. Emergency domiciliary visits are arranged by these departments. Ordinary domiciliary visits, of course, are paid by the doctors at the polyclinic. Factories and large stores have their own polyclinics. Sick notes in the first place are given by doctors at these industrial clinics.

A number of clinics are grouped round one general hospital, which admits all their patients. Nearly all confinements take place in hospital. I tried to visit a mental hospital, but they were rather unwilling to grant facilities. Doctors have no surgeries of their own. They are all salaried officers. They work about 5 to 5½ hours a day, and get long holidays and regular off-duty days. Facilities are readily available for specialization. The initial salary of a doctor is 800 roubles a month, rising up to 1,500 roubles. For specialists it rises up to 3,000 roubles. They compare very unfavourably with doctors' incomes here, but there are compensating advantages, like regular hours, plenty of leisure and time for studies, no worries about finding locums, and no practice expenses. On retirement there is a very generous pension for the doctor and his wife. Generally speaking, the position of a G.P. in the Soviet Union is no better than that of a skilled factory worker. My impression is that from the point of view of the patient our Health Service is much better; but for the doctor, the Soviet system has many advantages, apart from his income.—I am, etc.,

Birmingham, 32.

D. R. PREM.

Is Tonsillectomy Necessary?

SIR,—Mr. John Fry (*Journal*, August 4, p. 302) applies a false criterion of efficacy to his management of the tonsil problem. His criterion is: Can my patients survive recurrent tonsillitis treated conservatively with unimpaired health? He has good reason to believe that they can, for he states in his letter that his child patients grow up into healthy adolescents. The criterion in this problem should surely be: Will my patients grow into healthy adolescents having spent less time in bed and away from school without tonsillectomy than they would with it?

We have progressed beyond the stage where our concern in this matter is with survival or preventing gross impairment of health. Septicaemia, bronchopneumonia, mastoid, and chronic otitis media can generally now be taken care of. Our present concern is with days in bed and absence from school, and it is on this point that Dr. Fry should give us information. Tonsillectomy is a risky operation, but if it

could be shown that there is a considerable lessening of morbidity after tonsillectomy that would surely provide a fair case for taking the calculated risk. If tonsillectomy failed to produce this effect then I should join Dr. Fry in advising my patients to hang on to their tonsils.—I am, etc.,

London, S.E.26.

JOHN BURKINSHAW.

Athlete's Foot

SIR,—Regarding the recent letters of Dr. D. Hooker (*Journal*, May 26, p. 1239) and Dr. G. R. Addlestone and Dr. M. D. A. Heller (*Journal*, June 23, p. 1486), in connexion with athlete's foot, I would like to make the following comment.

In our warm climate, athlete's foot and hyperhidrosis with severe maceration occur frequently, often together, and are often clinically indistinguishable. It would not be practical to make microscopical examinations in all cases. In uncomplicated cases the following routine has proved very effective and practical as an addition to other adequate hygienic measures:—First day: (1) Swab foot and between toes with methylated spirit. (2) Paint between toes and other affected areas with pig. Castellani. Second day: Paint between toes and any macerated areas with tinct. benz. co. When the balsam is dry, dust with talcum powder. Third day: Repeat as in first day.

These alternate applications are continued for several weeks, and after the subsidence of symptoms a bi-weekly application of gentian violet or pig. Castellani alternated with tinct. benz. co. during the summer months will usually prevent a relapse. It is important that any residual balsam be removed before application of fungicide, to facilitate penetration. The above gives equal importance to treatment of maceration and possible fungal infection. It is well tolerated and completely effective in a very high percentage of cases.—I am, etc.,

Johannesburg, S. Africa.

C. B. SROKA.

Shoe-fitting X-ray Fluoroscopes

SIR,—In the *Journal* of August 4 (p. 269) there is an eight-column article by Dr. E. D. Dyson on x-ray viewing machines in shoe shops, with a most elaborate investigation of their possible dangers.

Surely the problem can be restated in words of one syllable. If a shoe fits it is comfortable. If it doesn't fit it isn't. It is just as simple as that. Is it really necessary to use a complicated and potentially dangerous machine to decide whether a new shoe hurts or not? A one-clause Act of Parliament making pedoscopes illegal would appear to be the sanest solution.—I am, etc.,

Morley.

W. STANLEY SYKES.

Purpose of Medical Education

SIR,—Without going into details of Professor G. W. Pickering's exposition on the purpose of medical education (*Journal*, July 21, p. 113) I should like to comment on three points which he makes.

(1) From the Planning Committee of the Royal College of Physicians he quotes the following: "The average student leaves his medical school at about the age of 25; during the subsequent 30 or so years of professional life his ability to learn from his own experience and that of others, and to keep abreast of the stream of advancing medical knowledge, depends entirely on those qualities in which his training has left him defective." (2) He says: "Will the medical course be arranged primarily in the interests of educating the student, or primarily in the interests of the prestige of the teachers?" (3) He says: "I have no doubt that with a little encouragement they could open a new era in medical education in this country. They have a right to expect, and I hope would receive, support from other faculties in achieving this."

It is perhaps misleading to pick out individual comments from their context, but with regard to (2) I believe sincerely that the medical curriculum should be arranged in the interests of the public upon which it is going to be practised. Concerning (3), I feel that the planning authorities should show new "vision" in the training of a science where its

practitioners are, whether they like it or not, called upon to minister to the deepest needs of humanity. This leads to point (1), where one must agree wholeheartedly that "the training is defective" in those essential qualities which are needed to treat adequately the whole man.

Very many students, unfortunately, come from materialist homes, for we live in a materialist age; they are precipitated into a scientific training and launched out on an unsuspecting public veritable cripples, for they are intellectually one-sided and spiritually defective, although their future work lies in ministering to the spirit/mind/body of humanity. It seems to me, therefore, that just as the minister of religion in this scientific age is one-sided and unable to be of full use to his "people," so the medical scientist, without some sort of serious training in philosophy, and especially in theology, is not able to use the knowledge which he has acquired for the full benefit either of his own life or of that of his patient.

I must therefore refer back to a letter I wrote (*Journal*, June 9, p. 1363) and reiterate the need for a certain number of men and women who feel "called" to insist on a dual training and so form the "leaven" which would lift up both the Church and medical science to their proper place of usefulness and influence among society. This would necessitate a new faculty, but, as Professor Pickering says, we have "a right to expect, and I hope would receive, support from other faculties" in achieving expansion along progressive lines which would give fuller usefulness to the public whom we wish to serve.—I am, etc.,

JANE H. THOMPSON.

Morpeth, Northumberland.

Poliomyelitis in Cork

SIR,—In view of the wide publicity caused by the B.B.C. broadcast of August 9 in relation to a seaman who travelled from Cork to Liverpool on s.s. *Glengariff* on Saturday, August 4, and was found on arrival to be suffering from poliomyelitis, the impression has been created that this case was badly missed by the public health authorities here. In fairness to this department, therefore, I would be grateful if you would afford me the opportunity of placing the following facts before your readers.

On July 29 the seaman in question was in Glasgow. He was suffering from sore throat and consulted a practitioner in that city. He was told, I am informed, that he had laryngitis and city. His ship, the m.v. *Birchfield*, left could carry on his occupation. His ship, the m.v. *Birchfield*, left Glasgow on July 30 and put into Whitehaven on July 31. It arrived in Cork on August 2 and remained here until August 4, when it sailed for Dublin. During its stay in Cork the sailor certainly consulted a practitioner, and was, I believe, informed that he was suffering from the effects of either "slipped disk" or "fibrositis." In view of the circumstances the master requested that he be taken from Cork to Liverpool by the *Glengariff*, and this request was granted.

The first I heard of this case was in the early afternoon of Thursday, August 9, when I received a letter from Dr. J. B. O'Regan, City Medical Officer, Dublin, in which he recorded the essential facts as reported to him by Dr. John Walker, Port Medical Officer, Dublin. By that time the B.B.C. broadcast had been on the air and in a very short time inquiries were being received from newspapers both in this country and in Great Britain. I do not wish to be taken as criticizing those responsible for the broadcast, which, in the circumstances, was thoroughly justified. I merely wish to dissipate the impression that has gone abroad that the Cork health authorities have slipped up on this case. If I had any idea of what was happening the patient would certainly not have undergone the ordeal of that journey from Cork to Liverpool.

Since the occasion of this letter has arisen I would further ask your hospitality to enter a protest against the exaggerated newspaper notoriety afforded to the poliomyelitis epidemic here. The total number of cases recorded to date from June 1 amounts to 91. Among these there has been one death, affording a fatality rate of 0.9%. There has been no indication so far of any change in trend, and the proportion of non-paralytic cases remains about 52%. In these circumstances I think it is likely that this epidemic will go down as one of the mildest on record. Meanwhile

a state bordering on mass panic has been engendered among the people of this city which reflects no credit on the newspapers concerned. This criticism does not apply to Irish newspapers only.

I take the opportunity of expressing my appreciation of the help afforded me by Dr. A. B. Christie, medical superintendent of the Fazakerley Hospital (as well as the two colleagues mentioned), in elucidating the essential facts of this incident.—I am, etc.,

J. C. SAUNDERS,
City Medical Officer.

Cork.

"Strawberry Lesion" of the Recto-sigmoid

SIR,—May I avail myself of the hospitality of your columns to congratulate Mr. G. K. Thomas on his grasp of this novel syndrome which he describes (*Journal*, July 28, p. 209), and to make one or two suggestions to explain certain difficulties which he encountered?

He mentions that he has only come across one case in five months showing the above lesion as contrasted with our Eastbourne incidence of one case in two months on an average. At that time we were receiving all the local public health material in the way of loose stools. That might explain the incidental difference. The failure to find spirochaetes might be due to (1) over-zealous lavage prior to sigmoidoscopy; (2) failure to use the diagnostic silver stain (Fontana); (3) using films which were too thick. I may be quite wrong in making these suggestions, and, if so, trust I may be forgiven. In our cases the lesion swab films usually showed embryonic, massed short forms in vast numbers.

The highly original suggestion of carbasone suppositories seems ideal for the adult case, but in children I think that oral acetarsol preferable, as I have reason to believe that the intestinal involvement is very extensive. At any rate, stained films from the stools show sometimes 100 or more spirochaetes per field. For primary diagnosis, the finding of spirochaetes in thin—very thin—films of the stools in appreciable numbers saves much time.

In conclusion, may I congratulate Mr. Thomas on his accurate study of the meagre literature of the subject, and for his generous appreciation of my efforts to put this syndrome "on the map." He would have seen a full demonstration at the B.M.A. meeting last month at Brighton. But perhaps he did?—I am, etc.,

Eastbourne.

A. GEOFFREY SHERA.

St. George-in-the-East Hospital

SIR,—The very same day that I read in the papers that St. George-in-the-East Hospital will close (see *Supplement*, p. 103), it was announced in Vienna that in the Allgemeines Krankenhaus a special "heart attack rescue unit" is to be started which will deal with cases suffering from coronary infarction.

As it seems that there are enough beds in the area of the North-east Metropolitan Regional Hospital Board, would it not be possible to start, as an experiment, a special "coronary unit" in that region, to which heart attack cases could be rushed to obtain speedy benefit of specialist treatment?—I am, etc.,

Crowthorne, Berks.

RUDOLPH PAYNE.

Purkyně's Letters

SIR,—Having recently completed an edition of the complete works of J. Purkyně, I am preparing to publish his letters. In this connexion I am seeking especially letters which he wrote to the British physiologist Martin Barry (1802–1855), and also any letters which show Purkyně's relations with the Royal Society. I should be grateful if anybody possessing letters by or concerning Purkyně, or anybody knowing of their whereabouts, would write to me.—I am, etc.,

Komenského nám. 2,
Brno, Czechoslovakia.

VLADISLAV KRUTA.

Perhaps Scot Skirving's epitaph was truly written by an Edinburgh physician over 50 years ago in one of the testimonials now in front of me which "Scot S." used as his application for the appointment of assistant physician to the Prince Alfred Hospital: "A gentleman in feeling and breeding, and actuated by high moral principles, he is possessed of those personal attributes which make him the best and most desirable of colleagues."

T. BATTERSBY JOBSON, M.D., D.P.H.

Dr. T. Battersby Jobson, who inaugurated the ear, nose, and throat department at the Royal Surrey County Hospital, Guildford, died suddenly on August 1 at the age of 84. After giving up his hospital work in 1946, on account of age, he continued to specialize in private practice, seeing a patient on the morning of the day on which he collapsed. He was blessed with remarkably good health throughout his long and active life, apart from an attack of diphtheria which he contracted from a patient on whom he performed an emergency tracheotomy in 1929.

Thomas Battersby Jobson was born at Donaghdee, Naas, Co. Kildare, on July 22, 1872, and was educated at Cork Grammar School; Fawcett's School, Cork; and Cranbrook School, in Kent. He entered Trinity College, Dublin, where he graduated B.A., winning the gold medal in natural science, in 1894. In the medical school he took the degrees of M.B., B.Ch. and subsequently the M.D. in 1897. He then worked at St. Bartholomew's Hospital, and took the D.P.H. of the English Royal Colleges in 1901. He engaged in general practice at Hendon and Ilford before the first world war, but, his mind turning towards special work, for which his education and temperament made him particularly well fitted, he became registrar at the Central London Throat Hospital in 1912-13. After the war, in which he served as a captain in the R.A.M.C. in England and Egypt, he lived at Guildford while undertaking special work in London. Appointed ear, nose, and throat surgeon to the Royal Surrey County Hospital, he inaugurated the department in 1919. It had grown to be one of the largest in the hospital when he retired in 1946. He took an active part in the affairs of the British Medical Association, being a member for some time of the executive committee of the Guildford Division, and many meetings were held at his house. In 1944 he was elected president of the Section of Otolaryngology of the Royal Society of Medicine, an honour of which he was justly proud, as it comes to comparatively few whose work is done in the provinces. The subject which he chose for his presidential address was the audibility of the radio voice, and in preparing the address he enlisted the aid of Mr. John Snagge. Dr. Battersby Jobson's name is associated with several improvements in technique and with certain inventions, such as Jobson's scoop, an auto-anaesthetic apparatus, a mouth-breathing apparatus, and tonsil clamps. He was twice married. First, in 1905, to Muriel Maconechy, who was descended from John Hunter. His own family was also connected with Hunter, although more remotely. This relationship and connexion made him an enthusiastic Fellow of the Hunterian Society, and he made many interesting contributions to the Hunterian Museum. In recognition of his work he was elected an honorary Fellow of the Society in 1953. He had four children; his son, Dr. P. H. Jobson, succeeding to his father's position in the ear, nose, and throat department of the Royal Surrey County Hospital. Mrs. Jobson died in 1933, after a long and painful illness. In 1935 he married

Miss Marjorie Minns, daughter of Dr. A. Minns, of Thetford, Norfolk, who survives him, together with his son and three daughters.

Dr. J. BURNETT RAE writes: Although our work took us along very different paths, I never lost my admiration for Jobson's good judgment and the delicacy of his touch and skill, which always inspired confidence in his patients and made him many friends. He was essentially an all-round man. This was due no doubt in part to his wide experience, not only in medicine and surgery, but in everyday affairs and sport. He was always keen on athletics, cricket, and, especially, golf, winning many trophies at the latter game, including the Ulster Cup at the Annual Meeting of the B.M.A. at Porstmouth in 1923. He was not a man of many words and he greatly disliked public speaking, but behind all that he said and did was a depth of good thought and feeling. One of his older colleagues writes: "In all the years I have known him, I do not think I ever heard him say an unkind word about anyone, and his untiring work at the hospital helped greatly to raise it from what was no more than a larger cottage hospital to what it is now." With T.B.J. go some precious links with the past, but the memory of a good doctor and a fine man remains.

E. W. S. writes: Dr. T. B. Jobson, like many provincial consultants in the past, graduated to his specialty through general practice. This method of adopting a specialty, now no longer possible in the National Health Service, may have had drawbacks, but it had the advantage of bringing with it a broader outlook both on the patient's difficulties and the needs of general practitioners. This quality contributed in no small way to Jobson's success. After demobilization from the R.A.M.C. in 1918 he settled in Guildford. The staff of the Royal Surrey County Hospital at that time were all general practitioners except for an ophthalmic surgeon and a dental surgeon. The time was ripe for the creation of special departments, and it fell to the lot of Jobson to start the E.N.T. Department. Such was his energy and ability that soon the department was large and flourishing. The hospital was in a state of rapid development, both in size and efficiency, as other departments were being opened, and Jobson's regular attendance and wise council on committees helped materially in this progress. I think the most outstanding side of his character was his unfailing kindness and good temper.

Mr. DUGALD CAMERON, for many years surgeon to the West Kent General Hospital, Maidstone, died suddenly at Scarborough on July 31. He was in his 65th year, and had been in practice in Maidstone for nearly 30 years. Originally intending to read law, Dugald Cameron, who was born on February 27, 1892, took his M.A. at Edinburgh University in 1914. This date probably had a profound effect upon him, as upon many another. He joined the Royal Field Artillery for service in the first world war and was present at the Gallipoli landings. He rose to the rank of captain, was wounded several times, and was awarded the Military Cross. On his return to civilian life he read medicine at his old university, where he graduated M.B., Ch.B. in 1923. He then held the appointment of resident house-surgeon at Edinburgh Royal Infirmary. Later he became surgeon and medical superintendent at the Randolph Wemyss Memorial Hospital, Buckhaven, Fife, at the same time conducting a practice at Leven. He returned to Edinburgh to take his Fellowship of the Royal College of Surgeons of Edinburgh in 1928. In the following year he settled at Maidstone, and was appointed surgeon to the West Kent General Hospital. He served the town and the hospital with skill, experience, and faithfulness, and was still on the active list when he died. He leaves a widow and a son of 19, who is studying law at London University.

R. H. P. writes: Few would claim that mutual magnanimity was a conspicuous feature of the professions.

Yet even in Dugald Cameron's lifetime it was remarked that he seemed to have no jealousy at all. However, one had only to hear him speak of incompetence or injustice to find that his attitude came from philosophy and not from softness. A lay friend described him as a dour Scot whose manner was not understood by all. I think it was understood by his patients and by all who knew him at all. He suffered in health in his last years, but concealed this entirely from his colleagues; but he had not looked well in recent months. It is, perhaps, too easy to call a death tragic, but there can surely be no other word for Cameron's untimely end, while on holiday, and a few short months before the retirement he had so very well earned.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on July 7 the following degrees were conferred:

D.M.—C. W. Bartley.
B.M.—G. Richman, J. A. F. Barnes, D. H. S. Stephens, K. P. S. Lumley, E. A. Morris, D. Y. Sharples, J. H. Scott-Wilson, A. B. Shrank, J. M. Brindle, H. L. Craig, R. D. Stedford, D. A. Lilliecrap, W. H. Clarke, Pamela M. Fullerton.

Dr. A. G. M. Weddell has been appointed a Curator of the Bodleian Library for ten years from the first day of Michaelmas Term, 1956.

The Horatio Symonds Studentship in Surgery for 1956 has been awarded to Michael Peter Wright, B.M., B.Ch., of Magdalen College.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At the quarterly comitia of the College held on July 26, with the President, Sir Russell Brain, in the chair, the following Fellows of the College were elected officers for the ensuing year: *Harveian Librarian*, Sir Charles Dodds, F.R.S.; *Assistant Registrar*, Dr. M. I. A. Hunter.

Sir Russell Brain was reappointed the College representative on the governing body of the British Postgraduate Medical Federation, and Sir Adolphe Abrahams on the Professional Classes Aid Council. Dr. T. C. Hunt was appointed as representative on the advisory committee of the Empire Medical Association, and Dr. J. visory Bureau of the British Medical Association, and Dr. J. Forest Smith on the council of the London Association for Hospital Services.

The following lecturers were appointed for 1957: Lumleian, Dr. L. C. Hill; Goulstonian, Dr. R. Daley; Oliver-Sharpey, Professor J. R. Squire; Mitchell, Dr. F. P. Lee Lander; Langdon Brown, Dr. R. Bodley Scott; Marc Daniels, Dr. W. D. Brooks. For 1958: Croonian, Dr. P. H. Wood; FitzPatrick, Dr. W. S. C. Copeman; Watson Smith, Dr. M. Sydney Thomson.

