Field Workers: Dr. I. A. Bolz and Miss M. R. Elliott, Cardiff; Dr. G. R. Baxter and Mrs. E. R. Beard, Leeds; Dr. A. R. Fox and Miss R. M. Edward, Leyton; Dr. B. J. Griffiths and Miss O. I. Howell, Manchester; Dr. Beryl Anscombe, Dr. A. M.-M. Payne, and Miss C. H. Rudkin, Oxford; Dr. Joan Moignard, Miss M. D. Smith, and Miss W. E. Bennett, Poole; Dr. A. T. W. Powell and Mrs. H. M. Johnston, Walthamstow; Dr. J. C. McDonald, Miss M. M. Wall, and Miss E. E. Wilden, Tottenham and Wembley.

Laboratory diagnostic tests were made by: Dr. G. J. G. King and Mr. E. C. Young, Bournemouth; Dr. J. Marks and Professor Scott Thomson, Cardiff; Dr. H. D. Holt, Mr. G. V. Heimer, and Mr. J. Hollingsworth, Colindale; Professor J. W. McLeod, F.R.S., Dr. D. E. Nicholson, Dr. G. C. Turner, and Miss B. B. Waller, Leeds; Dr. W. W. Walther and Mr. K. R. Podger, Leyton; Dr. Mary O. Adams and Mr. A. G. Harbour, Manchester; Dr. W. H. H. Jebb, Oxford; Dr. F. Marsh, Mr. E. F. Browning, Mr. P. Lovell, and Mr. G. Hoy, Walthamstow.

Laboratory tests for antigenic potency were made by: Mr. A. F. B. Standfast, Lister Institute; Dr. Margaret Pittman, U.S. National Institutes of Health, Bethesda; Dr. Pearl Kendrick and Dr. Grace Eldering, Michigan Department of Health; Dr. A. E. Francis and Mr. H. Proom, Wellcome Research Laboratories; Dr. D. G. Evans and Dr. F. T. Perkins, M.R.C. Laboratories, Hampstead; Dr. J. Ungar, Glaxo Research Laboratories, Dr. Mary O. Adams, Manchester; Dr. Naomi Datta, Colindale.

The field trials were put in train and supervised by Dr. W. C. Cockburn.

The analysis of the field and laboratory results were made and the report prepared by Dr. P. Armitage, Dr. W. C. Cockburn, Dr. D. G. Evans, Dr. J. O. Irwin, Dr. J. Knowelden, and Mr. A. F. B. Standfast.

batches tested at the same time in the same area. There were therefore no unvaccinated control groups, but in some of the trials records were kept of the incidence of pertussis in the siblings of vaccinated children when the vaccinated children and the siblings were known to be exposed to infection by a primary case in the family. This was the main difference between the new and the earlier studies; otherwise the procedure in the field was similar to that described in the 1951 Report.

Children in the 1948-51 trials were allocated to a vaccine group in succession as their names were received. In the 1951-4 trials, when only two vaccines were tested in each area at one time, children born on odd days of the month were allocated to one group and children born on even days to the other. After the injections had been completed, arrangements were made for each child to be visited monthly for about 24 months. Special visits were paid when it was known that a child was being exposed to pertussis or had symptoms which might be those of the early stages of the disease. Swabs were taken from vaccinated children with coughs and also so far as possible from infective cases to which vaccinated children were exposed. The doctors and nurse-investigators visiting children during the follow-up period did not know which vaccine a child had received.

Trials Made Between 1948 and 1951

Seven separate trials were made in six areas—Cardiff, Leyton, Manchester, Oxford, Poole, and Walthamstow; two were made in Manchester and one in each of the other areas. The vaccines used—V1, V2, V3, V3b, V4, V5, V5a, V6, and

V7—were prepared by different methods from the same strains of *H. pertussis* (Table I). In each trial three vaccines were tested in parallel. Vaccines V1, V2, and V3 were tested in Cardiff, Poole, Leyton, and Walthamstow, vaccines V3b, V4, V5a, V5, V6, and V7 in Manchester, and vaccines V2, V3b, and V4 in Oxford.

Children 6-18 months old were given three doses of vaccine intramuscularly with an interval of one month between injections. The first two doses were each 0.5 ml., the third 1 ml., and the total dose, in terms of the U.S.A. opacity standard, was approximately 70,000 million organisms. Consent forms were received from the parents of 11,093 children in all areas; 9,794 (88%) of the children completed the course of three injections.

Reactions and Untoward Sequelae

In the trials with plain suspension vaccines—V1, V2, and V3—940 children, about 20% of the total, were visited 24-48 hours after each injection, and degrees of redness, swelling, and general malaise, and other reactions were estimated. According to the trial area, one-half to one-third of the children had no local or general reaction. Of those who had reactions, all but nine had mild malaise of 24-48 hours or redness or swelling about an inch (2.5 cm.) in diameter. Three of the nine children with more serious reactions had malaise severe enough for them to be kept in bed for 24-48 hours and six had screaming attacks in the evening of the day of injection; between the screaming attacks the children were said to be pale and limp. These episodes were not confined to any one of the three injections; some occurred after the first, some after the second, and some after the third. Three of the nine children were given subsequent injections without ill effect. In the Manchester trial with the alum-precipitated vaccines V3b, V4, and V5a, 194

children, 7% of those followed up, were similarly visited after each injection. One severe reaction was noted, in a child who developed extensive redness and swelling after the third injection.

Particular attention was paid to the occurrence of convulsions in all children vaccinated in all areas. Four children had convulsions within 72 hours after an injection. One of these children was given a subsequent injection without ill effect. None of the children showed evidence of permanent cerebral damage.

None of the children developed poliomyelitis within four weeks after injection.

Similarity of Groups

To determine whether the vaccine groups in each trial were essentially alike certain attributes were examined.

Table II records the results of the tests for similarity; it is clear that with each set of three vaccines the groups were similar.

Incidence of Pertussis

The results of all trials are given in Tables III and IV. Altogether 1,325 cases of pertussis were diagnosed, and in 68% the diagnosis was confirmed bacteriologically. By all three methods of comparing the vaccines—the attack rate per 1,000 child-months (Table III) and the percentage attack rates for “home exposures” and “other exposures” (Table IV)—no striking differences in protective effect were seen. Some slight differences did, however, exist, and these are referred to later.

Since there were no unvaccinated control groups in these trials, an absolute estimate of the value of the vaccines could not strictly be made. In the previous trials (M.R.C., 1951) the attack rate in “home exposures” in the unvaccinated control groups was 87%. Similar high attack rates in susceptible children exposed in their own homes have been reported by others (Wheeler, 1936; Kendrick and Eldering, 1939; Court *et al.*, 1953). In the present study, taking all vaccines together, 547 children were exposed in their own homes; of these, 379 (69%) developed the disease. This attack rate is much nearer the 87% in the unvaccinated than the 18% in the vaccinated groups in the previous study. Furthermore, only one vaccine, V3b in the Oxford trial, gave a home exposure attack rate of less than 50%, and this was based on only 18 home exposures (Table IV). All the vaccines in this new series of trials were therefore poor.

Trials Made Between 1951 and 1954

11 trials were made in this series, in Cardiff, Leeds, Manchester, Oxford, Poole, Tottenham, and Wembley (Tottenham and Wembley were considered as a combined area). The Michigan Department of Health provided a vaccine—V8—in

sufficient quantity for it to be used as a reference vaccine against which the other vaccines could be compared. In each trial half the children were given the reference vaccine V8 and the remainder were given either one of three British vaccines—V9, V10, or V12—made by methods similar to those used by the Michigan Department of Health, or vaccine V11, which was prepared by the State of New York Department of Health from liquid medium culture (Cohen and Wheeler, 1946) using the same strains of *H. pertussis* as were used in the preparation of V8 (Table I). In each area except Oxford, two trials were made. Each vaccine except V9 was tested in parallel against V8 in two areas; V9 was tested against V8 in all areas except Oxford (Table V).

In all the areas the parents of 36,811 children 6 months to 3 years old agreed to have them vaccinated. Three intramuscular or subcutaneous injections were given at monthly intervals. Each dose was 1 ml., and the total dose consisted of 60,000 million organisms (U.S.A. opacity standard). Because of reports that convulsions might occasionally occur after pertussis vaccine, particularly in children with a personal or family history of convulsions or epilepsy, children with such a history were not vaccinated, and on account of this 1,601 children were not accepted. In addition, 2,108 children failed to arrive at the clinics for the first injections. Of the 33,102 who had their first injection, 31,557 (95%) completed the course.

When the trials began it was not known how many children might be presented for vaccination, as vaccination was becoming popular in the trial areas, and hence there was some difficulty in deciding whether all or only a portion of the children could be followed up. At first it was thought that it might suffice to follow only vaccinated children in families where there was also an unvaccinated child with no history of pertussis, such potential “home exposure” families being the ones from which it was known by experience that the most accurate information could be obtained. However, the proportion of children from such families was not more than 10%, and to avoid jeopardizing the studies by having too few children under observation it was decided to increase the numbers taken into the follow-up. After the first few weeks of the trial, approximately all the children were followed up in Cardiff, Oxford, Poole, Tottenham, and Wembley, and approximately half the children in Leeds and Manchester. The total number of children followed up was 19,005. In the areas where half the children were followed up, every second child presented for vaccination was chosen, and the others, though not followed up, were given a full course of vaccine.

Reactions and Untoward Sequelae

Local and General

One child in five from the follow-up groups was visited 48 hours after each injection to determine the incidence of local and general reactions. Children chosen for visiting after the first injection were also visited after the second and third injections. Nearly 10,500 visits were made. There was considerable variation in recording between areas, pre-

sumably due to observer differences, but very little difference within areas between vaccines and between the first, second, and third dose. Redness more than 2 in. (5 cm.) in diameter was noted on 6% of visits (not of children) and the child appeared “obviously disturbed by the tenderness” on 0.4% of visits. Other reactions noted were that three children were kept in bed for more than 24 hours, 99 vomited once or oftener within 48 hours after an injection, and 72 were described as “fretful,” “didn’t sleep,” or “had lost their appetites.” Local and general reactions were therefore not serious.

Convulsions

As in the 1948-51 series of trials, special notes were kept of children who developed convulsions after vaccination. Children not in the follow-up were visited after the first and second injections if they failed to return to the clinic for the next injection, and convulsions in these children were recorded if they occurred. The children not in the follow-up, however, were not visited after the third injection. All children known to have had convulsions, whether or not in the follow-up group, were visited at intervals until May, 1955.

A report by Byers and Moll (1948) indicated that in cases of encephalopathy associated with vaccination the first convulsion occurred within 72 hours after an injection. In this series of trials eight children had their first recorded convulsion within 72 hours after one of the three injections. It is impossible to say whether or not the number of cases observed was greater or less than might be expected to occur by chance in this period. Thirty-four children had their first recorded convulsion 4 to 28 days after injection. There is no reason to consider their convulsions were precipitated by the vaccine. Of them, 11 (32%) had more than one convulsion during the period of observation. Of the eight children who had convulsions within 72 hours after injection, three (38%) had more than one attack. The proportions of the two groups are similar and, though based on small numbers, suggest that serious cerebral damage, as manifested by repeated convulsions, did not occur as a result of the injections. None of the children with repeated convulsions showed evidence of gross cerebral damage such as was noted by Byers and Moll, but one child had five convulsions during the period of observation and two had four. These three children had their initial convulsions 12, 17, and 20 days after injection.

In over 30,000 vaccinated children, therefore, there was no definite evidence that convulsions or encephalopathy were directly related to vaccination. As previously stated, children with a personal or family history (the family for the purpose was taken to include only father, mother, sisters, and brothers) of convulsions, epilepsy, hydrocephalus, mental defect, or similar conditions were not accepted in the trial. In addition, children were not injected within a month after attacks of measles, mumps, influenza, chicken-pox, and similar diseases, or smallpox vaccination. These precautions may account for the freedom from cerebral accidents, but it may also be that the risk of

* Measles, chicken-pox, mumps, rubella.

are given in the last two columns of Table 1X.

It should be emphasized that these relative potencies are properties of the vaccines when tested at the same time. For example, V8 is shown as being about seven times as potent as G61. When these two vaccines were tested together, however, V8 was new and G61 was some two to three years old. If each vaccine gradually deteriorated it may be that V8, when new, had about the same potency as G61 when new. In the absence of a standard vaccine known to be stable, the possible deterioration of these vaccines cannot be measured with certainty. However, for almost every vaccine which was tested over a period of more than a year, the ImD_{50} values showed a gradual trend upwards. On the average, this was equal to about 0.2 logarithmic unit a year, equivalent to a loss of potency of 40% per annum. This trend may have been due to a gradual change in the test conditions or to a real deterioration of the vaccines, or both. When comparing the mouse-protection results with those of the field, it has been assumed that the trend was due entirely to deterioration of the vaccines.

The Mouse-Agglutination-Production Test

A number of vaccines were also tested for their ability to produce agglutinin in mice, using the method described by Evans and Perkins (1953, 1954). Groups of mice were given two spaced injections of vaccine separated by an interval of 14 days, and the geometric mean agglutinin titre of the sera was determined 10 days after the second dose. Since the method was introduced late during the field studies, it was not possible to test all vaccines extensively. However, 13 vaccines were tested—one from the previous trials and 12 from the new series. With each vaccine the agglutinin response to a total dose of 10×10^9 organisms was determined, and in the case of five of the vaccines the response to two additional smaller doses, 2.5×10^9 and 0.625×10^9 , was also obtained. Each vaccine was tested in parallel with a reference vaccine which gave only a slight variation in response in the different tests. The detailed results have already been reported (Evans and Perkins, 1953, 1954).

A rough comparison of the vaccines may be made from the results shown in Table XII, in which the response obtained with each of the 13 vaccines to a total dose of 10×10^9 organisms is given.

Production of Agglutinin in Children

Tests were made with 13 of the vaccines to determine their ability to produce specific agglutinin in children. Two independent studies were made. In the first, tests were made by Dr. Mary O. Adams on the sera of children immunized with vaccines V1 to V8 and V12. These sera were taken from children aged 6 to 18 months 2 to 10 months after their third inoculation, and the titrations were made using as antigen a suspension of living *H. pertussis* according to the method described by Evans and Adams (1952). In the second study the tests were made by Dr. Naomi Datta on the sera of children immunized with vaccines V8, V10, V11, and V12. These sera were from 2- to 5-year-old children, and were taken 6 to 10 weeks after the third dose of vaccine. The titrations were made by a method similar to that used by Dr. Adams, except that a killed suspension of *H. pertussis* was used as antigen. Similar results were obtained by both

workers in testing sera from children immunized with vaccines V8 and V12; more than 90% of the sera with these two vaccines gave titres of 16 or more in both studies. It was therefore considered justifiable to compare the vaccines by grouping the results of all the tests in spite of the fact that the tests had not all been made by a standard method (Table X).

TABLE X.—Comparison of Vaccines by the Agglutinin Response in Children

COMPARISON OF FIELD AND LABORATORY TESTS**Field Trials and Mouse-Protection Tests**

A comparison of the prophylactic effect of vaccines in the field is most safely made when the vaccines are tested at the same time in the same centres, otherwise the comparison may be distorted by changes in the field conditions or deterioration of the vaccines. These strict comparisons, made on the home-exposure attack rate for reasons given in the first section of this report, are presented in Table XI alongside the corresponding potencies estimated in the laboratory. Differences in either field or laboratory results which are significant at the 0.05 level of probability are also indicated.

Though field and mouse-protection test results occasionally put vaccines in different orders of potency, there are no definite contradictions; on no occasion was a significant

* These vaccines were not used at the same time, but a large part of the subsequent follow-up periods overlapped.

difference found in one direction in the field and in the opposite direction by the mouse-protection test. Furthermore, in certain comparisons, both field and mouse-protection test results gave significant differences in the same direction. These were: (a) that V3 was better than both V1 and V2, and (b) that both V3b and V4 were better than V2.

The results of Table XI may be supplemented by a rather less rigorous comparison of the field and mouse-protection test results for all vaccines. Table XII shows, for each vac-

cine; (a) the home-exposure attack rate for all children inoculated with that vaccine, and (b) the estimated potency-ratio by the mouse-protection test of the vaccine, at about the middle of the period during which it was used in the field, in comparison with the potency of G61 at the beginning of 1947. The assumption has been made here that each vaccine deteriorated at a rate of 0.2 log unit of potency each year. Thus vaccine V5a was used during a period centred at about the beginning of 1949. Its log-potency-ratio in comparison with G61 when tested simultaneously is given in Table IX as -0.159. We assume that G61 declined in potency by 0.2 log unit during each of the years 1947 and 1948. Then the log-potency-ratio of V5a at the beginning of 1949, in terms of G61 at the beginning of 1947, will be estimated at $-0.159 - 2(0.2) = -0.56$.

Chart showing the relationship, with 18 pertussis vaccines, between home exposure attack rate in the field and potency as estimated by the mouse-protection test.

The relationship between the home-exposure attack rates and the potency-ratios, estimated by the mouse-protection test, is shown in the Chart. There appears to be good correlation. In interpreting these results it should be remembered that both the attack rates and the potencies are subject to sampling errors which may have exaggerated or detracted from the true correlation, that attack rates are possibly subject to variations from one area or one period of time to another, and that the assumptions that the vaccines deteriorate at a constant rate of 0.2 log unit a year may be invalid. However, as the second column of Table XII shows, the different vaccines within each of the three groups were used in the field over fairly short periods of time. Consequently, a false assumption about the rate of deterioration would affect principally the relative potencies between the three groups rather than those within the groups. Even when attention is restricted to fluctuations within the three groups of vaccines, the correlation between the home-exposure attack rate and the potency-ratio is still significant. These results suggest that the mouse-protection test is of some value in predicting field results.

Field Trials and Agglutinin Tests

Table XII also shows for a number of vaccines the relationship between (a) the home exposure attack rate, (b) the agglutinin produced in mice to a dose of 10×10^9 organisms, and (c) the agglutinin produced in children to their course of immunization. It is evident that there is a close correlation between the production of agglutinin in mice and in children; of the 11 vaccines tested by both methods, 7 gave a poor response and 4 a decidedly higher response in both cases.

It is also evident that there is a general correlation between protection in the field and agglutinin response. Six vaccines which showed substantial protection each gave a good agglutinin response in mice, and four of these also gave a good response when tested in children. On the other hand, nine vaccines which showed poor protection each gave a poor agglutinin response in children, and seven of these also gave a poor response when tested in mice.

CONCLUSIONS

Two series of field trials were made in which 28,799 children were followed up for an average of two years after inoculation with pertussis vaccines. Severe local or general reactions were not encountered and there was insufficient evidence to show that pertussis vaccine precipitated repeated convulsions or initiated serious cerebral damage. In three cases of poliomyelitis which occurred within 28 days after injections, the site of paralysis was confined to the injected limb.

Fourteen batches of vaccine were used; their protective effect was assessed mainly on the basis of home-exposure attack rates. The nine batches of vaccine used in the first series of trials were poor, but the five batches used in the second series gave substantial protection.

As is shown in Table I, the vaccines in the first series were all made from the same strain of *H. pertussis*. They were prepared from 24- or 48-hour cultures on Bordet-Gengou medium containing horse blood or from culture in liquid medium. In all of them formalin was used as the killing agent, but some were preserved with phenol and others with thiomersalate. Between initial isolation and use in the vaccines, the strain had been repeatedly subcultured in the laboratory. The vaccines in the second series were made from a mixture of four, six, or seven freshly isolated strains which had been subcultured on very few occasions before being freeze-dried. Three vaccines were made using Bordet-Gengou medium containing sheep's blood, one using Bordet-Gengou medium containing human blood, and one using liquid medium. All were killed, and preserved with thiomersalate.

It is clear that the vaccines in the first series differed in many ways from those in the second series, but it is not

possible to say which of the differences were responsible for the widely divergent results.

The field studies showed that in the second series three vaccines (V9, V10, and V12) made in this country from strains of *H. pertussis* isolated here were as effective as the reference vaccine (V8) made with American strains and supplied by the Michigan Department of Health, and that the vaccine prepared by the State of New York Department of Health (V11) from the same American strains as the reference vaccine, but grown in liquid medium, was, in a preliminary trial, also as effective as the reference vaccine.

At the same time as the field trials were in progress, laboratory tests were made in which the vaccines were extensively tested for their ability to protect mice against intracerebral pertussis infection. Some of the vaccines were tested for their ability to produce agglutinin in mice, and sera from a number of vaccinated children were titrated for agglutinin.

There was a correlation between protection in children and three laboratory tests: (a) protection of mice against intracerebral infection with *H. pertussis*, (b) production of specific agglutinin in mice, and (c) production of specific agglutinin in children. Though the three laboratory tests gave results parallel with those obtained in the field, it does not necessarily follow that the laboratory tests measure directly the factor or factors responsible for the production of immunity in children. Pillemer and his colleagues (1954) have prepared from *H. pertussis* an antigenic fraction which protects mice against intracerebral infection, but which produces a very poor agglutinin response in mice (Evans and Perkins, 1955). The protective potency of this fraction in children is being tested at present in Liverpool and preliminary results suggest that it is giving protection. The mouse-agglutinin-production test therefore may not be a reliable guide to the value of all vaccines in children. Agglutinin production in children has been accepted by some workers as evidence of protective potency, and the tests reported here support this conclusion. Production of agglutinin, however, is only one of the properties of *H. pertussis* and may be different from, and not always run parallel with, protective potency. In any event it would scarcely be practicable to estimate the agglutinin response in children before each batch of vaccine produced commercially was issued for general use.

Of the three laboratory tests, therefore, the mouse intracerebral challenge test is considered, on the basis of present evidence, as the most satisfactory. It is correlated with protection in children, and in mice it measures protection from infection with a virulent strain of *H. pertussis*. A British standard pertussis vaccine has been established in terms of which the potency of other vaccines may be assayed by means of comparative tests. The standard has been prepared from vaccine V12 (Table I), which gave substantial protection in the field, by freeze-drying in 6% dextran. No instability has been detected in the dried standard, and its use in comparative tests will be the subject of a separate communication (Armitage and Perry, 1956).

In view of these results it would seem wise before the issue of a vaccine for use in children to submit it to the mouse intracerebral protection test to ensure that it has an adequate potency in relation to the British standard vaccine. It is also clear that a vaccine need not necessarily be made by the Michigan method; the results of the present trials show that one produced from cultures made in a liquid medium can give equally good results.

SUMMARY

In two series of field trials, 14 pertussis vaccines were tested for their protective potency in 28,799 children. The vaccines used in the first series of trials were poor, but those in the second series gave substantial protection, which was maintained for at least two and half to three years after vaccination.

At the same time as the field trials were in progress, laboratory tests were made in which the vaccines were tested for their ability to protect mice against intracerebral pertussis infection. Some of the vaccines were also tested for their ability to produce specific agglutinin in mice and in children.

A comparison between the field and laboratory results showed some correlation between the potency of vaccines in protecting children and their ability to protect mice against intracerebral infection. There was also evidence of a correlation between protection in children and ability to produce agglutinin in both mice and children.

It is concluded that in future only those pertussis vaccines which have been shown, by the intracerebral mouse-protection test, to have an adequate potency in relation to the British standard pertussis vaccine should be issued for use in children.

The Whooping-cough Immunization Committee of the Medical Research Council and the medical officers of health in the areas where the trials were made are grateful to the parents who consented to have their children injected. They wish to thank Glaxo Research Laboratories, the Lister Institute of Preventive Medicine, the Michigan Department of Health, the State of New York Department of Health, and the Wellcome Research Laboratories for the free supply of the pertussis vaccines, and the World Health Organization for its interest and for some financial help towards the cost of the second series of trials. They particularly wish to record their indebtedness to Dr. Pearl Kendrick, corresponding member of the Committee, who gave help and advice on the preparation of the vaccines during visits to this country and also by correspondence. The vaccine for the preparation of the British standard pertussis vaccine was generously provided by Glaxo Laboratories.

Medical Memorandum

Repeated Delayed Splenic Bleeding Into the Lesser Sac

Spontaneous rupture of a normal spleen is a rare occurrence, and only about 100 cases have been reported in the world's literature. The case described below appears to be the first recorded instance where haemorrhage took place almost entirely into the lesser sac of the peritoneum, and is the first example of spontaneous splenic rupture in a case of arterial hypertension.

CASE REPORT

A woman aged 29 was admitted to hospital on April 14, 1951. Two days previously she had been discharged from another hospital, having had an operation there about six weeks before "for bleeding from a mesenteric vessel." On the day of admission she took a laxative for constipation, after which generalized abdominal pain and vomiting began and continued up to the time she was examined (3 p.m.). On direct questioning she admitted that about 24 hours

previously she had had left shoulder-tip pain which had continued for several hours, but it had disappeared at the time of examination. She felt very weak. She said she had some "heart trouble," but that her symptoms of that complaint, chiefly headaches, had been much less noticeable during the past few weeks. Her last menstrual period was in February, 1951. No other symptoms were present. Her doctor sent her to hospital with a diagnosis of ? ruptured ectopic gestation, ? internal haemorrhage.

Two previous pregnancies were normal. She had had occasional bouts of epistaxis, heavy menstrual periods, and excessive bleeding following dental extractions. The previous hospital admission had been advised because of symptoms similar to those presenting now. In addition, whilst an in-patient there, about two weeks previously, she experienced a bout of abdominal pain and vomiting lasting a day or so, which was diagnosed as "gastritis." Her mother had died at 36 years of age from "a stroke."

The patient was a thin, pale woman, anaemic and shocked. The pulse rate was 130 a minute, temperature 97° F. (36.1° C.), respiratory rate 20, blood pressure 90/? mm. Hg. Examination revealed no gross cardiac enlargement; an apical systolic murmur was present. The lungs were normal. In the abdomen, distension was obvious. A healed scar extended from the pubis to half-way between the xiphoid and umbilicus. There was no rigidity, but generalized tenderness was found. Peristalsis was absent. Vaginal examination revealed no abnormality. Later, under general anaesthesia, a mass was palpable in the epigastrium. It was dull, and the dullness was continuous with liver dullness. A provisional diagnosis of intraperitoneal haemorrhage ? due to leaking splenic aneurysm was made.

After resuscitation, operation was undertaken on April 15. Through a midline epigastric incision the mass previously felt was seen to be the stomach pushed forward by a lesser sac full of old blood clot. There was unclotted blood in the greater sac. The spleen was adherent to the diaphragm and not easily mobilized, and it was removed; the splenic vessels had previously been ligated in continuity proximally, lest the site of section be placed distal to a ruptured aneurysm of the splenic artery. The abdomen was closed in layers and a stab drain inserted.

With the spleen were two splenuli and the tail of the pancreas. The weight of the total specimen was 450 g. Most of the upper half of the organ was occupied by old blood clot, which had disorganized the pulp. There was a tear in the capsule on the diaphragmatic surface of the spleen, but no large subcapsular haematoma otherwise. The haematoma surrounded the pedicle. No aneurysm was found. The splenic vein was thrombosed.

Convalescence was protracted owing to the development of a *Staphylococcus aureus* coagulase-positive bacteraemia, which was finally controlled with chlortetracycline. On discharge her blood pressure was 195/140 mm. Hg.

On August 11 she was readmitted because of intractable vomiting. She stated that polyuria and polydipsia had appeared since the operation. She died on September 17.

Post-mortem examination (Dr. E. Milford Ward): Tuberculous meningitis, without evidence of tuberculosis elsewhere, was found. Heart: marked hypertrophy of the left ventricle. Both kidneys were reduced in size. The capsules stripped with difficulty and the surfaces were coarsely scarred. Histologically they showed the picture of chronic non-suppurative pyelonephritis.