It was announced that the Murchison Scholarship for 1956 had been awarded to Dr. Alwyn Michael Parfitt.

The following, having satisfied the Censors' Board, were admitted Members of the College:

G. M. Aber, M.B., B. G. Barnard, M.B., A. R. Bird, M.B., G. H. Blair, M.B., J. Blake, M.D., H. D. Breidahl, M.D., D. H. Davies, B.M., R. E. Eban, M.B., R. T. D. Emond, M.B., E. J. Epstein, M.B., J. C. Farrell, M.B., I. B. Hales, M.B., C. J. Hayter, M.B., G. E. Hession, M.B., E. W. Jones, M.B., R. V. Jones, M.B., Captain, R.A.M.C., G. F. Joplin, M.B., D. M. Krikler, M.B., G. C. R. Morris, B.M., A. D. Munro, M.B., J. F. Niall, M.D., I. C. S. Normand, B.M., Captain, Faure, B.M., N. J. O'Doherty, M.B., G. Pampiglione, M.D., A. J. Peppert, R.A.M.C., N. J. O'Doherty, M.B., D. B. Shaw, M.B., Muriel E. M.B., M. Rayne, M.B., H. E. Reef, M.B., D. B. Shaw, M.B., Muriel E. Sidaway, M.B., F. G. Silberberg, M.B., K. Sinclair, M.B., Isabel G. Stubbe, M.B., R. W. Smithells, M.B., R. Sougin-Mibashan, M.D., J. L. Stubbe, M.D., Bidi M. Wild, M.B., C. W. E. Wilson, M.B., K. G. Wormsley, M.B., S. Zwi, M.B.

Licences to practise were conferred upon the following 122 candidates who have passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and who have complied with the bylaws of the College:

E. O. O. Arbener, G. M. D. Archer, G. W. Arthur, J. K. Arthur, R. M. Baddeley, B. H. Bee, N. C. Bhandari, R. M. L. Bowles, P. H. Boyle, R. P. Britt, J. R. Burgess, Barbara L. Burroughs, G. W. Chance, M. D. B. Clarke, G. Cohen, Elizabeth A. Coles, F. L. W. Collins, D. C. Colwell, M. R. Colwill, B. J. E. Cooke, C. C. Cory, G. Cowburn, Margaret J. Darch, J. K. Dauncey, D. B. A. L. Davies, W. H. E. Davies, B. P. Day, W. Deighton, R. A. Delevante, G. C. Denton, T. S. Dogra, J. N. Drinkall, C. J. Drouet, G. S. Duncan, Elizabeth M. Everard, G. W. M. Faris, Barbara S. Finch, D. B. Fowler, C. Williams, P. N. Williams, D. Wilson, R. H. Wilson, C. W. O. Windsor, P. Wolstencroft, H. O. Wooller, G. Yates, J. M. Young, M. J. Young.

The following diplomas were conferred jointly with the Royal College of Surgeons of England:

DIPLOMA IN ANAESTHETICS.—Mary P. Armstrong, S. Baigel, T. W. Baillie, D. R. Ball, D. C. F. Banks, Colette A. Barouch, M. E. H. Barrow, R. C. Bellingham, E. D. L. Bennett, G. Berry, J. Biggins, T. R. Bonomi, Eileen S. Browne, A. F. Buck, J. C. Burt, G. W. Burton, D. C. T. Bush, Anne Cairns, M. S. Chayen, T. H. Chillingworth, Pauline M. Collins, H. R. P. Coutanceau, Davina M. Cowan, N. C. Das, R. D. McC. Davie, R. C. Davison, Josephine Dec, P. H. Dennison, D. W. A. Drew, Lillie S. Dummer, W. S. Dykes, J. W. C. Fox, A. Ganesan, Patricia E. Gardner, Patricia Gorman, W. H. Graham, R. J. J. Gray, T. Grogan, M. Grossberg, T. K. Hardy, S. Harrison, R. D'A. Harvey-Kelly, P. J. Healy, W. J. Hegarty, A. W. G. Housby, J. D. Hunter, Frances C. E. Hutchison, C. G. Ingram, Beryl E. Jack, D. C. Jackson, J. B. Jacovelli, S. W. Kemp, M. H. Lawrence, J. W. Leach, A. F. M. Little, C. G. Lloyd, H. F. F. Lorang, J. D. Lumsden, M. J. Lyons, Betty McCarthy, D. T. McClements, Jean M. MacDonald, Margaret E. McMullin, W. D. McNaul, D. M. McWilliams, Hannah M. R. Marks, Shelagh Mathias, F. X. Micallef, J. B. Montgomery, T. R. Morley, C. Moss, Sheila M. Mullally, Jean C. Munro, T. J. Nagle, A. P. M. Nicol, Carol A. N. Nompozo, M. H. Norman, Patricia Painter, Isabella R. Paterson, L. A. Phillips, T. Pimblett, Barbara A. Renwick, J. Rintoul, Lydia J. Rose, Rosamund O. F. Shanks, P. Steward, A. P. Thomas, Sheila M. Topping, M. E. Tunstall, Margaret M. Voysey, Ethna A. Walsh, C. S. Ward, D. J. Waters, Dorothy A. Wescott, Mary F. West, W. M. Wilkinson, Cynthia M. Worrall, S. Yousuf.

DIPLOMA IN CHILD HEALTH.—K. D. Coorey, C. Lucey, T. Valaas.
DIPLOMA IN INDUSTRIAL HEALTH.—J. R. Bowker, A. J. de Villiers, J. E. Epsom, T. A. Evershed, M. N. Guha Majumder, C. E. S. Myers, D. A. Narasimhan, J. K. Sehgal, A. S. Sethi, K. N. Sharma, D. Tingle, M. Zeville.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—I. E. Backwell, Margaret V. Bickerton, V. Briffa, S. Das Gupta, L. S. Goldman, G. B. Hill, D. A. James, D. A. L. Lourensz, A. M. K. Mojis, R. R. Patel, J. S. Ritchie, T. S. N. Sinha, J. A. van der Merwe, R. W. Ware, J. S. H. Whitehead.

DIPLOMA IN MEDICAL RADIOLOGY.—A. W. Atukorala, P. E. Billimoria, W. I. H. Bourne, Eva E. Epstein, W. A. Evans, B. B. Fazackerley, A. K. Kouppas, B. Kramer, J. I. Levy, N. J. McKellar, D. G. Potts, M. A. Rahman, M. C. Stevens, D. A. Symers, V. Visweswariyah, M. Weerasena.

DIPLOMA IN MEDICAL RADIOTHERAPY.—G. A. B. Cowan, I. Fix, G. E. Flatman, J. A. G. Holt, N. Howard, R. J. R. Johnson, B. Lall, Marjorie E. Nobbs, J. S. Scott, A. K. Turnbull, Eileen M. Williamson.

DIPLOMA IN PATHOLOGY.—J. G. Azzopardi, E. F. Bowers, R. R. Chaudhuri, Helen L. D. Duguid, R. J. Elvy, A. F. Ollerenshaw, Carolyn C. Rigby, A. M. Womack.

DIPLOMA IN OPHTHALMOLOGY.—H. Akhtar, J. Anderson, E. J. Arnott, R. Banerji, K. K. Biddappa, J. S. Brown, D. H. Coop, Margaret E. Coop, A. J. Dark, Doris M. Davies, G. B. Davies, Jean A. Fairhurst, C. R. A. Fenton, A. D. Fox, A. H. Haley, Mary J. L. Hall, S. A. Husain, S. I. Husain, A. G. H. Ishak, C. R. Kanagasundaram, V. V. Kayarkar, T. H. Khan, S. Kumar, O. Lawrence, E. C. B. Mackey, E. A. McWilliams, Khan, S. Kumar, O. Lawrence, E. C. B. Mackey, E. A. McWilliams, I. B. O. Odd, H. N. O'Donoghue, M. E. Quatermass, Y. P. Singh, I. B. Speight, S. Stead, Hilary K. R. Steen, E. J. Trencery, P. L. Wong.

DIPLOMA IN PHYSICAL MEDICINE.—S. K. Banerjee, S. K. Dutta, T. G. Hovenden, N. R. Lewis.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—W. McC. Anderson, T. Baasher, L. B. Bartlett, Enid Caldwell, A. Capstick, A. Chakraborty, J. A. Clark, D. Craigen, J. L. Crammer, M. S. De Mowbray, G. P. S. Fernandez, R. T. D. Franklin, N. G. Fraser, J. A. Gorst, Sarah K. R. Gray, A. C. R. Hamer, O. E. F. Hodgson, J. A. Hutchinson, I. M. Ingram, S. Iskandar, E. H. Jacobs, G. G. Macdonald, N. J. C. McGill, D. H. Malan, E. Mellor, T. J. K. Merritt, H. Nichol, C. Ounsted, R. A. Pargiter, J. M. Pencheon, N. J. Prichard, P. E. Rixon, P. P. E. Savage, J. P. Scrivener, B. P. Shah, A. Sittampalam, P. M. Tow, H. J. Walton, R. D. Watson, N. V. Wilkinson, J. L. Wilson, Lorna G. Wing.

DIPLOMA IN PUBLIC HEALTH.—Colina C. Adeniyi-Jones, C. C. A. Adeniyi-Jones, O. B. Alakija, Margaret M. Bates, B. H. Burne, Margaret Capra, Engenie F. Coetzer, Marjorie T. Dare, Rachel Jacobs, Katie Keane, Anne D. Lepine, Joan M. MacCarthy, R. D. MacLean, May T. McQuaid, Geraldine T. O'Carroll, A. A. Qureshi, P. T. Regeer, G. A. Roberts, S. K. Sarkar, Marjorie Smail, Gwendolyn R. Tapp, T. B. Whitehead.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—D. M. Du Toit.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on July 26, with Sir Harry Platt, President, in the chair, the Handcock Prize was awarded to R. D. C. Southcott, of Guy's Hospital Medical School.

Diplomas were granted, jointly with the Royal College of Physicians of London, in Anaesthetics, in Child Health, in Industrial Health, in Laryngology and Otolaryngology, in Ophthalmology, in Medical Radiodiagnosis, in Medical Radiotherapy, in Psychological Medicine, in Physical Medicine, in Public Health, in Tropical Medicine and Hygiene, and in Pathology to the successful candidates whose names are printed above in the report of the meeting of the Royal College of Physicians of London, also held on July 26.

Vital Statistics

Summary for British Isles for week ending **July 28**
(No. 30) and corresponding week 1955.

Figures of *cases* are for the countries shown and London administrative county. Figures of *deaths* and *births* are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1956					1955				
	Eng. & Wales	Land.	Scot.	N. Ire.	Eire	Eng. & Wales	Land.	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Includes puerperal pyrexia.

• **Средства массовой информации:** Газеты, журналы, радио, телевидение.

Poliomyelitis

Poliomyelitis notifications in the week ending August 4 (31st week of the year) were as follows: Paralytic 73 (71), non-paralytic 58 (89), total 131 (160). This is a decrease of 29 compared with the previous week, the figures for which are in parentheses.

Cases notified from the beginning of the year (with rate per 100,000 population in parentheses) are as follows for districts of relatively high incidence: Macclesfield M.B. 25 (69); Whitehaven M.B. 22 (87); Ennerdale R.D. 18 (63); Yeovil M.B. 19 (79); Guildford M.B. 32 (64); Manchester C.B. 212 (30); Woking U.D. 17 (30); and Reigate M.B. 16 (33).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

ACUTE POLIOMYELITIS

Week Ending August 4

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 426, whooping-cough 2,146, measles 3,220, acute pneumonia 196, acute poliomyelitis 131, dysentery 603, paratyphoid fever 8, and typhoid fever 1. There were no cases of diphtheria.

Infectious Diseases

The notifications of infectious diseases did not show any large fluctuations in England and Wales in the week ending July 28. Notifications of scarlet fever rose by 43, from 530 to 573, and of measles by 19, from 3,251 to 3,270. Whooping-cough notifications fell by 170, from 2,558 to 2,388. The decline in dysentery notifications also continued, from 970 to 843, a fall of 127. Notifications of paratyphoid fever rose from 16 to 25, while those of typhoid numbered 4 as in the previous week.

Of the paratyphoid notifications, 5 came from Yorkshire West Riding (Leeds C.B. 4, Morley M.B. 1), 4 from Kent (Bexley M.B. 4), 4 from London (Bethnal Green 1, Camberwell 1, Fulham 1, Hammersmith 1), and 4 from Middlesex (Acton M.B. 1, Hendon M.B. 2, Tottenham M.B. 1).

In Lancashire 89 cases of food-poisoning were notified, more than in the previous week; the main centres were Oldham C.B. 35, Liverpool C.B. 17, and Royton U.D. 14. In Warwickshire 68 cases were notified, an increase of 61 over the previous week's cases; the rise was due to an outbreak at Birmingham C.B. 64.

Medical News

International Action on Atomic Energy.—International co-operation in the field of nuclear energy is quickening and extending. The council of the International Organization for Standardization—a body of which the British Standards Institution is the United Kingdom member—has decided that its technical committees should turn at once to the question of securing agreed international standards. The first standards to be dealt with are those concerned with terminology, definitions, and symbols; safety standards for protection against radiation hazards; and standards for the safe and effective operation of reactors. Taking advantage of the recent meeting of the First International Congress of Human Genetics (see p. 412), W.H.O. convened an international study group in Copenhagen immediately after it to discuss the effects of radiation on human heredity. The W.H.O. group, which includes among its members Professor L. S. PENROSE, F.R.S., Dr. T. C. CARTER, Dr. W. M. COURT BROWN, Dr. C. A. B. SMITH, and Professor A. C. STEVENSON, began its meetings (which were due to last for a week) on August 7. Other evidence of international co-operation is the signing in London on July 31 of a ten-year agreement between Britain and Western Germany on the peaceful use of atomic energy. The agreement provides for Western Germany to obtain from Britain research reactors and their fuel, training facilities at the Atomic Energy Authority, and

certain unclassified information on the design and operation of nuclear reactors.

New Surgeon-General.—Dr. L. E. BURNLEY has succeeded Dr. Leonard A. Scheele as surgeon-general of the United States Public Health Service. Dr. Scheele resigned unexpectedly last June (see JOURNAL, July 14, p. 109). Dr. Burnley, who is 49 years of age, has been an assistant surgeon-general for the past two years. Most of his professional life has been in the public health service, and he served as public-health commissioner in Indiana from 1945 to 1954. The surgeon-general's salary is \$22,626 per year.

Intradermal T.A.B. for Boosting.—The War Office announces that in future the Army booster doses of T.A.B. will be given "into the skin," not under it. This is to avoid the usual reaction from T.A.B., which it is stated "is associated with the giving of an injection under the skin." Intradermal injection has not been adopted earlier, in spite of its known low reaction rate, because there were doubts about the immunity it conferred. Now, states the War Office announcement, evidence from the United States that the method is effective for reinoculation against enteric (though inadvisable for primary inoculation), and favourable confirmatory experiments at the Army vaccine laboratories at Everleigh, allow the change to be made. The Army is continuing its investigations of the intradermal technique, with the object of adapting it to both primary inoculation and combined prophylactics.

Dr. Ravdin Honoured.—The Royal College of Surgeons of England announces that it has conferred its honorary fellowship on Dr. I. S. RAVDIN, of Philadelphia. Dr. Ravdin is the chairman of the Board of Regents of the American College of Surgeons and is professor of surgery at Pennsylvania University. He intends to visit London in December, when he will sign the Roll of Honorary Fellows and deliver a Moynihan lecture at the College.

London University.—Dr. NORMAN MORRIS, first assistant in the obstetric unit at University College Hospital, has been appointed to the university readership in obstetrics and gynaecology tenable at the Institute of Obstetrics and Gynaecology. Mr. H. M. PICKARD has been appointed to the university readership in conservative dentistry tenable at the Royal Dental Hospital of London.

Harben Lecturer.—Professor PHILIP DRINKER, professor of industrial hygiene at the Harvard University School of Public Health, has been appointed Harben lecturer for 1956 by the council of the Royal Institute of Public Health and Hygiene. Professor Drinker will give his lectures next year (May 13, 14, and 15) in London. His subject will be "Air Pollution and the Public Health."

COMING EVENTS

Institute of Biology.—A symposium on "The Biology of Ageing" will be held on September 27 and 28 in the Anatomy Theatre, University College, London, W.C.1. Details from the general secretary, Institute of Biology, 41, Queen's Gate, London, S.W.7.

European Association Against Poliomyelitis.—Annual symposium, at Bologna, September 20–22. Details from the general secretary, European Association Against Poliomyelitis, 67, Boulevard A. Reyers, Brussels.

Association of Anaesthetists of Great Britain and Ireland.—Annual meeting at the Royal College of Surgeons, 45, Lincoln's Inn Fields, London, W.C.2, on November 1 and 2. Those wishing to read papers should send a 250-word summary to the secretary before August 30.

Sixth Congress of the European Society of Haematology.—Copenhagen, August 26–31, 1957. Details from the secretary-general, Blegdamsvej 11, Copenhagen, Denmark.

International Symposium on Medical-Social Aspects of Senile Nervous Diseases.—Venice, July 20 and 21, 1957. Details from the secretariat, Viale Morgagni 85, Firenze, Italy.

Twelfth International Congress on Occupational Health.—Helsinki, July 1-6, 1957. Details from the secretary-general, c/o Työterveyslaitos, Haartmaninkatu 1, Helsinki-Töölö, Finland.

Sixth International Congress of Otolaryngology.—Washington, D.C., May 5-10, 1957. Details from the general secretary, 700, North Michigan Avenue, Chicago 11, Illinois.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 40, No. 6) is now available. The contents include:

FACTORS AFFECTING THE HYDRATION OF THE CORNEA IN THE EXCISED EYE AND THE LIVING ANIMAL. Maurice E. Langham and Irvin S. Taylor.
VASCULARIZATION OF THE OPTIC PATHWAY. IV. OPTIC TRACT AND EXTERNAL GENICULATE BODY. J. François, A. Neetens, and J. M. Collette.
DESCRIPTION OF BEHCHET'S SYNDROME IN THE HIPPOCRATIC THIRD BOOK OF ENDEMIC DISEASES. Aryeh Feigenbaum.
BLOOD IN THE CANAL OF SCHLEMM. Redmond Smith.
NORMAL INTRA-OCULAR PRESSURE. M. Alimuddin.
CONCOMITANT ESOTROPIA OF LATE ONSET. PATHOLOGICAL REPORT OF FOUR CASES IN SIBLINGS. Atilio L. Norbis and Enrique Malbrán.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Heart Journal.—The new issue (Vol. 18, No. 3) is now available. The contents include:

ABSENCE OF THE LEFT PULMONARY ARTERY IN FALLOT'S TETRALOGY. Richard W. Emanuel and J. Norman Pattinson.
PREMATURE OBLITERATION OF THE FORAMEN OVALE. G. Austin Gresham.
ABERRANT BEATS OF WOLFF-PARKINSON-WHITE CONFIGURATION IN ARTERIO-SCLEROTIC HEART DISEASE. Irwin Hoffman, Milton H. Morris, Louis Friedfeld, and Robert D. Gittler.
SUPERNUMERARY CHAMBERS TO THE LEFT HEART. P. J. Barnard and A. J. Brink.
THE VALVE OF THE INFERIOR VENA CAVA. John B. Hickie.
LEFT ATRIAL "PULMONARY CAPILLARY" AND OESOPHAGEAL BALLOON PRESSURE TRACINGS IN MITRAL VALVE DISEASE. Alvin J. Gordon, Leslie Kuhn, Salomao S. Amram, Ephraim Donoso, and Eugene Braunwald.
CHRONIC GENERALIZED MYOCARDIAL ISCHAEMIA WITH ADVANCED CORONARY ARTERY DISEASE. W. F. M. Fulton.
THE DIAGNOSIS OF CONGENITAL HEART DISEASE IN INFANTS BY CATHETERIZATION AND SELECTIVE ANGIOCARDIOGRAPHY. Ib Boesen, John Lind, B. Merrild-Hansen, Th. Rosendal, Ole Storm, and Carl Wegelius.
ANOMALOUS PULMONARY VENOUS DRAINAGE. John B. Hickie, T. M. D. Gimlette, and A. P. C. Bacon.
SELECTION FOR ANTICOAGULANT THERAPY IN CARDIAC INFARCTION USING THE HEPARIN RETAINED COAGULATION TIME. A. A. Fitzgerald Peel.
FURTHER STUDIES ON THE CEREBRAL BLOOD FLOW ESTIMATED WITH THORIUM-B LABELLED ERYTHROCYTES. Erik Gustave Nylin, Hans Blömer, Hardin Jones, Sven Hedlund, and Carl-Gösta Rylander.
TWO MORE FAMILIES WITH CARDIOMEGALY. Maurice Campbell and Margaret Turner-Warwick.
SPECTRAL PHONOCARDIOGRAPHIC STUDIES IN CONGENITAL HEART DISEASE. Victor A. McKusick, Oliver N. Massengale, Jr., Milton Wigod, and George N. Webb.