COMMENT

This was an interesting clinical problem of diagnosis. Common causes of severe anaemia (Hb 29%) in a female are nutritional, or due to bleeding from the genito-urinary or gastro-intestinal tracts. Other possibilities considered here were splenic infarction from subacute bacterial endocarditis, and polyarteritis nodosa acuta. But no other signs

of endocarditis were present, and muscle biopsy done at laparotomy was negative.

The presence of essential hypertension favoured the possibility of an arterial source of bleeding, such as a leaking aneurysm. Chevallier and Bernard (1944) have shown that vascular arterial lesions are the second commonest cause of haemoperitoneum in women, although occurring 25% less often than in men. It is rare to make a correct pre-operative diagnosis. Of 41 cases previously reported, only 2 were accurately diagnosed.

The occurrence of this case completes the possible anatomic-pathological picture of haemorrhage from the spleen. Recalling the fact that this organ lies in relation to two peritoneal lined cavities, and that a postero-lateral relationship to the kidney brings it into contact with an extra-peritoneal area, there are three possible ways in which symptoms and signs may present: (1) the commonest is bleeding into the greater sac, diagnosis often being confused with other causes of peritoneal irritation; (2) the next most frequent one is rupture into the lesser and greater sacs, a pancreatic lesion being most often diagnosed; and (3) the rarest is extraperitoneal extension into the loin, where a renal lesion is usually suspected. The present case is the first in which major and repeated bleeding took place into the lesser sac.

In several cases of normal spleens undergoing rupture a predisposing cause has been found. Undue mobility due to absence of the phrenico-colic ligament is said to occur in 2% of subjects (Susman, 1927). A vascular abnormality confined to the spleen—namely, angioma—has been once reported (Mondor and Boutron, 1938), but such a spleen is not truly "normal." Various alterations in contour with partial deficiency have also been found, but rupture did not always take place at the site of abnormality. It was impossible to discover a predisposing cause in this case.

The commonest event initiating spontaneous rupture is sudden increase in blood volume in the splenic vein. In the absence of any pertinent history this could not be established here. According to Price (1950) aseptic infarction of the spleen is commoner than realized and is often found in cardiac disease. In the absence of other evidence it must be assumed that this was the primary event in the present subject: an infarct was certainly shown microscopically.

Splenic histology is notoriously difficult to interpret. Wohl (1925) noted that, by the age of 36, 50% of spleens showed evidence of intimal thickening and hyaline change in the Malpighian bodies. Evidence of hypertensive disease is difficult to find unequivocally in this organ and was not found here, although other arteries in the body showed a characteristic histological picture of arterial hypertension.

It could not be established what the initial event producing haemorrhage was, and the relation of coexisting arterial hypertension remains speculative if not entirely coincidental.

I wish to thank Mr. J. C. Barrett for permission to publish this case and also Dr. E. Milford Ward, who reported on the specimens and performed the necropsy.

To help local authorities in their Clean Food campaigns the Ministry of Health has produced a new coloured poster on the theme "Hands Spread Germs." A series of pictures and slogans emphasizes the importance of covering cuts and sores, fingering food as little as possible, and washing hands thoroughly before preparing food.

Reviews

BIOCHEMISTRY AND PHYSIOLOGY OF
BONE

The Biochemistry and Physiology of Bone. Edited by Geoffrey H. Bourne. (Pp. 875; illustrated. £7 3s.) London: Academic Books Ltd. 1956.

This book comes out at a most suitable moment, since there is now an increasing interest in the subjects of bone diseases and of disorders of calcium metabolism. It consists of a series of articles by well-known authorities, who review in turn a wide range of subjects, starting with anatomical and structural matters and proceeding to the microscopy and ultrastructure of bone. It continues with further considerations of the growth of bone and of the effects of various vitamins and hormones. The articles naturally differ from each other in style and content, some comprising uncritical compendia of the work on the subject with full references, others being more critical and selective and therefore more readable. A good example of the latter is the chapter by F. C. McLean on the parathyroid glands and bone, which should do much to remove the many current misconceptions on this matter. The book does not deal, except in the most cursory manner, with many of the interesting current medical problems of bone disease and its treatment, but nevertheless it should be a useful work of reference for those whose specialty necessarily overlaps other specialties, in particular orthopaedic surgeons, paediatricians, and urogenital surgeons.

C. E. DENT.

COMPLICATIONS OF REGIONAL ANALGESIA

Complications of Regional Anesthesia: Etiology, Signs and Symptoms, Treatment. By Daniel C. Moore, M.D. (Pp. 291 + xv; illustrated. 75s.) Oxford: Blackwell Scientific Publications. 1956.

Regional analgesia for surgery is by and large a rarity in this country. A combination of a critical public, antipathetic surgical opinion, and a high standard of general anaesthesia have contributed to this state of affairs. On the other hand, nerve-blocks for a variety of therapeutic and diagnostic reasons are on the increase. A knowledge of the complications which may follow these procedures is therefore important, and a comprehensive review of these is now available. Drawing from his own large experience and from the literature, Dr. Moore includes not only the local and general complications of nerve-blocks, but also those of spinal and epidural analgesia. In a separate section entitled "Incidental Complications" he gives excellent brief accounts of such complications as atelectasis, amnesia, and retention of urine. This book, with its high standard of writing and illustration, is easily one of the best and most important in its field, the long list of references at the end of each chapter being particularly valuable. In case a comprehensive and scholarly book of this sort may give the wrong impression, the author himself writes as follows in his introduction: "Although this book is entirely devoted to the complications of regional block procedures, this should not be construed to mean that complications following regional nerve blocking occur frequently, or that this type of anesthesia is more dangerous than other types." This book is one of outstanding merit and will repay careful study.

W. W. MUSHIN.

STRESS

Fifth Annual Report on Stress, 1955-56. Edited by Hans Selye, M.D., Ph.D., D.Sc., F.R.S.(Canada), F.I.C.S., and Gunnar Heuser, M.D. (Pp. 815; illustrated. \$20.) New York: MD Publications Inc. 1956.

This *Annual Report on Stress* has the same editors and the same general format as its predecessor. The first 100 pages give the views of Selye on the general physiology and pathology of stress with emphasis on the stress concept as he

sees it in 1955, and a review of the principal lines of research in this field during the same year. The next 100 pages contain an excellent series of review articles by various workers: "Primary Aldosteronism, a New Clinical Entity," by J. W. Conn and L. H. Louis; "Hormonal Influences on Inflammation and Detoxification," by T. F. Dougherty and R. D. Higginbotham; "Stress and Catechol Hormones," by U. S. von Euler; "Adrenal Influences upon the Stomach and the Gastric Response to Stress," by S. J. Gray, C. G. Ramsey, R. Villarreal, and L. J. Krakauer; "Some Questions Relating to the Role of the Adrenal Cortex in the Etiology of Disease," by D. J. Ingle; "Adrenocortical Secretion and Factors Affecting that Secretion," by D. H. Nelson; "Neurosecretion," by E. Scharer; "Some Observations on Psychiatric Stress in Infancy," by R. A. Spitz; and "Cortisone in Relation to Lymphoid Tissue and Immunity," by H. C. Stoerk. The special physiology and pathology of stress occupy the next 340 pages and take the form, now usual in these volumes, of a series of annotations of the results described in the many publications covered. I had some difficulty at first in finding the way through this section, but the table of contents and the index were of use in this respect. The alphabetical list of between 5,000 and 6,000 references, complete with titles, forms one of the most valuable sections. A reference copy of this book should certainly be available in every medical library.

G. W. HARRIS.

SKIN TUMOURS

Tumors of the Skin. By Herbert Conway, B.S., M.S., M.B., M.D., F.A.C.S. (Pp. 267 + xiv; illustrated. 97s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The first half of this book is devoted to benign tumours and is well presented, though it is not as complete as one would expect in a work devoted solely to the subject of skin tumours. The text opens, for instance, with sebaceous cysts, but no mention is made of their naevoid and familial features or of the association with intestinal polyposis and cancer. The only treatment mentioned is surgical excision. Angiomata are adequately reviewed, though the author does not seem convinced that true cavernous angiomata can recover spontaneously. In relation to malignant lesions, which take up the latter half of the book, the field is again not covered in detail, as might be expected, and much space is given to illustration of surgical procedures. A good deal more text might usefully have been devoted to fuller clinical descriptions of the ordinary basal and squamous-celled carcinomata and to the causative and predisposing factors. Very much more might have been said of the intra-epidermal and superficial carcinomata. The erythroplasia of Queyrat is mentioned, but not the plasma-celled balanitis which exactly mimics this type of carcinoma but is purely inflammatory. There is no mention of the cranioparietal and telangiectatic carcinomata of skin seen particularly in relation to breast cancer, nor is there adequate discussion of the mode of spread in the skin. It is now well recognized that a lesion described under the terms "molluscum sebaceum," "kerato-acanthoma," or "pseudo-epithelioma" has until the last few years been diagnosed by clinicians and pathologists alike as an acute epithelioma, whereas the condition is benign and clears spontaneously. This disease is not mentioned. The impression is given that all malignant melanomata are gravely malignant. The lentigo maligna, the relatively benign type seen particularly in the elderly, is not discussed.

The approach to the problem of skin tumours is very much that of the surgeon, and especially the plastic surgeon. For the student there is not much more than he will get in the ordinary textbook, and the work is not adequate for the specialist. Nevertheless it is of value to have a consideration of neoplasms in this fashion, and the book will, as the author intends, serve as a ready reference text and as an aid to diagnosis. It is well produced and the numerous illustrations are good.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY AUGUST 25 1956

HYPOGLYCAEMIC SULPHONAMIDES

Ten months ago two groups of German physicians^{1 2} announced that many diabetics could dispense with insulin injections and have their diabetes treated by tablets. The drug used was a sulphonamide, sulphanilyl-*n*-butylurea (BZ 55, "carbutamide," "invenol," "nadisan"). As Professor F. G. Young points out in the opening article in this week's *Journal*, the discovery that some sulphonamides had a hypoglycaemic action was by no means new, for it was originally reported by M. Janbon and his colleagues³ in Montpellier in 1942, and French workers⁴ have been studying the biochemical mechanisms involved since that time. It was in Germany, however, that these drugs were first used on a large scale for the treatment of diabetes. The original reports made it clear that BZ 55 had no place in the treatment of the young insulin-deficient diabetic, but it was claimed that many of the older more stable diabetics could use it instead of insulin injections. Even with this limitation the reports aroused great interest both among diabetic patients and among their doctors. The Hamburg results were brought up to date by a further article from F. Bertram and his colleagues⁵ early this year, and reports from other countries in Europe⁶⁻¹¹ and elsewhere¹²⁻¹⁵ have confirmed the German claims.

In Britain and in the United States there was considerable scepticism. From observation of the German clinics it was clear that too many of their diabetics were treated with insulin, and that dietary control was largely ignored even in the grossly obese; and it was felt that although in Germany these patients might be treated with insulin and could be switched satisfactorily to BZ 55, in a British clinic many would be dieted without insulin and that BZ 55, even if the German claims were sustained, would be indicated only in comparatively few cases. Another reason for scepticism was the uncertainty over the way in which the drugs produced their effect on the blood sugar, and the possibility that long-continued use would lead to undesirable metabolic or enzymatic disturbances. Finally, the record of the sulphonamides as a cause of fatal toxic reactions, blood dyscrasias, and allergic responses is a bad one, and it seemed unlikely that any member of this group of drugs could be given safely for a period of years.

Dangerous side-effects may have to be accepted if the drug in question is the only one that can be used for a seriously ill patient; with mild diabetics, however, there is already a safe physiological remedy available, and any proposed alternative must be equally innocuous.

We publish this week six articles reporting the observations of British workers who have been treating patients with this drug. The reports from Edinburgh (p. 433) and the Whittington Hospital in London (p. 440) are accounts of extensive in-patient trials. Out-patient experience or less comprehensive in-patient studies are reported from King's College Hospital (p. 445) and the Middlesex Hospital in London (p. 451) and from Dundee (p. 448) and Glasgow (p. 452). A total of 193 patients are reviewed; of these about 170 fulfilled the German criteria as being likely to respond to BZ 55 and 125 did so (73%). These studies confirm that the type of patient responsive to this treatment is the middle-aged or elderly diabetic who has never had ketosis and who needs less than thirty units per day of insulin (a few patients on larger doses did respond satisfactorily). The report from the Whittington Hospital suggests that if the fasting blood sugar after stopping insulin is over 275 mg. per 100 ml. satisfactory response is unlikely. In general, grossly obese subjects were excluded from the British trials. One point that the reports bring out is the danger of stopping insulin in what seems to be a suitable stable diabetic not apparently liable to ketosis. Several clinics encountered patients of this type who developed severe diabetic ketosis within a few days, and it is clear that if transfer of an insulin-taking diabetic to sulphonamide therapy is contemplated the patient must either be seen daily after stopping the insulin or admitted to hospital.

Attempts were made to select suitable cases by a test in which the blood sugar is followed for five or six hours after a large oral dose of the drug. The results were disappointing, but it does seem that good selection can be made purely on clinical grounds, one group of workers having 23 successes out of 24 patients.

The most disturbing feature of the British reports is the description of the side-effects observed. Both in this country and abroad sulphonamide rashes have been encountered: the incidence in this British series of cases is about 9%, but the rash invariably cleared when the drug was stopped. Much more serious are the alterations in the blood picture. The original German reports^{1,2} stated specifically that there were no changes in the blood count. From the United States there has been a report¹⁵ of severe leucopenia (1,900 W.B.C. per c.mm.) and from the Middlesex Hospital in this country (p. 451) of neutropenia (2,100 W.B.C. per c.mm.; 10% polymorphs). The Edinburgh workers mention persistent leucopenia, and L. W. Kinsell and his colleagues¹⁶ have seen leucopenia with bigger doses. One patient who developed severe leucopenia was kept on the drug and the blood count returned to normal¹²—a procedure that few would recommend. In Edinburgh thrombocytopenia was found in eight patients and purpura occurred in two. Fatal reactions believed to be due to BZ 55 have occurred in the United States—in one case agranulocytosis was the cause and in another sulphonamide allergy of the type described by R. H. More and his colleagues¹⁷ ten years ago. It is not yet known where the BZ 55 used in these cases was manufactured. The possibility of some impurity cannot be excluded, although it seems unlikely, and we wish particularly to draw attention to "A Warning Note" published at p. 454 in this issue. It is the considered opinion of the signatories of this note that BZ 55 should at present be used only under careful hospital supervision, and some would even go further and recommend the discontinuance of trials until more is known about the toxicity of the drug.

The possible danger attached to the use of BZ 55 has increased the importance of another hypoglycaemic compound recently described (D 860, "rastinon," "orinase").¹⁸ BZ 55 has the formula

D 860 is *p*-tolylsulphonyl-*n*-butylurea

It differs from BZ 55 in having a methyl group instead of an amino group on the benzene ring and might therefore have less tendency to produce blood dyscrasias; this substitution also leads to loss of

all antibacterial action. Clinical reports¹⁹⁻²³ show that it is as effective as BZ 55, with perhaps less tendency to produce skin reactions, and as yet there are no reports of any blood dyscrasias. Because of the loss of the amino group the concentration of the drug in the blood cannot be estimated by the procedure devised by Bratton and Marshall, although a method by which it can be done has been worked out.²⁴ It is excreted in the urine as an oxidation product which may give a false positive reaction in the sulphosalicylic acid test for proteinuria.²⁵ The drug is now undergoing trial at a number of centres in this country, but after the experience with BZ 55 it will be some time before any recommendations can be made.

The mode of action of the hypoglycaemic sulphonamides remains obscure despite a year's intensive research in many countries. German workers have suggested that these compounds damaged the α -cells of the pancreatic islets and stopped the production of the hormone glucagon, which raises the blood sugar.²⁶ The changes in the α -cells, however, are inconsistent, and other possibilities have to be considered. C. H. Best²⁷ has recently reviewed the position. Indirect action through another endocrine gland has been excluded. It seems clear that some insulin must be present for the compounds to have a hypoglycaemic action. The possibility that they increase insulin production, originally suggested by A. Loubatières,²⁸ has been further studied by R. E. Haist²⁹ in Toronto, who gave very large doses of BZ 55 to rats and noted islet hypertrophy. A second theory of their mode of action is that they interfere with insulin destruction, and I. A. Mirsky³⁰ has reported that both BZ 55 and D 860 reduce insulinase activity of the rat liver. The third possibility is that they potentiate insulin by action on enzymes, probably in the liver.³¹ It has been established that the release of glucose from liver slices is reduced by these compounds,³²⁻³⁴ but information about how this is achieved is not yet available.

There can be no doubt that the hypoglycaemic sulphonamides will lower the blood sugar in many mild, stable, middle-aged diabetics. Some of these patients who need insulin to keep their blood sugar at a reasonable level may be able to dispense with injections and take tablets instead. But the action of these compounds differs from that of insulin,²⁴ and although they may lower the blood sugar they need not necessarily correct the other metabolic disturbances of diabetes. The British and American experience suggests that BZ 55 is a dangerous substance unsuitable for long-term control of mild diabetics. D 860 may prove safer, but prolonged trial will be needed. Three questions have to be answered about this compound and other similar ones that may be produced. First, do they ever produce dangerous

side-effects? Secondly, what exactly is their mode of action? If it is by enzyme inhibition, can this be harmful if continued for years? Thirdly, although the blood sugar may be lowered by these compounds, do they correct the other metabolic consequences of diabetes? Will they prevent the development of retinitis and nephropathy? It will take a long time to obtain satisfactory answers to these questions, and until they are answered the hypoglycaemic sulphonamides must be regarded as experimental and used only under strictest supervision.

IMMUNIZATION AGAINST WHOOPIING-COUGH

Five years ago we published the report¹ of the Medical Research Council's Whooping-Cough Immunization Committee on a series of controlled trials of pertussis vaccine. In these trials batches of vaccine from three manufacturers, two American and one British, were put to the final test of efficacy: the incidence of whooping-cough was measured by careful observation over a period of 24 months or more in a group of children 6 to 18 months old and compared with that in a similar group injected only with an anticatarrhal vaccine. The parents of all the children had agreed to their inclusion in the trial and the children were allocated randomly to the groups receiving pertussis or anticatarrhal vaccines, so that neither parents nor the medical staff observing the children knew which vaccine any individual child had received. All the batches of vaccine thus tested provided substantial protection, the attack rates being less and the disease when it occurred milder in the vaccinated than in the control children. Commenting on this report at the time, we wrote: "What is particularly needed now is some laboratory yardstick which will differentiate between good and poor vaccines," and in fact it has been the lack of a satisfactory test to measure the antigenic potency of pertussis vaccines that has delayed official approval of combined diphtheria-pertussis prophylactics. Before the controlled trials were completed further field trials in conjunction with laboratory tests had already been started in an attempt to provide this yardstick, and the report on these combined investigations appears elsewhere in this issue (p. 454). Because of the success of vaccine in the controlled trials it was no longer possible to have a control group given a placebo, and instead two or more vaccines were compared in parallel in each subsequent trial. In each of

the series of seven trials carried out during the years 1948 to 1951 volunteer children were allocated in rotation to groups receiving three British vaccines: in total nine batches of vaccine prepared from the same strain of *H. pertussis* by several different methods were used, and just under 10,000 children kept under observation. In the 1951-4 series of eleven trials five vaccines were used, each prepared from several strains of *H. pertussis*. A large batch from the Michigan Department of Health, whose vaccine gave greatest protection in the original controlled trials, was used in about half the children in each trial. The other half were given one of three British vaccines prepared by the Michigan method or one made by the State of New York Department of Health from liquid-medium culture of the same strains used in the Michigan vaccine. The 19,000 children observed in these later trials were allocated to the group receiving the Michigan reference vaccine or to the group receiving the other vaccines according to whether their birthdays fell on odd or even days of the month. In other respects the conduct of the trials in both series followed the pattern of the earlier controlled trials, and the performance of the vaccines was assessed by measuring the incidence of pertussis in three ways—the attack rate per 1,000 "child-months" of observation, the percentage attack rate in children exposed to infection in their own homes, and the percentage attack rate in children exposed elsewhere.

No large differences were observed between the protection afforded by the vaccines used in the 1948-51 series of trials or between those used in the 1951-4 series. However, all three measures of incidence were substantially lower in the latter trials. For example, the attack rate in the 1948-51 series among children exposed to the disease in their homes was 69% overall, and in only one small trial was less than 50%. In 1951-4 this was 14% overall, with a maximum of 29% in one trial. In all the previous controlled trials combined, the corresponding rate was 87% for unvaccinated and 18% for vaccinated children, suggesting that unless the infectivity of pertussis or the general level of immunity had changed considerably the 1948-51 series of vaccines were poor, whereas all the 1951-4 series were probably giving good protection. Although there was no control group to substantiate this interpretation it was neatly confirmed in the 1951-4 studies. In three of the larger participating areas records were kept of the incidence of pertussis in households in which vaccinated children and their unvaccinated siblings were exposed to infection by a primary case in the family. In 56 such households there were 69 vaccinated and

¹ The Prevention of Whooping-Cough by Vaccination—A Medical Research Council Investigation, *British Medical Journal*, 1951, 1, 1463.
² *Lancet*, 1954, 1, 1257.

62 unvaccinated children exposed to risk. Only fourteen (20%) of the vaccinated developed pertussis compared with 51 (82%) of the unvaccinated.

The laboratory investigations conducted in parallel with these field trials were of three kinds—the mouse-protection test, the measurement of the ability of the vaccines to produce agglutinin in mice (the mouse-agglutination-production test), and the measurement of the ability of the vaccines to produce agglutinin in children. In the first of these tests mice were injected intraperitoneally with graded doses of vaccine, and the level of protection measured by injecting 14 days later a challenge dose of virulent *H. pertussis* intracerebrally. An alternative test by which the challenge dose of bacteria was given intranasally was found to be less sensitive and was abandoned. From the proportion of deaths observed within 14 days of challenge, the dose of vaccine required to protect 50% of animals (ImD_{50}) was calculated. In each test two vaccines were compared simultaneously, one of which was a reference vaccine. The error of this test was found to be large despite careful standardization of reagents, procedures, and the use of mice of inbred stock. In all, 18 vaccines, including some used in the controlled field trials, were tested by this method. The tests were carried out over a period of years, and from repeated tests on the same vaccines the ImD_{50} values suggested a deterioration of about 40% in potency per annum, and this assumption was made when the final order of potency for the vaccines was calculated from the results of this test. The mouse-agglutination-production test was introduced late in the field studies and could not be applied to all the vaccines. Groups of mice were given two injections at a 14-day interval and the agglutinin titre determined 10 days after the second dose. The vaccines were graded according to the agglutinin response to a fixed dose of organisms. Two independent studies were made of the ability of some of the vaccines used in the field to produce specific agglutinin in children. The technical details differed in some particulars, but the results obtained on the same vaccines were similar and the two series were combined in grading the vaccines thus tested.

The results of these three laboratory tests were related to the attack rate among vaccinated children exposed to the disease in their own homes—the most stable measure of performance of a vaccine in the field. The report states that though field and mouse-protection tests occasionally put vaccines in different orders of potency there were no definite contradictions, and the general correlation, though not high, suggested that the mouse-protection test was of some value in predicting the efficacy of a vaccine in pro-

tecting children against pertussis. There was a close correlation between the production of agglutinin in mice and in children, and a definite but less close correlation between the results of these tests and prophylactic potency of the vaccines judged by the field trials.

Although there is correlation between the protection of children in the field and the results of the three laboratory tests, it does not follow that the laboratory tests measure directly the factor responsible for producing immunity in children, and this must influence the choice of test for standardization of commercial vaccines. As a yardstick the production of agglutinin in mice might be favoured had not L. Pillemer and his colleagues² at Western Reserve University prepared from *H. pertussis* an antigenic fraction which protected mice against intracerebral infection but gave a very poor agglutinin response. This antigen is now undergoing test in a field trial in this country. It would plainly be impracticable to estimate the agglutinin response in children before each batch of vaccine produced commercially was issued for general use, and the M.R.C. report therefore recommends that in future only those vaccines which have been shown by the intracerebral mouse-protection test to have an adequate potency should be released. In order to establish a British standard pertussis vaccine for use in such comparative tests, one of the British vaccines which gave substantial protection in the field in the 1951-4 trials has been freeze-dried, and this dried product, unlike the parent liquid vaccine, has shown no instability. Since vaccines made by both Michigan methods and from cultures made in a liquid medium gave equally good results, the report makes no specific recommendations about the appropriate method of manufacture.

AN EXTERNAL DEFIBRILLATOR

A defibrillator—an apparatus for applying an electric current directly to the exposed heart—is now generally accepted as a necessary piece of emergency equipment during cardiac operations, and defibrillation with this instrument combined with cardiac massage has now proved a safe and effective method of treatment. The use of the defibrillator presupposes that the patient is in the operating theatre with the heart exposed or that immediate facilities are available for doing this. Apart from surgical or anaesthetic emergencies, however, ventricular fibrillation may be a cause of sudden death in cardiac infarction, Stokes-Adams disease, and toxic reactions to digitalis, quinidine, or procaine amide. In these conditions facilities for opening the chest, applying the defibrillator, and performing cardiac massage are seldom

² Beck, C. S., Weckesser, E. C., and Barry, F. M., *J. Amer. med. Ass.*, 1956, 161, 434.

⁴ Zoll, P. M., et al., *New Engl. J. Med.*, 1956, 254, 727.

available, though C. S. Beck and his colleagues³ at Cleveland have recently described the revival by these means of a physician who "died" from a heart attack outside a hospital and was having cardiac massage in an operating theatre within five minutes: the ventricles were found to be in coarse fibrillation, and after several unsuccessful shocks defibrillation was at last achieved half an hour after the onset of the attack. The patient made a good recovery.

P. M. Zoll and his colleagues⁴ at Boston have now described the termination of ventricular fibrillation in man by externally applied electric shock. The external defibrillator is built on the same principle as a direct defibrillator, but the strength of the countershock applied is much greater, the voltage used being in the region of 200 to 700 volts instead of 120 to 150 volts in the case of the direct defibrillator. Large copper electrodes, mounted on heavily insulated handles and smeared with electrode paste, are held firmly in place against the chest wall, one to the left of the sternum and the other on the anterior axillary line. The duration of the current applied is fixed at 0.15 second. Defibrillation was successfully achieved with this instrument in four patients. The episodes of ventricular fibrillation occurred in the course of myocardial infarction, after intravenous procaine amide for rapid arrhythmia, in digitalis intoxication, and in Stokes-Adams disease. Although defibrillation was achieved eleven times in these patients, only the patient with Stokes-Adams disease recovered, and he was also the only patient in whom resuscitation was accomplished within two to four minutes of the onset of fibrillation, the interval in the remaining patients being not less than seven minutes.

The external defibrillator represents a real advance in methods of resuscitation, but in spite of its theoretical advantages in the avoidance of a thoracotomy its usefulness will probably prove to be restricted. For successful resuscitation it must probably be applied within less than five minutes of the onset of fibrillation, which presupposes that the instrument is already set up by the patient's bedside and that an electrocardiogram is also immediately available—conditions which are very unlikely to be fulfilled unless the episode of ventricular fibrillation has been anticipated.