CASE REPORTS:
PATENT DUCTUS ARTERIOSUS WITH PROGRESSIVE DILATATION OF THE PULMONARY ARTERY. J. A. Cosh.
CARDIAC FAILURE DUE TO PRIMARY AMYLOIDOSIS. Heather Ashton.
HEART FAILURE DUE TO EXTREME OBESITY. T. B. Counihan.
STOKES-ADAMS ATTACKS IN ACUTE RHEUMATIC CARDITIS. T. C. Gibson and J. P. Hughes.
ABSTRACTS OF CARDIOLOGY.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Journal of Neurology, Neurosurgery and Psychiatry.—The new issue (Vol. 19, No. 2) is now available. The contents include:

OBSERVATIONS ON THE EXTENDED USE OF THE MARCHI METHOD. Marion C. Smith.
THE RECOGNITION AND PREVENTION OF ARTEFACTS OF THE MARCHI METHOD. Marion C. Smith.
STUDIES IN SENSATION: OBSERVATIONS ON THE LOCALIZATION OF THE SENSATIONS OF TOUCH AND PRICK. John Marshall.
REFERENCE OF SENSATION AT THE SPINAL LEVEL. P. W. Nathan.
AWARENESS OF BLADDER FILLING WITH DIVIDED SENSORY TRACT. P. W. Nathan.
TWO CASES OF MYOPATHY LIMITED TO THE QUADRICEPS. John N. Walton.
A STUDY OF 25 CASES OF COMPRESSION OF THE CAUDA EQUINA BY PROLAPSED INTERVERTEBRAL DISCS. W. Bryan Jennett.
E.E.G. ABNORMALITIES FROM THE TEMPORAL LOBE STUDIED WITH SPHENOIDAL ELECTRODES. G. Pampiglione and J. Kertridge.
THE EFFECT OF INSULIN COMA AND E.C.T. ON THE SHORT-TERM PROGNOSIS OF SCHIZOPHRENIA. J. Hoenig, D. M. Lieberman, and I. Auerbach.
SODIUM AMYTAL AND BEHAVIOUR IN NEUROTIC SUBJECTS. S. G. Lavery and C. M. Franks.
DISSEMINATED SCLEROSIS TREATED WITH ISONIAZID WITH A METHOD OF EVALUATING CHRONIC NEUROLOGICAL DISORDERS. Barbara M. Ansell and Edwin Clarke.
ISCHAEMIC AND POST-ISCHAEMIC PARAESTHESIAE: NORMAL RESPONSES IN THE UPPER LIMB WITH SPECIAL REFERENCE TO THE EFFECT OF AGE. E. W. Poole.
FAMILIAL PERONEAL MUSCULAR ATROPHY AND ITS ASSOCIATION WITH THE FAMILIAL ATAXIAS AND TREMOR AND LONGEVITY. Raymond Hierons.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Thursday, August 23

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., special lecture by Dr. J. R. Lindsay (Chicago): Vascular Accidents as They Affect Vestibular Function.

APPOINTMENTS

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—J. P. Partridge, F.R.C.S., Resident Assistant Surgeon; Judith N. Nicholas, M.B., B.S., D.A., Junior Resident Anaesthetist; J. P. Stanfield, M.D., M.R.C.P., Winifred Burgess, M.B., B.S., M.R.C.P., D.C.H., and M. L. Weidman, M.D., House-physicians; S. W. Mannion, M.B., Ch.B., and D. A. M. Ellis, M.B., B.S., House-surgeons; G. G. Woodruff, M.D., Assistant Medical Registrar; A. C. Woodmansey, M.D., M.R.C.P., D.P.M., D.C.H., Part-time Medical Officer in the Department of Psychological Medicine; F. R. H. BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Davis.—On August 3, 1956, at King's College Hospital, London, S.E., to Margaret (formerly Liddle), S.R.N., wife of Leslie R. Davis, M.D., a son, Richard Burn.
Lennox.—On August 9, 1956, at B.M.H. Hostel, B.A.O.R., to Elizabeth Leslie (formerly Handasyde), M.B., Ch.B., wife of Ian Gordon Lennox, M.B., Ch.B., a daughter.
Nagley.—On August 1, 1956, at Farnborough Hospital, Kent, to Sylvia, wife of Dr. Martin M. Nagley, a son—Timothy Nigel.

DEATHS

Armour.—On July 31, 1956, at Crichton House, Anstruther, Fifeshire, Matthew David Sutherland Armour, M.B., Ch.B.
Beck.—On July 27, 1956, at Martyrwell, Cheriton, Hants, William Distin Beck, M.D.
Buist.—On July 24, 1956, at Cape Town, South Africa, Herbert John Martin Buist, C.B., C.M.G., D.S.O., M.B., C.M., Colonel, late R.A.M.C. (retired), aged 88.
Cameron.—On July 31, 1956, at Scarborough, Yorks, Dugald Cameron, M.C., M.B., F.R.C.S.Ed., of 114, Tonbridge Road, Maidstone, Kent.
Crabtree.—On July 23, 1956, at Stansfield Hall, Tordomden, Lancs, Walter Crabtree, M.C., M.B., Ch.B., formerly of Nelson, Lancs, aged 80.
Duncan.—On August 2, 1956, James Matthews Duncan, O.B.E., M.D., of Murtle, Sunninghill, Ascot, aged 82.
Eppyn-Phillips.—On August 1, 1956, at Oulton Broad, Suffolk, Mary Elizabeth Eppyn-Phillips, M.B., aged 81.
Greville.—On July 29, 1956, the result of an accident, Andrew C. Greville, M.B., Ch.B., D.M.R.D., of Eaton Lodge, Roby Road, Roby, near Liverpool, aged 37.
Heller.—On July 20, 1956, at his home, 1, Beckett Close, Worcester, Alois Heller, M.D.
Jobson.—On August 1, 1956, at Maryknoll, Guildford, Surrey, Thomas Battersby Jobson, M.D., D.P.H., aged 84.
Jocelyn.—On July 25, 1956, Frank Steven Jocelyn, M.D., of 10 Marius Road, Balham, London, S.W.
Loosely.—On July 20, 1956, in a nursing home, Hindhead, Surrey, Alfred Edward Arthur Loosely, M.B., F.R.C.S.
O'Beirne-Ryan.—On July 24, 1956, at Oddmeads, Langford Budville, Wellington, Som., Charles O'Beirne-Ryan, L.R.C.P.&S.I. & L.M., Surgeon Lieutenant-Commander, R.N.V.R. (retired), late of Harrogate, Yorks.
Reichert.—On July 21, 1956, Edward Reichert, M.D., of "Patria," Norley Road, Cuddington, near Northwich, Cheshire, aged 57.
Rice.—On July 23, 1956, at Newport, Rhode Island, U.S.A., Alexander Hamilton Rice, M.D., aged 80.
Toogood.—On July 30, 1956, at Point House, Fowey, Cornwall, Frederick Sherman Toogood, O.B.E., M.D., D.P.H., Lieutenant-Colonel, R.A.M.C. (retired), aged 93.
Vane-Percy.—On July 17, 1956, at Shenton Park, Western Australia, Nora Aileen Vane-Percy, M.B.
Walker.—On July 16, 1956, in a nursing-home, Torquay, Devon, Henry Roe Walker, M.R.C.S., L.R.C.P., of Ipplepen, Newton Abbot, Devon, aged 85.
Wall.—On July 20, 1956, at the home of his daughter, "Cranleigh," Fell Drive, Grange-over-Sands, Lancs, Douglas Larmer Wall, M.C., M.B., Ch.B., formerly of "Fairlawn," Hoo, Kent.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Coitus in Old Age

Q.—Am I right in advising aged married couples to continue coitus if both parties so wish and are in good health? There seems to be a widespread idea that sexual intercourse is harmful in old age.

A.—With the exception of those cases where there might be some medical contraindication to physical exertion there is no reason why married couples should not continue coitus in old age if they so desire. Many cases are encountered where regular sexual relations continue well into the seven-ties, or longer. However, the post-menopausal woman, owing to diminishing secretion of mucus and atrophy of the vagina, may suffer from a degree of dyspareunia varying from slight discomfort to severe pain, and this may bring the sexual relationship to an end quite unnecessarily. Pathological conditions having been excluded by examination, advice on the use of a lubricant jelly or, if necessary, carefully supervised local or general oestrogen therapy can alleviate this dyspareunia. Regular coitus can then often be satisfactorily maintained into old age with benefit and comfort to both partners.

Olecranon Bursitis

Q.—One meets a number of cases of olecranon bursitis with effusion that fail to clear up on aspiration alone. Are sclerosants of use here, and, if so, which is advised?

A.—There are several causes of bursitis in this region. Some instances are due to injury, and some of them respond well to the injection of sclerosing solutions, but the use of sclerosants is at best uncertain and often very painful. Excision of the affected bursa is a simple little operation which is much more reliable, and which can be done in which is much more reliable, and which can be done in many most cases quite safely as an out-patient procedure. A variety of rheumatoid arthritis; others have a gouty basis. Sclerosing injections are, of course, inadvisable in both these types.

If a sclerosant is used, ethanolamine is probably the safest.

Oral and Intravenous Procaine

Q.—What are the clinical effects of giving procaine (a) orally, (b) intravenously? I heard it claimed recently that oral procaine was sometimes successful in relieving severe pain when all else had failed. If intravenous procaine is safe, can it be combined with morphine for the relief of pain?

A.—A considerable literature has accumulated on the effects and therapeutic uses of intravenous procaine. In the main, it has been used for the relief of pain, particularly the pain of post-operative pain and that due to burns, for the treatment of peripheral vascular disease, for the prevention of arrhythmias during cardiac surgery, and for the relief of pain and spasm in various arthritic conditions. It has also been used to produce general anaesthesia and obstetric analgesia. The method is safe only if administered by someone able to deal with the effects of overdose, which may appear with dramatic suddenness. Convulsions, respiratory arrest, and severe hypotension may all come on with little warning. An intravenous drip of procaine should never be left running with only a nurse in attendance. Intravenous procaine is not advised in conjunction with morphine, because the combined effects of both drugs on the respiration may be severe. The uses of intravenous procaine have been reviewed by Mushin and Rendell-Baker¹ and by Graubard and Peterson.²

The administration of procaine by mouth has been described by Roka and Lajtha.³ These authors, on a basis of x-ray investigations, claim that 100 ml. of 1% procaine taken orally, once or twice a day, will relieve non-organic pyloric spasm. Nearly complete paralysis of the pylorus appears to occur within ten minutes. This treatment, they claim, may also relieve vomiting due to gastric ulceration, and also benefit patients with carcinoma of the stomach, allowing nutrition to be improved before surgical treatment. No published account of the treatment of pain by oral procaine can be found.

Cortisone and Corticotrophin in Disseminated Sclerosis

Q.—Has cortisone or corticotrophin any place in the treatment of disseminated sclerosis?

A.—As soon as cortisone and corticotrophin were available experimental treatment was carried out in disseminated sclerosis, at first in the United States. Almost from the first the results were conflicting, some observers noting "significant improvement," others results that were "profoundly disappointing." The position up to 1955 is reviewed, together with references, by McAlpine, Compston, and Lumsden.¹ At the time of writing there would seem to be no evidence at all that either of these preparations has any effect in this disease, but as with all forms of treatment in this disease the assessment of results is wellnigh impossible. It may, however, be true that corticotrophin has an important therapeutic role in acute disseminated encephalomyelitis (which is an allied though different condition), and the position here has been reviewed by Miller.²

Pain and Urinary Retention after Haemorrhoidectomy

Q.—What are the best ways of preventing retention of urine and pain on defaecation after operation for internal haemorrhoids?

A.—After haemorrhoidectomy the reduction of pain and avoidance of complications, of which retention of urine is the most common, depend on attention to a number of points, such as (1) correct choice of cases for operation—this involves selection of third-degree piles which are free from recent infection and thrombosis; (2) correct operative technique, which must be based on accurate knowledge of ano-rectal anatomy—it is particularly important that an accompanying dorsal fissure should be recognized and dealt with, preferably by adequate drainage and suitable division of the internal sphincter in the right posterior quadrant; (3) a well-chosen post-operative regime, which must be well understood by the nursing staff and carried out with gentleness, thoroughness, and confidence. Many of the rectal cases are of the nervous, apprehensive type and need much reassurance. It is a great help to use a type of anaesthesia which permits the male patient to be stood out of bed early to pass urine, and a combination of local analgesia (2% aqueous procaine) with intravenous thiopentone and gallamine has proved to be the ideal method. Spinal analgesia has been discarded owing to the high incidence of post-operative retention of urine. Finally, in patients of the nervous type it is a great help to give phenobarbitone, $\frac{1}{2}$ gr. (32 mg.) twice daily, for the first week after operation. Most patients treated on these lines will need only one injection of injectio papavereti (B.P.C.) on the night after operation, and it is gratifying to find that the majority now say that their fears were groundless and that their post-operative course has been much better than anticipated. It

is curious how the old tradition of patients having "excruciating pain" after operation for haemorrhoids still persists, but each additional patient successfully dealt with on modern lines should help gradually to kill this myth.

Exact Control in Diabetes

Q.—On the assumption that it is impossible to stabilize exactly a diabetic who is having insulin, is it better to aim for slight hypoglycaemia rather than slight hyperglycaemia in order to avoid complications and prolong life? Is prolonged slight hypoglycaemia detrimental to health in any way?

A.—It is true that it is impossible to imitate exactly the normal physiological control of carbohydrate metabolism by means of injected insulin, but the object of treatment should be not to produce a state of either slight hypoglycaemia or hyperglycaemia but rather, if possible, so to arrange the diet and insulin that the blood sugar is within normal limits at the time of maximum insulin action. The duration of this period of normoglycaemia will, of course, depend upon the type of insulin and number of injections given daily.

It is difficult to say whether the diabetic whose blood sugar is constantly slightly below normal is better off than the one who is always a little hyperglycaemic; but, as it is impossible to be sure that the hypoglycaemia will always be slight, it is probably safer to err a little on the side of excess, or, in other words, it is safer to have the urine tests sometimes green rather than always blue. This is particularly true in elderly patients with evidence of coronary artery disease.

There is no evidence that prolonged slight hypoglycaemia is detrimental to health, but it is quite impossible to maintain this state with any degree of safety in the diabetic patient. There is always the danger, if an attempt is made to do so, that the patient will sooner or later have a severe attack of hypoglycaemia.

Failure to Settle at Night

Q.—A healthy boy aged 6 has a fear of going to bed. When persuaded to go to bed at 7.30 p.m. he lies awake and often comes downstairs to the living-room at any hour up to 11 p.m. or into his parents' room later in the night with a request for a drink or something. He is very intelligent, has been at school a year, and is happy. He has a brother aged 3 of whom he has no need to be jealous. The father is a professional man and happily married. The boy himself does not know why he cannot get to sleep. He has his brother in the room with him and a night-light by request. His parents are immediately available if he wants them. Should I administer a barbiturate or should I seek psychological help? The trouble now has been going on for some months.

A.—If the child stays awake and gets up because he cannot bear to give up the pleasures of the day, firmness is needed. If it is badly received, it may be tempered with a barbiturate for a couple of weeks. The questioner's account of the case is, however, clear, and one has to accept his first sentence at its face value. The cause of the fear of going to bed has eluded a careful doctor and intelligent parents; therefore they should seek for help, and from whom better than from a good children's psychiatrist? Nevertheless, one cannot help wondering whether there are not other clues in this admirable clinical précis—e.g., "He is very intelligent," but has he been enough in the day to be mentally tired at bedtime? "He has a brother aged 3 of whom he has no need to be jealous." Is there insecurity here? For it would have been simpler to say, "Of whom he is not jealous."

Salivation in Glaucoma

Q.—A patient with glaucoma suffers from excessive salivation. What drugs are available for dealing with the salivation without affecting the eye condition?

A.—On the assumption that the excessive salivation is due to the drops the patient is using for his glaucoma, it may

be worth while trying a different method of treatment. Pilocarpine drops are more apt to produce salivation than eserine, and the tendency to salivation may perhaps be inhibited if systemic absorption of the drops is avoided by taking care that none pass into the mouth via the lacrimal duct and the nose; this may be achieved by compressing the lacrimal sac at the root of the nose when the drops are put into the conjunctival sac. If in spite of these measures the salivation still persists, it is a moot point whether the systemic use of atropine or its derivatives would be justifiable. In addition to influencing the salivation there would be many other effects, some of them highly undesirable—and this quite apart from the danger of precipitating acute glaucoma from the cycloplegic effect that these drugs all have. If such drugs are to be used, hyoscine-N-butylbromide ("buscopan"), with its poor cycloplegic effect, might be considered. It should, however, be appreciated that excessive salivation is a symptom, and no treatment should be undertaken until an accurate diagnosis has been reached.

Obstinate Sycosis Barbae

Q.—What treatment is advised for a case of sycosis barbae of 20 years' duration? Epilation, local penicillin, chloramphenicol, chlortetracycline, oxytetracycline, and x-ray therapy have all been tried without success.

A.—This is evidently an extremely difficult case. The questioner makes no mention of a search for chronic infection in the nose, accessory sinuses, or the mouth. Any of these sites may provide a reservoir of infection by which the skin disease is perpetuated. If this has not already been considered, a scrupulous search should be made in these areas. Even in the absence of clinical signs of infection, mild degrees of chronic rhinitis—for example, from smoking—may enable staphylococci to be carried in the nose and to reinfect the skin.

There are three usual local applications which have not been mentioned: the old and well-tried Dalibour water (copper and zinc sulphates lotion, B.P.C.), "graneodin" ointment (neomycin 2.5 mg. and gramicidin 0.25 mg. per g.), and "quinolor" compound ointment. Any of these local applications gives occasional success where others have failed.

NOTES AND COMMENTS

"Approved Names."—In the supplementary list of "approved names" printed in our issue of June 16 (p. 1423), sodium calcium-edetate, a substance which has been recommended for the treatment of lead poisoning, was stated to be obtainable from manufacturers of laboratory reagents. We now understand that Riker Laboratories Ltd. are the sole suppliers of this substance for therapeutic, as distinct from commercial or chemical, purposes. They market sodium calcium-edetate under the proprietary name of "calcium disodium versenate."

Corrections.—In discussing the very variable results with topical hydrocortisone, Dr. G. B. Mitchell-Heggs is reported (*Journal*, July 21, p. 152) as suggesting that this was "possibly owing to the deficiencies in the various preparations. . . ." The word "deficiencies" should have read "differences."

In Dr. John Bullough's letter (*Journal*, August 11, p. 360) the dosage of rectal thiopentone was wrongly printed as 1 gr. per 50 lb. (23 kg.) instead of 1 g. Dr. Bullough omitted to give the reference to the technique he described in 1952—this should be Bullough, J., *Lancet*, 1952, 2, 999.

FIRST oral trichomonacide

TRITHEON*
BRAND OF AMINITROZOLE TABLETS TRADE MARK

for male and female

Because of their systemic action, TRITHEON tablets reach resistant trichomonads in their hiding places throughout the genito-urinary tract. Unlike local trichomonacides, TRITHEON tablets eradicate the organism in male and female as proved by negative culture.

Clinical investigation has demonstrated that TRITHEON tablets administered orally eradicate trichomonads for culture-proved cure of more than 70 per cent of female patients whose husbands are treated simultaneously with TRITHEON tablets. Even when only the wife is treated, cures are effected in approximately one-third of the patients.