OPIUM IN INDIA

Attempts to suppress the abuse of opium and its derivatives and to limit the supply to their indispensable administration for the relief of pain have been made by various International Conventions, from the first in 1912 until the most recent Opium Protocol of the United Nations in 1953. A comprehensive survey of the opium position, both past and present, in India has been made by Sir Ram Nath Chopra,¹ focusing attention on its quasi-medical use as distinct from addiction or legitimate therapy. As early as 1813 the Government of India attempted to restrict the habit of opium eating, but in 1895 a Royal Commission concluded that the consumption of opium by adults and its administration to children were based on an age-long tradition of belief

in its efficacy as a common domestic remedy, and that this generally moderate use had not resulted in any extensive physical or moral degradation. This view was upheld in 1911 by the representative of the British Government, Lord Harding, who stated that it would not be practicable to draw a distinction between the medical and non-medical uses in the distribution and sale of the drug and that it was not necessary to prohibit the manufacture and sale of opium except for medical purposes in British India. In spite of the criticism, both local and international, evoked by this policy it was not until 1946 that the Government of India decided at first to prohibit the smoking of opium and later to discourage its production except for medical and scientific use.

Opium has been extensively used by Hindu and Mohammedan physicians since the fifteenth century, both internally and externally as a "paint" application, for the alleviation of pain such as headache and toothache, and for its astringent qualities in diarrhoea and dysentery. In 1928 an investigation by Chopra and his co-workers into the problem of opium consumption in India showed, surprisingly, that only a small fraction of the population indulged in opium so habitually as to become addicts, and that when addiction did follow it was usually initiated by its use for some disease or ailment. The drugging of infants as a cure for abdominal discomfort, diarrhoea, and teething troubles, and also to keep them quiet while the mother was at work, was undoubtedly very prevalent in certain parts of India up to about 1934. The dosage, said to be equal in weight to a poppy seed— $\frac{1}{16}$ gr. (12-24 mg.)—was generally begun at the age of three weeks to three months, and increased gradually to obtain the desired effect. Most of these children were small, emaciated, and anaemic, with protuberant abdomens, conjunctivitis, corneal ulcers, and purulent otitis media. With adults, the quasi-medical consumption of various preparations and infusions made from the unlanced capsules of the poppy heads has long been a favourite method of indulgence in the drug, particularly the beverage known as "post." The average daily amount of 5 to 10 capsules, soaked in water, strained, diluted, and mixed with sugar, gives a dose of 3-5 gr. (0.2-0.32 g.) of alkaloids, comprising a very small quantity of morphine and large quantities of narcotine, papaverine, and codeine, which appear to act more as stimulants than depressants and are probably responsible for the euphoric effect of this beverage. About 40% of habitués to "post" begin to take it in the hope of curing some ailment or illness, but when addiction is established, even with small doses, mental and physical deterioration follows, with symptoms of chronic poisoning of the nervous system, varying from excitation to eventual complete paralytic breakdown.

The smoking of opium has never presented such a serious problem of addiction in India as in China, and, except for the relatively small number of registered smokers (2,519 in 1954), is now subject to severe restrictions. Quasi-medical consumption has diminished during the last decade, owing partly to the extension of

¹ *Bull. Narcot.*, 1955, 7.

medical relief services, which remove the chief initial cause of the habit and its progress to addiction, but chiefly to the measures taken following the All India Opium Conference of 1949, particularly the recommendation which relates to "effective steps to bring down the per capita consumption to a level not exceeding the League of Nations limit" (12 lb. (5.4 kg.) for every 10,000 of population). These measures have resulted already in a decrease in consumption of about 45%. With strict control of the cultivation of the poppy, enforcement of the Dangerous Drugs Act, and legislation controlling the sale of opium, the quasi-medical use of such preparations as "post" is expected to cease entirely in the near future, and the problem of the consumption of opium in India as it existed before 1948 will no longer exist.

SJÖGREN'S SYNDROME

From 1888, when W. B. Hadden¹ first described the symptoms of what is now known as Sjögren's syndrome, to the review of it in 1956 by M. Thompson and S. Eadie,² the relationship of the ocular abnormality to the arthritic lesions of rheumatoid disease has remained obscure. The early observations of H. Gougerot,³ A. W. M. Houwer,⁴ and H. Sjögren⁵ were made primarily from the ophthalmologist's point of view, and the widespread nature of the lesions was not generally appreciated. Now that the diagnosis is made more often it is generally agreed that kerato-conjunctivitis sicca is the essential clinical feature of Sjögren's syndrome, but well-established cases exhibit dryness of the mouth, parotid swellings, rhinitis sicca, and in two-thirds of the cases a rheumatoid type of arthritis. This variable clinical picture has been further confused by the inclusion of such disorders as Raynaud's phenomenon, skin changes of various kinds, both hyper- and hypoglycaemia, epilepsy and mental changes, achlorhydria and indigestion, to mention but a few. Some of these associations are undoubtedly coincidental, and recently the limits of the syndrome have become more clearly defined.

Of the 18 cases investigated by Thompson and Eadie, 14 (77%) suffered from rheumatoid arthritis, an equal number complained of dryness of the mouth, and 66% showed signs of laryngo-pharyngo-rhinitis sicca. These authors examined 210 patients with rheumatoid arthritis and found the incidence of kerato-conjunctivitis sicca to be 14.3%—a figure which agrees well with that of 13.4% given by S. Holm⁶ and 11% by T. Stenstam.⁷ Indeed, Holm found that kerato-conjunctivitis was a more common complication of rheumatoid arthritis than iritis, the incidence of which was only 1.2%. The question remains whether an association of this order of frequency indicates a pathogenetic connexion between the ocular and arthritic lesions. J. W. Henderson⁸ and P. Ellman and his colleagues⁹ are not entirely convinced that arthritis is an integral part of the syndrome. They point out that clear-cut evidence of Sjögren's syndrome is rare in women with rheumatoid arthritis, which

itself is a common disease. On the other hand, two-thirds of patients with kerato-conjunctivitis sicca have frank arthritis or fleeting arthralgia, and many observers are prepared to consider both groups of symptoms as manifestations of a common rheumatic process.^{6 10 11} Further evidence that this is so is now being brought to light. K. J. Gurling¹² has reported the association of Felty's and Sjögren's syndromes and uncovered in the literature several examples in which the features of both syndromes were present. Thompson and Eadie have also encountered the same combination, and it is of interest that D. H. Collins¹³ reported that the symptoms and signs of Still's disease—another rheumatic disorder in the group of collagen diseases—could develop into those of Felty's syndrome, which is characterized by chronic arthritis, splenomegaly, and leucopenia. Disease of the joints is a feature in all three disorders.

The lack of opportunities for examining post-mortem material has hindered the understanding of the basic pathological changes, most studies being based on biopsy specimens from the conjunctiva and the lacrimal or parotid glands. Although Sjögren⁵ recorded the necropsy findings in one case in 1933, B. C. Cardell and K. J. Gurling¹⁴ could find by 1954 no more than seven single case reports in the literature, to which they added three. They concluded that Sjögren's syndrome was a distinct entity characterized by widespread degenerative and atrophic changes in the conjunctivae, lacrimal and salivary glands, and the submucous glands of the respiratory and upper alimentary tracts, with secondary changes in the particular mucous membranes; and they were impressed by the resemblance of the histological changes in the affected glands to certain non-inflammatory lesions of the thyroid. In the early stages lymphocytic infiltration predominates, giving way after a number of years to parenchymal atrophy and replacement with fibro-adipose tissue containing peculiar epithelial islets. It is worth noting that evidence of polyarteritis nodosa was found in 2 of the 10 cases examined at necropsy. Those with the urge to classify may with some justification place Sjögren's syndrome with rheumatoid arthritis among the diseases of collagen; but this does little to increase our knowledge of this strange and unpleasant disease.

Air Vice-Marshal P. B. Lee Potter has been appointed Director-General of the R.A.F. Medical Services from February, 1957, in succession to Air Marshal Sir James Kilpatrick.

SOME PRINCIPLES AND METHODS OF INTERNATIONAL HEALTH WORK

BY

H. S. GEAR, M.D., D.P.H., D.T.M.&H.

Assistant Director-General, World Health Organization,
Geneva

Increasing numbers of the medical and related professions of all countries are taking part in the work of the World Health Organization. They do so as W.H.O. consultants and advisers to the large number of countries which seek assistance from the Organization; as members of W.H.O. panels and committees giving the necessary technical guidance to the Organization; as contributors of technical information; and as members of the large number of national institutions contributing to world services concerning epidemiology, health statistics, therapeutic substances, medical education, communicable diseases, and many other subjects.

This relationship is different from that of the full regular staff members. It is also a much more comprehensive relationship. At December 31, 1955, for example, W.H.O. had 152 medical and related scientists on its regular staff. These occupied mostly medical and technical administrative posts, as the Organization does not have its own clinical, laboratory, or other medical institutes. On the other hand, at the same date W.H.O. was using 295 senior consultants, advisers, and demonstrators in 63 countries and territories, and during 1955 appointed 59 specialists to serve on eight of its expert committees. In addition, large numbers of medical and other associated scientists from the majority of countries attended a variety of meetings, conferences, seminars, study groups, etc., sponsored by the Organization. There were representatives from every branch of medicine—clinical, institutional, laboratory, and administrative. Such a relatively large number of medical people helping W.H.O. each year makes some of its arrangements and methods especially important to the medical and related professions.

Constitution of W.H.O.

There is no need here to give the history of international health co-operation or to consider the detail of the W.H.O. constitution or organization. Much of this has been given previously in the *British Medical Journal*.¹ It is perhaps enough to say that the overwhelming need for an international health body developed not only from medical but also from welfare, social, and economic requirements in all countries. The consequent formal association of countries already has a history of over a hundred years, of which W.H.O. is the present expression.

The countries of the world created W.H.O. to do on their behalf such things as providing appropriate international health services; giving technical information and counsel; assisting governments to meet their health needs; and, of especial importance in view of events, co-ordinating international health work. Arrangements were made for universal membership of States. To-day, with 81 Member States and four Associate Members, such universality has almost been obtained (though a certain few governments do not take an active part). The governments also authorized the basis for W.H.O.'s administration, including authorities for staff, finance, regionalization, and relations with other organizations.

It is in the Constitution that the principles are found which explain the arrangements and methods used by W.H.O. The

¹ *British Medical Journal*, 1950, 1, 1021-51.

Constitution is itself based on the concept of an association of sovereign States. If this principle is constantly recalled, the way W.H.O. works will usually be understood. Put conversely, W.H.O. is not a form of supranational organization. As Mr. Hammarskjöld, the Secretary-General of U.N., put it at the Pilgrims' Dinner in London on March 18, 1954, when referring to the United Nations: "We need to think of the institutions of the United Nations not as parliamentary in character but as a framework within which the Governments can, by trial and error, build up traditions of world community. . . ."

The important consequence of this is often overlooked—namely, that an international organization like W.H.O. does not itself directly control or undertake medical and health programmes in countries. It is the national services assisted by W.H.O. that give effect to the field programmes adopted by the World Health Assembly.

Nature of the Organization

The Constitution provides for an intergovernmental policy-making organ—the World Health Assembly. This has an Executive Board of eighteen individuals designated by as many governments, and there is then an administrative machine—the Secretariat—to carry out the instructions of the policy-making bodies. The constitutional character, and the developing mode of operation of these two, the Assembly and the Board, are themselves worthy of study, but for present purposes one emphasis is required. The World Health Assembly is a meeting of governments. It is not a gathering of medical men in a professional congress or conference. It is essential, therefore, and quite legitimate, for the Health Assembly in establishing international health programmes to take note of many factors—economic, administrative, and even political—which a purely medical or technical meeting could perhaps ignore. As W.H.O. is an intergovernmental and not a supragovernmental body its resolutions are normally recommendations to governments for action. It is to be noted, with a few specific exceptions, that even the decisions of the Health Assembly are not automatically binding on governments.

The Secretariat, headed by the Director-General, operates in and from seven offices—the Headquarters in Geneva and the six Regional Offices: temporarily in Geneva (presently to be in Copenhagen) for Europe; Washington, D.C., for the Americas; Manila for the Western Pacific; New Delhi for South-East Asia; Alexandria for the Eastern Mediterranean; and Brazzaville for Africa. The Secretariat is an international civil service. It is not a policy-making body, and it is not its own master.

These are further facts which, if always remembered, would simplify understanding and avoid frustrations among some medical and technical groups associated with W.H.O. It is the governments, not the Secretariat, which prescribe policies, define programmes, and provide the means. However, the young international public service which exists in W.H.O. can claim to have something of the nature of such a national civil service accorded the descriptions: "Permanent, Independent and Influential," and " . . . Growth without Bureaucracy."

It is permanent in the sense that it does not come and go with annual decisions of the Health Assembly. It is independent in its constitutional obligations, set out in Article 35 of the Constitution:

"The paramount consideration in the employment of the staff shall be to assure that the efficiency, integrity and internationally representative character of the Secretariat shall be maintained at the highest level,"

and further elaborated in Article 37:

"In the performance of their duties the Director-General and the staff shall not seek or receive instructions from any Government or from any authority external to the Organization. They shall refrain from

² The British Civil Service, *The Times*, November 23 and 26, 1953.

any action which might reflect on their position as international officers. Each Member (that is, Member State) of the Organization on its part undertakes to respect the exclusively international character of the Director-General and the staff and not to seek to influence them."

In that the W.H.O. Secretariat is not a direct operative civil service it cannot have a direct type of "influence." However, apart from the opportunity for "influence" which follows respect for the honesty and efficiency of any service, the W.H.O. Secretariat has several significant formal rights. For example, Article 32 of the Constitution says: "The Director-General shall be the *ex-officio* Secretary of the Health Assembly, of the Board, of all commissions and committees of the Organization and of conferences convened by it." Further, the Director-General may make proposals for the agendas of the Health Assembly and the Executive Board, and, apart from formal reports to these bodies, he may make statements, oral or written, before them.

A frequent misunderstanding would be avoided if another constitutional provision was remembered. Article 71 reads:

"The Organization may, on matters within its competence, make suitable arrangements for consultation and co-operation with non-governmental international organizations and, with the consent of the Government concerned, with national organizations, governmental or non-governmental."

This contains a remarkable principle pregnant with opportunity. It means that W.H.O. is not limited to "official" interests only, important though these are. It has been given the privilege of associating both official and non-official organizations in international health and medicine. In W.H.O. the professional, medical, and other similar groups of the world, through both their international and their national associations, take their essential part. Thus they may have a direct say, under certain conditions in the governing bodies—the World Health Assembly and the Executive Board—in influencing major policy and administration. This is in addition to the contributions they make to the technical arrangements of the Organization. Such international medical professional bodies as the World Medical Association, International Association of Microbiological Societies, World Federation of Mental Health, International Unions against Cancer, Tuberculosis, and Venereal Diseases, International Dental Federation, International Council of Nurses, and many others in medical, social, and health fields are associated with W.H.O. in this way. To take one example only, the World Medical Association has greatly assisted W.H.O. by its authoritative guidance on a variety of subjects, including industrial medicine, pharmacopoeias, and medical education.

The basically advisory nature of W.H.O.'s relationship with governments on the operative side in connexion with the execution of programmes is one safeguard against some bureaucratic faults. Generally W.H.O. may not exercise central administrative control of, nor direct or supervise, local country activities. It has no right to interfere in any way in the internal affairs of any country or community. There are, however, other tests of the absence of bureaucracy, and these too, I think, can be met.

Some W.H.O. Policies

The work of W.H.O. may be conveniently divided into its direct advisory services to governments requesting assistance, and into certain technical services of general international interest, though there is inevitably an overlap on occasions. In the first group are the projects in most countries covering practically the whole range of public health and medicine. Yaws control in Haiti and the Philippines; trachoma studies in Iran and North Borneo; advice on medical administration in Burma and Panama; nutrition surveys in Brazil and Indonesia; maternal and child health in India and Thailand; assistance to nursing schools in Malaya and Syria; are examples of these services. At December 31, 1955, there were 218 such programmes in 63 countries and territories being assisted by W.H.O. It is

these programmes which at present are of most interest to the medical and other professions, as it is to work in them that most of the consultants and advisers come to serve W.H.O. for short periods.

Certain policies governing these advisory services may therefore be usefully discussed because of their general professional interest. W.H.O. operates a project only on the request of a government, and only by providing assistance to the government. For example, a country desiring help to develop a programme of venereal diseases control submits a request to W.H.O. The consultants sent out by W.H.O. then work by advising and assisting the local services. They do not establish a separate W.H.O. venereal diseases service in the country.

Governments retain entirely the right to express their own wishes regarding the type of international health assistance they desire. This partly explains the disappearance of the original "priorities" established by the First World Health Assembly in 1948. Planning at that early stage being unavoidably somewhat academic, the Assembly had prepared a world programme giving priority to six subjects: malaria, maternal and child health, tuberculosis, venereal diseases, nutrition, and environmental sanitation. Further, countries have increasingly extended their requests to cover integrated health and medical services rather than to limit them to the isolated subjects of the "priorities." To-day, therefore, these "priorities" can no longer be followed in developing the advisory services. However, the Health Assembly and Executive Board have defined certain principles in the selection of requests. Some of these have become fundamental not only in W.H.O. but in many other international organizations when giving technical assistance to governments.

One of these principles is now almost enshrined as a philosophy in all work where governments receive assistance. It is that projects should be designed "to strengthen national health administrations." This may sound like a simple platitudinous phrase. It is not. In the earlier years some people argued that W.H.O. should meet government requests by itself dealing directly with the particular local problems. For example, using this latter method to help a malarious population, W.H.O. would go in and develop its own *ad hoc* malarial organization and conduct a direct anti-malaria campaign. This call for direct so-called practical action had, understandably, much appeal.

However, the importance of self-help and local responsibility; the avoidance of extreme centralization of direction and technical planning, and of remote control; the need to adapt medical arrangements to local social and economic circumstances, and to resist the creation of a large permanent international civil service, were amongst the compelling arguments against the system. These, added to the recognition of national sovereignty, determined the policy that W.H.O. should assist countries by "strengthening national health administrations." This bald statement of the policy has occasionally been misinterpreted. It does not mean that W.H.O. services are available only to a central official governmental service. They can provide assistance through governments to any form of institution, organization, or service fitting into the local pattern. It is fortunate that an early Assembly took a decision to adopt this fundamental principle, which is sound administratively and in harmony with most accepted views on good public health and medical practice.

The abandonment by the Health Assembly of "priorities" has not meant rejection of the need for W.H.O.'s assistance to be distributed sensibly. The Health Assembly and Executive Board require some tests to be applied in both the Central and the Regional Organizations before acceptance of projects. Such criteria³ to be met include, in general terms: international feasibility and acceptability; benefit to the largest possible number of Member States and people; availability of qualified person-

³ *Off. Rec. Wld Hlth Org.*, 1951, 32, 55-63.

nel; preliminary studies and preparations have been made; the ability of the national government to continue and complete the work; full account has been taken of related possibilities of financing and action by other agencies and integration with related projects; and financial feasibility.

Vague though the language of some of these criteria may be, there is enough indication of several important principles to be followed. In the preliminary stages of negotiation on programmes between W.H.O. regional directors and governments and of discussion at the regional committees, some classification of government medical requests thus becomes feasible. Patently unsuitable projects are now rejected—indeed, are being less frequently presented. A country suffering heavy mortality and morbidity from more easily preventable conditions for which "outside" technical assistance is suitable is now not likely to demand as more urgent an electron microscope or a highly specialized hospital.

In certain regions the development of "country projects" is now following a pattern of study and application. An identified health problem often first needs examination internationally by a study group, by one or more experts visiting several countries concerned in the matter, or by simultaneous and co-ordinated studies in selected countries, before methods of dealing with it can be determined. The results of such an examination can then be disseminated on a wider basis through seminars, conferences, symposia. From this phase there often emerges a need for a new type of training suitable to be organized on an inter-country basis where controlled experiments can be arranged on new curricula, team training, etc.

Another general policy influencing the system of advisory services to governments is for W.H.O. to support the training of medical and health workers. This purpose is met in two general ways. Firstly, by a system of international W.H.O. fellowships, and, secondly, by helping countries to establish or improve their own medical training institutions. These two methods, owing much to earlier international experience, have combined to give W.H.O.'s programme of professional and technical education both success and popularity. In 1955 W.H.O. provided 1,028 fellowships, almost all postgraduate. The fellows came from 108 countries and territories and visited 75 countries and territories to receive their training. In keeping with the principle of "strengthening national health services," W.H.O. fellows are obliged to return for a minimum period of three years' service in their own country.

A significant feature of this international medical policy is that both "receiving" and "giving" countries and their medical professions contribute and benefit. A country like the United Kingdom, through W.H.O., is each year the source of numbers of senior medical teachers from its leading universities, who go to other countries to assist the development of their medical faculties and training institutions. Conversely, the well-known institutions of the United Kingdom, also through W.H.O., in 1955 gave advanced training in all branches of medicine to 206 doctors and scientists from other countries. Here, indeed, is a mutually beneficial process both to the countries sending fellows and receiving consultants and to the United Kingdom in having its institutions linked with developments in many countries. It extends, too, good will and even material advantage far beyond strictly medical circles.

A further expression of the various principles mentioned above is that W.H.O. does not possess its own medical institutions or operative medical services. Reference is not intended here to the long-established and accepted general international services connected with epidemiological and health statistical reporting, biological standardization, and other similar subjects, but to the fact that W.H.O. does not have its own hospitals, field medical services, or research institutions. This policy is an expression of the view that variety, freedom, and elasticity of conditions are needed by science and medicine in both investigation and application. These are more likely to be found in a number of different country institutions than in a centralized uniform official organization.

This method of working through the institutions of others is sometimes misunderstood by medical and other scientists, individualistic by training and experience. Accustomed to work in the laboratory, at the bedside, or in the field directly on their own programmes, the change to the more detached role of adviser or of medical administrator is often disturbing. It is a further facet of the position of indirect relationship, mentioned above, which W.H.O. has with its constituent governments which, once realized, enables suitable adjustment by the staff to be possible in most cases.

Co-operative Arrangements

Co-operation, co-ordination, and integration are words of common currency, if not yet debased to jargon, in international life. Yet they have more urgency and importance than in national operations. If international work is to mean anything, then co-operation and co-ordination are fundamental principles. To ignore their importance leads to inefficiency, waste, and even the disrepute of the concept of governments working harmoniously together through the existing system of international agencies. This is certainly true of international health work. The W.H.O. Constitution and numbers of policy decisions of the World Health Assembly and the Executive Board emphasize the development of all programmes by co-operation with all other interested agencies, and their integration into associated arrangements, international and national.

Achievement of the ideal is not yet here. There are the difficulties in co-ordination of work by the various international administrations themselves, with interests overlapping in many places. Interdepartmental and inter-organizational problems are not peculiar to national services. Indeed, the interests to be reconciled are more numerous.

In actual country work the problems for international agencies of co-ordination and integration are accentuated. Each agency can achieve there no more and no less than the authority and administration of the local government provides. Each faces, too, the additional complexity that there are usually other international agencies assisting the same government in related fields of work.

A disease control programme, for example, can be influenced by decisions taken by: (a) the United Nations General Assembly, the Economic and Social Council, the Technical Assistance Committee, the World Health Assembly, the Food and Agriculture Conference, and others; (b) the executive organs of the various agencies; and (c) the numerous national bodies concerned in local administration, agriculture, labour, health, etc.

This complex background to health work gives the principle of co-operation and co-ordination its importance. It calls for negotiation, adjustment, and considerable compromise before international health programmes are planned, provided for, and finally undertaken. Qualities of diplomacy, persistence, tolerance, and patience are required in the staff of the Organization to a greater extent perhaps than in any national situation.

One of the lessons, perhaps hesitantly learned by many medical men accepting the role of advisers to governments, is that more "medicine" is not necessarily the most urgently desirable step to improve general health. The dependence of community health on economic, social, and political interplay, in which more hospitals, clinics, and medical specialists do not always figure prominently, is sometimes hard for doctors to acknowledge. Then, too, it is sometimes unpalatable to accept the view that the cost of health should be measured against other claims. This need, described for instance by Ffrangcon Roberts in the *British Medical Journal* and elsewhere,⁴ is occasionally overlooked in situations where national resources are limited. It is forgotten that the application of medicine is not outside economic laws.

Nevertheless, in all governmental developments—social, economic, industrial, or agricultural—medical advice is essential to put standards of living on a sound, durable basis.

⁴ *The Cost of Health*, 1952. Turnstile Press, London.

Though sometimes he may be denied his hope of medical institutions being immediately established, the medical adviser has yet an important role in international assistance to all types of country. Often he will be helping the cause of health more by giving medical advice in relation to an agricultural scheme or an industrial enterprise than by limiting himself to a purely medical institutional programme.

Some Administrative Arrangements

There are many other policies influencing type and method of work, but only one more is selected for reference here. Article 35 of the Constitution, mentioned above, gives the importance of efficiency and integrity of the staff, but it further says: "Due regard shall be paid also to the importance of recruiting the staff on as wide a geographical basis as possible." The problem of securing geographical distribution in origin of staff has been a recurring problem for all intergovernmental agencies. The League of Nations found that "a decision to think only of building an efficient staff and to let the blows to national *amour-propre* fall where they may, would be defensible in theory. But the results would be serious. A system which depends upon the co-operation of Member States cannot ignore the factor of national prestige and interest."

A regular staff originating from a single region and culture and/or with technical experience in certain "advanced" countries only, could not sponsor successfully a world-wide health and medical programme in which adaptation to local needs and co-operation with innumerable national and social groups are fundamental. It is fortunate, therefore, that the arrangements for the advisory technical staffs on the one hand, and the regular form of appointment for the central and regional administrations on the other, provide elasticity. This helps to satisfy the call for wide geographical distribution without necessarily neglecting technical standards in recruiting staff. Results of recruitment have to bear analysis by national delegations, diplomatic services, country administrations, and, perhaps the most important, by the medical and scientific professions of the world. Whether the technical standards and achievements of W.H.O., dependent upon the ability and skill of its staff, merit respect, will be judged by the medical groups of all countries.

Constitutions and policies are ultimately revealed in administrative action. Much of this outcome has been given above, but certain other administrative methods are selected for examination.

There is the type of public service created by W.H.O. to carry out its work. Several of the facts about it have been mentioned. It is already clear that W.H.O. does *not* have a large centralized force of permanent officials, doctors, sanitarians, nurses, laboratory people, and their administrative and clerical assistants. The intention of its constitution and of its legislative authority to advise governments, and not to assume supragovernmental status, is secured through two groups. Firstly, there is the regular staff who, as already indicated, perform the essential continuing technical and administrative functions and who assist in providing certain advisory and "permanent" general technical services. Then, secondly, as also previously mentioned, there is a large specially recruited technical staff to give direct assistance to governments. While they are on W.H.O. projects these people are under its general service code, which naturally requires, *inter alia*, observance of objectivity, and loyalty to the Organization.

The use of temporary and not "permanent" staff in this work has certain advantages. The technical problems vary from year to year and some conditions are unlikely to require continuing W.H.O. assistance. Only a very large permanent technical staff could meet such continually changing demands. Further, W.H.O.'s indirect method of work would mean almost insuperable difficulty in a truly

"permanent" staff retaining a specialized technical skill. An "expert" can continue as such only by constant direct practice in his special work.

Specially recruited staff, on the other hand, enables W.H.O. to seek the best available adviser for each particular local problem, to adjust country technical staff continuously to the needs of the moment, to avoid staff redundancy when programmes end, and to guard against an international organization depriving national services permanently of their own essential technical staff. In practice, most consultants and advisers have adjusted themselves well as international officers in new spheres of work. This type of service indeed enriches all concerned—the "receiving" and "giving" countries, the "expert," and W.H.O.