Dosage: One tablet three times daily for 10 days
Available: Bottles of 30, 180 and 1000 tablets; each tablet contains 100mg 2-acetyl amino-5-nitrothiazole

LITERATURE ON REQUEST

Ortho Pharmaceutical Limited • High Wycombe • England

* TRITHEON is the original brand of 2-acetyl amino-5-nitrothiazole tablets developed in the Ortho Research Foundation for the oral treatment of trichomoniasis

The esters of NICOTINIC, SALICYLIC and p-AMINO BENZOIC acids bring relief to cases of arthritis and rheumatism

"Thank you, doctor"

IN CASES OF soft-tissue rheumatism, and arthritic disorders, many doctors are tending more and more to regard Transvasin as an indispensable adjuvant to treatment.

For Transvasin is composed of the esters of nicotinic, salicylic and p-aminobenzoic acids. These esters readily pass the skin barrier in therapeutic quantities, and so enable an effective concentration of drugs to be built up where they are needed.*

Transvasin not only induces vasodilation of the skin with a superficial erythema, but also brings about a deep hyperaemia of the underlying tissues. It is non-irritant and can be safely used on delicate skins.

It is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

**Therapeutische Umschau*
VIII, 1952, 10, 143.

Salicylic acid tetrahydrofurfuryl-ester...	14%
Nicotinic acid ethyl-ester.....	2%
Nicotinic acid n-hexyl-ester.....	2%
p-Aminobenzoic acid ethyl-ester.....	2%
Water-miscible cream base ad	100%

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD

11 Waterloo Place, London, S.W.1. Tel. WHITEhall 8654/5/6

The **KEYSTONE**
of anti-hypertensive
Therapy

'RAUWILOID'

"This was by far the most effective and useful orally administered agent for reducing blood-pressure which we have yet used. In our opinion this substance is fully worthy of a trial in every case of essential hypertension in which treatment is thought to be necessary. The severe cases, which always need treatment, are as likely to respond as the mild".

British Medical Journal (1955) 1:809

'Rauwiloid' is a selected fraction of the alkaloid hydrochlorides of *Rauwolfia serpentina*, and combines the hypotensive activity of reserpine and rescinnamine with that of the other desirable alkaloids of the crude drug. 'Rauwiloid' can be regarded as the basic treatment for most grades of hypertension.

If sufficient lowering of blood-pressure is not apparent after 2/3 weeks' use, 'Rauwiloid + Veriloid' and 'Rauwiloid' + Hexamethonium, tried in that order, are suggested as suitable agents. In each case 'Rauwiloid' reduces the side-effects of the potent antihypertensive, and in both combinations dosage is regulated solely by the patient's requirements for the more potent agent.

Dosage of 'Rauwiloid' is simple — two tablets at night are usually sufficient, and this dosage can be reduced to one for maintenance therapy.

The daily cost to the National Health Service on full dosage is 5d.

'RAUWILOID' and 'VERILOID' are Registered Trade Marks

HYPOGLYCAEMIC AND ANTIDIABETIC SULPHONAMIDES

BY

F. G. YOUNG, D.Sc., F.R.S.

Professor of Biochemistry, University of Cambridge

In 1942 Janbon and his colleagues at Montpellier, in the course of treating typhoid fever patients with *p*-aminobenzenesulphonamidoisopropylthiodiazole (=I.P.T.D., 2254RP, P.A.S.I.T., see formula I), observed that hypoglycaemia sometimes developed and that this could be fatal under the dietary conditions obtaining in France at that time. Professor Auguste Loubatières was able to follow up these interesting chemical observations by laboratory experiments at Montpellier despite the difficult conditions which then prevailed. He has recently summarized his findings concerning the action of I.P.T.D. (Loubatières, 1955). He finds that the administration of the drug by oral or by intravenous means can induce substantial hypoglycaemia in numerous species of animal under conditions of fasting, and in a dog from which the pituitary gland, or the adrenal glands, or the thyroid plus parathyroid glands, together with the gonads, have been removed. Nevertheless, he states that complete removal of the pancreas prevents the hypoglycaemic action of I.P.T.D., although the drug is capable of augmenting the utilization of glucose in the partially depancreatized dog. In the alloxan-diabetic rabbit the daily administration of I.P.T.D. was found by Loubatières to reduce or abolish the diabetic symptoms. Similar but less striking and consistent results were seen in the alloxan-diabetic dog. No evidence was found that the drug could oppose the diabetogenic action in the dog of a crude extract of anterior pituitary tissue.

Cross-circulation experiments with a donor dog treated with the drug, and an alloxan-diabetic recipient animal, led Loubatières to deduce that I.P.T.D. stimulates the secretion of insulin by the β -cells of the pancreatic islets. On the basis of these and other experiments he concludes that the drug may have a dual action on the islets—that of stimulating the secretion of insulin by β -cells and depressing the secretion of glucagon by the α -cells.

In 1952 Davis made the interesting observation that the administration of "synthalin" (decamethylene-diguanidine, see formula II) induces degenerative changes in the α -cells of the pancreatic islets of the normal rabbit. This substance was developed many years ago as a synthetic hypoglycaemic and antidiabetic agent, active by mouth (Frank, 1927), and when von Holt and his colleagues at Hamburg (1954, 1955) found that I.P.T.D. also exerts a toxic action on the α -cells of the pancreatic islets it seemed possible that the effects of these two substances might be related. von Holt has

in fact ascribed the hypoglycaemic action of I.P.T.D. to its destructive action on the α -cells of the pancreatic islets. (For recent reviews see Ferner, 1956; von Holt *et al.*, 1956.)

Mechanism of Action

On October 7, 1955, a series of publications appeared in the *Deutsche medizinische Wochenschrift* (Franke and Fuchs, 1955; Achelis and Hardebeck, 1955; Bertram

I. *p*-Aminobenzenesulphonamidoisopropylthiodiazole (=I.P.T.D., 2254RP, P.A.S.I.T.)

II. Decamethylenediguanidine (synthalin)

III. *N*₁-Sulphanilyl-*N*₂-*n*-butylcarbamide (=BZ 55, Nadisan, U 6987)

IV. *N*₁-*p*-Tolylsulphonyl-*N*₂-*n*-butylcarbamide (=D 860, U 2043, Orinase)

et al., 1955) describing the hypoglycaemic and antidiabetic action of *N*₁-sulphanilyl-*N*₂-*n*-butylcarbamide (*N*-butyl-*N*'-sulphanilylurea, BZ 55, "nadsan," U 6987, see formula III), the substance being active when administered by mouth or parenterally. Apparently, as with I.P.T.D., this sulphonamide derivative was found to possess an important effect on carbohydrate metabolism as the result of chance clinical observation. The first suggestion about the mechanism of its action was that it might inhibit the activity of the α -cells of the pancreatic islets, in line with the views of von Holt and Ferner about the action of I.P.T.D. Subsequently Mirsky and his colleagues (1956) found that BZ 55 and related substances are non-competitive inhibitors of the enzyme found in the liver which destroys insulin (insulinase), and that a diminution in insulinase activity is associated with the hypoglycaemia induced by these substances. The natural suggestion was therefore made that these substances act on carbohydrate metabolism,

at least in part, by preventing destruction of insulin. The fact that these drugs were capable of controlling the symptoms of diabetes in a proportion of patients suffering from this disease might indicate that in some diabetic patients abnormally vigorous destruction of insulin could be a significant factor in the maintenance of the condition (Mirsky *et al.*, 1956).

In addition to its action on insulin BZ 55, like I.P.T.D., appears to stimulate the secretion of insulin by the β -cells of the pancreatic islets (Kracht and Rausch-Stroomann, 1956).

Animal Experiments

In our own laboratory we have given BZ 55 orally to a cat with a diabetic condition which had persisted for about a year after a short period of treatment with growth hormone (metahypophyseal diabetes). In the cat, untreated metahypophyseal diabetes usually shows spontaneous remission after six to twelve months (Young, 1948), but in this particular animal (No. 286) the diabetes had become mild (5–10 g. of glucose excreted daily) with no sign of complete remission over a period of many months. After two daily oral doses of 20 mg. of BZ 55 the diabetic condition disappeared, and during the following ten days the blood sugar averaged about 50 mg. per 100 ml., as compared with 250 mg. per 100 ml. before treatment with the BZ 55. The animal was killed ten days after the diabetic condition had disappeared, and histological examination of the islets kindly carried out by Mr. K. C. Richardson showed extensive hydropic changes in both α - and β -cells of all the pancreatic islets examined. In cats which show spontaneous recovery from metahypophyseal diabetes the α -cells are usually normal in appearance while the β -cells are intensely hydropic (Young, 1948).

Among the chemical relatives of BZ 55 that have been shown to be hypoglycaemic and antidiabetic, the most highly active appears to be N_1 - p -tolylsulphonyl- N_2 - n -butylcarbamide (D 860, U 2043, "orinase," see formula IV). This substance is not an obviously active antibacterial agent.

It is of interest to recall that for long it has been known that acridine derivatives possess hypoglycaemic activity (Nielsen, 1929; Monasterio, 1931), while more recently Mendes-Alves (1952) and Mendes-Alves and Gomes (1954) have demonstrated an antidiabetic action of penicillin in partially depancreatized dogs and in alloxan-diabetic rats. The studies of Mendes-Alves were undertaken as the result of the observation that the administration of penicillin to certain diabetic patients induced an alleviation of the diabetic condition, which could not obviously be attributed to the suppression of an infective state. In some instances the amelioration of the diabetic condition persisted after cessation of the treatment with penicillin, and the possibility of an action of penicillin on the cells which produce insulin was suspected (Mendes-Alves and Gomes, 1954).

When one considers the range of substances which exert some degree of hypoglycaemic and antidiabetic action—guanidine derivatives, acridines, sulphonamides, and penicillin—one is struck by the fact that all possess some antimicrobial action. Can these two actions reasonably be related?

At this point I should like to recall the fact that Markowitz, Rappaport, and Scott (see Markowitz and Rappaport, 1951) observed that, although dogs usually die if the hepatic artery is ligated, they survive the operation when given large amounts of penicillin to facilitate post-operative recovery. This unexpected finding led Markowitz and Rappaport (1951) to survey the literature concerning the bacteriology of normal liver. It appears from this that the livers of many species of animal normally contain spore-bearing anaerobic bacteria, and in numerous instances *Cl. welchii* can be isolated. Moreover, tissues of normal animals other than the liver are frequently found to contain bacteria, often anaerobic organisms. But as Markowitz and Rappaport strikingly comment, "It is logical that the liver, situated

at the head of the portal system which drains a cesspool, should have bacteria in it more consistently than other tissue." They conclude that penicillin prevents death in the dog, when the hepatic artery is ligated, by inhibiting the growth of anaerobic organisms which otherwise might flourish and produce lethal enzymes such as lecithinase.

Two Pertinent Questions

Although there is evidence that bacteria can lurk in normal tissues and might therefore play a part in the economy of the normal animal, such an idea is foreign to modern thought and is usually ignored. Nevertheless it is not possible that the breakdown of insulin in the normal or in the diabetic animal or patient might result in part from the activity of bacteria present in normal tissues? Is it possible that insulinase might be in part at least of bacterial origin? Certainly proteolytic enzymes are known to be present in many bacteria, including *Cl. welchii*, while the exacerbating effect of infection on clinical diabetes is well recognized. Although no conclusive answer can be given to these questions, the possibility can reasonably be envisaged that the antidiabetic sulphonamides might exert a significant effect by diminishing the number of bacteria, and therefore the amount of proteolytic enzymes, in the tissues, particularly those of the liver. An objection that might at once be raised to this view is that the antidiabetic action and the antibacterial effectiveness of the sulphonamides are not quantitatively related. In particular D 860, which is effective in many diabetic patients, is not obviously antibacterial.

However, when we are dealing with bacteria surviving in normal tissues under presumably special conditions, the question of the accession of the drug to the microbe may well be of paramount importance. A substance with a hydrocarbon non-polar grouping at both ends might have special advantage in this respect and be enabled to bring weak antibacterial action to bear with vigorous effect at the needed site of action. Furthermore, the possibility that the substance which is effective in the tissues is a metabolite of that which we have given to the patient or animal, and not the administered drug itself, should not be ignored in such an instance.

There is evidence that the antidiabetic sulphonamides not only depress the catabolism of insulin but also stimulate the secretion of insulin by the β -cells of the pancreatic islets. Such an action might depend on the stimulation of the secretion of glucagon or other hyperglycaemic substances by the α -cells of the pancreatic islets (cf. Young, 1955), and if such an action occurred the changes in the α -cells observed by some investigators to follow the administration of sulphonamides might be accounted for.

There is at present no simple solution to hand of the problem of the mechanism of action of the antidiabetic sulphonamides. But clearly the observations made in Montpellier in 1942 foreshadowed much that is of growing interest and importance to-day.

A CLINICAL TRIAL OF BZ 55

BY

Edinburgh University

Two groups of German workers have recently reported the successful control of most elderly or middle-aged patients suffering from mild diabetes by BZ 55 (N-butyl-N'-sulphanilylurea) (Franke and Fuchs, 1955; Bertram *et al.*, 1955). It is, however, difficult to assess the therapeutic value of the drug from these reports because the data given are inadequate. When exact figures for diets are stated they seem unduly high by British standards. Certainly many of the patients in whom control was successfully achieved with BZ 55 appeared to have the type of diabetes which would usually have responded to dietary restriction alone, without the use of insulin or an insulin substitute (*British Medical Journal*, 1955).

It was therefore felt that further carefully planned and fully documented clinical trials were necessary to establish the place of these sulphonamide compounds in the management of diabetes.

Selection of Patients

We considered that orally administered BZ 55 would have its main practical use as a complete substitute for parenteral insulin. Since the German work emphasized that such a complete substitution was only rarely possible in the young diabetic, we limited this initial study to patients over the age of 45 suffering from mild diabetes who were not overweight by more than 10% of their ideal weight (Metropolitan Life Insurance Company, Statistical Bureau, 1943, quoted by Dunlop *et al.*, 1953), but who, on a fully restricted diet, continued to show significant hyperglycaemia and glycosuria, and to experience diabetic symptoms in the absence of insulin therapy.

From the diabetic out-patient clinic 65 active patients (5 male, 60 female) who appeared to be of this type were selected and observed as out-patients for periods varying from one to six weeks. None of these patients had had any active focus of infection, although many had had retinopathy and neuropathy of the diabetic type. Only five were not currently receiving insulin, but they were inadequately controlled by diet alone. Control in those receiving insulin was good or moderate.

At the first visit each patient was impressed with the necessity of adhering strictly to the diet which they were at that time supposed to be taking, and the administration of insulin was stopped. Thereafter each was seen once or twice weekly, when the blood-glucose concentration was estimated, 24-hour and fasting urine samples were tested for glucose and ketone bodies, and weight and symptoms were recorded.

It was possible to complete the trial of the drug in only 44 of the 65 patients initially selected. Of the 21 patients withdrawn from the trial, either in the out-patient adaptation period or after admission to hospital,

seven developed severe ketosis consequent on the withdrawal of insulin, necessitating its further administration. One of these, previously well controlled on 24 units of insulin zinc suspension, was admitted to hospital almost comatose only three days after discontinuing insulin, while another became seriously ketotic on the second day, both of them emphasizing the possible dangers of stopping the administration of insulin even in cases of apparently mild diabetes. Three were rejected because their blood-glucose concentrations four hours after a meal consistently exceeded 480 mg. per 100 ml., and, on the other hand, 10 were discarded when it became clear that adequate control was achieved by dietary restriction alone. In another patient the development of a severe drug fever necessitated the prompt withdrawal of BZ 55 before data were complete.

It can be seen from Tables II and III that all the 44 patients finally included in the analysis required treatment with insulin or an insulin substitute in addition to dietary measures.

Methods

The first 22 patients were studied in hospital for twenty days, and constitute Group I. The remaining 22 patients were in hospital for eight days only, and form Group II.

On admission to hospital all patients were assessed for a control period of seven days in the case of Group I and three days in the case of Group II. BZ 55 was started on the eighth and the fourth day respectively, and the effect of continued dosage was studied for the remainder of the patients' stay in hospital.

The reduction in hospital stay for Group II was made, firstly, because it was clear from experience obtained with Group I that the patients had, with an occasional exception, adhered to their diets during the out-patient adaptation period, so that surprisingly steady levels of hyperglycaemia and glycosuria occurred in the control period in hospital (Figs. 1 to 6); and, secondly, because we were satisfied that the response to therapy could for clinical purposes be accurately assessed by the fifth day of treatment.

The design of the trial was to some extent governed by clinical considerations. Thus, although most factors were kept constant throughout for all patients, the diets were individually prescribed and the dosage of BZ 55 was adjusted according to the clinical response.

Each patient continued to receive the diet which had been taken as an out-patient. The total calculated daily calories, carbohydrate, fat, and protein were kept constant throughout the trial. The same meal each day contained a constant calculated quantity of these proximate principles.

All patients were ambulant, and daily activity was kept as unaltered as possible throughout the trial. Each patient was weighed at the same time daily in the same clothes.

Venous blood was withdrawn by one or other of us each day at 8.30 a.m. (patient fasting), at 4 p.m. (three and a half to four hours after lunch), and at 8.45 p.m. (two hours after the main evening meal). These times were chosen as being best fitted to demonstrate the daily profile and excursion of glycaemia. The specimen taken at 8.45 p.m. reflected the postprandial rise in blood glucose. The blood-glucose content was estimated by one of us (J. D. B.), using the Nelson (1944) modification of the Somogyi method.

24-hour urine collections were obtained daily (8.30 a.m.–8.30 a.m.). The glucose content was estimated by Benedict's quantitative method and nitrogen by the micro-Kjeldahl method by one person.

In the majority of patients, glucose tolerance was measured in the control period either by the standard oral procedure, using a loading dose of 50 g. of glucose (16 patients), or by the intravenous technique (14 patients) (Duncan, 1956). In patients whose response to BZ 55 was satisfactory the test was repeated after five to ten days of

treatment. Due allowance for the glucose given in these tests was made in the daily diet.

Haemoglobin, red blood cell count, white blood cell count, platelet counts, and differential white-cell counts were estimated in the first 22 patients. In the remainder it was possible to estimate only haemoglobin and white blood cell counts. In all, the following tests of liver function were made: plasma albumin and globulin, total serum cholesterol, thymol turbidity, colloidal gold flocculation, and serum bilirubin. Observations were also made on plasma electrolytes, non-protein nitrogen, and CO₂ combining power. In seven patients 24-hour urine A.S.F.S. (acid-stable formaldehyde-steroids) were determined (Tompsett and Smith, 1954), and in six patients tracer doses of radio-iodine were given for assessment of thyroid activity. All these observations were repeated during treatment with BZ 55.

In the first 12 patients treatment with BZ 55 was started with 3 g. (six tablets) given by mouth before breakfast. In

32 patients the dose was 4.5 g., and in addition blood was withdrawn at hourly intervals for five hours thereafter and its glucose and BZ 55 content were determined. The patient remained in bed and food was withheld during the period of the test. It was hoped that the response to this single dose might be of value in predicting the patient's subsequent response to the continuous administration of BZ 55.

Further dosage was dependent upon the response of the patient. If it was satisfactory, the dose was gradually reduced over three or four days to 1.5 g. (Figs. 2 and 3), but when the response was inadequate it was continued at 4.5 g. daily for several days (Figs. 4 and 5).

The BZ 55 concentration in the blood was estimated by the method of Bratton and Marshall (1939), pure BZ 55 being used for the preparation of standards.

Patients whose response was considered to be clinically satisfactory were discharged on a daily maintenance dose of BZ 55 varying from 1 to 1.5 g. They are being seen

regularly at intervals of one to two weeks at a special clinic by one or other of us. Each patient is weighed and brings a 24-hour urine collection, the glucose content of which is determined. A sample of blood is withdrawn and estimated for glucose and BZ 55 content, the patient having fasted since breakfast, taken at least four hours previously. Initially Haematological examinations are done at intervals. Initially the patients were instructed to test fasting and evening urine specimens for a few weeks after discharge, but this practice was later discontinued and dummy tablets have been substituted in 12 patients to date. After a period on "dummy therapy," when it became clear that control of the diabetes was deteriorating, they were again given BZ 55. Both substitutions were made without the patients' knowledge. Many, however, were quick to recognize a return of diabetic symptoms while taking dummy tablets.