There is another extensive arrangement by which W.H.O. draws on the technical resources of the world. This is the wide use of expert advisory panels and committees. The Health Assembly and Executive Board rely on such bodies for the general technical guidance needed to prepare programme policy. Serving on them are large numbers of the world's eminent medical scientists and health administrators in the W.H.O. fields of work. This expert panel and committee system has considerable advantages. Again, W.H.O. is able to draw quickly, efficiently, and economically on the best skills and knowledge required for the problems of the moment. It has its technical policies governed by a wide range of experience and knowledge, unlikely to be concentrated in a permanent official full-time staff. These advantages, generally, more than balance certain well-recognized weaknesses of the committee system in technical subjects.

On the whole the W.H.O. expert committees are forming a suitable instrument for their purpose. They have provided the scientific guidance and stimulus for the adoption of the international health statistical nomenclatures, international sanitary regulations, pharmacopoeia, and biological standards. They too have advised the Organization on public health, clinical and laboratory aspects of tuberculosis, child health, nutrition, malaria, and many other subjects.

The expert opinion, whether from the panel, committee, or individual, is integrated into W.H.O. programmes by the Executive Board and the Director-General. The fact that the full views of the expert are not automatically endorsed is occasionally questioned. Quite naturally the expert does not always accept happily a decision allotting more weight to other than technical considerations. But any organization concerned in problems with political, economic, administrative, as well as technical features, is obviously unable on occasion to adopt immediately all the desirable proposals put to it.

Numerous medical institutions in many countries are linked with W.H.O. There are long-established international centres, such as those at London and Copenhagen holding the accepted international biological standards, the influenza centres in London and Washington linked with a world-wide network, and others in health statistics, virus, blood work, and a variety of subjects.

Relatively small money grants are the material contribution that W.H.O. makes to such centres—a contribution which in no way measures the valuable two-way interchange that occurs. On the one hand, through W.H.O. countries everywhere draw on the resources of the central system, with many medical, economic, and industrial advantages. On the other hand, medical institutions and professions of an increasing number of countries become active partners with W.H.O., thereby contributing and gaining many things.

Many critics, especially such individualists as medical men, will wonder if W.H.O. can avoid the more serious evils of over-organization and over-administration. They will think with Sir J. F. Wolfenden, Vice-Chancellor of the University of Reading, that "a cure must be found for the modern scourge of 'organization.'"

* Wolfenden, J. F.—Address to Conference of Education Association, London, January 3, 1952.

Bureaucratic Risks

Some of the answers have been given in this article when the Constitution and legislative policies were quoted as a protection against W.H.O. becoming an exaggerated, ever-expanding international civil service, busying itself with too much detail. However, there are bureaucratic risks. Meetings—legislative, expert, or liaison—are multiplying in international work, and correspondingly absorb staff, time, energy, and money. Meetings there must obviously be in any representative organization, but when does their number cause too much diversion from progressive work? A round of meetings, tours, and reports in national or international life too easily becomes an end instead of a means.

The meetings involving W.H.O. are only to a limited extent under the control of the Secretariat. Through its obligations and agreements W.H.O. must send representatives to numbers of both international and national meetings. To decline invitations is also too often a cause of aggrivement. Thus the Secretariat itself is restricted in its power to control meetings and travel. This must largely come from the Member States of the various international organizations themselves.

Another administrative element exposed to bureaucratic exaggeration is the production of reports and documents. As Jules Romains puts it: "The peculiar symptom that betrays the bureaucrat is an unslakable thirst for paper." Paper now pours forth in both national and international work—reports, publications, questionnaires, documents, and working papers. Many services use much of their time and energy merely to read and initial correctly this volume of paper. Again, the best administrator, not to be confused with the bureaucrat, desiring to treat paper as but a means to an end, can himself only partly cut off the flow. Much of it is demanded by assemblies, conferences, and committees, which it is his duty to serve. This could become an insidious evil if governing bodies and their servants accepted the report as the completion of a task instead of an item to reach that end.

This is but one of the many problems the modern organized world has in dealing with the method of communication. Much of the recent examination made by the University of London of the difficulties of communication applies to an international form of organization. A relevant example from this study is where Sir Geoffrey Vickers says: "The transmission of information is limited in the first place by logistics. The sender is absolutely limited by what the receiver can absorb in the time which he can spare from action. Volumes of paper which are circulated 'for information' are pulped without ever informing those for whom they were chiefly intended, simply because these recipients did not have or make time to read them."

The Executive Board of W.H.O. has been conscious of the obstruction to purposeful work of excessive meetings, travel, and paper. These problems, too, are under continuous scrutiny by the staff. This vigilance is to some extent the assurance that such flowerings of bureaucracy will be regularly pruned.

Medical and other scientists coming to work directly or indirectly with W.H.O. will perhaps find one administrative principle particularly reassuring. It is that the Secretariat operates on a basis of delegation of responsibility. The individual units manage their own affairs with the minimum of interference from others. The technical officers and groups are free, too, in their respective technical fields. Their proposals, translated to the administrative sphere, may be subject to administrative and financial influences, but intrinsic scientific and technical data and opinions are protected.

Conclusion

This brief account has but superficially given some of the main elements determining the methods of work of W.H.O. likely to interest the medical and similar

* Vickers, Sir G., *Studies in Communication*, p. 82, 1955. Martin Secker and Warburg, London.

professions. These circumstances explain both the limitations and the opportunities of those doctors and scientists from all countries assisting the Organization on its regular or temporary staffs. They cannot always have the full satisfaction of following all their own inclinations in what they do, nor of running their own institutions, nor of ignoring elements they may dislike.

They do have the reward of playing a worthy part in giving of their technical and human knowledge and skill to assist mankind everywhere; of joining with colleagues of all countries in the extension and diffusion of medical experience; and of presenting and advocating the cause of medicine in the international and intergovernmental counsels of the world. Perhaps no other group has such opportunity, indeed responsibility, for showing the possibilities for good in international association and work. Here is an important way to the inherent universality of the science and humanitarianism of medicine.

SYMPOSIUM ON ARTERIOSCLEROSIS

[FROM A SPECIAL CORRESPONDENT]

A conference on arteriosclerosis organized by the Swiss Academy of Medical Sciences was held in Basle from August 8 to 10. The president of the Academy, Professor A. GIGON, invited to the meeting research workers from 10 countries and 4 continents who are actively engaged in problems associated with arteriosclerosis.

Professor GIGON, opening the proceedings, outlined the basic idea behind the symposium. The programme was divided into two major sections. The first day was devoted to papers on blood vessel factors and arteriosclerosis, including all generalizations on morphological changes in the vessel walls and problems on the haemodynamics of the coronary system, and so on; these subjects were considered in a series of 10 papers. The second and third days were occupied by a series of 26 papers on the problems of metabolism and arteriosclerosis. This rather wide category was further subdivided into three sections—the blood lipids and lipoproteins, dietetic factors in arteriosclerosis, and hormonal factors in arteriosclerosis. The conference was completed by a discussion on the papers and additional discussion on the problem in general.

Professor Gigon explained that Professor G. Lyman Duff (Montreal) was to have presented the opening paper under the title of "A Survey of Recent Experimental Investigations of Arteriosclerosis," but with regret he had to announce that Professor Duff was unable to be present. Consequently he called upon Professor WILLIAM DOCK (New York) to give the opening lecture.

Problems Outlined

Professor DOCK, who had originally been scheduled to speak towards the end of the congress, chose for his lecture the provocative title "Are There Effective Ways of Managing Arteriosclerosis?" In a spirited address he made it quite clear at the outset that the answer to this question at the present time appeared to be definitely in the negative. He quickly gave a skilful outline of the many morphological and metabolic problems which confront the investigator in the field of arteriosclerosis, and drew attention to the anatomical difference which exists between the intima of the newborn male infant compared with the female infant as one possible factor predisposing the male to coronary atherogenesis. The well-known sex difference in the incidence of the clinical presentation of this disease between males and females in the white population was reviewed by the speaker, and he commented on the loss of immunity by females after the menopause. Professor Dock went on to say that one of the most striking results in the field of sex hormones in

* *The International Secretariat of the Future*, p. 22, 1944. The Royal Institute of International Affairs, London.

relationship to coronary artery disease had been the observations of W. S. Bauld and associates in Montreal, who had demonstrated that the metabolism of oestradiol-17 β was different in normal healthy males compared with males of the same age suffering from coronary artery disease.

The speaker then went on to the subject of diet and disease, and commented (without reference to the source of the information) upon the very high incidence of coronary deaths among young males called up for national service with the United States Forces. It appeared that this section of the American population is required to consume vast quantities of butter, cream, eggs, and animal fat during their military service, and Professor Dock implied that this parameter required immediate investigation. The possible role of cigarette smoking and the differences which appear to exist between the incidence of certain forms of arteriosclerosis in communities who ingest animal fats and the incidence in communities who ingest largely vegetable fats were very briefly mentioned. The speaker concluded by contrasting the economics of prescribing a diet designed to lower the serum cholesterol against the cost of the so-called hypocholesterolaemic drugs, and said that the patient nowadays required education in the cholesterol content of various foods and the cholesterol content of his own tissues. Thus he hoped that a return to a diet "normal for man" might be the method of choice of the Hippocratic physician.

Morphology

Among the many interesting papers presented in the period devoted to morphological studies was a communication delivered by Dr. P. COHRS (Hanover), who focused attention on the fact that the parrot exhibits spontaneously a type of atherosclerosis which is similar in appearance and distribution to that prevailing in man. The birds studied by the speaker varied a great deal in age, and some were known to be older than 30 years. The diets were of course uncontrolled, but it did seem to your correspondent that the parrot might have a useful place in investigations of this type, since the lesions were more closely related to those found in the human than those occurring in the lipoidoses in other birds such as ostriches and turkeys.

Professor A. MÜLLER (Fribourg) gave an authoritative account of some of his studies on the haemodynamics of the coronary system. He developed the mathematical arguments in favour of a sort of backward shock wave from the periphery towards the aorta, which leads to changes in the velocity of the blood in the coronary system of the order of 50–60 cm./0.2 sec. Professor Müller showed that the consequences of these effects would be most apparent at positions further removed from laminar flow, and this would be at the bends in the coronary system.

Professor J. B. DUGUID (Newcastle) put to the meeting in a concise manner his general thesis that the process which causes narrowing of the arterial system is not fatty change but thrombosis. This speaker went on to say that there were all types of thrombi, from the large type which filled the lumen down to small wisps of fibrin attached to the intima. The fibrin masses were often to be found covered by a layer of endothelium, and Professor Duguid concluded that thrombosis does not necessarily depend on fatty changes in the arteries, as in his view the fatty changes are the result, rather than the cause, of thrombosis. He emphasized that pathologists must differentiate between lesions which are primary fatty changes and secondary fatty changes seen after thrombosis.

Metabolic Factors

In the metabolism section of the congress Dr. F. T. LINDGREN (Berkeley) discussed the relationship of the blood lipids and lipoproteins and coronary disease. The plasma lipids are almost solely in the form of lipoproteins, and the author gave the chemical analysis of some of the low density lipoproteins. From studies which Dr. Lindgren had made as a member of Dr. Gofman's group in California, he

presented data to support the argument that the rate of development of arteriosclerosis can be calculated from ultracentrifugal analysis of the low and high density serum lipoproteins, and this information was computed into an "atherogenic index." It was shown that this index was higher in individuals with angina who went on to myocardial infarction than in another group who had angina only. It was shown that the atherogenic index was lowered by the administration of heparin or desiccated thyroid and also by the consumption of a low fat diet. The speaker concluded that, when an ultracentrifuge was not available, serum cholesterol studies should be combined with concurrent serum total lipid determinations in order to obtain maximum information.

Professor A. FASOLI (Milan) delivered an interesting paper on a study which he had made of the filter paper electrophoresis method of lipoprotein assay, contrasting this with the ultracentrifugal method. Professor Fasoli showed that the electrophoretically determined alpha:beta lipoprotein ratio must always be interpreted with great caution, as he had observed considerable variation in both normal and pathological serum samples.

Professor G. SCHETTLER (Marburg) showed that in several patients who appeared to be mildly hypercholesterolaemic a diet of about 1,000 calories daily for about 10 days produced a fall in the serum cholesterol of approximately 30%. He went on to discuss the effect of the unsaturated fatty acids in lowering the serum cholesterol, and concluded that a low fat diet and/or caloric restriction may be desirable in subjects who present with hypercholesterolaemia, but persistence over a long period would be required in order to establish the usefulness of this regime. This paper was followed by a similar contribution by Professor H. MALMROS (Lund), who also showed that vegetable fats lowered the serum cholesterol and mentioned that this effect was independent of the cholesterol content of the foodstuffs. Professor Malmros presented some of the results which he obtained in association with Professor A. Keys (Minneapolis) in which the serum cholesterol values of clerks, foremen, and heavy workers in Malmö, Sweden, were compared with similar workers in Naples, Italy; the Neapolitans were all significantly lower than the Swedes. Professor Malmros urged that only well-characterized acids should be employed in all studies on the effect of the so-called "essential fatty acids" on the serum cholesterol. He showed that the incorporation of these unsaturated fatty acids into a normal diet could keep the serum cholesterol down for periods up to six months in certain selected cases.

Alpha and Beta Lipoproteins

Professor D. P. BARR (New York) gave a review of some of the studies performed by his group, utilizing the modified Cohn fractionation procedure to derive the distribution of cholesterol between the alpha and beta lipoproteins of serum. The author pointed out the statistically significant difference which exists between the serum of normal young women and normal young men, the latter having less cholesterol bound to the alpha lipoprotein than the former. This sex difference completely disappeared in older "normal" subjects, but males or females with coronary artery disease always had a lower alpha:beta ratio than had "normal" subjects of comparable age. Professor Barr went on to show that the administration of 1 mg. of ethinyl oestradiol daily to subjects with abnormal lipoprotein patterns, such as occur in xanthomatous cases, coronary artery disease cases, cretins, and in cases of myxoedema, always resulted in the serum lipoproteins shifting towards normality.

Dr. G. S. BOYD (Edinburgh) reported that the administration of small doses of triiodothyronine and triiodothyroacetic acid could result in depression of the serum cholesterol without influencing the basal metabolic rates of the subjects, but larger doses of these drugs overcame this dissociated action with a resultant rise in the B.M.R. Speaking

Amnion Implantation in Peripheral Vascular Disease

SIR,—The treatment of peripheral vascular disease gives no cause for complacency, and Mr. E. Troensegaard-Hansen's paper (*Journal*, August 4, p. 262) is welcome in suggesting a possible new method of treatment for patients suffering from this distressing disease. I have been carrying out this method of treatment for about the same length of time and would like to record some of my impressions.

The first twelve patients that I treated were unselected, unlike Troensegaard-Hansen's, who has limited his cases to Boyd's classifications 1 and 2. The experience with these twelve cases showed that the treatment was really only of value in Boyd's type 2; it caused no real relief to those patients who had rest as well as exercise pain, for those with incipient gangrene, and, in addition, there was no evidence of any improvement in two patients who had Raynaud's disease. The interesting fact about the patients who did improve was that the improvement was entirely subjective. I was never able to achieve any objective improvement in support of the patients' claims. On every patient the blood pressure was carefully kept, and E.C.G. was taken before and after operation, prothrombin time was similarly estimated, oscillometry and skin thermometry were also carried out, and in none of these tests were any changes noted. For the next three cases, which were all of Boyd's type 2, I carried out in addition arteriograms before and after the amniotic implants, and no alteration was seen in the arterial pattern. I realize that this is a very small number and that the test is inconstant, but I think it does denote that there is no dramatic increase in the collateral circulation.

Since Walder¹ published his paper describing a method of measuring blood flow utilizing radioactive sodium, Dr. W. Kulke, consultant radiotherapist at the Liverpool Radium Institute, has used this technique in measuring blood flow before and after amniotic implants on six cases up to the present time, and the results conform quite closely with those published by Troensegaard-Hansen. In the published graphs, however, there are some points which are subject to criticism. In the first place the patients are exercised for two minutes prior to the amniotic implant; in many of our cases the patients cannot exercise for one minute owing to the onset of pain. Secondly, the inter-exercise hump as described in Fig. 2 has not been obtained by us in any case. Thirdly, in Figs. 9 and 11, the uptake of sodium after exercise appears to be greater than before or during, which is certainly not normal, and it is difficult to assess.

Clinically, the more recent cases that I have done have been successful, and I feel that this method of treatment may well have a selected place in the treatment of intermittent claudication. I think, however, that this article should be treated as a preliminary publication. There is no direct evidence for many of the hypotheses put forward in the discussion. There is also no evidence that nucleated cells in the epithelial zone are the active part, nor is there any proof that this action is specific to amnion. Much work requires to be done in the use of living tissues in producing a similar effect—possibly another serous membrane such as pleura or peritoneum—and only time can tell whether the effect of amnion will be permanent or whether relapses will increase as the period after implantation lengthens. Like other new methods of treatment, early results may be misleading and should be treated with considerable reserve and caution.

I should like to express my gratitude to Messrs. Smith and Nephew Research Ltd. for supplies of amnion and for their constant help and encouragement.—I am, etc.,

J. G. GOW.

Nova et Vetera

ONLY EIGHTY YEARS AGO

Go back only 80 years, and in what an incredible world of medicine you find yourself! What masterly pharmacological orchestration! Come and look over the shoulder of Dr. Tschudi Madsen¹ as he peers at a tattered Prussian medical diary found hidden in the loft of a house in Bergen, the second largest town in Norway. In addition to the standard information characteristic of medical diaries, this volume had several spare pages into which a general medical practitioner, Dr. Harald Lehmann, had in 1873 crammed his medical records. He can have had no thought of ulterior publication as he jotted down his notes in a handwriting so fine that a magnifying glass is needed to decipher them. Many of his 543 patients, whose names are given, had patrician family names and were the social cream of this Hanseatic town. Their complaints? Much the same as those of 1956. But how varied the remedies for them! And how Hippocratic the differentiation of symptoms and diagnosis! For whooping-cough an infusion of tonka (from the African tonka bean). For phthisis, lichen Islandicus. For haemoptysis, salt, secale, and extractum hyoscyami. For catarrh with blood-stained sputum, cod-liver oil, rum, and milk. For asthenia, tinctura absinthii composita. For epilepsy, subcutaneous injections of ergotin in the nape of the neck. For goitre, a bag of salt on the spot every night. The versatile Lehmann took his remedies from the animal as well as from the vegetable kingdom, and he drew on the musk-ox (tinctura moschi for heart failure), the beaver, the Spanish fly (cantharides on the chest for asthma), and above all the leech. For pain in the praecordium and anywhere else, for exudative pleurisy, and for a bruised knee, always the leech. It was applied to the temples for tinnitus and for pneumonia running a fatal course. Eight leeches at a time *ad anum*. At about this time, when Lehmann was 56 years old, the sands had begun to run out for himself. He evidently referred to himself when he jotted down: "Icterus with stinking intestinal catarrh . . . lassitude . . . tar pills, tincturae aurantii and nucis vomicae, aqua regiae, and aqua ferripyrofosforici." Surely he had earned a holiday; and he took it in Italy with a small library consisting of the Bible, Baedeker, Björnson's poems, and three of Ibsen's plays. There was also a whole medicine chest. Its alphabetical list began with elixir paragoricum (good old tinct. camp. co.), and ended with vinegar. Tidy to the last, he had slipped into his medical diary a note of what he had paid for cab fares in Genoa, Naples, and Florence.

CLAUDE LILLINGSTON.

Effect of Fatty Meals on Blood Coagulability

SIR,—May I be permitted to reply to Professor H. W. Fullerton's comments (*Journal*, August 11, p. 356) on my paper (*Journal*, July 28, p. 207) on the effect of ingested fat on blood coagulation? My choice of the coronary arteries as an example of vessels commonly affected by atheroma was fortuitous: I might equally well have selected the aorta, where in fact atheroma is even more frequently found.¹ If atheroma was confined to, or even most frequently found in, the coronary vessels the unique character of the coronary blood flow might perhaps be incriminated as a necessary, if not effective, cause: but this is not the case. What Professor Fullerton does not mention is the correlation between the frequency of atheroma and the pulse pressure in various parts of the aorta. The pulse wave is greatest in the abdominal aorta, and it is here that atheroma is commonest. Yet there is no likelihood of systolic "reduction or cessation of flow" at this point which would "readily allow deposition of pre-formed fibrin" in the way he suggests as occurring in the coronary arteries as the earliest lesion of atheroma.

My main intention in repeating Professor Fullerton's experiments, using modified techniques, was to illustrate once more the importance of method in this field of research, and not to advance or repudiate a theory. However, there is one aspect of Professor Fullerton's hypothesis on which I would like to comment: it is the validity of using estimates of clotting time as a measure of blood coagulability. Under certain experimental conditions the clotting time of a specimen of blood is inversely proportional to its lipid content. This only means that the process of coagulation has been accelerated: it does not necessarily mean that coagulation is therefore more likely to take place, as the factors which govern the speed of coagulation are quite different from those controlling its inception.

I would close by reiterating my original point: that proportionality of clotting time to lipid content is found only in the absence of platelet activity. This does not occur in the body, and the phenomenon described is probably only a reflection of the ability of chylomicrons to imitate the action of platelets² and is not an indication of changes in blood "coagulability."—I am, etc.,

Benzhexol in Parkinsonism

SIR,—I was frankly amazed to read the report on a series of cases of this distressing condition by Drs. H. B. Porteous and D. N. Ross (*Journal*, July 21, p. 138), and to learn that patients were, apparently, immediately put on 7.5 mg. of benzhexol hydrochloride daily, except in the case of one aged 80. This person was only given an initial dose of 5 mg. daily.

By experience as a mere general practitioner, I am obliged to be more cautious in my dosage. I find that for sometimes a week or even more I can only prescribe one-third of a 2-mg. tablet a day, but by dint of persevering the dose can be increased to the normal 6 mg. per day, and increased after that. One fails to see why a condition so chronic, albeit progressive, should receive the full impact of high doses. In all drugs where time is more of a secondary nature, an initial low approach is surely a "must."—I am, etc.,

Tonypany, Glam.

E. B. PHILLIPS.

Maladjusted Children

SIR,—I must thank your correspondents for their support in this matter. Dr. J. G. Howells's enterprise and initiative in Ipswich (*Journal*, July 21, p. 179) are admirable, and will, I hope, encourage others to do likewise.

I appreciate that many younger graduates have had more training in child psychiatry than was customary in my youth, but my experience with young graduates is that they have little practical knowledge of how to manage a case. They

usually know all about the Oedipus complex and forgot to ask whether the parents are still living together, and without a proper history remedial psychiatry is impossible. The course I had in mind for assistant medical officers of health (*Journal*, June 23, p. 1487) was of a more formal kind. Clinical lectures with actual cases are difficult to manage in the presence of more than a few students without disturbing the patient, and actual cases could be discussed in formal lectures, as well as more systematic tuition. In this way larger groups of medical officers could be instructed.

Dr. J. S. Owen's suggestion (*Journal*, July 7, p. 47) that some psychiatrists are not in favour of dilution is interesting. When I tried to persuade the late Sir James Spence that Newcastle was very backward in having no child guidance clinics, he took the opposite view. He was not at all sure that psychiatrists were the best people to treat maladjustment, or indeed mental diseases in general, and his view is shared by many physicians. We all think we understand human nature, but we must stop making jokes about psychiatrists, since this undermines patients' confidence. I suppose the reason behind the psychiatrists' objection to dilution is that a difficult case in unskilled hands may be worse after treatment. This is, of course, unanswerable, except that an important part of my training course would be the early recognition of such cases and their immediate referral to the psychiatrist. Another safe guide would be the lack of progress under treatment.

Sir David Henderson points out (*Journal*, August 27, 1955, p. 519) that of every hundred births eight will have a nervous breakdown and three of these will be of such severity as to require admission to a mental hospital, and the amount of minor illness, both purely functional and psychosomatic, which any practitioner sees is colossal. Indeed, any psychiatrist will be the first to admit that the only well-adjusted person he knows is himself.

Psychiatry has its limitations, but they are not considerable. The experience of totalitarian countries has shown how easily humanity can be conditioned, but we in the democracies have been very slow in following up Pavlov's work. Child guidance will not revolutionize our communities in a generation, but in time it can work wonders. Both Goethe and Plato, and no doubt many other philosophers, recognized the importance of the proper rearing of children for attaining an ideal state, and both considered that mothers were the last people to be entrusted with the care of their own children. While we consider to-day that difficult it can be with the unintelligent, or the mother who cannot bear the idea that she is the cause of her child's difficulty, but even the mothers of problem families can be trained—for example, as in London, where they are housed in blocks of flats with a permanent warden, which, with other recognized aids, should be fruitful. In time the method of rearing children would become common knowledge, and then 'twill be bliss to be alive.

As I said in my last letter, I look for your support, Sir, in filling the gaps in this most important branch of medicine.—I am, etc.,

MAX PARK.

Virilism with Mental Symptoms

SIR,—The case history given below seems worthy of record because of the unusual nature of the symptoms and the fact that to-day, ten years after medical and surgical treatment ceased, the patient is fit and well.

A married woman of 25 was referred for an opinion because a profound change had taken place in her habits and attitude towards others: from being a happy and active, though shy person, she had become silent, morose, and careless in her personal habits and appearance. The deterioration came gradually following the birth of her only child three years previously. Her husband reported that she had refused all medical attention. The patient remained almost silent during the first interview and kept muttering: "Let me die, let me die." She was unkempt and there was a luxuriant growth of hair on the chin with acne and scurfy

hair. Social conventions were disregarded, and she lounged in a chair smoking cigarettes. Beyond taking her pulse no examination was allowed. After several interviews the patient permitted a superficial examination. Her general condition was sound, but there was an excessive growth of hair on the abdomen and legs. Conversation was monosyllabic and it was impossible to establish any rapport. A diagnosis was made of a schizoid-depressive illness with marked endocrine disturbance.

Mr. L. R. Broster saw the patient in consultation, and he considered that her mental condition was related to an endocrine dysfunction. He advised operation, but this was declined by the patient and by her relatives. Eventually she was persuaded to enter a nursing-home, where she remained with special nurses for three months. Treatment began with was by E.C.T. and insulin shock, and followed by psychotherapy. An improvement took place after two months' treatment: conversation became connected, and it was possible to gain her co-operation in the simple psychotherapy which was used. While still careless in her dress, she was tidier, and her social adaptation improved, although her mental condition was unstable and erratic. Ultimately she accepted the need for further treatment and her relatives withdrew their objection to an operation. Special examinations followed: uroselectan and x-ray examinations of both kidneys showed a normal function; but the shadows of both adrenals were larger than normal. She was secreting 11.9 mg. of ketosteroids daily.

Mr. Broster again saw the patient and agreed to operate. On operation it was found that both adrenal glands were enlarged; the right ovary was cystic, and the left solid and without corpora lutea. The hypertrophied left adrenal—2 in. by 1 in. (5 cm. by 2.5 cm.)—was removed. Shortly after the operation the ketosteroid secretion showed a 50% reduction. The patient made an uninterrupted recovery from the operation, and after it she was able to depilate herself with satisfactory cosmetic effects. Her complexion improved, the acne disappeared, and her hair lost its scurfy appearance. There was a rapid improvement in her mental condition. For the first time in almost four years the patient undertook responsibility of a mild nature such as shopping. A notable feature was the development of initiative and the return of her sense of humour. After a few weeks' holiday she went home and resumed domestic life.

During the next two years progress was intermittent and there were relapses with a reappearance of the schizoid-depressive features and negativistic behaviour; but these symptoms cleared up without treatment. Progress since then has been steady, although the home circumstances required considerable patience and common sense. Three years ago—that is, seven years after medical treatment had terminated—the patient became pregnant, and after a normal pregnancy and confinement bore a healthy child. She is now leading a normal life, interested in her family and taking part in social activities.