Comparison of Responsive and Unresponsive Patients

Clinical Features

The clinical data for both groups are presented in Table I. All our patients were over the age of 45 at the time of the trial, and within this middle-aged or elderly group age did not seem to have any bearing on the patient's response to BZ 55. Within the ranges observed in this series, the duration of clinical diabetes, the age of the patient when the diagnosis was made, the daily dose of insulin previously administered were unrelated to the result obtained with BZ 55. The presence of degenerative diabetic changes, or a family history of the disorder, were also without influence upon the result.

The total calorie and carbohydrate content of the daily diet was higher in the unresponsive group. This was due to the fact that on the whole these unresponsive patients were more underweight in relation to their ideal weight than the responsive group.

In seven of the nine unresponsive patients significant ketonuria had previously been recorded. Ketonuria had also been noted in 5 of the 35 responsive patients, but only at the time of diagnosis or in the presence of infection or considerable stress. We formed the strong impression that patients who are prone to develop ketonuria easily do not respond well to BZ 55.

FIG. 1.—Case 2: man aged 64. Note steady values of blood and urinary glucose during control period; immediate response to BZ 55 but no change in daily profile of glycaemia.

FIG. 2.—Case 15: woman aged 64. Note immediate response to BZ 55; glycosuria completely abolished because of higher renal threshold than Case 2; increase in weight mainly due to full diet not being taken as out-patient.

FIG. 3.—Case 20: woman aged 55. Note extreme response to single-dose test causing hypoglycaemia; slower response to continued treatment.

Effect on Hyperglycaemia and Glycosuria

The summarized results for both groups of patients are presented in Tables II and III. From a consideration of the blood-glucose levels and degree of glycosuria found in each patient during the control period it is apparent that all these patients really required insulin. We were impressed by the fact that the level of fasting blood glucose was not a true expression of the impairment of glucose tolerance. Thus, in this series, relatively low fasting blood-glucose levels were combined with poor glucose tolerance, as indicated by a considerable postprandial hyperglycaemia and a relatively heavy glycosuria (Fig. 4). Conversely, high fasting levels were not infrequently associated with a surprisingly good glucose tolerance (Fig. 5; Fig. 6, Case 36). In some of the patients having high blood-glucose values, particularly when the disorder was of long standing, the renal threshold for glucose was elevated so that the small amount of glycosuria present was often misleading (Fig. 2).

Group I

Of the 22 patients in this group, 16 responded favourably to the drug. A fundamental observation on the character of the response was that the amount by which the blood-glucose values were reduced by treatment was virtually the same for each of the three daily determinations for any one patient. Thus there was no appreciable change in the difference between the fasting and postprandial blood-glucose levels before and during treatment (Figs. 1-6). (Mean difference in control period, 91 mg. per 100 ml.—range 46-136 mg.; during treatment, 95 mg. per 100 ml.—range 42-146 mg.) We were therefore unable to confirm the finding of Bertram *et al.* (1955) that the daily profile of glycaemia was narrowed. The mean absolute fall in fasting blood-glucose concentrations for the responsive patients was 112 mg. per 100 ml. (range 71-157 mg.). When the fall is expressed as a percentage of the fasting blood-glucose value, the mean was 50.6% (range 40-61%) (Fig. 8).

In this group all the responsive patients were adequately controlled clinically in that symptoms were abolished, blood-glucose levels were satisfactory, and glycosuria was reduced by at least 75% of the control values. It was considered that adequate control had been achieved when the fasting

blood-glucose concentration did not exceed 150 mg. per 100 ml., the postprandial value was below 260 mg. per 100 ml., and the average daily blood-glucose level was less than 200 mg. per 100 ml. (Figs. 1-3). It will be seen that the mean values for the group as a whole were much lower than these limits. Some patients who had particularly high blood-glucose concentrations before treatment tended to have a high renal threshold for glucose. Thus glycosuria and symptoms were often abolished with treatment in spite of the persistence in a few cases of relatively high blood-glucose levels. Data for three of the patients successfully controlled by BZ 55 are shown in Figs. 1-3.

Six patients in this group were unresponsive to the drug. The mean absolute fall in their blood-glucose levels was only 13 mg. per 100 ml. (range -33 to +25 mg.). When expressed as a percentage of the fasting blood glucose the mean fall was 5% (-7.5 to +10%) (Fig. 8). All these

patients continued to show blood-glucose values exceeding the limits defined for adequate clinical control. Data for two of the patients unresponsive to BZ 55 are shown in Figs. 4 and 5.

In Group I there was no difficulty in assessing the response of any one patient. In all cases it was quite obvious by the fifth day whether or not they were responsive to the drug. Analysis of the response at the fifth day shows that usually it was not significantly less than that at the twelfth day (Table II). The hypoglycaemic effect was therefore rapid and definite (Figs. 1 and 2). The response improved significantly after the fifth day in only three cases, but even in these the absolute fall in fasting blood-glucose levels was greater than 60 mg. per 100 ml. by the fifth day (Fig. 3). This contrasts with the experience of Bertram *et al.* (1955), who found that in 11 of their 28 patients a significant effect was delayed to between the fourth and thirteenth days.

Group II

The effect of BZ 55 on 16 of the 22 patients in this group was of the same character and magnitude as that seen in the responsive patients in Group I. The mean absolute fall in all blood-glucose values was greater than 60 mg. per 100 ml. (range 62-146 mg.). Expressed as a percentage of the control fasting blood-glucose concentration, the mean fall was 43.4% (range 38-55%) (Fig. 8). During treatment each of these patients showed a reduction in glycosuria of at least 75% of the control value, and all of them satisfied our criteria for adequate clinical control.

Three patients showed an absolute reduction in all blood-glucose levels greater than 60 mg. per 100 ml. (mean 74 mg.; range 62-96 mg.). However, their blood-glucose values during the control period were significantly higher than those of the previous 16 patients (Table III). Thus, if the reduction is expressed as a percentage of the control value, it is in all cases less than 30% (mean 23%; range 21-27%) (Fig. 8), and glycosuria was reduced by less than 75% (mean 47%; range 45-54%). These three patients obviously responded to the drug to some extent, but they could not be

classed as clinical successes according to our criteria of adequate clinical control, in spite of high dosage with BZ 55. Data for two of these patients are shown in Fig. 6.

In three patients the drug was entirely ineffective although again BZ 55 was given in high dosage. The mean rise in their blood-glucose concentration was 1 mg. per 100 ml. (range -17 to +15 mg.) and glycosuria increased by 1 g. daily.

The seven patients who developed ketonuria are not included in this analysis. Four of them were admitted to hospital for the trial. Three developed ketonuria during the control period, and this continued in spite of high dosage with BZ 55, so that insulin had to be administered. When, as a result, hyperglycaemia was less severe and ketonuria absent the patients were subjected to a further trial of BZ 55, again without effect. The remaining patient developed severe ketonuria after five days of treatment with BZ 55, which was therefore replaced by insulin.

Blood-Glucose Values in the Control Period

It can be seen from Tables II and III that both the mean fasting blood-glucose values and the difference between the fasting and postprandial blood-glucose levels of the unresponsive group were considerably higher than those of the

responsive group. There is, however, no clear-cut distinction in this respect between the two groups, hence those values are of little use in predicting response or otherwise in the individual case.

Attempt to Predict Response

Of the 44 patients selected for their probable response, there were 35 who responded to continued dosage with BZ 55, but only 32 of these responded well enough to be classed as clinical successes. Owing to the difficulty of predicting therapeutic success clinically, an attempt was made to obtain this information by the response to the single dose of BZ 55 previously described.

Of the 32 clinical successes, 25 were tested in this way, and in them the mean fall in blood-glucose levels at five and two hours was 115 mg. per 100 ml. (range 68-185 mg.), and two hours was 115 mg. per 100 ml. (range 68-185 mg.). When expressed as a percentage of the fasting level the mean fall was 53.2% (range 40-73%). The three responsive patients who were not clinical successes had a mean fall in blood-glucose levels at five hours of 148 mg. per 100 ml. (range 123-177 mg.). When expressed as a percentage of the fasting level the mean fall was 47.0% (range 44-51%).

Eight of the nine patients who did not respond to continued dosage with BZ 55 were tested. In this group the mean fall was 78 mg. per 100 ml. (range +1 to 135 mg.). When expressed as a percentage of the fasting blood-glucose level the mean fall was 30% (range 0-47%). Three of them level the mean fall was 30% (range 0-47%). During this test there was no difference between the blood sulphonamide levels reached by the responsive and unresponsive groups. Thus the value of the test in predicting an individual response is limited to the fact that no patient who showed a fall of less than 35% responded clinically to the drug in continued dosage. A fall of over 40%, on the other hand, did not necessarily mean of directly related to that obtained with continuous dosage in any individual case.

Factors Affecting Response

Fasting Blood Glucose.—In responsive patients who were also clinical successes the fall in fasting blood-glucose was roughly proportional to the fasting blood-glucose concentration in the control period. In the unresponsive group, however, there was no such relationship. The three responsive patients who were clinical failures occupied an intermediate position (Fig. 7). If the absolute fall is expressed as a percentage of the control fasting blood glucose, the patients group themselves in the same way (Fig. 8).

Difference between Fasting and Postprandial Blood Glucose.—The degree of fall in both groups bears no relation to this value.

Blood Sulphonamide Level.—The dosage of the drug was determined by its clinical effect upon the blood-glucose concentration, and varied widely from patient to patient. In any one patient following a known dose, the concentration of BZ 55 in the blood remained remarkably constant, but in different patients given the same dose considerable variation in the blood levels occurred. The levels produced in both the responsive and unresponsive groups were of the same order, although the latter received much larger quantities of the drug. For each responsive patient there seemed to be a minimal therapeutic blood level which again varied from patient to patient.

Other Observations

Urinary Nitrogen Excretion.—It was not practicable to undertake absolute nitrogen balances in such a number of patients. The daily urinary nitrogen excretion was, however, estimated in 22 patients over 20 days. Since the daily diet was kept constant and the number of observations was large, some significance may be attached to the results. From Table I it can be seen that in the 16 responsive patients in Group I the mean control 24-hour urinary nitrogen was

13.7 g., whereas the mean value from the fifth to the twelfth day of treatment was only 11.6 g. This change is statistically significant ($P=0.005$). In this connexion it may also be of interest to note that in the unresponsive patients there was no change in the urinary nitrogen excretion, the values being 14.9 g. for the control period and 15.0 g. for the period of treatment.

Glucose Tolerance

Three measurements of glucose tolerance have been employed.

(1) The difference between the fasting and postprandial blood-glucose concentration was used as a rough index of glucose tolerance. From Tables II and III it can be seen that there is no appreciable change in this value in the responsive or unresponsive groups as the result of treatment with BZ 55 (Figs. 1-6).

(2) Oral glucose-tolerance tests before and during treatment were carried out on 10 of the successfully treated patients. At the time of the test the mean fasting blood glucose in the control period was 247.6 mg. per 100 ml., and during treatment 146.5 mg. per 100 ml. It can be seen from Fig. 9 that BZ 55 was without effect either

on glucose tolerance or on the rate of its absorption. (3) Intravenous glucose-tolerance tests before and during treatment were performed on 11 of the successfully treated patients. At the time of the test the mean fasting blood-glucose concentration in the control period was 221.8 mg. per 100 ml., and during treatment 108.5 mg. per 100 ml. The mean increment index (Duncan, 1956) for the control test was 1.46 (S.D. 0.3) and during

FIG. 4.—Case 12: woman aged 60. Note relatively low fasting glycaemia with marked postprandial hyperglycaemia; lack of response to BZ 55 but sensitivity to insulin; slow fall in blood BZ 55 concentration following cessation of treatment.

FIG. 5.—Case 8: woman aged 65. Note high fasting glycaemia but small postprandial effect; minimal response to BZ 55 but sensitivity to insulin.

FIG. 6.—Case 37: woman aged 67. Case 36: woman aged 66. In spite of good response to single-dose test and significant response to continued high dosage with BZ 55, neither patient satisfied criteria of successful clinical control.

FIG. 7.—Graph relating fasting blood glucose to absolute reduction in fasting blood glucose obtained by treatment with BZ 55. F.B.G. (1)=Mean of values in control period. F.B.G. (2)=Mean of values during treatment.

FIG. 8.—Graph relating fasting blood glucose (1) to reduction in F.B.G. obtained by treatment with BZ 55, the reduction being expressed as a percentage of F.B.G. (1). F.B.G. (1)=Mean of values in control period. F.B.G. (2)=Mean of values during treatment. (Symbols as for Fig. 7.)

FIG. 9.—Mean of oral glucose-tolerance curves obtained in 10 responsive patients before and during treatment with BZ 55.

treatment 1.45 (S.D. 0.3). It is therefore clear that BZ 55 is without effect on glucose tolerance. We are reporting these observations in detail elsewhere.

Insulin Sensitivity.—We were unable to confirm that "unresponsive patients reacted poorly to insulin" (Franke and Fuchs, 1955). All our unresponsive patients were given a test dose of 20–30 units of soluble insulin in the fasting state, and all showed a profound drop in blood glucose, three becoming clinically hypoglycaemic (Fig. 4). All these patients are now very well controlled on small doses of insulin.

Weight.—While in hospital no very significant changes in weight were observed in the responsive patients.

Side-effects

A few patients complained of mild headache, malaise, and drowsiness when receiving the higher initial doses of the drug. When the dose was reduced to maintenance levels these symptoms disappeared.

In one patient a definite drug fever occurred on the fourth day, necessitating temporary withdrawal of the drug. The hypoglycaemic response had, however, been so good in this patient that after four weeks of out-patient observation, when no insulin was given, the administration of BZ 55 was once again cautiously started in daily doses of 0.5 g. No untoward effects occurred, and control has since been most satisfactory (Fig. 10, Case 45).

FIG. 10.—Data of six out-patients in whom courses of BZ 55 were interrupted with a return of hyperglycaemia and glycosuria. Values during periods A and B are the mean of those obtained in hospital during the control and treatment periods respectively. The blood-glucose concentrations refer to the fasting values.

In three patients a sulphonamide rash was seen, which, however, spontaneously regressed.

We have so far observed no alteration in the liver-function tests, serum electrolytes, or urinary A.S.F.S. as the result of treatment. There was some depression of iodine uptake by the thyroid in the six patients so tested during the initial two weeks of treatment, which, however, returned to normal during maintenance therapy (Kinsell *et al.*, 1956). One patient, who had for years been receiving 1 gr. (65 mg.) of thyroid daily for myxoedema, became increasingly hypothyroid after two months' treatment with BZ 55, but improved again when the dose of thyroid was doubled.

In the series as a whole there was a definite granulocytopenia in the initial two weeks of treatment. In the majority the count returned to normal despite continuance of BZ 55 in maintenance dosage, but in a few leucopenia has persisted. The lowest white-cell count recorded was 2,000 per c.mm.

A more disturbing feature has been the depression of the blood platelets. One patient reported with spontaneous purpura after only 10 days' treatment with BZ 55, and was found to have a platelet count of 60,000 per c.mm. The count returned to normal and the Hess test became negative within a week of discontinuing treatment. A test dose of 1.5 g. of the drug for two days resulted in a recurrence of thrombocytopenia and a positive Hess test. Another patient then presented with spontaneous purpura, and in this case a leucopenia was also present, the white-cell count being 2,300 per c.mm. This patient is at present being investigated in hospital.

Consequent on this experience platelet counts have been made on 30 out-patients, in none of whom the daily maintenance dose of BZ 55 had exceeded 1.5 g. The technique used was that of Oettle and Spriggs (1951), which gives a normal range of 250,000 to 350,000 per c.mm. Six of these 30 patients have been found to have counts under 180,000 per c.mm., the lowest value being 90,000 per c.mm., associated with strongly positive Hess tests, bringing the total of patients with thrombocytopenia to eight. Three of these had had platelet counts made during the control period before BZ 55 was given, all of which were at the lower limits of normal. Three other patients, although not thrombocytopenic, have shown a substantial fall in platelet counts in comparison with their control figures, and one of these has experienced severe menorrhagia. Among the patients who showed no reduction in platelets, four showed a slightly positive Hess test, a not unusual finding in elderly diabetics, particularly those with retinopathy (Beaser *et al.*, 1944).

Thus the haematological findings so far suggest that BZ 55 has a toxic action on the platelets, and, to a less extent, on the white blood cells. The red cells appear to be unaffected. A more detailed haematological investigation is at present being undertaken and will be fully reported at a later date.

Follow-up

Since discharge from hospital all the clinically responsive patients have been seen regularly. Five have been observed for 18 weeks, 2 for 16, 8 for 10, 4 for 8, 7 for 5, and 6 for 4 weeks. While receiving BZ 55 they have continued to be free of diabetic symptoms and have felt well. Blood-glucose levels and BZ 55 concentration in the blood have remained remarkably steady and satisfactory, and glycosuria has been absent or minimal. A slow but definite increase in weight has been recorded in most patients during this out-patient period of observation. Two patients on a maintenance daily dose of 1 g. of BZ 55 reported symptoms typical of hypoglycaemia which disappeared when dosage was reduced to 0.5 g. daily.

Dummy tablets have been substituted for BZ 55 in 12 patients. In all these the blood-glucose level and glycosuria started to increase within two weeks of stopping the drug, subsequently reaching the levels observed prior to treatment—10 within one month after stopping BZ 55 and 2 by the end of eight weeks. In most cases the hyperglycaemia and glycosuria were associated with a return of diabetic symptoms. The rate at which each of these patients became uncontrolled corresponded to the rate at which their diabetes became uncontrolled after withdrawal of insulin prior to the trial. At this point treatment with BZ 55 was reinstituted and good control was again achieved in all within one week (Fig. 10).

It was notable that an increase or a decrease in glycosuria lagged behind corresponding changes in blood-glucose concentration, which suggests that the drug may have some effect on the renal threshold for glucose. The three patients in Group II who showed a response to BZ 55 but were

classified as clinical failures were continued on 2 g. daily as out-patients and have been observed for three weeks. All three must continue to be classed as clinical failures, though in one there has been some diminution in glycaemia and glycosuria (Fig. 6).

Discussion

There can be no doubt that BZ 55 has a remarkable hypoglycaemic action in some diabetic patients. From our observations this would seem to be due to a reduction in the fasting blood-glucose value. Glucose tolerance is unchanged and there is no alteration in the daily profile of glycaemia, though the absolute values are set at a lower level and glycosuria is reduced or disappears. How this level and glycosuria is reduced or disappears remains unknown, hypoglycaemic action is brought about remains unknown, and this preliminary clinical study was not designed to elucidate this point.

The number of patients likely to benefit from the administration of BZ 55 is limited. The evidence suggests that the drug is of little or no value in the treatment of the young type of diabetic and absolutely contraindicated for those with a marked tendency to develop ketosis. On the other hand, though the mild diabetes of obese patients may not respond satisfactorily to the drug, there should be no substitute for dietetic restriction in the control of such patients. There remains a limited group of middle-aged or elderly non-obese patients suffering from comparatively mild diabetes who, in spite of dietetic treatment, require small or moderate doses of insulin, and for these BZ 55 may provide a welcome alternative. From a group of 55 patients of this type only 33 were adequately controlled by the drug. This is a smaller proportion of successful cases than has been claimed by other workers (Franke and Fuchs, 1955), who, however, may well have used BZ 55 as a substitute for dietary restriction.

When our clinical failures are considered, some are found to have been completely refractory to the drug; in some the response was insignificant; and in a few, although a good response occurred as evidenced by a fall of 60 to 90 mg. per 100 ml. in the blood-glucose concentration, this was insufficient to establish clinical control owing to the very high initial blood-glucose levels. Patients who readily became ketotic proved unsuitable subjects for this treatment. They seldom responded to it, and the drug itself was without effect on diabetic ketosis.

In those patients in whom treatment with BZ 55 resulted in satisfactory clinical control the reduction in glycaemia was of the order of 100 mg. per 100 ml. (range 65–160 mg.). Besides having their blood-glucose levels reduced to satisfactory figures and their glycosuria abolished or greatly reduced, these patients were rendered free from diabetic symptoms. They felt well and put on weight, and there seemed little doubt that some improvement in nitrogen balance occurred. When dummy tablets were substituted for BZ 55 deterioration began to take place within a short space of time, so that in these patients there did not seem to be any place for intermittent treatment, which has been suggested by Franke and Fuchs (1955).

A high incidence of toxic effects was observed in this series—skin reactions, drug fever, slight granulocytopenia, and particularly thrombocytopenia, associated in two cases with spontaneous purpura.

It may well be questioned whether convenience alone justifies the replacement of a well- tried and safe parenteral preparation by an oral substitute in the case of a small percentage of diabetics, especially when its toxic potentialities are considered and when the dangers of its misuse in unsuitable cases are appreciated. Even in patients who might seem to be suitable for such treatment selection is possible only by trial and error, and in those who prove unresponsive ketosis may develop rapidly on withdrawing insulin. Further, in patients who are ordinarily well controlled by BZ 55 an intermittent infection may produce dangerous ketosis which is unaffected by the drug.

BZ 55 will almost certainly prove to be a valuable research weapon which may help to elucidate some of the obscure problems of diabetic metabolism. Nevertheless, we believe that it would be premature at the present time to make it generally available for therapeutic use. This should await the results of further study in special centres to establish the pharmacological action of the drug, to assess its long-term toxicity, and to crystallize more completely the indications and contraindications for its use in any individual patient.

Summary

BZ 55 proved to be an effective substitute for insulin in 33 of 55 middle-aged or elderly diabetic patients.

The drug was without effect on ketosis or on those patients who readily developed ketosis.

The difficulties in selecting the responsive patient and the dangers of withdrawing insulin in the unresponsive patient are emphasized.

The character of the hypoglycaemic response has been analysed with particular reference to the daily profile of glycaemia, glucose tolerance, and its relationship to fasting blood-glucose values.

From follow-up studies it is concluded that maintenance treatment with BZ 55 requires to be continuous and not intermittent.

Minor toxic effects were encountered in several patients, and there appears to be a possibility that thrombocytopenia may occur with alarming frequency.

BZ 55 should not be given as a substitute for dietary restriction. If this principle is observed the number of patients in whom it can replace insulin is more limited than reports to date have suggested.

We are indebted to many people for nursing, dietetic, biochemical, and medical assistance, and particularly to our patients, whose co-operation enabled the study to be undertaken. Our thanks are due to the British Insulin Manufacturers for supplies of BZ 55.

The work of the department of obstetrics in Adeyo Hospital, Nigeria, which serves three-quarters of a million people, is described in the "Clinical Report" of the department of obstetrics, University College, Ibadan, for the period April 1, 1953, to December 31, 1954. The report is by Drs. J. B. Lawson and U. G. Lister and contains 25 tables analysing the work of the department. Ibadan is the largest city in tropical Africa; more than half the population are Mohammedans, and the majority are polygamous. The diet is grossly deficient in proteins needed for a pregnant woman, and anaemia of pregnancy is the most serious complication encountered. The patients themselves are suspicious of scientific medicine; native medicines are often the cause of major disorders. Of a total of 5,985 patients, 5,582 were delivered in hospital. There were 76 maternal deaths (only 3 of which were considered to be not ultimately preventable), 409 stillbirths, and 333 neonatal deaths. The department's facilities were "at an appallingly low level," but a mile away a new hospital has been built where there will soon be 110 obstetric beds.

TRIAL OF AN ORAL HYPOGLYCAEMIC AGENT IN DIABETES

BY

AND

ARNOLD BLOOM, M.D., M.R.C.P.

Physician-in-Charge of Diabetic Unit, Whittington Hospital

During an investigation in man of the chemotherapeutic properties of some new sulphonamides, Franke and Fuchs (1955) reported that one, N-butyl-N'-sulphanilyl-urea (BZ 55), produced hypoglycaemia. Following this observation the compound was examined clinically in diabetics by Franke and Fuchs and by Bertram, Bendfeldt, and Otto (1955). Pharmacological observations were described by Achelis and Hardebeck (1955).

Subsequently, another hypoglycaemic agent, N-(4-methyl-benzosulphonyl)-N'-butyl-urea (D 860) was discovered, on which joint clinical and pharmacological studies were described by Bänder *et al.* (1956). This preparation is not a sulphonamide and has no bacteriostatic activity, but its hypoglycaemic properties are similar to those of BZ 55.

It was evident from German data that these compounds successfully controlled hyperglycaemia and glycosuria in some diabetics, many of whom were overweight. This latter fact suggested to us that in this country some of their successful cases might have been treated by diet alone.

In view of this we decided to undertake a detailed in-patient study on a group of 45 diabetics, from which we attempted to obtain information on the effect of stopping insulin under conditions of constant diet. If hyperglycaemia and glycosuria persisted BZ 55 was administered orally to ascertain its value as a substitute for injected insulin. In addition, information was sought on the possibility of establishing a short-term test which might enable us to predict the usefulness of this drug in long-term therapy.

Studies of free and conjugated sulphonamides in blood and urine were undertaken in an attempt to find correlation between these levels and therapeutic activity.

Methods

Selection of Cases.—Although an attempt was made to get a representative cross-section of the diabetics attending the hospital clinic, numbering just over a thousand, the necessity of spending two weeks in the wards meant a preponderance of middle-aged or elderly female diabetics in those who were admitted. The majority (34) were out-patients already receiving insulin, the need for which had previously been established. Eleven others had not been receiving insulin. Seven of these were newly diagnosed diabetics who would normally have received insulin. Four others have had diabetes for several years, controlled by diet alone; but increasing glycosuria, hyperglycaemia, and loss of weight had latterly suggested their need for insulin. A group of six

young and brittle diabetics were admitted for a few days only and took part in a short-term test.

Design of Trial.—On admission each patient was given a diet suitable for his or her physique and metabolic needs, prepared in a diet kitchen. For out-patients of long standing this was a continuation of the diet to which they were accustomed. These diets have been maintained since the patients were discharged. Apart from the group of young diabetics, patients were kept under observation in the wards for at least two weeks, and were then followed up twice weekly in a special out-patient clinic. For the first five days after admission patients were maintained without insulin on diet alone. Once the initial control period had been completed, a two-day test was performed. On these two days no breakfast was given, but on the second day BZ 55, in a dose of 50 mg./kg. body weight, was administered by mouth. This sequence enabled us to assess the effect simply of the omission of breakfast. In a first group of 12 patients, blood and urine sugar and sulphonamides were estimated hourly for six hours, while in subsequent tests samples were obtained every three hours under the same conditions. The patients were kept in hospital and maintained on BZ 55 for at least a further five days. If there was evidence that hyperglycaemia and glycosuria were diminishing, the diabetics were continued to be maintained on BZ 55 as out-patients for at least two weeks. In those who failed to respond even to an increased dosage, insulin therapy was resumed.

Dosage.—The initial dose was 50 mg./kg. body weight for each case—that is, 2.5 to 3.5 g. a patient—and was given in the morning. Except for the young and brittle cases, patients received a dose of 2 g. on the following morning, followed by 1 g. daily for at least five days as in-patients, and then as out-patients. Where control was poor, 3 g. daily was begun on the eighth day and continued for five days. In some, rapid loss of weight and ketosis necessitated an earlier resumption of insulin therapy, which also eventually became necessary in those patients in whom trebling of dose had been attempted.

Body Weight.—Patients were weighed daily; this was continued when they attended as out-patients.

Laboratory Tests.—On admission of patients the following examinations were performed to exclude relevant disease and for later reference: urine tests for albumin and casts; haemoglobin estimation, white-cell count and differential; and serum bilirubin, thymol turbidity, and alkaline phosphatase.

Urine Sugars and Sulphonamides.—Each day 24-hour specimens of urine were collected, the volume was measured, and the total sugar was estimated by Benedict's quantitative method (King, 1951). When BZ 55 was given, the amounts of free and conjugated sulphonamides were estimated by the method of Bratton and Marshall (1939). Urine was also tested four-hourly for sugar and acetone and charted in the usual way.

Blood Sugar and Sulphonamides.—Samples of venous blood were obtained at least three times daily, including a fasting, pre-lunch, and post-lunch specimen, and the sugar was estimated by the method of Hagedorn and Jensen (1923). When BZ 55 was administered the levels of free and conjugated sulphonamides were also estimated by the method of Bratton and Marshall. All estimations were continued on out-patients whenever they attended, bringing with them a 24-hour specimen of urine in a winchester provided.

Results

The patients were divided into two groups, successes and failures, depending upon their response to BZ 55. The blood-sugar levels of those in the successful group fell to within normoglycaemic limits following the administration of the drug, either whilst the patients were in hospital or during the subsequent follow-up as out-patients, and glycosuria almost or completely disappeared during the corresponding period of observation. Within the group of failures

the blood-sugar levels either were not reduced following the administration of BZ 55 or were reduced, but not to within the normoglycaemic range, and the amount of glycosuria was still significant.

Within these two classifications the data were studied statistically under the following headings: (1) Previous history of diabetes. (2) The mean change in blood sugar, glycosuria, volume of urine excreted, body weight, and sulphonamide levels during up to five days in hospital after treatment with BZ 55 compared with the corresponding period in hospital before treatment, during which the patient received no insulin. (3) The two-day test referred to under "Methods," in which the patient received BZ 55 for the first time.

In all the analyses which follow, the maximum amount of data available has been used. For example, it was obviously impossible to continue the administration of BZ 55 to the young and brittle diabetics beyond the first dose in the two-day test because of ketosis and the consequent risk of coma. In such instances the results can be included only when considering data from the two-day test or from previous history of diabetes.

Sex, Present Age, and Duration of Diabetes.—Table I shows the results from 45 cases. An analysis of variance revealed neither regression of age on the duration of dia-

TABLE I.—Distribution of Sex, Present Age, and Duration of Diabetes

Present Age (Years)	Successes (19)		Failures (26)	
	Males (3)	Females (16)	Males (10)	Females (16)
21-40	0	0	4	2
41-60	1	3	3	6
61-80	2	13	3	8
Mean age and range (years) ..	65 (51 to 77)		55 (22 to 80)	
Duration of Diabetes (Months)	Successes		Failures	
0-12	9		6	
13-60	6		5	
61-120	1		7	
121-240	3		2	
>240	0			
Mean duration and range (months) ..	50 (0 to 192)		104 (0 to 324)	

betes nor any significant difference in the duration of the disease in successes and failures. This is not surprising in view of the wide range of the duration of diabetes within each group. In the successful cases the mean age is slightly higher ($P < 0.05$) than in the failures. Since the majority of patients in this study were elderly female diabetics the significance of the age factor would probably have been increased if a larger number of young diabetics could have been included, since none of the young brittle diabetics responded at all to BZ 55.

Family History and Complications.—There was evidence of diabetes in the families of 3 out of 16 successful cases and in 3 out of 25 of the failures. The complications are shown in Table II. These data are collected from too small

TABLE II.—Number of Cases Showing Complications

	Successes	Failures
Retinopathy	4	5
Nephritis	1	1
Claudication	0	2

a number of patients for a significant statistical assessment, but there does not appear to be any difference in the distribution of complications between the two groups.

Insulin Requirements.—Table III shows the mean daily dose of insulin given to patients in both the successful and unsuccessful groups at the time when the present study was

started, and the mean change in insulin requirements from the time when the disease was first diagnosed.

TABLE III.—Correlation Between the Daily Requirements of Insulin Just Prior to the Test with BZ 55 and the Amount of Insulin Required When the Diabetes was First Diagnosed

	Daily Dose of Insulin Just Prior to the Test with BZ 55		Change* in Daily Dose of Insulin from Time when Diabetes was First Diagnosed until Just Prior to Test with BZ 55		No. of Cases
	Mean (Units)	Range (Units)	Mean (Units)	Range (Units)	
Successes ..	13.3	0 to 32	-9.8	-54 to +6	16
Failures ..	40.8	0 to 120	+10.7	-24 to +90	25

* —, Decrease in insulin requirements. +, Increase in insulin requirements.

A statistical analysis revealed that the insulin requirements of those patients in the group of failures were significantly greater ($P = 0.001$) than the requirements of those in the successful group prior to the administration of BZ 55, and the successful patients needed slightly less insulin at this time and the unsuccessful patients slightly more ($P = 0.05$) than they did when the diabetes was first diagnosed.

Present Age, Duration of Diabetes, and Deviation from Ideal Body Weight.—The ideal body weights of 38 patients were determined, using the table of Kemsley (1951-2), and are shown in Table IV. There was no significant difference

TABLE IV.—Deviation of Actual Body Weight from the Ideal Body Weight

	Deviation* from Ideal Body Weight (lb. and kg.)		No. of Cases
	Mean	Range	
Successes ..	-3 (-1.36 kg.)	-44 to +42 (-19.96 to +19.05 kg.)	15
Failures ..	-11 (-4.99 kg.)	-46 to +16 (-20.86 to +7.26 kg.)	23

* —, Underweight. +, Overweight.

between the mean deviations in body weight for the two groups, nor was there any correlation between the deviation from ideal body weight and the duration of diabetes or present age when the data in Table I were analysed with those of Table IV.

Deviation from Ideal Body Weight Before Administration of BZ 55 and the Change in Body Weight Whilst in Hospital following its Administration.—One possible action of BZ 55, if it restores a normal metabolism, would be its effect on the body weight of the patient where an obese patient might be expected to show a decrease in weight and a thin patient an increase. The data from 37 cases were available in which daily observations on body weight were made carefully in the period before and after the administration of BZ 55 while the patients were in hospital. Table V shows

TABLE V.—Deviation from Ideal Body Weight Prior to BZ 55 Administration and Change in Body Weight Following its Administration

	Deviation from Ideal Body Weight lb. (kg.)	Change in Body Weight oz. (g.)	No. of Cases
Successes { Mean Range	-3 (-1.36 kg.) -44 to +42 (-19.96 to +19.05 kg.)	-14 (-397 g.) -13 to +54 (-368 to +1,531 g.)	15
Failures { Mean Range	-16 (7.26 kg.) -49 to +16 (-22.25 to +7.26 kg.)	-7 (-198 g.) -88 to +44 (-2,495 to +1,247 g.)	12

the results obtained. There was no correlation between the change in body weight after BZ 55 and the deviation from the ideal body weight for either group, nor was there any significant difference between the two groups in either change in body weight or deviation from ideal weight. The lack of significance, however, could be due to too small a

number of cases or too short a period of observation of body weight after BZ 55.

Effect of BZ 55 on Fasting (6 a.m.) Blood-sugar Levels.—The results of the mean 6 a.m. level of blood sugar for the group of successes and failures, averaged over five days without insulin, together with the mean reduction in blood-sugar level averaged over the five days following the administration of BZ 55, are summarized in Table VI, and

TABLE VI.—Effect of BZ 55 on Fasting (6 a.m.) Blood-sugar Levels

	6 a.m. Blood-sugar Level Before BZ 55 (mg./100 ml.)		Reduction in Blood-sugar Level After BZ 55 (mg./100 ml.)		No. of Cases
	Mean	Range	Mean	Range	
Successes	215	132 to 275	73	15 to 132	16
Failures	267	123 to 421	29	-60* to 150	18

*—, Increase in blood-sugar level.

FIG. 1.—Effect of BZ 55 on fasting blood-sugar level.

expressed graphically in Fig. 1. The correlation between the 6 a.m. mean blood-sugar level before treatment and its reduction after treatment is statistically significant ($P < 0.01$), and the mean 6 a.m. blood-sugar level is higher among the group of failures than among the group of successes ($P < 0.05$). When the regression on initial blood-sugar level is allowed for, the fall in the 6 a.m. blood-sugar level after BZ 55 is significantly greater ($P < 0.01$) in successes than in failures.

There is therefore, in general, a fall in the resting blood-sugar level of the failures after BZ 55 administration, but it is less pronounced than that observed in the successes, and, in view of the higher mean initial levels in the former, their blood sugar levels are not reduced to within the normoglycaemic range.

Effect of BZ 55 on the Postprandial (2 p.m.) Blood-sugar Levels.—The results of the mean 2 p.m. level of blood sugar for the two groups of patients averaged over five days without insulin, together with the mean reduction in blood-sugar level averaged over the five days following BZ 55 administration, are summarized in Table VII. An analysis of variance revealed no correlation between the fall in blood sugar after BZ 55 and the mean level before administration, which is in contradistinction to the results for fasting (6 a.m.) levels. The average blood-sugar level at

TABLE VII.—Change in Postprandial Blood-sugar Levels (2 p.m.) After Administration of BZ 55

	Mean	Range	Mean	Range	
Successes	272	165 to 376	87	171 to 37	15
Failures	354	176 to 474	-182*	197 to -182	18

*—, Increase in blood-sugar level.

2 p.m. before treatment is lower for the successful group than for the failures ($P = 0.01$), and the reduction in blood sugar is greater in the former group than in the latter ($P = 0.01$).

Mean Rise in Blood-sugar Levels from 6 a.m. to 2 p.m. Before and After Administration of BZ 55.—This analysis was undertaken to determine the effect of BZ 55 in controlling the postprandial rise in blood-sugar levels. The average of the mean initial blood-sugar levels at 6 a.m. before and after treatment, and the corresponding average of the mean difference between the 2 p.m. and 6 a.m. blood-sugar levels are shown in Table VIII. There is no regression

TABLE VIII.—Mean Rise in Blood-sugar Levels from 6 a.m. to 2 p.m. Before and After the Administration of BZ 55

	6 a.m. Blood-sugar Level (mg./100 ml.)		Increase in Blood-sugar Level at 2 p.m. (mg./100 ml.)		No. of Cases
	Before BZ 55	After BZ 55	Before BZ 55	After BZ 55	
Successes	Mean 211 Range 132 to 298	Mean 140 Range 89 to 197	Mean 55 Range 0 to 164	Mean 46 Range 3 to 107	15
Failures	Mean 267 Range 123 to 421	Mean 238 Range 119 to 396	Mean 83 Range -3* to 162	Mean 118 Range -140* to 408	18

*—, Decrease in blood-sugar level.

of the postprandial rise in blood-sugar level on the 6 a.m. level; the mean 6 a.m. level is lower after BZ 55 administration (successes, $P = 0.001$; failures, $P = 0.05$); the mean blood-sugar level of the failures is higher at 6 a.m. than that of the successes ($P = 0.001$). The most important finding, however, is the lack of a significant difference between the postprandial rise before and after treatment with BZ 55 and the fact that this rise is greater in the group of failures than in the group of successes ($P = 0.01$). Furthermore, the postprandial rise is more variable in the group of failures after treatment with BZ 55 than before ($P < 0.002$). These findings suggest that BZ 55 exerts no action on the utilization of exogenous glucose and that it therefore may control the mechanisms of gluconeogenesis, glycolysis, or glycogenolysis.

Acute Effect of BZ 55 on Blood-sugar Levels of Overnight Fasted Patients whose Fasting is Continued from 6 a.m. to Midday.—The methods previously outlined for the two-day test were used and the mean 6 a.m. level of blood sugar following the administration of BZ 55 is recorded in Table IX. There is a positive regression of the reduction of blood sugar after BZ 55 on the initial 6 a.m. level, which is shown in Fig. 2. When the reduction in blood-sugar level is corrected for the initial 6 a.m. level it is greater in the successful group than in the failures ($P = 0.001$).

In addition the reduction in blood-sugar levels in the two-day test—that is, from 6 a.m. to midday—is greater than the mean reduction in fasting blood-sugar levels in the five days after administration of BZ 55 for the same patients.

TABLE IX.—Acute Effect of BZ 55 on Blood-sugar Levels of Fasted Patients from 6 a.m. to Midday

	6 a.m. Fasting Blood-sugar Level on Day BZ 55 was given (mg./100 ml.)		Amount by which Blood-sugar Level was Reduced 6 Hours after Administration of BZ 55 (Midday) (mg./100 ml.)		No. of Cases
	Mean	Range	Mean	Range

Failures	290	119 to 450	123	-15 to 249	14

Effect of BZ 55 on Glycosuria.—The mean of the amounts of glucose in 24-hour samples of urine (6 a.m. to 6 a.m.) for the five days prior to the administration of BZ 55, and the amount by which the glucose excretion is reduced in a corresponding period after treatment with BZ 55, are summarized in Table X. There is a positive regression of the reduction of glycosuria on the mean level before treatment

FIG. 2.—Effect of BZ 55 on 6 a.m. blood-sugar level. (Two-day test.)

with BZ 55 ($P = 0.001$), and when the reduction of glycosuria is corrected for the mean initial level it is more pronounced in successful cases than in unsuccessful cases ($P = 0.01$). The regression is shown in Fig. 3, and the high degree of correlation for the successful group is clearly evident. In nearly every instance there is virtually no glycosuria in the successful group following treatment with BZ 55.