The psychiatric treatment was successful up to a point, but the original gloomy prognosis remained until after the operation. The adrenalectomy was the decisive factor in treatment; without it she would almost certainly have ended her days in a mental hospital.—I am, etc.,

E. A. BENNET.

London, W.1.

Trendelenburg Tilt

SIR,—Few anaesthetists will disagree with the contention of Dr. J. M. Inglis and Mr. B. N. Brooke (*Journal*, August 11, p. 343) that modern anaesthetic technique can prevent that encroachment of the intestines upon the pelvic operating field which Trendelenburg's position was designed to diminish. Although their paper refers primarily to the steep tilt it nevertheless unfortunately implies that even a moderate (say 15°) tilt has no place in modern operating technique. During the synchronous combined excision of the rectum this degree of tilt is necessary if only to bring the perineum up to the level of the seated surgeon while

leaving the table as a whole low enough for the standing operator to work comfortably in the abdomen. I feel sure my surgical colleagues at St. Mark's Hospital would be reluctant to abandon the "lithotomy-Trendelenburg" position for that operation.

From the anaesthetic viewpoint the authors' remarks upon the disadvantages of the position raise issues calling for further comment. The impression is given that it is regarded as a disadvantage to have to use controlled respiration and a cuffed tube. It is disturbing that, 10 years after the introduction of curare into anaesthetic practice, reference to a "partially curarized diaphragm" working against gravity should be additional evidence of a widely held, semi-mystical belief in the virtue of inadequate spontaneous respiration, as compared with efficient controlled respiration. One had hoped that the routine use of an apnoeic technique in major abdominal surgery (with its corollary of a cuffed tube) would no longer be discouraged by writers associated with a teaching hospital centre.

As far as the vasomotor system is concerned, if the patient is moved into a moderate degree of tilt by stages during the interval between induction and the approach to the pelvis and returned to the horizontal even more gradually during the corresponding period between peritoneal closure and the return to bed, the hydrodynamic disturbances of the circulation are minimal and cause little apprehension even in known "cardiac" cases. The speed at which the table is tilted appears to be more important than its final angle. Although it would be easier if the tubing of National Blood Transfusion Service giving sets were 18 in. (45 cm.) longer, it is still possible to have the transfused arm retained alongside the patient whether he is horizontal or tilted. The nerve palsy objection (which anyway only applies to a steep tilt) is then met by careful placing of the shoulder-rests.

In short, Sir, I feel it would be a pity if surgeons who asked for a moderate degree of Trendelenburg tilt were left with the impression that they were presenting their anaesthetist colleagues with a major problem involving an increased hazard for the patient.—I am, etc.,

Loughton, Essex.

DONALD V. BATEMAN.

Antibodies Against Cancer

SIR,—Apropos your leading article (*Journal*, August 4, p. 290) on antibodies against cancer, would it be of interest to you to hear of the following experiment performed about 1940?

From an adenocarcinoma of the colon, removed at operation, about the size of a large cricket ball, non-tumour tissues were dissected away immediately as far as possible, and from the tumour masses an antigen was produced by the same method exactly as that used in the preparation in my laboratory of a Wassermann antigen, but using the malignant tissue in place of the human heart tissue. With this tumour-extracted antigen a Wassermann test was performed on about 25 of the sera which had been received that day for the ordinary Wassermann test, using the standard technique.

Two strong positives and one positive were found, and, on checking with the Wassermann bench, the results were identical with the Wassermann results: the remaining sera were negative by both tests.—I am, etc.,

Maidstone, Kent.

E. R. JONES.

Shoe-fitting by X Rays

SIR,—While Dr. E. D. Dyson (*Journal*, August 4, p. 269) has clearly indicated the hazards from the x-ray fluoroscopes so commonly used in the shoe shops of to-day and has indicated the need for control measures to prevent harm from this source, may I suggest that the opportunity be taken by the Ministry of Health committee to consider the total prohibition of the use of these machines in the fitting of children's footwear?

There is no doubt that these machines have been found to be an excellent medium for salesmanship, and are used

mainly to impress parents with the need for the purchase of new footwear on the grounds of short-fitting shoes. The machine, of course, cannot give a proper estimate of the fit of a shoe, since it is only able to relate the length of the foot skeleton to the length of the sole of the shoe. It is quite impossible for a machine of this kind to estimate the width or girth required to give a true fitting of a child's foot, although cumbersome devices, which are rarely used, exist which claim to do this. This, of course, is the really important part of shoe-fitting, and can only be done by trained and experienced fitters. The introduction of an x-ray machine to a shop gives a sense of false security to the shop assistants and to the prospective purchasers regarding the fitting of the shoe and encourages the use of untrained and uninstructed girls straight from school to practise their salesmanship. This is done on the basis of a shoe's pleasing appearance to the eye and the extremely doubtful advantage of having looked at the foot skeleton under a "pedoscope."

The high incidence of foot deformity among school-leaving girls (almost certainly in the region of 75% showing hallux valgus caused by bad fitting of footwear) does call for some control in the shoe-fitting practice of the country. If no one were allowed to fit shoes to children and no shoes were allowed to be sold without the fitting being done by a trained and qualified fitter, then the need for the pedoscope would be obviated, hallux valgus would become a thing of the past, and the potential hazards from shop x-rays would be eliminated.

I hope the Ministry's committee will be able to use its influence to prohibit the use of these machines and to obtain the trade's co-operation to a system of shoe-fitting which would rest upon the trained eye and hand rather than the pseudo-scientific fitting that is accepted so glibly by the general public under pressure of the boot and shoe trade. The harm that is being done to children's feet and health is not nearly so much from the radiation of this toy as from the ignorance of the poorly paid shop assistants, who are so often dependent upon commission on sales to enable them to secure a reasonably adequate livelihood.

Dr. Dyson's article has given us an opportunity to review the whole position in relation to children's shoe-fitting, and, as one who has been interested in this subject for a number of years, I feel this opportunity should not be allowed to pass without making a real step toward the prevention of hallux valgus among the population as a whole.—I am, etc.,

London, W.5.

W. G. BOOTH.

Medical Evidence at Inquests

SIR,—The letter (*Journal*, August 11, p. 356) of Dr. F. M. Rose, of Preston, as to coroners is of significant interest: I have no doubt that the present system is capable of improvement both locally, for some local authorities do not find it possible to see to all the needs of the coroner, and generally by alteration of the law. But the work has to be done by someone. Coroners as a whole are not averse to comment, even adverse comment, upon their methods, but it should be accurate. Dr. Rose clearly knows something about the subject-matter of his letter, but his allegation about a block grant is entirely untrue: his conclusion that the coroner personally benefits ("a direct saving to the coroner personally") appears to be almost libellous, though no person with any knowledge would take it seriously. How does he justify it, or does he retract?—I am, etc.,

London S.E.1.

Chiropody Associations

SIR,—In your issue of August 4 (p. 308) you report an exchange of views between Mr. Somerville Hastings, M.P., and Mr. Robert Carr, M.P., the Parliamentary Secretary to the Minister of Labour, regarding the recognition of the Society of Chiropodists, during which Mr. Carr stated that "The British register was maintained by the B.M.A., which recognized only the Society."

I think, for reasons of clarity, it should be pointed out that the "British register" (by which is meant the *National Register of Medical Auxiliary Services*, maintained and published by the Board of Registration of Medical Auxiliaries) is not maintained by the B.M.A., as such. The Board is an independent body set up in 1936 jointly by the B.M.A., the Society of Apothecaries of London, and a number of medical auxiliary organizations, to establish a register of properly qualified medical auxiliaries. The Society of Chiropodists is the only chiropody body recognized by the Board, because it is the only body whose standards of training, curriculum, and ethical rules are considered adequate.—I am, etc.,

London, W.C.1.

A. M. A. MOORE,
President,
Board of Registration of Medical Auxiliaries.

Invalid Aid

SIR,—As a sufferer from Parkinson's disease, I find that one of its many disabilities is the difficulty of getting in and out of a bath. In hospitals it is hard work for one male nurse or two female nurses, and a frightening performance. At home I can do this practically unaided owing to a simple arrangement my wife devised some years ago to enable her to manage unassisted.

This device is a strong right-angled steel rod, fixed across and above the bath: one arm enters the wall through a socket 14 in. (35.5 cm.) above the rim of the bath, and 17 in. (43 cm.) from the taps; the other arm is firmly fixed into a 6-in. (15-cm.) socket screwed to the floor, leaving a clearance of 8½ in. (21.5 cm.) between it and the side of the bath to facilitate cleaning. Where the bath stands clear of the wall two vertical and one horizontal rods would be necessary and probably a central stay rod at right angles to the horizontal rod, fixed to the wall beyond the taps or right-angled to the floor.

Provided a person is able to use his arms it is very much easier to lower or pull himself up in the forward plane and especially in conditions where balance is affected. Most elderly, weak, or disabled people would find this arrangement a much greater help than side rails, and the use of it entails much less strain on the nursing staff with consequent time-saving, one nurse being able to manage with ease where two would normally be required.—I am, etc.,

Newcastle, Co. Down.

F. S. MAYNE.

Effect of Glycyrrhetic Acid on Eczema

SIR,—Recently glycyrrhetic acid has been introduced in dermatology as having a similar action to hydrocortisone. We have tried to assess its value on a series of in-patients with various patterns of eczema, using the paired limb comparison technique, employing independent observers, and deciding the effect without knowing on which side the control ointment was applied. The preparations of glycyrrhetic acid used were a 2% ointment supplied by Genatosan, and in the last six patients a 2% ointment marketed by Biorex Ltd. We first compared the effect with 1% hydrocortisone, and in eight patients the response to the hydrocortisone was greater. We next compared glycyrrhetic acid ointment with ung. emulsificans aquosum (B.P.) and later with the

exact inert base. In 12 out of 19 patients the side treated with the active ointment showed no difference from the control side. In three the active ointment was slightly better, and in four the inert base was slightly better. There did not appear to be any difference in the effect of the two makes of the glycyrrhetic acid.

From this small series of cases it would seem probable that glycyrrhetic acid in the two preparations used has no effect.—We are, etc.,

Bristol.

CLIFFORD D. EVANS.

Sickling in African Community

SIR,—Drs. H. Lehmann and A. B. Raper are to be congratulated on the important contribution they have made to the problem of sickling in African communities (*Journal*, August 11, p. 333), but their article contains one misleading suggestion. It is not true that the loss of life from malaria acting differentially upon the normal homozygote can be reduced by the simple expedient of deferring malarial mortality until other diseases have reduced the child population. Their own figures show this to be an illusion. Thus in Table III they postulate 157 deaths of AA homozygotes from a mean population of ½ (648+491), or a mortality of 27%. Table IV shows 69 deaths from a mean population of ½ (282+213), again a mortality of over 27%. The reference to 6.9% of all children born alive is a red herring.

It is possible to carry the authors' conclusions a step further. Having considered the elimination of normal homozygotes both before and then after other mortality, they continue: "If malaria is imagined as causing deaths concurrently with other diseases . . . the figures observed would lie somewhere between the limits assigned." The "limits" referred to are in effect one and the same mortality of 27%, and it is easy to show that it remains the same even with concurrent mortality. Let us assume that the population is reduced by death so as to follow an exponential curve expressed by the equation $N.e^{-at}$, where N is the initial population and " a " the exponential rate of decline. Let " μ " be the uniform mortality affecting all children, and " m " the mortality due to malaria operating upon normal homozygotes only. The two population curves are then $P.e^{-\mu t}$ and $P.e^{-(\mu+m)t}$ respectively. The ratio of these populations at the onset is P/P or unity and after the lapse of time " t " becomes $\frac{P.e^{-\mu t}}{P.e^{-(\mu+m)t}}$ or e^{-mt} . In other words, the proportional reduction due to malaria is independent of other mortality operating and will be the same whether acting alone or concurrently.

The authors quote mortality rates from the Belgian Congo of 22 deaths from malaria per 1,000 per annum below the age of 3, and from Accra of 17 per 1,000 under 1 year and 10 per 1,000 from ages 1 to 5 years. These account for approximately 66 and 57 deaths per 1,000 exposed to infection and are still far from the required 27%. Support for the views that these rates are not far from the maximum likely to be found in susceptible populations can be given from data referring to Uganda itself. An analysis was made of all registered deaths of non-Africans in Uganda in the five-year periods straddling the years in which a census was taken. The death rates per 1,000 per annum from malaria in its widest meaning were:

	Death Rates per 1,000 per Annum			Cumulative Mortality to Age 15 per 1,000
	Under 1 Year	1-4 Years	5-14 Years	
1909-13	4	6	4	68
1919-23	5	1	2	29
1929-33	7	8	14	29
1946-50	2.9	3.6	6	12.5

These figures include deaths from "fever" and "cerebral malaria" as well as microscopically confirmed malaria, but

on the other hand it is likely that deaths in the first months of life may be underestimated. The influence of modern methods of control is well illustrated, and it is interesting that the earliest rate approximates so well to that found among African children elsewhere.

From the available data there is still seen to be a big gap to be closed between the 24% reduction in population needed by this hypothesis and the 7% or so which malaria can effect. If sickling heterozygotes are not completely immune to malaria the gap would of course become larger.—I am, etc.,

Dundee.

WILLIAM A. WILSON.

Prevention of Tetanus

SIR,—Your leading article (*Journal*, August 11, p. 348) emphasizes some of the difficulties inherent in the application of passive immunization against tetanus and renews the doubts which have recently arisen as to its overall prophylactic value. Few will now question the preference for active immunization; it is the practical difficulties which are the barrier retarding progress towards a complete civilian active immunization comparable with that pertaining in the Services.

The early fears that the use of the triple toxoid would necessarily result in the lowering of the antitoxin titres of any one of the three has now largely been dispelled by the recent work of Barr *et al.*¹ and Ungar.² But the more potent deterrent seems to be the question of the cost of mass triple toxoid immunization, and this boggy is frequently used as an argument against its introduction. It is a difficult one to refute, since it is not easy to ascertain what the present practice of passive immunization costs the nation. It can only be pointed out that in the three hospitals reviewed³ the yearly cost of passive immunization alone must have been nearly £400, and that at least one large supplier of the diphtheria-tetanus-pertussis prophylactic makes no additional charge for the tetanus constituent of D.T.P.P. as against that for the diphtheria-pertussis prophylactic. One presumes that the Ministry of Health could, without difficulty, ascertain the saving of cost to the nation which active immunization might well afford apart from its intrinsic value, and could dispel the possible illusion that such an innovation would be as costly as is often suggested.

Finally, many recent authorities in America, Australia, and in this country have urged the necessity for a record card for inoculations and have deprecated haphazard and unrecorded immunizations. It has already been suggested that there seems to be no valid reason why the National Health Medical Card (form E.C.4) should not be redesigned to cover this need. Once again this suggestion has to overcome the inertia of the Ministry of Health before it can be implemented. The sooner a start is made in that quarter the sooner will civilian prophylaxis become as efficient as the excellent Barr-Sachs report⁴ indicates that it has become in the armed Services.—I am, etc.,

London, N.W.1.

Food-poisoning

SIR,—The main efforts to control food-poisoning in this country have been concentrated upon improving hygiene in kitchens and other places where food is prepared or sold. Despite the fact that this campaign has been waged for several years, the incidence of food-poisoning is still increasing. Sir William Savage (*Journal*, August 11, p. 317) is of the opinion that increased methods of exhortation will be necessary before this campaign has any great effect. Although this may be so, I believe, at least as far as salmonella infection is concerned, that it could be very

Obituary

E. M. LOURIE, M.B., M.R.C.P., D.P.H.

Dr. E. M. Lourie, chief of the Section of Biological Standardization of the World Health Organization, died suddenly in Geneva on August 11 at the age of 52.

Born at Johannesburg, South Africa, on February 18, 1904, Emanuel Mannie Lourie obtained the London Conjoint diploma in 1927 and the London degrees of M.B., B.S. in 1928, after receiving his medical education at the University College Hospital Medical School. He took the D.T.M.&H. of the London School of Hygiene and Tropical Medicine in 1930, the D.P.H. in 1934, and was elected M.R.C.P. in 1948. Two years after qualification Lourie went to Palestine to work on leishmaniasis with his friend, Professor Saul Adler. In 1930 he joined the staff of the Liverpool School of Tropical Medicine, and in the following year became Rockefeller Research Fellow of the Medical Research Council and worked in Chicago with Professor W. H. Taliaferro. There he devised a method for testing drugs on avian malaria which subsequently was adopted in laboratories throughout the world. In 1934 he returned to Liverpool as a Beit Memorial Fellow under the direction of Professor Warrington Yorke, with whom he was intimately associated in continuous work on the chemotherapy of protozoal infections until the death of Professor Yorke in 1943. Lourie was then appointed the first director of the department of chemotherapy of the Liverpool School of Tropical Medicine and so served until 1948. After a short period in the department of pharmacology in Oxford he finally assumed the office of chief of the Section of Biological Standardization of the World Health Organization, a post which he held until his untimely death. In 1945 he was awarded the Chalmers Memorial Gold Medal by the Royal Society of Tropical Medicine and Hygiene for his outstanding contributions to tropical medicine.

A man of ability, indefatigable industry, and complete intellectual honesty, Lourie's publications were numerous and of high quality. The pharmacology of the synthetic drugs and the problem of drug-fastness were his special interest, and he did much to advance knowledge in each of these fields and published many papers on these and allied subjects. Together with Warrington Yorke he discovered the diamidine series of drugs and developed them in the treatment of protozoal infections of animals. When penicillin first became available it was Lourie who showed its efficacy against spirochaetal infections in laboratory animals and forecast its role in the treatment of human syphilis. This shortly afterwards was substantiated by himself and others. During the early years of the second world war he was in West Africa investigating an epidemic of sleeping sickness, and there he initiated extensive field trials on the treatment of the disease with the diamidine group of drugs, which fulfilled the promise of his initial experiments. On his return home the ship in which he and his wife were travelling was torpedoed.

As a man, Lourie was charming and accomplished, and a delectable companion; no mean athlete, he equally was interested in the arts and muses. Of great personal integrity, he was singularly free from a desire for personal advancement and from those jealousies which may cloud scientific endeavour. His generosity to his junior colleagues is evident in the lists of authorship

profitably aided by directing a little more attention at points earlier in the process of food production.

As an example of this, may I refer to the position with regard to emergency-slaughtered animals? For the benefit of your readers who are not acquainted with meat production I would mention that these are sick animals taken to abattoirs for slaughter in the hope that their carcasses will be suitable for human consumption. In large abattoirs a room is set aside for the slaughter of such animals, but in many small ones all animals, sick and healthy, have to be slaughtered out of necessity in the same room and by the same personnel. Meat inspection in these small abattoirs is usually not a continuous process, and consequently some considerable delay may occur before an emergency-slaughtered animal is officially inspected, during which time the slaughter of healthy animals continues.

Emergency-slaughtered animals have been responsible for some of the most severe outbreaks of food-poisoning ever recorded. It is not unusual, too, for some of them to be found to be suffering clinically from other diseases, such as tuberculosis, that are communicable to human beings. I firmly believe that emergency-slaughtering, particularly in the small abattoirs, merits much more serious attention from those concerned with the maintenance of public health.—I am, etc.,

Stock, Essex.

H. WILLIAMS SMITH.

Broken Probe

SIR,—May I suggest that Dr. G. H. Gibbens (*Journal*, July 28, p. 240) buy one or two Jobson Horne's probes? These are standard equipment in E.N.T. work and will do all that his pieces of wire will do and will last longer than the owner. They are made of stainless steel and are about 18 cm. long and 2-3 mm. thick in the middle of the shaft, which is usually octagonal in cross-section and tapers towards the ends, one of which is flattened with fine lateral serrations on the terminal 1.5 cm. or so and the other of which carries a fine loop about 3 mm. in diameter.

The use of cut wire, as described by Dr. Gibbens, to do anything with an eye (or an ear) seems unwise. It is impossible to cut wire without leaving the ends rough. If the art of digital eversion of eyelids has not been acquired, a wooden "applicator" is the best instrument. The applicator undoubtedly is unsatisfactory, because of its excessive diameter, for mopping out ears. However, if any reader can suggest something more suitable for use at home by patients' relatives in those cases needing more frequent aural toilet than can be given by the practitioner, I shall be glad to hear of it.—I am, etc.,

Gaillimh, Ireland.

SEAGHAN UA CONCHUBHAIR.

POINTS FROM LETTERS

"Pop-gun" Containers

Dr. JOHN M. HARDY (Burnley, Lancs) writes: May I draw attention to a danger to children from the plastic containers of tablets with a well-fitting cork? When empty and with the stopper in position, a sudden squeeze projects the stopper with remarkable force—certainly equivalent to the old cork "pop-gun."

Innovation in Technique for Dental Gas

Dr. C. J. COOPER (Blanes, Spain) writes: "... A suitable mouth prop is inserted ... and the child is instructed to blow out and in through the nose" (*Journal*, May 12, p. 1085—my italics). Dr. Arthur Tom appears to have thought of everything in his paper "An Innovation in Technique for Dental Gas," so I shall not cavil at the slight misuse of language in saying "blow ... in" for "breathe in" when referring to the nose, if in practice he gets the more forcible respirations that he wants. But I should like to know why he does not simply say to his young patients, "Put your tongue on the roof of your mouth (or put your tongue up) and breathe hard in and out." Is it not possible that those whose "nasal respiration is not satisfactory" have simply omitted to put their tongues up in the moment of stress? The child has his mouth propped open and cannot ask questions, so is it not important to give very clear instructions?

of papers on which his name appears. They and his very numerous friends in various parts of the world share a great sense of loss with his wife, Olga, and their young son, Michael.—A. R. D. A.

LILIAN HUTTON, M.B., D.P.M.

The death of Dr. Lilian Hutton at the age of 52 on August 8 after a long illness has brought a sense of grief to her colleagues and patients, whom she so loved, at the Burden Neurological Institute, Bristol, at which she was clinical director.

Lilian Hutton was born on March 25, 1904, and was trained at the Royal Free Hospital, London, graduating M.B., B.S., London, in 1928. Her early experience in psychiatry was obtained at Harton Hospital, South Shields, and at Rainhill Hospital, Liverpool. In 1932 she took the D.P.M. of the English Royal Colleges, and in the following year obtained an appointment at Horton Hospital, Epsom. She left Epsom in 1939 to join the staff of the Burden Neurological Institute.

Dr. W. D. NICOL writes: In 1933 Lilian Hutton came south and I had the good fortune to have her as a colleague at Horton Hospital. She was the first medical officer to receive a clinical research appointment under the London County Council, and for some seven years she worked with me at the special malaria therapy centre, now the Mott Clinic, for the treatment of neurosyphilis. Her flair for research and her keen industry made for a happy team with Mr. Shute and myself, and several papers on the problems of neurosyphilis and malaria were published. It was a matter for regret at Horton when Dr. Hutton left to join Professor F. L. Golla as the clinical director of the Burden Neurological Institute. I always felt that there she was given a wider scope for her researches and I am sure the hopes which she entertained were abundantly fulfilled. At the Burden Institute her activities were switched to psychotherapeutic problems of the neuroses. Lilian Hutton was a remarkable person, and her death at the height of her powers is a severe loss to psychological medicine. To her mother, with whom she lived, we extend our sympathy.

Professor F. L. GOLLA writes: Dr. Hutton always desired to engage in psychotherapeutic research unhampered by the many difficulties and restrictions incidental to the organization of a large public hospital, and hence was willing to accept the joining the Burden Neurological Institute to accept the material sacrifices involved in exchanging a Government position for the freedom of an autonomous research centre. Her earlier work at Horton in the establishment of the celebrated clinic for the malarial treatment of neurosyphilis, and her researches on the aetiology of schizophrenia at the Central Pathological Laboratory at Denmark Hill, made it possible for her to appreciate the nexus between the bodily and mental disorder with full recognition of the validity of both psychological and physiological research methods.

At the Burden Neurological Institute in 1939, when she assisted at the introduction of electric convulsion therapy and leucotomy into this country, she published some pioneer papers on the psychological results of these methods and later participated in research work on imagery and neuroendocrinology. When war conditions made access to research patients easier she was able to devote herself to research on the psychotherapy of neurotic conditions. Both as a clinician and as a laboratory worker she was very alive to the value of the contributions of physiological psychology, but she had the wisdom to realize that in the present state of our knowledge there is little to be gained, and much to lose, by any attempt to elucidate disorders of conduct by an exclusive use of either physiological or psychological methods. She considered a pragmatic approach as the one

likely to be most fruitful. But, though she refused to be limited by methodological considerations, she came to see more and more clearly that phenomenism is not enough when we apply our methods of description to psychiatry.

Of a deeply religious nature, she felt that no system of psychotherapy is likely to succeed if it does not attempt to deal with the patient's spiritual difficulties. Though she subscribed to the teaching of Jung, that a neurotic is essentially a person in search of his soul, she felt that Jung's concept could be more fully expressed by a more activist attribution. To love, not to be loved, is, she maintained, the ultimate goal, in the quest for which psychological medicine requires the aid of religion. Love thus understood is not merely intrapersonal but must so be directed as to embrace the eternal values.

In her small clinic of in-patients and her larger collection of out-patients she obtained remarkable success with cases of neurotics of many years' standing. In some such cases that had hitherto proved to be refractory to every form of treatment her results were both dramatic and permanent. Though she wrote little her fame spread to other countries, and much of her time was given to answering inquiries from abroad and in interviewing colleagues from all parts of Britain. At the time of her death she was actively engaged in collating her great mass of clinical observations with a view to publication. She was loved by her patients and loved and admired by her colleagues. Those who knew her only as a physician mourn the loss in the fullness of her powers of a very great teacher and healer, and it is little short of a calamity that her early death has finally prevented her views from becoming made widely known.

H. P. PICKERILL, C.B.E., M.D., Ch.M., M.D.S.
F.R.A.C.S.

Mr. H. P. Pickerill, consulting plastic surgeon to the Wellington Hospital, New Zealand, died on August 10 at the age of 77.

Henry Percy Pickerill was born in England, at Hereford, in 1879, and was educated at Hereford College. In 1896 he was articled to a dental surgeon in Hereford, where he worked until 1900, when he entered Birmingham University as a dental student. He had a brilliant career there, winning the Charles Greene Memorial Medal and the senior prize among other awards. He obtained the diploma of L.D.S. of the Royal College of Surgeons of England in 1903 and the Birmingham B.D.S. in the following year. Having decided to take a medical qualification, he graduated M.B., Ch.B. in 1905 while holding the appointment of demonstrator at the Birmingham Dental Hospital. In 1906 he became assistant surgeon at the hospital and lecturer on dental histology and pathology in the university. In 1911 he was awarded the Cartwright Prize and Medal by the Royal College of Surgeons of England for his essay on the prevention of dental caries, and in the same year he proceeded to the M.D. and the M.D.S.