TABLE X.—Effect of BZ 55 on Glycosuria

*—, Increase in amount excreted.

FIG. 3.—Effect of BZ 55 on glycosuria.

Change in Volume of Urine Excreted and in Glycosuria Following Administration of BZ 55.—There is a reduction in the mean volume of urine excreted in both the successes and the failures which is not statistically significant (see Table XI). This is not surprising in view of the wide range in the volumes of urine excreted. There is no correlation between the change in urine volume and reduction in glycosuria in the successful group, but there is a significant correlation in the group of failures ($P = 0.001$). These differences in correlation are evident in Fig. 4. In the group of failures, therefore, the smaller the volume of urine excreted in 24 hours after BZ 55 the less sugar will that sample

contain. The lack of correlation in the group of successful cases may be due to too small a number tested and a narrower range in quantity of urine excreted.

FIG. 4.—Relationship between the change in volume of urine excreted and glycosuria after BZ 55.

Blood and Urine Sulphonamide Levels.—On the first group of 12 patients the blood sulphonamide levels on the day of the two-day test were estimated at hourly intervals after the dose of BZ 55; they showed a steady rise up to six hours in each patient. The blood sulphonamide levels at one hour and six hours after the treatment with BZ 55 are shown in Table XII. It can be seen that there are no differences between the levels of the successful cases and those of the failures. On all the other patients the blood sulphonamide levels were estimated on the day of the two-day test at six hours after the dose of BZ 55. The average level for free sulphonamide at this time was 11.9 mg. per 100 ml. for successes and 11.4 mg. per 100 ml. for failures, whilst the corresponding levels for conjugated sulphonamide were 0.8 mg. and 0.9 mg. per 100 ml. respectively. There was

TABLE XII.—Blood Sulphonamide Levels on the Day of the Two-day Test

	Mean	6.9		7.0	
6 hrs. after BZ 55	Range	9.5-11.7	0.8-2.5	9.5-11.7	0.8-2.3
	Mean	10.65	1.48	10.6	1.56

TABLE XIII.—Excretion of Total Free and Conjugated Sulphonamide in 24-Hour Specimens of Urine in Patients Receiving a Maintenance Dose of 1 g. BZ 55 Daily

	Mg. of Sulphonamide Excreted 24 Hours		Ratio Free: Conjugated	No. of Cases
	Free	Conjugated		
Successes	468	180	2.60	13
Failures	325	348	0.93	10

no significant difference between the levels in either group. On maintenance doses of BZ 55 the blood sulphonamide levels six hours after 1 g. of BZ 55 ranged from 7.7 to 12.5 mg. per 100 ml. (mean 11.7 mg.), and eight hours after, from 8.7 to 23 mg. per 100 ml. (mean 13.6 mg.).

The total amount of free and conjugated sulphonamide excreted in 24-hour specimens of urine was also estimated

steadily on 1 g. a day. Trebling of dose to 3 g. daily did not reverse this trend; she began to complain of thirst and polyuria. Insulin was reinstituted, with rapid improvement. This was an example of failure to replace insulin by BZ 55 as shown in Fig. 7.

Discussion

The fasting blood-sugar level would appear to be an important factor in assessing the effect of BZ 55. In none of our successful cases was this more than 275 mg. per 100 ml. While these patients were in the ward, on a measured diet but without insulin, they showed raised blood sugars and considerable glycosuria. There was, however, no acetonuria; thirst and polyuria were slight. They might thus be described as mild diabetics, and a maintenance dose of 1 g. daily was successful during the period of observation in keeping their blood level normoglycaemic and the urine free of sugar.

BZ 55 proved ineffective in the control of diabetics who easily developed acetonuria. The fasting blood sugars ranged from 123 to 421 mg. per 100 ml. In some patients substitution of the morning dose of insulin by BZ 55 had led by the afternoon to rising blood sugars, acetone in the urine, and symptoms of thirst, necessitating administration of insulin. These were young diabetics normally difficult to control. In the remainder of the failed cases the test dose of BZ 55 caused a significant drop from the fasting blood-sugar level, but subsequent maintenance therapy failed to prevent hyperglycaemia and glycosuria, and in some there was gradual onset of thirst, polyuria, and loss of weight. Trebling the dose of BZ 55 did not reverse this trend.

Failure to control these severe or moderately severe diabetics on oral therapy alone does not exclude the possibility

FIG. 5.—Excretion of free and conjugated BZ 55 in 24-hour specimens of urine when patients are receiving a maintenance dose of 1 g. of BZ 55 daily.

for patients during the in-patient period when they were receiving a maintenance dose of 1 g. of BZ 55 each day. On analysis, the results, presented in Table XIII, show that there is a significant positive correlation between the amount of free and conjugated sulphonamide excreted ($P=0.01$); the excretion of conjugated sulphonamide is higher in failures than in successes ($P<0.01$) and the difference between the excretion of free sulphonamide in either group is not significant. The evidence for the regression is shown in Fig. 5.

Complications of Treatment

Skin reactions occurred in 5 out of 45 cases. In four cases BZ 55 was then replaced by N-(4-methyl-benzosulphonyl)-N'-butyl-urea (D 860), and the rash, a typical maculopapular sulphonamide rash, in each case gradually disappeared. No other complications have occurred in our series so far.

Examples of Successful and Failed Cases

Case A.—A woman, aged 72. Diabetes was first diagnosed in November, 1955, following gradual onset of thirst, polyuria, lassitude, and loss of weight. On 20 units of insulin zinc suspension her urine was sugar-free. During the trial period in the ward without insulin her urine showed heavy glycosuria; her fasting blood sugars were over 200 mg. per 100 ml. and her postprandial blood sugars over 300 mg. per 100 ml. She was, however, symptom-free and had no acetonuria. The test dose of BZ 55 led to a marked drop in the blood sugar, and subsequently a maintenance dose of 1 g. daily cleared the urine of sugar and lowered her blood-sugar levels. This was an example of a successful replacement of insulin by BZ 55 as shown in Fig. 6.

Case B.—A woman aged 57. Diabetes was diagnosed six years previously, following a history of thirst and polyuria. Her diabetes had been controlled on 30 units of protamine zinc insulin daily. She was admitted to the ward and her insulin discontinued for five days. During this period she showed heavy glycosuria and acetonuria. BZ 55 was administered and caused some fall in the blood sugar the first day, but after that blood and urine sugars rose

FIG. 6.—Details of Case A, a woman aged 72. (Success.)

FIG. 7.—Details of Case B, a woman aged 57. (Failure.)

that BZ 55 given in conjunction with insulin might reduce the amount of insulin required or might lead to an easier control in unstable patients; these problems were not investigated.

The response of patients to BZ 55 was not related to the duration of their diabetes or to the incidence of complications. In the group of successes, however, there was generally a history of diminishing insulin requirements, and had, if the failures the need for insulin was greater, and had, if anything, increased with the progression of the disease. It may be that in the successful cases with mild diabetes BZ 55 acted either by stimulating the secretion of endogenous insulin or by preventing its destruction, while in the failed cases there was insufficient endogenous insulin.

In 39 cases the initial dose of BZ 55 produced hypoglycaemia which was greater than that produced by any subsequent dose. This suggests that following the initial dose the available insulin, or the mechanism regulating its use, was quickly exhausted in those diabetics who subsequently failed to respond.

BZ 55 exerted no control in either group over the postprandial rise in blood sugar. Its action is therefore probably on the mechanism controlling the utilization of endogenous glucose. With that in view, in all patients maintained on BZ 55 stress has been laid on the importance of adhering to the dietary regime.

German workers have indicated that BZ 55 and D 860 are most likely to be successful in obese diabetics. The present study showed the mean deviation in body weight present in successful cases to be slightly lower than the ideal weight, with only one case of gross obesity. This indicates that the drug can act as successfully in underweight patients as in those who are normal or overweight. During their period as in-patients, body weight did not alter significantly once BZ 55 therapy had begun.

Kinsell *et al.* (1956) found in two severe diabetics that the greater part of the sulphonamide excreted in the urine was conjugated in the patient treated successfully by BZ 55, whereas the greater part of the urinary sulphonamide was free in the patient who failed to respond. The present investigations were at variance with this, since it was found that the excretion of conjugated sulphonamides was higher in the failed cases than in the successes.

Skin reactions occurred in 11% of the cases, but gradually disappeared when the patients were transferred to D 860. In view of these toxic manifestations, and the possibility of other adverse effects which may appear, particularly in the blood or liver, caution must be exercised before deciding to treat a patient with these drugs. Finally, it must be stated that the mode of action of BZ 55 remains unknown, as does its influence on the complications in the vessels, kidneys, and eyes which occur in long-term diabetes.

For these reasons BZ 55 must not be regarded as having reached therapeutic status in the management of the diabetic patient.

Summary

The response to the administration by mouth of BZ 55 tablets was studied in a group of 45 diabetics normally requiring insulin. These studies were undertaken under conditions of controlled diet on in-patients.

Diabetics in whom the drug was successful often had a history of diminishing insulin requirements. In no instance was the fasting blood-sugar level greater than 275 mg. per 100 ml., and the fasting range was from 123 to 275 mg. per 100 ml.

Diabetics in whom the drug failed tended to have a higher insulin requirement than the previous group. The fasting blood sugars ranged from 123 to 421 mg. per 100 ml. and there was a tendency to acetonuria.

BZ 55 does not exert any influence over the postprandial rise in blood sugars, either in the group of successes or in the failures.

There is no difference in levels between free and conjugated sulphonamides in the blood between successes and failures. In the urine there is more excretion of conjugated sulphonamides in the failed cases than in the successful ones.

Five patients (11%) developed skin reactions due to the drug.

Our thanks are due to Dr. K. Thomson for his help in the wards; to Mrs. Collins for the supervision of the diets; to Mr. Garfield for unstinting support with the biochemistry; to the ward staffs; and to Messrs. J. V. Smart, T. Hobson, R. Neville, P. Roberts, D. Sutton, and J. Trethewey, of the Biological Control Laboratories, the Wellcome Foundation, for invaluable assistance with the biochemical and statistical analyses. We also thank the British Insulin Manufacturers for supplies of BZ 55 and Professor Ehrhardt, of Hoechst A.G., for D 860.

CLINICAL TRIAL OF THE NEW ORAL HYPOGLYCAEMIC AGENT BZ 55

BY

J. A. HUNT, M.B., B.S.

WILFRID OAKLEY, M.D., F.R.C.P.

AND

R. D. LAWRENCE, M.D., F.R.C.P.

From the Diabetic Department, King's College Hospital

The discovery of the hypoglycaemic action of certain sulphonamide preparations, and their use in the treatment of diabetes, has recently been the subject of a number of publications on the Continent, notably in Germany (Bertram *et al.*, 1955; Franke and Fuchs, 1955; Loubatières, 1955; Quilley, 1955). The drug most commonly used has been N-butyl-N'-sulphanilylurea (BZ 55, "nadsan," "carbutamide"), and the preliminary results obtained in a clinical trial of this substance in the Diabetic Department at King's College Hospital are briefly described.

In the absence of reliable information on the clinical type of diabetes and on the influence of diet in the cases treated in Germany and elsewhere, it was decided first to give BZ 55 to a small series of representative diabetics, with the object of correlating such broad clinical distinctions as age, severity, insulin requirement, and duration of the diabetes with responsiveness to the drug. From the results so obtained it was hoped that a group or groups of patients could be selected for treatment in the out-patient department; this policy was largely dictated by lack of beds.

Clinical Material

Representative Group.—A group of 21 patients were selected to cover a wide range of age, weight, and severity and duration of diabetes for the purpose outlined above; eight of these were in-patients.

Selected Group.—A group of 17 patients were treated in the out-patient department, the criteria for selection being based on results obtained in the representative group.

Methods

Diet control consisted of measured carbohydrate, with free protein and fat, and was accurate in hospital. Out-patients had previously received detailed instruction in diet, and, because none were gaining weight, they were presumed to be adhering to it within reasonable limits. Since a new treatment often leads to more rigid adherence to diet than usual, the patients were first studied for a control period of two weeks while receiving dummy tablets. In some subjects receiving insulin the dose was not changed during the trial; in the others insulin was discontinued at least one week before BZ 55 was given. All patients were weighed twice weekly. On the first and second days of the trial patients were given respectively 2.5 and 1.5 g. of BZ 55, the dose on subsequent days being 1 g. In patients who failed to show a satisfactory response by the seventh day the maintenance dose was gradually increased.

The total excretion of glucose in 24 hours was estimated daily in in-patients and twice weekly in out-patients. Capillary blood-sugar estimations were made by a modified Nelson technique at least three hours after breakfast, and at the same time on each occasion. In the group of 17 out-patients night and early morning specimens of urine were tested for sugar and acetone bodies, and the blood sugar was estimated at varying times after breakfast, but not less than two hours.

Results

Representative Group.—The results obtained in the group of representative diabetics are summarized in Table I. The response to BZ 55 was recorded as good, moderate, or no response, according to whether the glycosuria disappeared completely, was reduced in amount, or was unaffected. In nine cases the response was good, in six moderate, and in

six there was no response. In the nine cases classified as good the age of onset varied from 46 to 70 years, in the six moderate from 45 to 75, and in five of the six with no response from 9 to 46, the remaining failure being 65. Seven of the nine successes never required insulin, one was on 12 units and one on 48 units. In the moderate group four needed no insulin, the remaining two having been on 24 and 34 units respectively. Of the six who showed no response three had never had insulin, one being a child of 12 with diabetes of recent onset and severe ketosis; the remaining three needed relatively large doses of insulin. The cases with heavy ketonuria failed to respond to BZ 55. Of the 15 patients who showed a good or moderate response to BZ 55, the minimum age of onset of diabetes was 45, and maximum duration 22 years. Only four cases required insulin, the maximum period of insulin therapy being 18 years. No case showed ketonuria even after withdrawal of insulin.

Selected Group.—The results obtained in the group of 17 selected out-patients are summarized in Table II. All patients in this group developed diabetes after the age of 40, the range being 41 to 76; none showed significant ketonuria without insulin, and none were grossly overweight. In all cases diet alone failed to control glycosuria. In this group there was a good or moderate response to BZ 55 in every case, the final blood sugar being less than 180 mg. per 100 ml. in 11, between 180 and 200 mg. in three, and between 201 and 250 mg. in the remaining three cases. Insulin was replaced in three patients and avoided in two suffering from poor vision. Eight patients had previously been on insulin, the dosage varying between 12 and 88 units; the response was good in four and moderate in four, including the only two previously on large doses of insulin.

Toxic Reactions.—Transient giddiness occurred in five patients within two hours of the initial dose of BZ 55 and

lasted for about 15 minutes, but did not recur. Severe giddiness which persisted until the drug was stopped or the dose reduced occurred in three cases. In two cases there was an irritant erythematous rash which rapidly disappeared on stopping treatment. One out-patient developed a severe papular sulphonamide rash with some purpuric haemorrhages, and typical sulphonamide drug fever occurred in one case.

Sensitivity Test.—In view of the uncertainty of the clinical response to BZ 55 in diabetes it was decided to investigate the hypoglycaemic action of a single dose of the drug in a small series of patients. It was hoped that this type of sensitivity test might provide a useful guide in the selection of patients for treatment with BZ 55. The test was carried out on 16 patients and consisted in estimating the blood sugar in the fasting state and again four hours after a single dose of 50 mg. of BZ 55 per kilogram of body weight. A control test without BZ 55 was carried out on 11 of the 16 patients. The results of this investigation are shown in Table III. In patients known to respond to BZ 55 there was a significantly greater fall with than without the drug ($P=0.001$). A fall of less than 30% was observed in 9 out of 11 control tests. After BZ 55 the fall exceeded 40% in eight patients; in two of the remaining three a dose of 2 g. of BZ 55 had been required to produce a satisfactory response.

Arteriovenous Difference.—This test of sensitivity to BZ 55 offered a convenient opportunity to investigate the effect of the drug on the peripheral utilization of glucose. Simultaneous capillary and venous blood-sugar estimations were carried out during the period of maximum hypoglycaemic response to BZ 55, but no significant increase in arteriovenous difference was demonstrated; this would seem to indicate that BZ 55 does not increase the peripheral utilization of glucose.

Discussion

From the results obtained in the first series of 21 diabetics, to some extent representative in respect of age, duration, and severity of diabetes and insulin requirement, certain broad conclusions may be drawn regarding the type of patient in whom the drug may be expected to have some hypoglycaemic action. The presence of significant ketonuria either in patients treated by diet alone or after the withdrawal of insulin was consistently associated with complete failure to respond to BZ 55. In general it appeared that young diabetics and those requiring more than small doses of insulin show little or no response, nor was there reliable evidence that the administration of BZ 55 to such patients decreased their insulin requirement; two young diabetics actually passed more sugar when the drug was

the fall in blood sugar on BZ 55 is of the same order as in the first group, in no case is it significant. This is due to a greater fluctuation in blood-sugar levels in the insulin-treated group. Further analysis of this group is, of course, impossible until the numbers have been increased.

Case 15 is of interest. This patient was reasonably well controlled on 44 units insulin zinc suspension (I.Z.S.) daily. The reduction of this to 36 units resulted in ketosis developing within 24 hours. After she had been on 44 units of I.Z.S., with BZ 55 in addition, insulin dosage was reduced once more to 36 units. The patient was seven days on this regime without ketosis developing. The stoppage of BZ 55 on the eighth day was followed by ketosis on the ninth day, when the BZ 55 blood level was 4.6 mg. per 100 ml.

With the therapeutic use of BZ 55 in Cases 17-20, glycosuria was cleared in Cases 17 and 20 and, subjectively

and by urine tests, control was better in Case 19. There was no apparent response to the administration of BZ 55 in Case 18.

No constant effect of BZ 55 on the arteriovenous difference of blood sugar was found. A decrease in the difference occurred as often as an increase.

No change in weight was noted in spite of improvement in control.

Toxic Effects.—Two widespread and fairly typical sulphonamide skin rashes occurred. One cleared with the administration of antihistamines, and the other with the cessation of the drug. Two patients were mildly nauseated on high dosage.

Discussion

Statistical analysis of the data derived from the 10 patients in group 1 would lead to the following conclusions. BZ 55 would appear to have a "normalizing" effect on the blood-sugar levels of these mild diabetics, and the higher the initial fasting blood-sugar levels found the greater the effect. The effect does not seem to be due to an increased sensitivity to insulin.

The study of the effect of BZ 55 on the arteriovenous difference of blood sugar, and other unpublished observations we have made on serum inorganic phosphorus levels, would support this conclusion. In the more severe diabetics the fall in fasting blood sugar on BZ 55 was not statistically significant, and a larger group will have to be studied.

We can deduce no evidence in support of the contention that the drug is active only in overweight diabetics. The duration of the diabetic state has no correlation with the responsiveness of the patient. It is already evident from our limited experience of the drug that, although a satisfactory fall of blood-sugar and urine-sugar levels will occur in hospital on a carefully controlled diet, patients can relapse on a more liberal out-patient regime. In three of our patients it is now evident that 2 g. of BZ 55 is required daily to maintain a satisfactory clinical response. We have as yet no definite proof of the development of tolerance.

The fact that BZ 55 has already been shown to have toxic effects (Duncan, Baird, and Dunlop, 1956), and that it is also of course an antibacterial substance, is a challenge to the synthetic chemist to produce something better. Whether this compound proves ultimately to have a place in therapeutics or not, a laboratory tool of great importance is now available, and already new vistas in the intermediate metabolism of carbohydrate are appearing.

Summary

Results are reported of a clinical trial of BZ 55 on 20 diabetic patients, 14 of whom were in hospital. Ten mild diabetics, not satisfactorily controlled by diet alone, were studied under basal conditions and then on BZ 55 therapy and the same diet. Detailed measurements of blood and urine sugar were made, as well as of the blood level of BZ 55 and the daily weight. Three out-patients were studied similarly but in less detail. A further three patients who required insulin to prevent ketosis were studied in hospital when taking insulin and when taking BZ 55 in addition, the diet remaining constant. A fourth group of four patients were given BZ 55 simply as a therapeutic agent, in one case in addition to 128 units of insulin, and the effects were judged by the relief of symptoms and the results of qualitative tests for urinary sugar.