Soon afterwards Pickerill went to New Zealand, where he held a teaching post at the University of Otago. But the first world war brought him back to England as a member of the 1st New Zealand Expeditionary Force. Eventually he attained the rank of lieutenant-colonel in the New Zealand Medical Corps and became officer in command of the New Zealand section at Queen Mary's Hospital for facial injuries at Sidcup, in Kent. By this time he was widely known for his skill as a plastic surgeon, and for his services he was appointed O.B.E. in the 1919 Birthday Honours. He was promoted C.B.E. in the New Year Honours of 1923 for valuable services rendered since the war in connexion

with facial and jaw operations on wounded soldiers in New Zealand. In the same year he proceeded to the Ch.M. After the war Pickerill returned to his work in New Zealand, being appointed surgeon in charge of the facial and jaw department at the Dunedin General Hospital and director of the dental school of the University of Otago. In 1927 he moved to Australia and settled in practice in Sydney, becoming honorary plastic surgeon to the Royal North Shore Hospital there. He did not stay long in Australia, however, but went back to New Zealand in 1935, this time to Wellington, where he was plastic surgeon to the Wellington Hospital and, later, to the Middlemore Hospital, Auckland. He was elected a Fellow of the Royal Australasian College of Surgeons in 1930. In later years he and his wife, who is also a plastic surgeon, did much valuable work at the Bassam Hospital, Lower Hutt, correcting congenital deformities in children.

A member of the British Medical Association for nearly fifty years, Pickerill was chairman of the Otago Division in 1922. He was also a foundation member of the British Association of Plastic Surgeons; a former vice-president of the Section of Odontology of the Royal Society of Medicine; and an honorary member of the Société Belge de Stomatologie. An expert on facial surgery, he contributed numerous papers on his special subject to the literature. He was twice married: first, in 1906, to Miss Mabel Knott, and secondly, in 1934, to Miss Cecily M. Clarkson, a medical graduate of the University of New Zealand. He had three sons and two daughters.

Dr. L. D. B. COGAN died at his home at Northampton on August 6 at the age of 81. Lee Danby Buxton Cogan was born on January 23, 1875, the son of Dr. L. F. Cogan, who was medical officer of health for the county borough of Northampton for twenty-six years and a justice of the peace there. From Epsom College he went on to Guy's Hospital, qualifying L.S.A. in 1898. He saw service as a medical officer with the Ashanti Field Force and in the Northern Territories of the Gold Coast before qualifying for the diploma of L.R.C.S.Ed. in 1903. A little later he settled in general practice at Northampton in partnership with his father. Always keen on the Volunteer movement, Dr. Cogan joined the Territorial Army as a lieutenant in the R.A.M.C. some years before the outbreak of the first world war in 1914, during which he was present at the Gallipoli landings. Later he held the post of assistant director of medical services of the 29th and Southern Divisions, and was in command of the 88th Field Ambulance with the acting rank of lieutenant-colonel when he was awarded the D.S.O. in the 1919 New Year Honours. He was also mentioned in dispatches. After the war he returned to his practice at Northampton, and for a time acted as senior clinical assistant at the Metropolitan Ear, Nose, and Throat Hospital when the hospital was in Fitzroy Square, London. In 1925 he obtained the diploma of L.M.S.S.A. For many years he was medical officer to the Northampton Post Office and factory surgeon for the Northampton district. He was also medical officer to the prison. In 1935 he was president of the Medical Practitioners' Union and had served on the council of the Union. From 1938 until he resigned in 1953 Dr. Cogan was a member of the Northampton County Borough Council, being appointed an alderman in 1952. He leaves a widow, one son, and three daughters.

With the death of Dr. H. C. BARTLETT on June 16 Saffron Walden has lost one of her oldest and most distinguished citizens. He was 92 years of age. Born in London on July 7, 1863, Hedley Coward Bartlett began his medical career at the age of 16 as an apprentice to Dr. Henry

Stear, a general practitioner in the market town of Saffron Walden, in Essex. After qualifying M.R.C.S., L.R.C.P. from the Middlesex Hospital in 1886, he held a number of house appointments at the Middlesex Hospital and also became clinical assistant at the Royal London Ophthalmic Hospital. Later he returned to Saffron Walden as a general practitioner, having bought Dr. Stear's practice on the latter's retirement. He practised there for over fifty years and was on the staff at the Saffron Walden General Hospital for over forty-three years as surgeon (1890-1933) and later as senior surgeon. During the first world war he was locally responsible for two Red Cross hospitals for convalescent soldiers and also for the wounded at the Saffron Walden General Hospital. He practised midwifery in remote cottages and farmhouses, often assisted only by a "handy woman" and a coachman holding a lamp. Dr. Bartlett practised in an age when the tradition of the family doctor played a vital part in the lives of the community. He was friend and confidant, and many to-day still pay tribute to his kindness and brilliance as a surgeon and his devotion to medicine and healing. In the early days Dr. Bartlett covered many miles on his rounds in carriage and pair or in a dog-cart. He was an early pioneer of motoring and one of the first doctors in East Anglia to possess a motor-car. Interested in the legal aspect of medicine, he was called to the Bar at Gray's Inn. He was a member of the Medico-Legal Society and medical referee for many insurance companies. He was a Fellow of the Society of Antiquaries, being particularly interested in old furniture, of which he made a large collection. In 1912 he bought and restored a small mediaeval castle, known as Pembridge Castle, on the Welsh border, where he lived after he retired in 1939. In 1891 he married Miss Flora Sibley, daughter of Dr. Septimus Sibley, a London general practitioner. She died in 1948. He is survived by one son and four daughters. His eldest daughter on qualifying went into partnership with her father, the son joining the partnership ten years later.

The obituary of Dr. D. F. WHITAKER was printed in the *Journal* of August 11 (p. 365). C. M. S. writes: May a further tribute to Donald Whitaker be paid by one privileged to claim friendship with him, particularly on central committees during the past five years? No one could fail to be impressed by his deep sincerity, which added great weight to his invariably sound opinion. Ever jealous of the honour and traditions of his beloved profession, he had, like so many of his generation, become increasingly perturbed at many of the effects and implications of the N.H.S. that have become increasingly apparent since 1948: but nevertheless he firmly continued to give of his best, with far too great a strain on his constitution. Few committees could ever have had a more conscientious and valuable member, and yet, with it all, he managed to enjoy the good things of life to the full, as evidenced at the Brighton Meeting. He was impatient with the second-rate, and his acuity of vision enabled him to detect the sham when covered by a mask of plausibility.

W. E. S. writes: May I, as a fellow student of Donald Whitaker at University College Hospital, add a few words to the obituary notice published in the *Journal*? As a student he was a keen member of the hospital rugby team and an active supporter of numerous student functions. He was a tall man of distinguished appearance, but spoke always in a quiet voice, giving an outward impression of imperturbability. His dealings with patients were marked by conscientiousness, kindness, and common sense. Although in later years he became a member of many committees, his sense of humour prevented him from becoming pontifical. He was brought up in Hendon, where he retained many contacts and will be much missed, as also at the annual gatherings of old U.C.H. students. He married a daughter of the well-known surgeon, the late Mr. Mower White, and had three children, one of whom is entering the medical profession. To them and his widow deep sympathy is extended in their bereavement.

Medico-Legal

EYES OFFERED TO SAVE SIGHT NOT TO BE USED FROM LIVING PERSONS

Miss Pat Hornsby-Smith, Parliamentary Secretary, Ministry of Health, has stated why the Ministry could not take advantage of the offer a number of people had made to give in their lifetime one of their eyes to help save the sight of other people who would otherwise be completely blind. Replying to Lieutenant-Colonel Marcus Lipton, Labour M.P. for Brixton, who asked for an official ruling from the Ministry, Miss Hornsby-Smith says in a letter dated August 13 that similar offers have been made from time to time direct to the department. "The law on the matter is not certain, but I am advised that it is at least possible that for a surgeon deliberately to remove a sound eye from a living person, even with that person's consent, might be held to be a criminal offence. In any case it seems most unlikely that surgeons would be willing to perform the operation. At the same time I am glad to be able to let you know that we have recently been able to improve the arrangements for supplying the hospitals which carry out corneal grafting with eyes derived from patients who have died in these hospitals, and we hope that the shortage from which these hospitals have been suffering is being brought to an end. None of this, of course, detracts in any way from the splendid spirit of the people who have offered to give their eyes while they are still alive."

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

In Congregation on August 4 the following degrees were conferred:

M.D.—J. M. S. Knott, I. H. Mills, K. Brown-Grant, R. H. B. Protheroe, J. P. D. Thomas, M. F. Bethell, M. T. Parker.
M.B., B.Chir.—A. H. H. Johnson, *R. W. Lister, B. M. King, V. Whitehead, *J. A. D. Todd, F. Mansfield, *P. S. Bentlif, *P. D. Jackson, J. Shaw, *W. R. B. Jones, *G. Maisel.
M.B.—*L. G. Whitby, N. F. Jones, R. E. Scott, *G. M. Petrie, *G. Yates, *C. P. K. Watson, *R. T. Barrie-Adshad, *A. L. Gunn, T. W. Young, *R. W. M. Smith, *O. W. Hill, *R. K. L. Percival Smith, J. K. L. Jones, G. E. G. Williams, *C. A. Fox, G. W. M. Faris, N. D. Kilpatrick, M. G. Smedley, P. C. Bewes, T. W. Hoskins, *P. F. Gray, A. C. Keegan, *Jennifer M. D. Gibson, *Elizabeth D. Hocking, *Frances J. Keegan, *Brenda J. Sheail, *Jean E. Vallis, *Margaret F. Beard, Eleanor M. Bray, *F. G. Cooper, *V. Cope, *K. A. McL. C.-O. Swinburne.
*By proxy.

UNIVERSITY OF GLASGOW

The following degrees were conferred on July 7:

M.D.—*R. J. Calvert, *R. C. Curran, *J. T. G. Ewan, *K. C. Wybar.
Ch.M.—*W. T. Irvine, *W. B. Stirling.
M.B., Ch.B.—*R. T. Abbott, A. Abdurahman, G. Abrami, D. C. Azbo, Eleanor McL. Aitken, J. M. Allan, W. K. G. Allan, Catherine F. Anderson, R. L. Andrew, Sarah L. Armour (Mrs. Hemming), A. A. Atkinson, S. Azimuddin, Moira C. Baird, W. L. M. Baird, W. H. Beattie, J. M. Bell, Margaret J. A. Blackwood, T. Blair, B. B. Borthwick, M. F. Brewster, *K. A. C. Brown, *N. MacL. Brown, J. S. Bryden, G. D. Burnett, A. T. Calder, J. A. Caldwell, Veronica R. Carson, Georgina M. Chadwin, I. A. Chisholm, G. A. Clark, C. Comyns (name changed from Comens), Ruth S. R. Conacher, P. Connolly, F. M. Cranna, J. M. Crombie, Martha K. Cuthbertson, J. Dalling, T. W. B. Davidson, W. C. Davidson, Jean S. Dick, G. Drummond, A. A. Efunkoya, W. M. Elder, I. L. Felstein, A. K. Foli, W. Frank, A. S. Fraser, J. B. W. Galloway, I. D. G. Garvie, I. Ian J. Geddes, S. W. George, J. B. Gibson, Jane M. B. Gilchrist, Mary L. Girkins, J. F. Glencross, J. G. Graham, A. J. Hardie, Greig, R. C. Grievie, W. D. Guy, Elizabeth H. Hamilton, A. J. Kelly, J. R. G. Hayes, Robina M. Herd, Helen E. Holms, R. W. Irvine, Elizabeth J. A. Ives, *L. Johnson, D. Johnston, Julia A. Keane, J. H. Kleinglass, J. A. Kernohan, I. F. Kerr, J. F. Kirk, I. B. Kirkland, A. H. Klein, C. J. Laithwaite, T. W. Lindsay, Elizabeth R. Lohar, I. T. Loudon, C. J. Macaulay, Sheila H. McCulloch, A. R. McCutcheon, C. McDonald, W. W. McDougall, Grace N. Macfarlane, W. G. McKenna, Harriet B. MacKinnon, McHugh, J. MacKay, J. D. McKean, B. R. Maclean, B. G. P. Macnamara, (formerly Shaw), Sheila A. H. McLaren, J. MacShane, A. J. N. McNeill, A. D. McNeill, R. L. McRitchie, W. Miller, G. McN. Milne, Marshall W. Marsnall, A. MacG. Michael, J. Morrison, J. J. Morrow, N. R. G. McK. Mitchell, D. L. Morrison, J. Neilson, Barbara J. L. Morton, A. Munro, D. S. Munro, R. K. Murray, M. L. Peacock, J. L. Newman, T. L. O'Donnell, B. Patel, E. H. Paterson, M. L. Peacock, J. L. Price, A. J. Rintoul, K. K. T. Robertson, Ann F. M. Savage, I. W. H. Scott, Joanne E. M. Scott, Mary B. Simpson, M. W. Smellie, I. Soutar,

D. Stephen, R. McK. Still, J. Stothers, F. W. C. Surgenor, W. Susskind, R. M. R. Taylor, A. B. M. Telfer, *J. A. Thomson, R. G. B. Turner, D. A. L. Watt, Doris S. Whiteford, S. Witherspoon, D. G. Young, J. J. Young.

*With commendation. *With honours.

UNIVERSITY OF EDINBURGH

At a graduation ceremony on July 18 the following degrees and diplomas were conferred:

M.D.—B. A. Bembridge, *W. P. Cockshott, *J. R. Fountain, *I. C. Lewis.
Ch.M.—R. B. Duthie (awarded gold medal for thesis).
Ph.D.—*In the Faculty of Medicine*: K. B. Singh, M.S. (in absentia), H. P. Sinha, M.B., B.S. (in absentia), Maung Mya Tu, M.B., B.S.
M.B., Ch.B.—E. I. Adam, Margaret Aitken, W. B. Aitken, Mary M. Anderson, O. A. Audain, P. M. Barnes, J. S. Barr, J. C. J. Li. Bath, R. W. Bell, F. E. P. Bernard, G. W. Beveridge, R. D. R. Birtwhistle, L. McM. Black, Joan M. Bradley, D. P. Braid, C. Brough, Rose M. Brown, Bridget M. Buchanan, D. A. Buchanan, G. O. D. Busby, A. Cameron, A. E. Cameron, J. A. Cameron, R. V.-V. Cavaroli, W. G. Charlesworth, G. J. A. Clunie, A. D. Colledge, S. J. Cooper, I. C. Crawford, C. Croll, G. G. K. Davidson, C. A. R. Dennis, Ruth Douglas, *T. W. Fenton, A. J. W. Fordyce, D. F. Foster, G. L. Frank, Christina A. Fulton, P. W. Gason, W. K. Gibb, A. A. M. Gibson, A. B. J. Gilbert, W. L. A. Gilchrist, J. Gordon, J. G. Govan, D. E. Graham, G. S. Graham, G. C. Greig, A. R. Grievie, J. Gunn, T. Hall, T. Hamilton, Agnes M. Hay, C. P. Heflon, M. A. Henderson, W. E. Howieson, J. J. Huston, D. C. Ingham, J. T. Ireland, P. Jacques, Ann R. Karnitschnig (formerly Gaddum), G. M. Kay, K. M. G. Keddie, I. W. Kemp, R. Lampard, *A. O. Langlands, Annabel M. Lauchlin, *D. Leak, P. Lee, J. R. B. Livingstone, E. B. Longon, J. N. McCormick, H. R. Macdonald, Isabella S. Macdonald, F. M. McGurk, Catherine J. McHardy, J. C. MacInnes, I. MacG. MacIntyre, J. C. McIntyre, B. Mackay, I. M. Mackay, D. S. Mackenzie, J. Markie, Shirley A. Markintosh, Gillian E. MacKrell, A. R. MacLeod, J. MacLeod, J. P. A. McManus, F. J. McMinn, J. MacSweeney, D. O. Marsh, J. McK. Mason, M. D. Middleton, D. R. Millar, E. N. C. Milne, Norah Milne (formerly Symington), W. M. U. Moffat, D. Morton, N. J. Moule, Aileen C. Munro, J. C. M. Murphy, W. D. Murray, E. K. Newman, Marjorie S. Newton, R. T. Nicoll, D. L. Norrie, N. D. Ogilvie, F. R. Orr, Elspeth M. Paterson, R. S. Phillips, K. Protheroe, A. G. C. Renwick, G. R. Rogers, R. M. Savage, J. M. Scott, D. S. Sibbald, B. Simpson, Catherine M. Simpson, Barbara Somerville, N. A. McC. Somerville, D. A. Spence, S. C. E. Spink, B. R. Stead, J. D. Sutherland, Norma E. I. Temple, W. J. Thomson, M. A. Turner, B. J. Tyson, J. A. Waddell, Brenda Wainwright, A. A. Walker, Aline M. Watson, S. I. Williams, A. R. Wilson, P. Wilson, W. L. Yule.
DIPLOMA IN PUBLIC HEALTH.—A. H. Duncan, W. M. Fee, R. Y. Forbes, Ruth E. Graham-Yooll, J. M. H. Hopper, R. A. Ingles, Elinor K. Johnston, Ko Ko, H. R. W. Miller, A. R. Mills, S. R. Nair, Kee Saik Ooi, R. S. H. Pasqual, D. Shearer, R. Steele, W. Williams.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—G. C. Anbunathan, A. Annamalai, G. I. Forbes, Tun Tun Hlaing, A. D. McIntyre, M. P. Misra, P. Rabindran, A. McQ. Robertson, J. R. K. Robson, A. W. H. Thomson, Dorothy N. Ullah, S. K. Vaish, J. Wilkinson, V. Zaman, O. K. Hazari.

The following scholarships, etc., were awarded in the Faculty of Medicine: Cameron Prize in Practical Therapeutics, jointly to Professor W. D. M. Paton and Dr. Eleanor Zaimis in recognition of their work on methonium compounds. Ettles Scholarship and Leslie Gold Medal in Medicine, James Scott Scholarship in Obstetrics and Gynaecology, Beane Prize in Anatomy and Surgery, A. O. Langlands. Scottish Association for Medical Education of Women Prize and Dorothy Gilfillan Memorial Prize, Margaret Aitken. Buchanan Scholarship in Obstetrics and Gynaecology, Mouat Scholarship in the Practice of Physic, Keith Memorial Prize in Systematic Surgery, and Murdoch Brown Medal in Clinical Medicine, David Leak. Annandale Gold Medal in Clinical Surgery, D. P. Braid. Royal Victoria Hospital Tuberculosis Trust Gold Medal, G. O. D. Busby. Graduate Research Fellowships, G. D. Campbell, A. Peters, J. H. Tait, Elizabeth M. Humphreys. Sir David Wilkie Research Fellowship in Medicine, R. B. Cross. James Traquair Scholarship, J. Hindley. Graduate Research Scholarships, E. W. Horton, Margaret A. J. Moffat, J. A. Hodgson. Graduate Travelling Scholarships, J. A. L. Clark and T. T. S. Ingram. Ellis Prize in Physiology, E. A. Harris. Gunning Victoria Jubilee Prize in Public Health and Social Medicine, J. A. H. Lee. William Leslie Prize in Medicine, L. J. P. Duncan and B. C. Paton (equal). Lawrence Poole Prize in Rehabilitation after Poliomyelitis, W. J. W. Sharrard. Greig Medal for Tropical Medicine, J. Wilkinson. Wellcome Prize and Medal in the History of Medicine, E. W. Horton.

*Highly commended for thesis. *Commended for thesis. *With honours.

The Services

Major-General D. Bluett, O.B.E., late R.A.M.C., Deputy Director of Medical Services, Eastern Command, has been appointed Honorary Physician to the Queen, in succession to Major-General A. Sachs, C.B., C.B.E., retired.

Colonel W. D. Hughes, C.B.E., late R.A.M.C., has been appointed Honorary Physician to the Queen, in succession to Colonel (Honorary Brigadier) J. T. Robinson, O.B.E., retired.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending August 4 (No. 31) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1956					1955				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications in the week ending August 11 (32nd week of the year) were as follows: paralytic 54 (73), non-paralytic 75 (58), total 133 (131). This is an increase of 2 compared with the previous week, the figures for which are in parentheses.

Cases notified from the beginning of the year (with rate per 100,000 in parentheses) are as follows for districts of relatively high incidence: Macclesfield M.B. 25 (69), Whitehaven M.B. 22 (87), Ennerdale R.D. 18 (63), Yeovil M.B. 19 (79), Guildford M.B. 33 (70), Manchester C.B. 241 (35), Woking U.D. 21 (38), Reigate M.B. 17 (35), Middleton M.B. 14 (33), Guildford R.D. 15 (32).

Week Ending August 11

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 275, whooping-cough 2,134, diphtheria 4, measles 2,685, acute pneumonia 136, acute poliomyelitis 133, dysentery 443, paratyphoid fever 12, and typhoid fever 5.

Infectious Diseases

The incidence of infectious diseases fell in England and Wales during the week ending August 4. The decreases in the number of notifications were 242 for whooping-cough, from 2,388 to 2,146; 240 for dysentery, from 843 to 603; 147 for scarlet fever, from 573 to 426; 85 for food-poisoning, from 419 to 334; 50 for measles, from 3,270 to 3,220; and 29 for acute poliomyelitis, from 160 to 131.

The largest declines in the notifications of whooping-cough were 86 in Yorkshire West Riding, from 236 to 150, and 40 in Warwickshire, from 201 to 161. A fall in the incidence of scarlet fever occurred throughout the country, but no large local fluctuations were recorded. The largest variations in the local trends of measles were decreases of 105 notifications in London, from 363 to 258; 75 in Cornwall, from 284 to 209, and a rise of 99 in Oxfordshire, from 96 to 195. The outbreak in Oxfordshire was mainly confined to two areas, Witney U.D. (102) and Witney R.D. (54). No case of diphtheria was notified. This is the first week since records have been kept that a case of diphtheria has not been reported.

The chief centres of dysentery were Yorkshire West Riding 106 (Rotherham C.B. 39, Leeds C.B. 22); London 94 (Hackney 10, Greenwich 9, Stepney 9); Lancashire 69 (Liverpool C.B. 17); Warwickshire 59 (Coventry C.B. 38, Birmingham C.B. 15); Leicestershire 26 (Leicester C.B. 24).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

New Medical School in Africa.—The University College of Rhodesia and Nyasaland has appointed a committee to advise it on the desirability and practicability of establishing a medical school. The committee is to prepare proposals for the training curriculum, research facilities, buildings, the equipment, and staffing, and estimates of the costs. The following are the members: Mr. L. FARRER-BROWN (Director, the Nuffield Foundation), chairman; Professor W. MELVILLE ARNOTT (William Withering Professor of Medicine, University of Birmingham); Professor T. H. DAVEY (Middlemass Hunt Professor of Tropical Hygiene, University of Liverpool); Professor A. D. M. GREENFIELD (Dunville of Belfast); Professor of Physiology, Queen's University of Belfast); Professor P. B. MEDAWAR, F.R.S. (Jodrell Professor of Zoology, University College, London); Professor R. MILNES WALKER (Professor of Surgery, University of Bristol); Dr. HONOR M. V. SMITH (May Reader in Medicine, University of Oxford). The committee will make a preliminary visit to the Federation of Rhodesia and Nyasaland in January, 1957.

"Tranquillizers."—In a statement published in the *Pharmaceutical Journal* of August 11 (p. 97) the council of the Pharmaceutical Society calls attention to "the recent intro-

duction of a number of new products which owe their use to their depressant action on the central nervous system." The statement goes on: "While these drugs are not advertised to the public a widespread public knowledge of them has been created by newspaper articles, and there is a substantial demand for them otherwise than on prescription. The indiscriminate use of such drugs is, in the council's opinion, against the public interest, and the council are approaching the Ministry of Health requesting an early consideration of this class of drugs. Pharmacists are advised not to display them or to supply them unless satisfied they will be taken on medical advice."

High Energy Radiation Unit.—A new high energy radiation treatment unit at Cookridge Hospital, Leeds, was opened recently by the Princess Royal. This unit marks the completion of the first stage in the development of Cookridge Hospital as a regional radiotherapy centre, a development made possible by the co-operation of the Board of Governors of the United Leeds Hospitals, the Rockefeller Foundation, the British Empire Cancer Campaign (Yorkshire Council), the University of Leeds, and the Leeds Regional Hospital Board. The new unit is claimed to be unique in Great Britain in that it has been specially designed for the dual purpose of radiotherapy and radiation research. There is only one other therapeutic source of radio-cobalt of equivalent size in the country, a Canadian gift to the British Empire Cancer Campaign. Smaller cobalt units exist, however, in various British centres, the two in the Leeds region being at the General Infirmary at Leeds and the Radium Institute at Bradford. The Cookridge Unit has been established to provide new facilities for the treatment of cancer and for the study of the physical, chemical, and therapeutic action of high energy radiation. This sharing of a powerful radiation source by radiotherapists, chemists, and physicists was planned because of its economic use of expensive apparatus and also to bring together a group of medical and non-medical men working on problems which have much in common and are fundamental to radiobiology. The source of high energy radiation at this new unit will emit radiation equivalent to a machine working at about 3,000,000 volts.

Hunter House Memorial Fund.—A committee representing the University of Glasgow, the Royal Faculty of Physicians and Surgeons of Glasgow, and the East Kilbride Development Corporation has been set up to raise a fund for the renovation and preservation of the birthplace of William and John Hunter at Long Calderwood, East Kilbride (illustrated below). A nucleus of nearly £3,000 has been raised in Scotland. A total sum of £20,000 is aimed at, and, of this, £3,500 will be needed urgently to restore the fabric of the house, leaving the balance as an endowment fund. It is planned to organize a board of trustees with appropriate representative interests to maintain the restored house as a memorial, a museum, a place of pilgrimage, and, possibly, as a research centre. In its appeal, which is now

(Harry Blake, Strathaven)

extended to all medical men, the committee states that "urgent action is necessary to save this national historic monument as a fitting memorial to the two brothers whose names will ever be gratefully remembered for their unique achievements in the advancement of medical knowledge." Cheques should be made payable to the "Hunter House Memorial Fund" and sent to the Hon. Treasurer, Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, C.2.

Mental Health Research Fund Awards.—A grant of £200 has been made to Dr. JAMES A. HISLOP, of the department of human ecology and university health service, Cambridge, for investigation of the length of stay of patients admitted to Fulbourn Hospital from the Isle of Ely during the past hundred years. This area has been chosen because of its "immobile" population, which for generations has been served by the same hospitals. A Leverhulme grant has been made to the University of Leeds towards the cost of a senior research fellowship awarded to Dr. MAX HAMILTON, senior lecturer in the department of psychiatry, who is investigating constitutional and other aspects of the patient suffering from paranoid disorders with a view to finding some tests or assessments which will give information about the probable response to treatment by electric convulsion therapy or insulin shock. A travelling fellowship has been awarded to Dr. R. P. HULLIN, lecturer in the department of biochemistry, University of Leeds, to enable him to spend a year chiefly in the department of physiological chemistry, University of Pennsylvania, investigating new biochemical methods which may be applied to the study of the blood in manic-depressive psychoses and endogenous depression.

Forensic Clinic in Toronto.—A Forensic Clinic has been opened recently in Toronto by the Department of Health of Ontario. While under the jurisdiction of the Department of Health, the Clinic also forms a division of the Toronto Psychiatric Hospital, and as such is affiliated with the University of Toronto. It carries out psychiatric appraisals on cases referred by the courts of Metropolitan Toronto, and in suitable cases psychotherapy is given. On such cases, and on those referred by probation officers, a specialized function of the clinic will be research on the problem of the sex offender. Cases of sex deviation are being received from a wider field than the courts—for instance, from private doctors and community services, etc. At present there is one full-time psychiatrist and one full-time psychologist on the staff. A social worker will be appointed in the immediate future, and a full-time research worker will be added within a matter of months. Further additions to the staff are expected in due course.

Retirement of Medical Librarian.—Mrs. EILEEN R. CUNNINGHAM, librarian of the school of medicine of Vanderbilt University, Nashville, Tennessee, has retired after 31 years of service. Since 1939 she had been professor of medical library science at Vanderbilt. In 1948 she was president of the Medical Library Association and received the first Marcia C. Noyes award for outstanding achievement in medical librarianship. Mrs. Cunningham has served on numerous international and national committees concerned with library services and with the documentation and interchange of scientific literature, and she has been active in promoting the recently organized International Association of Medical Libraries. The best-known of her written works is *Classification for Medical Literature*, the fourth edition of which we reviewed earlier this year (March 3, p. 499). Miss ELEANOR G. STEINKE, assistant librarian at Vanderbilt since 1946, will succeed Mrs. Cunningham.

COMING EVENTS

Doctor and Law.—The seventh International Congress of Catholic Doctors takes place in Scheveningen, Holland, during September 9–15. The subject is "The Doctor and the Law." Particulars from the Secretariate, 35, Herenstraat, Utrecht, up to September 1, and thereafter from the Palace Hotel, Scheveningen.

Lectures for Parents of Deaf Children.—The Deaf Children's Society has arranged a course of six lectures to help parents of deaf children. These will take place at the National Institute for the Deaf, 105, Gower Street, London, W.C.1, and will be as follows: September 13, 7 p.m., "The Deaf Child in the Family"; September 27, 7 p.m., "Lip-reading"; October 4, 7 p.m., "Auditory Training"; October 16, 7 p.m., "Language for Juniors"; November 1, 7 p.m., "Language for Seniors"; November 15, 7 p.m., "Reading Readiness." The lectures will be given by experts and the charge will be 1s. 6d. per lecture or 5s. for the complete course. Further particulars from WILLA A. MOOJEN, 92, New Cavendish Street, London, W.1.

Anthropology and Psychiatry.—Dr. MARGARET MEAD, of the American Museum of Natural History, New York, will talk on "The Contribution of Social Anthropology to Psychiatry" in the lecture theatre at Maudsley Hospital, Denmark Hill, London, S.E.5, on Friday, September 14, at 12 noon. Postgraduates are invited to attend.

Mackenzie Industrial Health Lecture.—The B.M.A., in conjunction with the Association of Industrial Medical Officers, announces that the sixth Mackenzie Industrial Health lecture will be given by Dr. R. S. F. SCHILLING on September 25 at 3 p.m. in the Great Hall, B.M.A. House, Tavistock Square, London, W.C.1. His subject will be "Assessing the Health of the Industrial Worker." All lay and medical, interested in industrial medicine are invited. There will be no charge for admission.

Nutrition in Pregnancy.—The Scottish Group of the Nutrition Society is holding a symposium in Dundee on Saturday, September 29, on human and animal nutrition in pregnancy. Further particulars from Dr. J. DAVIDSON, The Rowett Institute, Bucksburn, Aberdeenshire.

London County Medical Society.—A meeting of the Society will be held at 5.30 p.m. on October 4 at the County Hall, Westminster Bridge, London, S.E.1. The society will be addressed by Sir CLEMENT PRICE THOMAS, and his subject will be "Carcinoma of the Lung." Members of the Association of Industrial Medical Officers, the Middlesex County Medical Society, and members of the London Divisions of the B.M.A. are invited.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Clift.—On August 8, 1956, to Dorothy (formerly Newell), M.B., Ch.B., wife of Arthur Clift, F.R.C.S., a daughter—Cecilia Margaret—a fifth child.

Eton.—On August 10, 1956, to Ilse (formerly Ursell), wife of Bruce Eton, M.B., M.R.C.O.G., of 1, High Street, Trumpington, Cambridge, a daughter—Rachel Caroline.

Heyworth.—On August 11, 1956, at Bank Hall Maternity Hospital, Burnley, to Freda and Frederick Heyworth, a daughter.

Levy.—On August 16, 1956, to Dr. and Mrs. Basil Levy, of 63, Anfield Road, Liverpool, a son.

MARRIAGES

Bhattacharyya—Bagchi.—On February 3, 1956, at Calcutta, Bhahani Bhattacharyya, F.R.C.S., to Puraby Bagchi, M.A.

DEATHS

Armstrong.—On August 5, 1956, at 514, Anniesland Road, Glasgow, William Hunter Stirling Armstrong, M.B., Ch.B., aged 79.

Baird.—On August 7, 1956, at 44, Station Road, Blackpool, James Campbell Baird, M.B., Ch.B.

Bradley.—On August 7, 1956, at Fremantle, Overwallop, Hants, Neville Bradley, M.B., Ch.B.

Brough.—On August 8, 1956, at 30, Craigleith Hill Gardens, Edinburgh, David Sands Brough, M.C., M.B., Ch.B., D.P.H.

Christie.—On August 3, 1956, Arthur William Stark Christie, M.B., Ch.B., F.R.C.S.Ed., of 4, Glencairn Crescent, Edinburgh.

Cogan.—On August 6, 1956, at Highfield House, Northampton, Lee Danby Buxton Cogan, D.S.O., L.R.C.S.Ed., aged 81.

Garnett.—On August 9, 1956, Graham Hogg Garnett, M.D., of 14, Croom's Hill, Greenwich, S.E.

Goldie.—On August 3, 1956, Ellis Gordon Goldie, M.D., of 11, Park Avenue, Mansfield, Notts, aged 79.

Gow.—On August 8, 1956, at Nestlea, Newbury, Berks, Henderson Gow, M.B., Ch.B.

O'Driscoll.—On August 3, 1956, at Lydney and District Hospital, Lydney, Gloucestershire, John Patrick O'Driscoll, M.B., B.Ch., of Bream, Gloucestershire.

Slocombe.—On August 2, 1956, Bernard Atkinson Slocombe, M.B., Ch.B., of Springfield, Keighley, Yorks.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Life Expectancy of Doctors

Q.—What is the life expectancy of medical practitioners as compared with the general population? Please give figures for various countries, if such are available.

A.—In the middle of the last century Neison¹ examined the mortality experience of members of the Royal Medical and Chirurgical Society, and found 96 deaths at ages 26–70 compared with 97.1 in the corresponding general population. Hill² studied the early records of the Royal College of Physicians, and for various periods has compared the expectation of life of physicians, at age 35, with that of peers, with the following result:

	R.C.P.	Peers
1570–1689	30.3 years	28.6 years
1690–1749	32.1 "	31.0 "
1750–99	35.3 "	33.7 "

On the basis of the Registrar-General's occupational mortality data for 1910–12 for England and Wales, Hill calculated the expectation of life of medical practitioners aged 35 to be 32.7 years, compared with 31.7 years for all males. In 1921–3 and 1930–2 the Registrar-General³ found the standardized mortality of male medical practitioners aged 20–65 to be respectively 1% and 6% higher than that of the general population. No later official figures for England and Wales have been published.

In Scotland, in a 25-year follow-up study of 899 Glasgow medical graduates of 1923–6, Meiklejohn⁴ found their mortality "a good deal lighter than the mortality of the Scottish population as a whole." In France in 1907–8,⁵ death rates per 10,000 population in the total population and among physicians and pharmacists were as follows:

	Age in Years	25–35	35–45	45–55	55–64
Total population		80	112	178	320
Physicians and pharmacists		70	111	194	442

In the United States of America, Dublin and Lotka⁶ reported the expectation of life of physicians aged 30 in 1925 to be 38.01 years, compared with 37.60 for the general population. In 1938–42 Dublin and Spiegelman⁷ found that "physicians experienced practically the same longevity and mortality as white males of the same ages in the general population." Expectations of life at age 25 were:

	Male	Female
Physicians	43.54	47.10
U.S. white population	43.31	46.86

Diseases with high mortality rate amongst physicians were leukaemia, gall-bladder disease, cerebral haemorrhage, heart disease, arteriosclerosis, and cirrhosis of liver. Their mortality was low from syphilis, tuberculosis, prostatic disease, non-automobile accidents, and ulcer of the stomach and duodenum. The mortality of specialists⁸ was only 71% of that of non-specialists.

In an occupational mortality survey⁹ covering ten States of the United States in 1930, the mortality of physicians and surgeons was 87% of that of all occupied males in selected occupations.

Radiography as a Career after Unilateral Oophorectomy

Q.—Should a girl who has had a cystic ovary removed be discouraged, on genetic grounds, from her intention of becoming a radiographer? The remaining ovary was normal at operation.

A.—There is no reason, from a genetic point of view, why this girl should be discouraged from taking up radiography as a career. The fact that one ovary has been removed is not relevant in assessing any genetic hazard from the effects of irradiation. The genetic effects of ionizing radiation depend on the fact that an increased rate of mutation of genes, in the chromosomes of the germinal cells, occurs as the result of accumulation of dose. The possibility of some genetic effects is not influenced by the fact of whether both ovaries are present or whether one has been removed—that is, whether the normal complement or half that complement of germinal cells are present—and there is no greater danger in the case of this girl.

The conditions of employment of radiographers are governed by the recommendations of the International Commission on Radiological Protection, recommendations which have recently been reinforced by the report of the Medical Research Council Committee on radiation hazards.¹ The relevant recommendation is that an individual occupationally exposed—for example, a radiographer—"should not be allowed to accumulate more than 50 r of radiation to the gonads, in addition to that received from the natural background, from conception to the age of 30 years." An accumulated dose of 50 r is an estimate of the dose which would produce a doubling of gene mutation rate. Paragraph 188 of the Medical Research Council report states: "One may conclude that, if a relatively small group of prospective parents receives a doubling dose of radiation, no noticeable effects will be produced either on their immediate offspring or upon their descendants. For levels of radiation up to the doubling dose, and even some way beyond, the genetic effects of radiation are only appreciable when reckoned over the population as a whole and need cause no alarm to the individual on his own account."

Inhalation of Mucolytic Agents

Q.—What is the value of inhalation therapy with the modern mucolytic agents?

A.—These mucolytic agents are claimed to reduce the viscosity of sputum, thereby making it easier to expectorate. To understand how they might act, it is necessary to describe how viscid secretions form in the bronchi. Respiratory mucus is a gel of fibrous protein and polysaccharide molecules, held together by linkages which normally include water molecules. The more water the gel contains the longer these linkages become, making the network looser and weaker. Therefore the viscosity of the mucus varies inversely with its water content.

Sometimes, as in fibrocystic disease and after the use of atropine-like drugs, mucus is secreted in a viscid dehydrated state. Under normal circumstances it is the drying of the mucus after secretion which renders it viscid and difficult to expectorate. During quiet breathing air reaches the main bronchi saturated with water at body temperature, having been humidified in the upper respiratory passages. If this is prevented, as it is by tracheotomy or endotracheal anaesthesia or during hyperventilation, then air will take up moisture from the bronchial mucus, leaving it increasingly viscid. Air saturated at body temperature contains three times as much water as air saturated at room temperature, but an aerosol at room temperature contains less than twice as much. Partially dried viscid mucus in the bronchi will imbibe water from a saturated atmosphere and become less viscid, and it will imbibe a little water from air partially saturated by forming an aerosol at room temperature. Thus

a simple aerosol of water may reduce the viscosity of mucus. Mucus dried to the point of crusting will not imbibe moisture unless first broken down by chemical action.

Two kinds of "mucolytic" solutions for administration as aerosols have been used. The first contains a detergent, glycerin, and sodium bicarbonate. There is no evidence that such a solution affects the viscosity of mucus *in vitro*, and no controlled trials of its effect in man have ever been published. The only theoretical advantage of the solution over water is that it forms a more stable aerosol which may carry more water into the bronchi. The second type of solution contains trypsin, which is claimed to be specifically mucolytic. Trypsin is, in fact, a proteolytic enzyme which will damage the mucosa if used in sufficient concentration to affect dried mucus. Even premalignant changes in bronchial mucosa have been reported after the use of purified trypsin.¹ Lastly, trypsin is a foreign protein and its repeated use leads to sensitization.

No safe specific mucolytic agent has yet been discovered. In its absence prevention of viscid secretions is better than treatment. This is best done by ensuring an adequate fluid intake, eschewing atropine-like drugs, and by increasing the water saturation of inspired air.

Athlete's Foot in a School

Q.—What is the best method of dealing with an outbreak of athlete's foot in a secondary boys' school? Should the use of shower baths be prohibited in school?

A.—Shower-bath floors favour the epidemic spread of fungous infection of feet. The regular scrubbing of such floors with fungicidal detergents and the wearing of slippers reduces the risk. Regular washing of feet, the wearing of cotton socks which are regularly boiled, and the use of dusting powder for the toes and feet are also important prophylactic measures.

It is important first to find the causative fungus by culture, for some are curable and others incurable. Infection by *Trichophyton rubrum*, which is becoming more common in this country, is very difficult to eradicate.

Benzoic and salicylic acid ointment or lotion (3% of each) at night and a fungicidal powder (undecylenic acid types) by day are a good method of treatment. There are, however, many other effective fungicides, including the mercurials and dyes. Brilliant green ($\frac{1}{2}\%$) and perchloride of mercury ($\frac{1}{2}\%$) in spirit is also effective, but stains clothes. The presence or absence of infection in the nails is important, and, if present, it may be necessary temporarily to remove the nails. Disinfection of socks and shoes by formalinization is also wise.

Involution of the Uterus and Oestrogens

Q.—Does the exhibition of oestrogens during the puerperium, to suppress lactation, delay involution of the uterus?

A.—No.

Inheritance of Friedreich's Ataxia

Q.—How is Friedreich's ataxia inherited? A woman, whose twin brother died from the condition at the age of 23, wishes to marry. What is the prognosis regarding her life and the chance of her children being affected?

A.—The clinical conditions labelled Friedreich's ataxia are not homogeneous. The great majority of those with early onset behave as if due to one or more recessive genes, and the illness is usually uniform within families and independent of sex. Much more rarely, dominant genes may give a somewhat similar clinical picture, these types showing much more variation of expression within families. While, therefore, it is probable that the gene concerned in the present patient's family is recessive and that there is little chance that she will develop the condition or will have affected

children (assuming she does not marry a near relation), a careful family history should be taken and an expert neurological examination made of the patient herself and of her parents for minimal signs of the disease.

NOTES AND COMMENTS

Functional Ciliary Spasm.—Dr. THOMSON HENDERSON (Hursley, Hants) writes: May I comment on your expert's explanation on functional ciliary spasm ("Any Questions?" July 28, p. 254), which, while orthodox in conception, is, when analysed, incapable of realization? According to established convention the vascular choroid functions as a counterweight to the lens and the unstriated ciliary muscle is actuated by a single nerve. If these two tissues were able to function in such a manner they would be absolutely unique in the whole range of the animal kingdom. Nowhere can a vascular structure be found subjected to constant stress or unstriated muscle actuated except by two nerves and functioning accordingly. The physiological function of unstriated muscle is to contract into a phase of rest, such as is appreciated by every human being on emptying the bladder. Thus it is that the contracted unstriated fibres support the zonular curvature and maintain the lens flattened. As discussed in my book *Principles of Ophthalmology* (p. 132), asthenia from whatever cause results in diminution of the general tonus of the body. The neuromuscular mechanism, that maintains the body erect, sags, the individual stoops, and the atonic stomach dilates. Similarly, the atonic ciliary muscle is unable to support the lens traction and likewise sags. The zonular curvature is lowered and lenticular myopic refraction induced. This sequence of events is the very opposite of the so-called spasm, and its treatment is essentially constitutional.

OUR EXPERT replies: Although the precise action of the ciliary muscle has been debated for many years it is now widely accepted that the action of both portions of the ciliary muscle is to slacken the suspensory ligament of the lens, causing the lens to become more convex. Furthermore, the circular fibres act directly as a sphincter which diminishes the circumference of the ring formed by the ciliary body and hence also aids in relaxing the suspensory ligament of the lens. It is interesting to compare the unstriated muscle of the urinary bladder with that of the ciliary body, but surely the neuromuscular mechanism of a hollow viscus such as the bladder is a very different matter. Whatever objection may be raised to the orthodox explanation of the action of the ciliary muscle, it still remains a fact, which can be proved by mere observation, that in functional ciliary spasm of any appreciable degree there is an accompanying spasm of the medial recti. If the process causing the "over accommodation" were atonic in nature then one would hardly expect an accompanying contraction of the synergic medial recti muscles.

Prolonged Constipation in Children.—Mr. E. W. GODDING (Westminster Laboratories, Ltd., London, N.W.1) writes: As manufacturers of the "senokot" standardized senna preparations discussed by Mr. H. Reid and your expert ("Any Questions?" August 11, p. 374), may we comment on the question of costs? Your expert is correct in saying that two drams (7 ml.) of liquid paraffin daily and a tablet of senokot daily is about one penny a week, in either case, but for prolonged constipation the comparison may be very different. While liquid paraffin has to be given indefinitely, senokot dosage is required at less frequent intervals, and usually dosage can be gradually reduced and eventually discontinued.

Correction.—In the Epidemiological Table in the *Journal* of August 18 (p. 426) the number of deaths in the first year of life in the 17 principal towns of Scotland should have been shown as 21, and the deaths at all ages (excluding stillbirths) as 482; these numbers were inadvertently transposed.

ZONOOSES AS A STUDY IN ECOLOGY

WITH SPECIAL REFERENCE TO PLAGUE, RELAPSING FEVER, AND LEISHMANIASIS

BY

R. B. HEISCH, M.D.

Senior Parasitologist, Division of Insect-Borne Diseases, Medical Research Laboratory, Kenya

According to Karl Meyer (1942) the term "zoonosis" was first introduced by Virchow. In a recent publication of the World Health Organization the zoonoses have been defined as "those diseases which are naturally transmitted between vertebrate animals and man." Other definitions have been given from time to time, most of which are not very satisfactory. That given by the World Health Organization is probably the best, but it includes the word disease, which perhaps ought to be avoided, as in certain zoonoses one or more of the vertebrate hosts may show no symptoms of disease. In a recent textbook of protozoology it is even suggested that infections common to man and animals cannot be regarded as zoonoses when the animal host shows no symptoms. Chagas's disease, in which symptomless armadillos act as reservoir hosts, is given as an example. I shall try to refute this idea, and to emphasize that usually resistant or relatively insusceptible animals are the most efficient reservoirs of the zoonoses. It is of course not always easy to know when an animal is feeling ill, and a friend pertinently remarked, "How do you know the armadillo doesn't get a headache"; this was difficult to answer.

A simple definition which avoids some of the more obvious pitfalls is *infections of man naturally acquired from other vertebrates*. According to Metchnikoff, "Infection must be considered as a struggle between two organisms, the parasite and its host. . . . This struggle brings about adaptations on both sides."

A zoonosis can be considered in reverse, the infecting organism passing from man to animals and not vice versa. Monkeys are sometimes infected with quartan malaria and certain filariae in this way. Such infections might be called "anthroponoses," but the term is really superfluous, as most of the zoonoses show this quality of reversal. The zoonoses can be divided into two main groups: those transmitted by arthropods, and those which are not. Only the first group is considered in this paper.

Evolution and the Zoonoses

Garnham (1952) has commented on the evolution of the zoonoses, and according to him the story is something like this. First, the parasite lives happily, passing between its animal host and arthropod vector; next, man breaks into the circle and accidentally becomes infected; the parasite flourishes in this abnormal host—and may be transmitted by a more domestic vector—for example, flea or louse. The disease then often

assumes an epidemic form, and may pass from man to man. Relapsing fever illustrates some of these points. The causative spirochaete seems originally to have been a parasite of merions, gerbils, shrews, and other small mammals, the vectors being ticks of the genus *Ornithodoros*. Man became involved in this cycle, and, after being bitten, developed relapsing fever; this still happens in North Africa and around Dakar.

It is worth trying to trace the evolution of *Spirochaeta duttoni*, which causes tick-borne relapsing fever in Kenya and other parts of tropical Africa, the vector being *Ornithodoros moubata*. Some years ago a spirochaete, named *S. dipodilli* and closely related to *S. duttoni*, was isolated from pygmy gerbils (*Dipodillus* sp.) and *O. erraticus* from small burrows on Crescent Island in Lake Naivasha (Heisch, 1950). Near the small gerbil burrows are large burrows, which are excavated by ant-bears, occupied by warthogs or porcupines, and often contain large numbers of *O. moubata* (Heisch *et al.*, 1953). The presence of *O. moubata* came as a surprise, for the ticks usually have domestic habits, frequenting native huts, rest-houses, and the camp sites of travellers; ant-bear burrows may be their original or natural habitat. It was thought possible that in the remote past the gerbil spirochaete might have become established in the "burrow-haunting" *O. moubata*, and then have evolved into *S. duttoni*. Unfortunately there is no evidence to support this possibility: specimens of *O. moubata* from burrows have always been negative for spirochaetes, and so have the few porcupines and warthogs examined. In Kenya and other parts of tropical Africa, even if there was once a reservoir host of *S. duttoni*, it appears to have faded into the background, tick-borne relapsing fever no longer being a true zoonosis; it thus differs from the disease in America, where man is infected in caves, various small mammals acting as reservoir hosts.

In recent years it has been found that certain tick-borne spirochaetes can infect lice (Baltazard *et al.*, 1947; Heisch and Garnham, 1948; Boiron *et al.*, 1948). Thus in Kenya strains of *S. duttoni* develop readily in lice, and infected lice have even been found in nature (Heisch, 1949). These results support the hypothesis, first suggested by Nicolle and Anderson (1927), that louse-borne spirochaetes evolved from tick-borne ones.

Other zoonoses, in which man breaks into a cycle in animals, are plague and leishmaniasis. Plague is primarily an infection of wild rodents, and man gets infected only by accident. In parts of Siberia gerbils are the

reservoir host of cutaneous leishmaniasis, which is transmitted by "burrow haunting" sandflies. Man sometimes gets bitten and epidemics have occurred among Soviet troops camped near infected burrows.

In Kenya kala-azar was almost unknown before the second world war. Early cases were sporadic, but in recent years there has been a severe epidemic in the Kitui District, and a smaller outbreak near Marigat in the Rift Valley. No animal reservoir has yet been discovered, and, though one may exist, it is believed that man is the usual host, and that interhuman transmission can occur on a large scale. In Kenya the epidemiology of kala-azar is highly complex, and at least three species of sandflies are suspected as vectors; these emerge from termite hills. Apparently evolution is still taking place, and it is difficult to know what the final epidemiological pattern will be.

Holistic Tendency in Nature

It is evident from Professor Garnham's observations that in nature organisms may be parasites of man, of animals, or of both, and it is the last or zoonotic phase which concerns us here. The conception of a zoonosis is complex and includes an environment, as well as man, animals, sometimes arthropods, and a causative organism, the various parts forming a biological whole.

The importance of "wholes" has been stressed by General Smuts (1936). According to him there is a holistic (from *ὅλος* = whole) tendency in nature, parts combining into wholes, which in turn again combine, forming even more complex and significant wholes. A whole is not just the sum of its parts, but something more, something new; it is not just a mechanical system but "dynamic, organic, evolutionary, creative." The concept has little in common with the static absolutism of Hegel and other philosophers, and should not be confused with it. In nature, every organism, whether plant or animal, is a whole, and the modern science of ecology attempts to show how these various wholes react on each other, becoming linked, or rather combined, into new wholes, which are continually modified by changes in the environment.

A zoonotic whole is best considered in relation to the infecting organism or parasite, which makes use of some of the existing ecological links between man and animals in an environment, forming cycles or wholes of varying complexity. In fact, a zoonosis is really a small natural whole or holoid built, as it were, round an infecting organism. As already shown such systems, cycles, wholes, or whatever one prefers to call them, are seldom static, and at any time a zoonosis may cease to exist, the parasite becoming adapted to man and the animal reservoir fading into the background. Or the parasite, after passing through a zoonotic phase, may again become confined to animals, man fading into the background. Treating zoonoses as wholes in this way is useful, but perhaps rather artificial, as it depends on distinguishing between man and animals.

The Zoonoses and Ecology

The foregoing remarks make it clear that a study of the zoonoses is essentially a problem in ecology. Ecology has been defined as the "study of interrelation between organisms and the environment." There are two approaches—the *synecological* and the *autecological*. Synecology, as the name implies, is synthetic or holistic in character, the various plants and animals in a community being treated as a whole, the parts of which are in dynamic relationship, and influenced continually by the environment. Autecology deals with single organisms or species in relation to the environment; it has more in common with physiology and is not really ecology at all. Clumsy words like *synecology* and *autecology* should be replaced by ecology properly defined in the true holistic sense.

Audy (1954) names the whole assemblage or array of parasites associated with a host population the "parasite-pattern," and includes under parasites "all those viruses, bacteria, protozoa, fungi, worms, and arthropods which live on or in or at the expense of higher organisms such as the vertebrates, whether harmlessly or harmfully." The vectors and causative organism of a zoonosis form part of a general parasite pattern, though, actually, while unravelling a zoonosis much of the general parasite pattern gets worked out as well. Many of the ideas tentatively outlined in this paper have been influenced by the opinions of Audy, who for a number of years has been working on the ecology of scrub typhus in Malaya. Audy has long appreciated the importance and holistic nature of synecology, and has discussed various aspects in an interesting note on medical geography (Audy, 1954).

The early work on plague in Kenya illustrates the limitations of an autecological approach. Everyone was so convinced that the domestic rat (*Rattus* sp.) was the reservoir host that it was considered in isolation and not sufficiently in relation to the wild rodents which are the real source of *Pasteurella pestis* (Heisch *et al.*, 1953). The working out of the life-histories of arthropods in the artificial atmosphere of laboratories also verges on autecology, and, though such studies have a certain value, they can never replace work in the field. Elton (1927) has pointed out that the discoveries of Darwin "had the remarkable effect of sending the whole zoological world flocking indoors, where they remained hard at work for 50 years or more, and whence they are now beginning to put forth cautious heads again into the open air. But the open air feels very cold."

Host-Parasite Relationship

A most important aspect of the zoonoses and indeed of parasitic infections in general is what is known as the host-parasite relationship, by which is meant the nature of the interaction between the host and the parasite. It is suggested that the most important reservoirs of zoonoses and other parasitic infections are relatively insusceptible animals rather than highly susceptible ones. There is nothing new in this idea, and as long ago as 1926 that great protozoologist, the late Dr. Wenyon, wrote: "Whenever a parasite is discovered which brings about the death of its host in a short time, it may be safely assumed that the host is not a natural one, or that it is a natural one that is in some unnatural condition. After a time adaptation may occur and a host that was at first an unnatural one may gradually become a natural host."

Resistant animals are very important in plague. Thus in Kenya domestic rats (*Rattus* sp.) are highly susceptible and rapidly almost exterminated, while certain wild rodents (*Arvicanthis*, *Mastomys*, and *Otomys* sp.) are resistant and perpetuate the infection during enzootic periods. In South Africa two species of gerbil are involved (*Desmodillus* and *Tatera* sp.), one of which is resistant and the other susceptible. In California susceptible ground squirrels (*Citellus* sp.) die in large numbers, but the primary hosts are now believed to be various resistant field-mice (*Peromyscus* sp.) and wood rats (*Neotoma* sp.) which harbour *P. pestis* almost indefinitely. In Kurdistan the sole reservoirs of plague are highly resistant merions (*Meriones* sp.). For many years regions occupied by resistant namaqua gerbils (*Desmodillus* sp.) and merions were believed to act as barriers to the spread of plague, instead of being regarded as the real source of the infection.

Recently kala-azar has been extensively studied in Kenya, but, as already noted, no reservoir host has yet been discovered. If an animal host does exist, it may be so resistant that the infection can be detected only by special methods. When isolating *P. pestis* from wild rodents in Kenya (Heisch *et al.*, 1953), the pooled-tissue technique was employed, batches of spleens being emulsified and inoculated into guinea-pigs, for it was only by this indirect

method that the infection could be demonstrated at all. The same principle is being applied in kala-azar, the spleens of animals being inoculated into hamsters. Two hamsters actually became infected, one after being inoculated from gerbils (*Taterillus* and *Dipodillus* sp.) and the other from mongooses (*Helogale* sp.), but this may have been due to cross-infection in the laboratory. All known reservoir hosts of leishmaniasis, which include dogs, jackals, gerbils, and foxes as well as man, show a marked resistance to the infection.