Statistical analysis of the data of the first group of 10 mild diabetics showed that the BZ 55 had a normalizing

effect on the fasting blood-sugar levels. The higher the initial fasting blood sugar the greater was the hypoglycaemic effect obtained. The four patients receiving BZ 55 in addition to insulin had better control than when receiving insulin only, but the series is too small to achieve significance. Studies of arteriovenous blood-sugar differences and of the changes in serum inorganic phosphorus levels provided no evidence that BZ 55 increased the effectiveness of the peripheral action of insulin.

We are grateful to Mrs. H. M. McGregor and Miss L. Constable for their biochemical estimations.

HYPOGLYCAEMIC SULPHONAMIDES IN TREATMENT OF DIABETES

BY

G. WALKER, M.B., M.R.C.P.

W. L. B. LEESE, B.M., M.R.C.P.

AND

J. D. N. NABARRO, M.D., F.R.C.P.

The Diabetic Clinic, the Middlesex Hospital

Recent reports from Germany (Bertram *et al.*, 1955) have suggested that certain relatively non-toxic sulphonamides with a hypoglycaemic action may be of value in the treatment of diabetes mellitus. Because of the interest which has been aroused by these reports, the following preliminary account is being published. It deals with experience in a diabetic clinic where 24 patients have been treated with N-butyl-N'-sulphanilylurea (BZ 55, "carbutamide") for periods up to seven months.

The German workers found that this compound was most effective in middle-aged "stable" diabetics: stable, in this context, meaning that if patients were not receiving insulin although they were hyperglycaemic they did not develop ketosis, and if they were using insulin it could be stopped without any immediate rise of blood sugar or the development of ketosis. Diabetics of this type are often obese, and, believing obesity to be undesirable in diabetics, it is the practice in this clinic to endeavour to control the condition with a low-calorie diet with less than the usual proportion of carbohydrate. In most cases if the diet is followed for a few weeks weight is lost, the blood sugar falls, and symptoms and glycosuria disappear. In a few, although the weight comes down, hyperglycaemia, glycosuria, and occasionally some symptoms persist. In the past it has been necessary to use insulin to achieve normoglycaemia in these patients; recently we have been assessing the possible use of oral BZ 55 as an alternative.

Selection of Patients

Patients were selected for trial with BZ 55 on the lines indicated above. Of the 24 patients, nine were men. Ages ranged from 38 to 82 years (mean, 63), and the diabetes had been recognized for from 1 to 42 years (mean, 10). Nine patients had developed their diabetes before they were 45 years of age. Ten had received insulin at some time, and in six of these it was being taken in doses of 10 to 84 units a day up to the time of the trial of BZ 55. All except two of the patients had glycosuria when BZ 55 was started, six had mild diabetic symptoms, most commonly polyuria, and five had diabetic retinitis. No patient had at any time

had any significant degree of ketosis, although mild ketonuria had previously been observed in two. Thirteen patients were underweight when treatment was started; the majority of the others were only slightly overweight. Prior to treatment, three blood-sugar estimations were made on consecutive weeks ("random blood sugar"—that is, taken during the clinic between 10.30 a.m. and 12 noon after a normal breakfast—method of Kingsley and Reinhold (1949) modified). The means of these pre-treatment blood sugars are shown in Fig. 1. Patients who were on insulin had this stopped and were put on a low-calorie and restricted carbohydrate diet. BZ 55 was not started until the blood sugar exceeded 200 mg. per 100 ml.

Technique of Treatment

In most cases treatment was started with 2.5 g. the first day, 1.5 g. the next day, and 1 g. a day subsequently. In a number of cases BZ 55 was preceded by two weeks on inert tablets. During the control period and first few weeks of treatment the patients were on a low-calorie and restricted carbohydrate diet (1,250 calories, 100 g. of carbohydrate, in 12 patients; 1,500 calories, 125 g. of carbohydrate, 5 patients; 1,750 calories, 150 g. of carbohydrate, 7 patients). When it

became clear that the tablets were controlling the blood sugar, diet was increased in the underweight patients. Initially the patients were seen at weekly intervals for clinical assessment, weighing, blood and urine sugar tests, and estimation of blood sulphonamide (method of Bratton and Marshall, 1939). The maintenance dose ranged from 0.5 to 2 g. a day (Fig. 1). Two patients have been treated for seven months, four for six months, and most of the remainder for three months or more.

Results

Diabetic symptoms when present have been relieved and many of the patients claim to have felt better as their blood sugars have come down. No alteration has been observed in the retinitis. The reduction of blood sugar is shown in Fig. 1; with two exceptions the level is now satisfactory. In one of these the dose of BZ 55 (0.5 g. a day) is probably too low; the other patient has a blood sugar of 238 mg. per 100 ml. although she is taking 2 g. of sulphonamide daily. Lack of control in this case is thought to be due to unsatisfactory dieting. Only two patients continue to have glycosuria—one the uncontrolled patient just mentioned, and the other on account of a low renal threshold. BZ 55 was discontinued temporarily in six

FIG. 3.—Case 1. Height 63 in. (160 cm.), weight 118 lb. (53.5 kg.). Effect on fasting blood sugar of stoppage and subsequent readministration of BZ 55, with concurrent BZ 55 blood levels.

FIG. 4.—Case 3. Effect on fasting blood sugar of doubling the dose of BZ 55, with concurrent BZ 55 blood levels.

FIG. 2.—Man aged 56. Diabetes 12 years. No insulin. Diet 1,250 calories (92 g. carbohydrate). High renal threshold. Diabetic retinitis. Response to BZ 55 and effect of substituting dummy tablets for two weeks.

patients and permanently in two, and within two weeks the blood sugar rose significantly (Fig. 2).

Eleven of the patients who were underweight before treatment have gained weight, six of the others have lost weight, and the remainder show no significant change. Whole-blood sulphonamide levels in patients taking 1 g. a day have been 5.2–9 mg. per 100 ml. (mean 6.7 mg. per 100 ml.)—expressed as sulphanilamide (to convert to whole-blood BZ 55 this should be multiplied by 1.7). Estimations on bigger doses suggest that the increase of blood level is less than expected and not directly proportional to the dose.

Side-effects.—Treatment had to be stopped after three and four weeks respectively in two cases on account of a widespread irritating rash. In one case there was a mild scaly eruption on the forehead which disappeared despite continued treatment. One patient developed mild hypothyroidism after five months' treatment with 1 g. a day; this has responded satisfactorily to treatment with L-thyroxine.

Discussion

Most middle-aged stable diabetics lose their symptoms if they keep to a low-calorie and restricted carbohydrate diet. In some, however, although the symptoms disappear, glycosuria and hyperglycaemia persist. Preliminary results suggest that in these cases the blood sugar can often be brought down with BZ 55. If the hyperglycaemia is the cause of such complications as retinitis and nephropathy, its control is of great importance to the patient. It will be of considerable benefit if this can be done by oral medication instead of insulin injections, which these patients, in the absence of symptoms, are not unnaturally reluctant to start. If, however, these complications are due to some other metabolic disturbance of the diabetes, there is no certainty that it will be influenced by the hypoglycaemic sulphonamides, and little is gained by prescribing them. Furthermore, it is still not known how these drugs work, and they may well prove to have dangerous toxic properties.

The hypoglycaemic sulphonamides are not "oral insulins" and have no place in the treatment of "insulin-deficient" diabetics. Diet remains the mainstay of treatment for the middle-aged diabetic with any tendency to obesity. The hypoglycaemic sulphonamides would seem to be indicated in only a comparatively small group. Until their value has been proved and their possible hazards more fully explored they cannot be recommended for widespread use.

Summary

A preliminary account is given of the use of a new hypoglycaemic sulphonamide in the treatment of diabetes mellitus.

Twenty-four stable middle-aged diabetics were chosen for treatment. Satisfactory reduction of the blood sugar was obtained in 23, but two had to be taken off the drug on account of a generalized rash.

We wish to thank the staff of the Routine Laboratories of the Courtauld Institute of Biochemistry of the Middlesex Hospital for the blood-sugar and blood sulphonamide estimations; Boots Pure Drug Company, of Nottingham, and Eli Lilly and Company, of Basingstoke, for supplies of BZ 55; and the Clinical Research Committee of the Middlesex Hospital for a personal research grant (to J. D. N. N.).

ADDENDUM.—Since this report was written the one patient who was responding poorly has developed a severe neutropenia. After ten weeks' treatment in which the dose ranged from 1 to 2.5 g. a day (total amount given 123 g.) she was found to have a white-cell count of 2,100 per c.mm. with only 10% polymorphonuclear leucocytes. There was a mild fever at this time which responded to penicillin. She has now been off the tablets for two weeks and the blood count shows 5,700 white cells per c.mm. with 33% neutrophils.

THE VALUE OF BZ 55 IN CONTROL OF DIABETES

BY

IAN MURRAY, M.D., F.R.C.P.Ed., F.R.F.P.S.

AND

IAN WANG, M.B., M.R.C.P.Ed.

From the Department for Metabolic Diseases, Victoria Infirmary, Glasgow

It has been reported that BZ 55 is capable of controlling the glycosuria of a middle-aged obese diabetic, but that it is ineffective in the young acute thin type of individual, the type which generally requires insulin, without which ketosis is very apt to occur. The obese diabetic in this country is generally treated by dietary restriction alone, and excellent results are commonly obtained as the weight is reduced to the "ideal." Nevertheless, one encounters from time to time the patient who has brought down the weight to the desired level, and who, although often devoid of diabetic symptoms, still shows hyperglycaemia and glycosuria, which eventually calls for the administration of insulin. Such patients would appear to be the type ideal for testing the efficacy of BZ 55. Bertram *et al.* (1955) concluded that success with this preparation was most likely to be obtained in the patient developing diabetes after the age of 45, who had not suffered from the disease for more than 10 years, and who, if treated with insulin, had not taken this for a period exceeding two years.

Accordingly, for the purpose of our investigation into the efficacy of BZ 55 in controlling hyperglycaemia and glycosuria we selected 23 patients who were over 45 years of age at the time of onset of the disease and who were now approximately the "ideal" weight. Of these 23 patients, 12 had formerly been obese (more than 20% above ideal weight), and 9 of these 12 had never received insulin. Another 11 patients had never been overweight, and eight of these had never had insulin. At the start of the trial no patient had ketonuria, but this had been noted at some time previously in seven patients, in three of whom this had been of considerable degree. In addition to these 23 patients, two younger diabetics were included in this study: one, who had recently developed the disease, in the hope that with the use of this preparation insulin might be avoided; the other, an unstable diabetic, to discover whether the insulin requirements might be reduced. The age and sex of the patients and the duration of diabetes are shown in Table I.

TABLE I

Type	Male	Female	Age (Years)	Duration of Diabetes		
				< 1 Year	< 10 Years	> 10 Years
Previously obese	4	8	56–79	3	4	5
Never overweight	4	7	50–70	3	6	2
Young	0	2	19–30	1	1	—

Methods

As many of the patients were devoid of symptoms it was thought unjustifiable to admit these to hospital for the purpose of this investigation, and a large proportion of our cases were studied as out-patients. They were all familiar with their prescribed diet, which provided, in measured quantities, adequate carbohydrate to satisfy their require-

ments. With such a diet the co-operation of patients is usually not difficult to obtain, particularly when they know that they are taking part in a study of this nature. However, for the first two weeks they were given dummy tablets ("A" tablets), and thereafter they had, for a further course of two weeks, tablets of similar appearance but each containing 0.5 g. of BZ 55 ("B" tablets). In each case the initial dose was five tablets, reduced to three on the second day, and thereafter two daily were taken. Blood-sugar estimations were done at noon on the 4th, 7th, 11th, and 14th days of each course. During the last six days of each course, 24-hour collections of urine were made, in each of which the amount of sugar and of creatinine, the latter as a check on the accuracy of the collection, was determined. With in-patients a similar procedure was adopted, but the control period on dummy tablets was restricted to six days, and throughout this time and the subsequent course of B tablets, daily blood-sugar and urine-glucose estimations were carried out.

Results

The results obtained in this trial of BZ 55 have been classified according to the degree of success. Those patients in whom the mean blood sugar at noon was reduced to less than 180 mg. per 100 ml. and who showed marked improvement in the urinary output of glucose were regarded as "successes." When the glycosuria was greatly lessened, although the noon blood sugar was relatively little affected and was above 180 mg. per 100 ml., the result was classified as a "partial success." The results obtained from the study of the 23 patients aged over 45 are summarized in Table II.

TABLE II

Result	No. of Cases	Previous Build		Previously Taking Insulin	Mean Noon Blood Sugar (mg./100 ml.)		Daily Urinary Glucose (g.)	
		Obese	Non-obese		"A" Tabs.	"B" Tabs.	"A" Tabs.	"B" Tabs.
Success	11	4	7	0	230	145	29	5
Partial success	6	5	1	1	276	227	49	12
Failure	6	3	3	6	282	262	48	61

It will be observed that 11 of these patients showed a completely satisfactory response. In some cases this was dramatic, the glycosuria virtually disappearing within 24 hours of the initial dose. It is noteworthy that none of these patients had ever received insulin, although, particularly in the case of the seven who had never exceeded the ideal weight, insulin treatment might well have become necessary.

The response to treatment with BZ 55 of the group classed as "partial success" was unsatisfactory, and, despite the quite appreciable reduction of glycosuria, these cases should probably be regarded as failures. Certainly the blood sugar, even if lowered in some instances, remained at an undesirably high level, and it is significant that four of the six cases showing this type of response are now getting insulin, and this will probably be required by the remaining two. Attention should be drawn to the fact that all of the group of six unquestionable failures had previously received insulin, although half of them had had this for less than two years. Sex and age distribution and duration of diabetes were similar in all three groups, and did not appear to account for differences in response to the drug.

One factor which appeared to militate against a satisfactory response to BZ 55 was the presence of sepsis. One patient who had a severe infection in the urinary tract failed to show any improvement with the drug, but after recovery from this the trial was repeated and the response was found to be excellent, the blood sugar averaging 150 mg. per 100 ml., and glycosuria became minimal. In another case with considerable sepsis of a leg, no response was obtained when BZ 55 was given at an initial trial, but after the sepsis had cleared up the mean blood sugar, with a

subsequent trial, fell from 276 to 204 mg. per 100 ml., and urinary sugar from 22.6 to 7.2 g. a day, and so was classified as a partial success.

A history of severe ketonuria in the past may be of significance. As mentioned above, this had been noted in three patients in this series. All of these failed to show any response to treatment with BZ 55.

The two younger patients to whom BZ 55 was given failed to show any improvement. In one who was a very unstable diabetic the drug did not diminish the insulin requirements. The other patient, a woman aged 30, had been diabetic for only two months, and, having heard of an oral remedy, was opposed to taking insulin; she showed no improvement in either blood-sugar level or urinary glucose output with BZ 55.

In no case was there any manifestation of toxic effects as a result of the administration of BZ 55.

Discussion

The results given above confirm previous reports that BZ 55 is efficacious in controlling the hyperglycaemia and glycosuria in certain diabetic patients. It is important to discover the type of case that might be expected to show a satisfactory response, but it is equally important to know whether the administration of this preparation might be fraught with danger. It has been suggested that observation of blood-sugar levels for four hours after a test dose of 4 g. of BZ 55 will show whether or not a patient is likely to derive benefit from the drug. We have tried this test in a number of patients, but our results have been equivocal, and more experience with the test is necessary before it can be relied on for this purpose. The definition given by Bertram *et al.* (1955) of the type to be considered suitable for treatment with BZ 55 is not quite adequate. Four of our patients who responded well had been diabetic for much longer than 10 years, while three of the failures had received insulin for less than two years. One would agree, however, that it is the older patient, over 45 years of age, who is most likely to respond.

Our results suggest, although the number of our cases is small, that a patient is more likely to benefit if never previously treated with insulin. Patients taking insulin might, of course, be regarded as more severe cases, and their failure to respond to treatment with BZ 55 attributed to this, but Bertram *et al.* (1955) reported that response to the drug was independent of the severity of the disease. The size of dose of insulin does not appear to be a criterion, as we had one patient, previously well controlled with only 16 units of insulin zinc suspension, who rapidly developed ketonuria and heavy glycosuria on stopping this and transferring to BZ 55. Moreover, when insulin is required we have not found that BZ 55, given in addition, has any insulin-sparing effect.

At the present time it appears that this preparation may be of value in the treatment of elderly diabetics who, if they have been obese, still show glycosuria after reduction to "ideal" weight, or those who, although never overweight and have never had ketonuria, are still uncontrolled by diet. It is unsuitable for the younger acute diabetic, who may rapidly develop ketosis if insulin is abandoned in favour of BZ 55.

Summary

A trial of BZ 55 in 25 diabetic patients is reported. In 23 patients, all over age 45 when they developed diabetes, and all approximating to the "ideal" weight, very successful control of hyperglycaemia and glycosuria was obtained in 11. The remaining 12 patients failed to respond satisfactorily. In two younger patients the drug proved completely ineffective.

BZ 55 proved ineffective in two patients while they were suffering from sepsis, but produced considerable effect when this was overcome.

No satisfactory explanation is given for success or failure with this drug, but it is pointed out that all patients in this series who showed no response had previously received insulin.

Ketosis may develop rapidly on the substitution of insulin by BZ 55 in patients who require the former for their control.

We wish to acknowledge our indebtedness and thanks to Mr. A. P. Kenny, of the Biochemical Department, Victoria Infirmary, Glasgow, for undertaking the blood-sugar and urine-sugar estimations, and to British Insulin Manufacturers, who kindly provided us with the A and B tablets.

A WARNING NOTE

In view of a recent report from America of a small number of cases of severe agranulocytosis and also of several cases of thrombocytopenia in this country, it is the considered opinion of the authors of the papers on BZ 55 appearing in this issue of the "British Medical Journal" that the drug in question should at present be used only under careful hospital supervision.

This view is shared by the majority of those who have had experimental and clinical experience of the use of BZ 55 in this country.

VACCINATION AGAINST WHOOPING-COUGH

RELATION BETWEEN PROTECTION IN CHILDREN AND RESULTS OF LABORATORY TESTS

A REPORT TO THE WHOOPING-COUGH IMMUNIZATION COMMITTEE OF THE MEDICAL RESEARCH COUNCIL AND TO THE MEDICAL OFFICERS OF HEALTH FOR CARDIFF, LEEDS, LEYTON, MANCHESTER, MIDDLESEX, OXFORD, POOLE, TOTTENHAM, WALTHAMSTOW, AND WEMBLEY*

In a previous report (Medical Research Council, 1951) the results were given of a series of controlled trials made to assess the prophylactic value of pertussis vaccine in children 6 to 18 months old. Five batches of vaccine from three different manufacturers were tested. Each batch gave substantial protection, but the two batches supplied by the Michigan Department of Health gave much greater protection than the others.

In 1948, before the previous trials were completed, further field investigations were begun in conjunction with laboratory studies to determine whether the protective effect of vaccines in children could be assessed by a laboratory test. Two series of trials were made—one from October, 1948, to March, 1951, using British vaccines, and the other from early 1951 to mid-1954, using British and American vaccines. The second series was planned not only to give information on the relation between field and laboratory results, but also to determine whether British manufacturers could produce good vaccines by methods similar to those of the Michigan Department of Health and to determine whether a vaccine prepared from culture in liquid medium was as effective as one from culture on solid medium. A description of all the vaccines used in the two series of trials is given in Table I.

INVESTIGATIONS IN THE FIELD

General Plan

The previous trials (M.R.C., 1951) were made on a strictly controlled basis to investigate whether pertussis vaccines were of any value in protecting against the disease. Half the children whose parents volunteered to have them injected were given vaccine and the rest were given injections of an inoculum which looked like pertussis vaccine but which did not contain *Haemophilus pertussis*. This procedure could not be continued after it was known that each of five different batches of vac-

cine used gave substantial protection, and it was decided that in all subsequent trials every child should be given pertussis vaccine, and that the results with one batch of vaccine should be compared with those with other