Armadillos and antelopes, which harbour pathogenic trypanosomes, are excellent examples of resistant animals acting as reservoir hosts, the parasites causing no obvious symptoms. In the zoonoses mentioned in this paper the reservoir complex, or whole, includes arthropods as well as vertebrates, both helping to maintain the infection in nature. Sometimes, as in mite and tick-borne typhus, tick-borne relapsing fever, and perhaps certain virus diseases, the arthropod vector may be the principal host.

It is rather difficult to know what to call the various kinds of host. Perhaps resistant or relatively insusceptible animals might be termed "permanent hosts," and highly animals might be termed "temporary hosts"; this would correspond to the natural and unnatural hosts of Wenyon (1926). Hosts can also be classified as "domestic" or "wild," and this may be important, as in many zoonoses the principal reservoirs are domestic animals, which bring the infection in close contact with man. The reservoir of a zoonosis is seldom just one animal, but usually includes several species, which are in close ecological association and act as a "zoological complex" or "biological whole." A good example is sylvatic plague in Kenya. At least three species of resistant rodents are involved, and these, acting in combination, probably perpetuate the infection far more efficiently than if one species acted alone. Highly susceptible hosts like *Rattus* are not included in the reservoir complex.

Hosts have also been classified as final or definitive and intermediate, depending on whether the development of the parasite in them is sexual or asexual. This results in certain ambiguities, and here the arthropod vector is regarded as the intermediate host, the final host being man or some other vertebrate.

Niches

Resistant and unduly susceptible animals fill different "niches" in nature. According to Elton (1927), the "niche of an animal means its place in the biotic environment, its relation to food and enemies." The word "enemies" is taken to include parasites.

Elton has also remarked that "when an ecologist says, 'There goes a badger,' he should include in his thoughts some definite idea of the animal's place in the community to which it belongs, just as if he had said, 'There goes the vicar.'" On seeing an arvicanthid round Rongai one might say, "There goes an animal that can have plague without noticing it."

Important niches are filled by vectors of zoonoses. Thus in plague the niche is filled by fleas, in leishmaniasis by sandflies, and in relapsing fever by ticks and lice. A particular niche is usually filled by different species in different parts of the world.

A study of niches enables us to see that in their organization different animal communities have much in common. It also helps in forming analogies. Thus it was hearing that Dr. Baltazard had discovered resistant hosts of plague in Kurdistan that made me look for similar animals in Kenya. The term "habitat niche" has a different meaning in ecology, which is explained below.

Focal Distribution of Zoonoses in Nature

A feature of certain zoonoses is their "focal distribution" in nature. This is well shown by plague, and, according to Karl Meyer (1942), "focal occurrence and discontinuous distribution is apparently one of the characteristics of

sylvatic plague." While studying plague near Rongai in the Rift Valley of Kenya, a "focus" was found in a field, where *P. pestis* could be isolated from wild rodents long after the widespread epizootic had died down and the animals in adjacent fields had become negative. After the field was ploughed up no more infected rodents were found, conditions apparently being too unstable for the formation of a permanent focus. At Rongai "permanent foci" of sylvatic plague are believed to exist on the foothills of the escarpments where rodent burrows are relatively undisturbed, and not in the Rongai plain. The unstable plains in the valley are ideal for the dissemination of *P. pestis* when conditions are suitable, but the infection probably retreats to the foothills between epizootics. Dr. Baltazard (1955, personal communication) has found permanent foci of sylvatic plague on the foothills of the Himalayas; these never seem to form in the cultivated plains below.

Focal distribution is a marked feature of scrub typhus in Burma and Malaya. The vector mites are found in forest clearings, where they congregate, sometimes in enormous numbers, on patches of secondary vegetation known as "mite islands," often only a few yards across, in which the rodent hosts abound. When the mite islands are infected they are known as "typhus islands"; these are "erratically but not fortuitously distributed" (Audy and Harrison, 1951).

Relapsing-fever spirochaetes may also have a patchy or focal distribution in nature. Thus in Africa, where tick-borne relapsing fever is endemic, only some huts contain infected ticks. Other examples are *Spirochaeta latichevi* and *S. dipodilli*, which are parasites of rodents, and *Ornithodoros* ticks in burrows; the spirochaetes have a very patchy distribution, infected burrows being few and far between. Both the rodent spirochaetes are pathogenic for man, but only mildly so.

In parts of Kenya and the Karamoja District of Uganda, bush-babies (*Galago*) are believed to be reservoirs of yellow fever virus. Dr. Haddow, of the Virus Institute, Entebbe, informs me that infection in these animals is very localized, neutralizing antibodies being confined to groups or families of bush-babies living in widely scattered parts of the forest.

Focal distribution seems characteristic of most parasites in nature, but the ecological factors concerned are still largely unknown.

Sites of Infection

Zoonoses are transferred to man and other vertebrates in a variety of places. Thus round Rongai man gets infected with plague in native huts, domestic rats (*Rattus* sp.) chiefly in village maize cribs, and wild rodents in burrows. In Kurdistan plague is almost entirely sylvatic, man being bitten by infected fleas near the burrows of merions. In East Africa tick-borne relapsing fever is contracted in huts; in America and the Middle East in caves. In Kenya kala-azar is probably caught away from houses near termite hills, while in India the disease is a domestic infection. In parts of Russia cutaneous leishmaniasis is transmitted to man near gerbil burrows by "burrow-haunting" sandflies. Yellow fever is often a house infection, but in Uganda man is infected in banana plantations on forest edges, and monkeys in forest canopies. In Malaya and Burma man contracts scrub typhus in forest clearings and forest edges.

These sites of infection show certain differences, some being unstable, others relatively stable. The plague-infected plain at Rongai and the forest clearings containing typhus islands are unstable areas, for man is continually ploughing up the one and cutting down the other. In fact, the balance of nature is always being upset. It is also doubtful whether the forest edges where man contracts yellow fever and scrub typhus are ecologically stable. In comparison huts, rodent burrows, caves, termite hills, and forest canopies are all relatively stable. Sometimes relatively stable habitats are present in an unstable area; they then partake of the general instability.

Ecologically unstable areas have certain characteristics. Plants and animals living in such zones are usually undergoing active succession, and are prevented from reaching that condition of relative stability known as climax. Species tend to appear that are absent from adjacent communities, and one or more species, whether present in adjacent communities or not, may appear in unusually large numbers. The occurrence of myriads of mites in the mite islands of Malaya, and the sudden appearance (when conditions are suitable) of innumerable wild rodents in the Rongai plain are examples of this. When such prolific species harbour parasites pathogenic for man his chances of becoming infected are much increased. Round Rongai it is only when the wild rodents are numerous that *P. pestis* reaches *Rattus* and finally man.

It is suggested here that it might be possible to call unstable areas "ecotones." The word is generally used, in a botanical sense, for transition or intermediate zones between adjacent plant communities. Might not this definition be too narrow? A striking feature of transition areas, marginal zones like edges, forest clearings, and cultivated plains is often their instability. The ecotone concept implies a state of tension in nature, a temporary or permanent loss of ecological balance. Ecotones may be man-made or occur naturally, as when places are periodically flooded, like certain river banks, mud-flats, and the sea-shore. A study of ecotones might throw light on the evolution of certain species. Audy and Harrison (1951) have pointed out that, in Malaya, rodents of the genus *Rattus* "have been greatly encouraged, and a number of commensal and subspecies have evolved in the artificial environments made by man."

A medical example of an ecotone might be the bowel of a patient suffering from dysentery. In a normal person the intestinal flora is in a state of equilibrium, but in dysentery and other infections of the bowel a single species may predominate and disturb the ecological balance. A similar effect may follow the administration of antibiotics. The elimination of susceptible organisms produces a bacteriological vacuum in which may develop a pathogenic staphylococcus, the life of the patient being endangered. Species of plant or animal which outstrip others and appear in abnormal numbers are comparable to cancerous cells, which defy the authority of the human organism as a whole and threaten to disrupt the co-ordinated complex of interlocking cell communities.

Forest edges are of particular interest, for they can be relatively stable or unstable and act as transition zones or end abruptly. Audy (personal communication) calls forest edges "fringe habitats" and the distinctive communities they contain "fringe communities"; such communities often contain species which are absent or very rare in adjacent regions. Important fringe species are *Aedes simpsoni*, the vector of yellow fever in forest edges in Uganda, and a species of *Chrysops* which transmits loa loa on the west coast of Africa. Transition zones, whether stable or not, are important meeting-places for animals and arthropods, and an interchange of parasites is very likely to occur. Perhaps in East Africa the two cycles of yellow fever are or were linked in such a zone.

Relatively stable habitats like huts, caves, animal burrows, and termite hills, near or in which zoonoses can be transferred to man, are known to ecologists as "habitat niches"; they are sanctuaries protecting certain species from a potentially hostile environment. Forest edges, other transition zones, and forest canopies, though sometimes unstable, may be relatively stable; they then have more in common with habitat niches than ecotones. It is, of course, sometimes difficult to decide whether a particular area is unstable or not, and the foregoing remarks are tentative only.

The suggestion has been made that in Kenya and India the permanent foci of sylvatic plague are more likely to be found on relatively stable foothills than in plains rendered unstable by cultivation. The idea may have a wider applica-

tion, and perhaps organisms causing zoonoses and other parasites can become firmly established in nature only if part of their life history is spent in an animal or animals living in a relatively stable environment. This view at present is somewhat speculative.

Food-chains and Cycles

A study of what ecologists call "food-chains" and "food-cycles" is an important aspect of the synecology of the zoonoses. Animals linked by food form food-chains, and all the food-chains in a community form the food-cycle. In an animal community herbivores are preyed on by carnivores, which in turn are preyed on by larger carnivores, until an animal is reached which virtually has no enemies. The animals at the base of the chain are smaller and more numerous than those at the top. Elton (1927) has called this the pyramid of numbers.

Elton has suggested that parasites are really small carnivores, though they often do not kill their prey. The large components of parasite food-chains get smaller instead of larger, and more numerous instead of fewer; in fact, the pyramid of numbers is inverted. A study of the food-cycle and plague at Rongai shows that various ectoparasitic fleas pick up *P. pestis* from several rodent hosts. Plague bacilli develop rapidly in these fleas and are transmitted to man. Eventually the plague bacilli in the fleas may be attacked and destroyed by even smaller and more numerous organisms known as bacteriophages.

The importance of food-cycle studies has been stressed by Elton, who wrote: "Since the food cycle is so important in determining many of the possible modes of transference of parasites from one host to another, it is plain that biological surveys carried out along food-cycle lines would be of great value in narrowing the field of inquiry when the life history of any particular parasite is being studied." The value of food-cycle studies, particularly in relation to the food preferences of various disease-transmitting arthropods, is now fully appreciated. Dr. Weitz, at the Lister Institute, under the inspiration of the late Professor Buxton, has formed a most valuable unit, which devotes much time to the identification of arthropod blood meals from all over the world.

Animal Communities

Most animals fluctuate greatly in numbers, and this must be taken into account when studying the zoonoses. At Rongai outbreaks of plague usually coincide with a remarkable increase in the wild rodents; when their numbers drop, which often happens quite suddenly, the link with the domestic rats (*Rattus* sp.) is temporarily broken and human infections cease for the time being. Plague and the regulation of numbers in wild animals has been discussed by Elton (1925), but the effect on resistant animals is not mentioned. In Kenya epizootic plague decimates the highly susceptible domestic rat, but several species of wild rodent are scarcely affected; they are, however, susceptible to other infections, and at times parts of the Rift Valley have been littered with wild rodent corpses. The periodic reduction of numbers in vertebrates is often caused by disease.

Other rodents as well as *Rattus* are highly susceptible to plague in other parts of the world, examples already given being ground squirrels in California and lobengula gerbils in South Africa. Periodically, these species are almost wiped out by plague in certain areas, and it may take as long as five years for their numbers to build up again; this affects the incidence of human infections. In South Africa the periodic fluctuation of rodent populations has been extensively studied by Davies.

Another important matter, which can only just be mentioned here, is the range or distribution of various species in nature. Animal hosts and arthropod vectors are dependent on their environment, and the occurrence of zoonoses in definite areas is essentially a zoogeographical problem.

Conclusion

Although the importance of a synecological or holistic approach is stressed, it would be a mistake to take this too literally. Ecological processes are so complicated that there is a danger of getting involved in a mass of irrelevant ecological detail, and of forgetting that when studying a zoonosis the natural history of the causative organism is our chief concern. The infecting organism is in fact the pivot round which the ecological investigation revolves.

If the views expressed here have any validity, they probably apply not only to the zoonoses but to parasitic infections in general.

Summary

The zoonoses, which are defined as infections of man naturally acquired from other vertebrates, are treated as a problem in ecology. This entails studying the interrelation between man, animals, a causative organism, the environment, and sometimes arthropods. Such an approach is holistic or synecological—wholes being regarded as more important than parts. Holism is a dynamic not a static conception.

The evolution of the zoonoses is discussed, particularly in relation to plague, relapsing fever, and leishmaniasis. The most important reservoirs of zoonoses and other parasitic infections are usually resistant or relatively insusceptible animals rather than highly susceptible ones. Plague and Chagas's disease illustrate this. Resistant and unduly susceptible animals occupy the different "niches" in nature. By "niche" is meant the place of an animal in its biotic environment. Zoonoses often have a "focal distribution" in nature. Thus wild rodents infected with plague may occur in "pockets," and the vector mites of scrub typhus congregate in "typhus islands."

An unstable environment often favours the transference of zoonoses to man and animals. Examples are the plague-infected plain of Rongai, in Kenya, the typhus-infected forest clearings in Malaya, and the yellow-fever infected forest edges in Uganda. Ecologically unstable areas are termed "ecotones." Zoonoses can also be transmitted in or near relatively stable sites such as huts, rodent burrows, caves, and termite hills. These are known as "habitat niches." Animals and arthropods in a community are linked by food, and the importance of what are known as "food chains" and "food cycles" is discussed in relation to the transference of zoonotic infections from one host to another.

Reference is also made to the fluctuations in numbers of various animals in nature, and how this affects the incidence of zoonotic disease. Certain highly susceptible rodents are periodically decimated by plague; this breaks the link with man, and human infections cease for the time being.

I wish to thank the Director of Medical Services, Kenya, for permission to publish this paper.

CHEMICAL AND CLINICAL PROBLEMS OF THE ADRENAL CORTEX*

BY

F. T. G. PRUNTY, M.D., F.R.C.P.

Professor of Chemical Pathology in the University of London; Physician, St. Thomas's Hospital

Some Factors Governing the Response to Corticotrophin

Growth Hormone

In 1951 Stack-Dunne and Young stated that they were able to obtain preparations from the anterior pituitary having two distinct kinds of activity. These separate preparations produced either a fall in the adrenal ascorbic-acid content or an increase in adrenal weight. They used growth hormone as a source of the adrenal weight factor, but did not consider that this factor was necessarily growth hormone itself. There seemed to be clinical data supporting the view at the same time, for at the same meeting to which Stack-Dunne and Young gave their paper we presented our early data on discrepancies between human response and the assay potency as determined by the Sayers method. However, as we have seen, this seems to have been explained on grounds of destruction or inactivation of the corticotrophin in the patients receiving it. The substance promoting adrenal weight and associated with, but not necessarily identical with, growth hormone also causes increased mitotic activity in the adrenal cortex and differs from the ascorbic-acid-depleting substance which is probably responsible for release and synthesis of corticosteroids (Cater and Stack-Dunne, 1955).

Forsham *et al.* (1955) summarized some experiments using a substance prepared by Rinfret from pig pituitary which was not itself steroidogenic but which, when given to a patient subsequently given corticotrophin, augmented the urine steroid response measured by the Porter-Silber method. A commercial growth-hormone preparation did not have a similar effect. We were fortunate enough to have at our disposal a small quantity of one of Young's growth-hormone preparations which he thought would be active with respect to the adrenal weight factor, although it had not been specifically tested for this activity. This substance was administered to a patient with Simmonds's disease whose adrenal had already been and continued to be stimulated with corticotrophin. We judged that in these circumstances the patient would also be deficient in growth hormone or the adrenal weight factor, and would be quite sensitive to it. There was a rapid increase in blood-sugar level, presumably due to the growth hormone itself, given intramuscularly 25 mg. twice daily for five days, but no increase in the ketogenic steroid or ketosteroid excretion. This negative result cannot be construed to be entirely contradictory to the hypothesis presented. It may well be that too little material was given for too short a time, or, as we shall see, that the absence of some other factor was limiting the response.

There is a clinical example before us worthy of attention with regard to this matter—namely, acromegaly. It is a commonplace that the adrenal cortices of patients with acromegaly are large and often contain subcapsular nodules. There is no unanimity of opinion about their

*Conclusion of the Humphry Davy Rolleston Lectures delivered at the Royal College of Physicians of London on May 15 and 17. The first part was published last week.

steroid production, but this might be expected to be low if the acidophil tumour caused sufficient reduction of anterior pituitary tissue. Adrenocortical insufficiency appears to be rare in acromegaly (Rummell, Baer, Hollister, and Kolb, 1951). In six patients with acromegaly the ketosteroid excretion was normal in three and low in three (Fraser *et al.*, 1941). In another group, three women and three men had high normal values, whilst one male with very prolonged disease had low values (Prunty, 1944).

Three cases have recently been studied. The first was a Polish grave-digger aged 36 with gross acromegaly. He excreted up to 22.5 mg. of ketosteroid daily and 18.4 mg. of ketogenic steroid. The second case was that of a man aged 43 who for five years had acromegaly with diabetes. He excreted up to 17.9 mg. of ketosteroid daily and 17.8 mg. of ketogenic steroids. The third patient was a woman aged 39 who 15 years previously had had an acidophil adenoma removed for eye signs. She had lately become very hirsute, with severe acne and pubic hair of male type. She excreted up to 34 mg. of ketosteroid and 12 mg. of ketogenic steroids daily. The last two patients were given corticotrophin according to the standard test. This was unfortunately of poor potency and had given apparently subnormal responses in several patients (see Table II). It had been used, however, in a patient with Cushing's syndrome due to hyperplasia of the adrenal cortex, with strongly positive results (S. E., Fig. 17). Such patients have a high sensitivity to corticotrophin. The two acromegalics gave a ketogenic steroid response which was low normal. The first acromegalic received a known potent batch of corticotrophin (89754) and did not show a brisk response. Clinically all these patients could be regarded as being in the active stage of the disease; although they presumably secreted excessive amounts of growth hormone, it does not follow that they did likewise with some other adrenal-cortical-activating agent. The results merely suggest that growth hormone itself did not appear to be a potent potentiating substance under these conditions of study.

Gonadotrophins

A second substance which has been implicated in having a subordinate effect on the adrenal cortex is the luteinizing hormone. Albright, Smith, and Fraser (1942) advanced complex arguments, based on the clinical relation between ovarian function and adrenal cortical function, that luteinizing hormone exerted an effect on ketosteroid secretion by the adrenal. Experiments based upon the suppression of ketosteroid excretion, which were thought to cause a simultaneous depression of luteinizing hormone and adrenal secretion of ketosteroid, seemed to support this hypothesis (Reifenstein, Forbes, Albright, Donaldson, and Carroll, 1945). We have conducted several experiments using preparations of luteinizing hormone ("pregnyl"; chorionic gonadotrophin) and follicle-stimulating hormone ("gestyl," prepared from pregnant mare's serum; serum gonadotrophin). The first of these was tried in the patient with Simmonds's disease who failed to show an effect with the growth-hormone preparation. No significant changes occurred when, in addition to corticotrophin, 1,000 units of gestyl was given daily for 10 days and on the fifth day 1,000 units of pregnyl daily was started for 10 days. This was in spite of the fact that a small menstrual period occurred, the first for many years.

In a second experiment a seemingly positive result was obtained. A patient with Hodgkin's disease was

under successful treatment with corticotrophin; on 20 "clinical units" daily he excreted 34 mg. of ketogenic steroid and 24 mg. of ketosteroid. The addition of 3,000 units of pregnyl daily (chorionic gonadotrophin) caused, on the fifth and sixth days, a rise in ketogenic steroids to 60 mg. and ketosteroids to 33 mg. There was a prompt fall in the steroid levels after withdrawing gestyl.

A third experiment with pregnyl in a patient with rheumatoid arthritis treated with corticotrophin was negative. Two other experiments have also been made with gestyl (from pregnant mare's serum) with negative results; if anything there was a fall in the ketogenic steroid excretion.

These results are difficult to interpret, and, even if the positive finding can be repeated, it should be noted that both ketogenic steroids and ketosteroids responded to chorionic gonadotrophin, which does not correspond with the theory of Albright. There remains little doubt that there is a complex reciprocal relation between the adrenal cortex and the gonads (Parkes, 1945), and studies in animals suggest that the ovaries may sometimes even replace the adrenal cortex (Hill, 1948). In guinea-pigs gonadotrophin has been found to suppress the response of the adrenal to corticotrophin, using the excretion of ketogenic steroids as a criterion (Clayton and Hammant, 1955b).

Effect of Tri-iodothyronine on Response to Corticotrophin

It has been thought for many years that there is an interdependence of the thyroid and adrenal cortex (Marine, 1930). Claims have been made that cortisone and corticotrophin reduce thyroid function (Hill, Reiss, Forsham, and Thorn, 1950; Wolfson, Beierwaltes, Robinson, Duff, Jones, Knorpp, Sieminski, and Eya, 1951; Lerman, 1955a). In the rabbit, radioactive iodine release by the thyroid is retarded by cortisone (Harris, 1955a). The low ketosteroid excretion in myxoedema has been found to rise when replacement therapy is given (Beierwaltes and Bishop, 1954; Lerman, 1955b). In our experience thyroid therapy has been required to produce significant clinical change in patients with myxoedema secondary to anterior hypopituitarism.

We have been able to conduct a single observation on the effect of tri-iodothyronine on the activity of the adrenal cortex. The same patient with Simmonds's disease was again under treatment with corticotrophin (Fig. 6), and tri-iodothyronine was given intravenously in a single dose of 0.5 mg. and two days later 0.25 mg. was injected. The typical effects of tri-iodothyronine are shown on the B.M.R. and the serum creatine and blood cholesterol levels. After an interval of two days the urine steroids and plasma hydrocortisone levels rose significantly. There were also effects on the level of blood sugar and on sodium retention. It can be concluded from this experiment that conditions exist in which increased thyroid activity can increase adrenal cortical secretion. The likely interpretation seems to be that when a near maximal stimulus by corticotrophin was applied the response was limited by a degree of hypothyroidism, the correction of which produced a good normal response. This effect might not so easily occur in patients treated for myxoedema, since in this situation, although thyroid hormone is raised to adequate levels for response of the adrenal cortex, the rate of endogenous secretion of corticotrophin could be the limiting factor.

Development of Resistance to Corticotrophin

Earlier, when inactivation in muscle or subcutaneous tissue was a common problem, the development of resistance to continued injection also occurred (Forsham, Renold, and Frawley, 1951). It has already been indicated how variable

the response of patients can be to different doses and batches of corticotrophin, and for this reason some direct measurement of corticotrophin activity seems essential before in clinical practice the conclusion is drawn that a patient does not show a symptomatic response to treatment.

This point has been stressed by West (1954) and is illustrated by J. J., a woman under treatment with corticotrophin for rheumatoid arthritis (Fig. 7). After a prolonged period of therapy she no longer responded well clinically. It was known that the batch of corticotrophin in use on day 88 was not very effective in other individuals, so it was changed to a known very potent one (89754) at the same dosage (10 "clinical units" twice daily). As the response at day 109 was poor we repeated the identical batch and dose given at the beginning—that is, corticotrophin (89754) in doses of 20 "clinical units" twice daily. The patient responded again, but to a smaller degree. Nevertheless the intravenous administration of 40 "clinical units" of the same material on day 118 produced a large response, the excretion rate reaching 6.1 mg. per hour. It must be concluded that this patient developed a partial degree of unresponsiveness which could easily be overcome with sufficient stimulus. This experience demonstrates another reason for avoiding assumptions about the dose-response relationship to corticotrophin. West (1956) has also observed under certain conditions a failure of adrenal response to long-acting corticotrophin which is capable of being overcome.

Responses to Operation

The first observations on the effect of trauma in man on adrenal cortical secretion were made by Venning (1945), who found by bioassay an elevation of cortin levels of urine extracts under these conditions. For this and other reasons it may be supposed that operative intervention is a good method of investigating a patient's response to endogenous corticotrophin and possibly of studying quantitative differences in the response from those obtained with exogenous corticotrophin. Post-operatively, the general pattern of events seems to be that there is often a short initial increase of ketosteroids, sometimes followed by a fall for several days (Forbes, Donaldson, Reifstein, and Albright, 1947; Prunty, 1953). When the Porter-Silber method was used the corticoid metabolites were found to

Fig. 6.—Effect of tri-iodothyronine on response to corticotrophin in a patient with Simmonds's disease. Tri-iodothyronine, two doses, was given intravenously. Eosinophils marked ●; plasma hydrocortisone ▲.

Fig. 7.—Long-term response of patient with rheumatoid arthritis to three batches and varying doses of intramuscular corticotrophin (except where marked, i.v.). The numbers on the top line, above the dosages, refer to different batches of corticotrophin.

increase early after operation and to persist for several days, depending on the amount of trauma (Moore, Steenburg, Ball, Wilson, and Myrden, 1955); this also occurs after burns (Wilson, Lovelace, and Hardy, 1955). With the method for ketogenic steroids the response is similar (Fig. 8). This has also been found by Jepson, Jordan, and Levell (1956). The magnitude of the response varies in different patients, but there is a tendency for the corticoid metabolites to increase to a greater extent than the ketosteroids. When methods of blood analysis for corticoids were used a sharp rise was also found immediately after operation, which may to a small extent be enhanced by temporary inability of the liver to metabolize the hormones as rapidly as normally (Sandberg, Eik-Nes, Samuels, and Tyler, 1954).

Adrenal Cortical Virilism and Hirsutism

In 1933 Broster and Vines classified patients with the adrenogenital syndrome into those occurring before puberty and those after puberty. The rise in urine ketosteroids is a much more pronounced feature in the former group, and the ketosteroid levels in these patients are often very high after the adrenarche at puberty (Mason and Engstrom, 1950). In the latter group ketosteroids may apparently be normal, high normal, or just above normal, which is seen to be the case in the group of patients described below. Recently Patterson has found that the pre-pubertal group is divisible into two subgroups according to a high or low level of dehydroepiandrosterone excretion (Broster, Patterson, and Camber, 1953). There seems to be no obvious clinical significance of this finding at the present time. It has been observed that even patients with virilizing adrenocortical tumours, who sometimes have high excretion rates of dehydroepiandrosterone, need not necessarily excrete large amounts of this substance (Mason and Engstrom, 1950; Prunty, 1950). Its excretion will depend on its further conversion by the adrenal and rate of metabolism after secretion.

F.F. 58 ♂

FIG. 8.—Response of "normal male" to lobectomy for bronchial carcinoma. Subsequently he responded normally to a poorly potent batch of corticotrophin.

FIG. 9.—Failure of corticoid synthesis in pre-pubertal virilism with excessive excretion of pregnanetriol and 11-ketopregnenetriol.

The greatest biochemical advances in the field of the pre-pubertal syndrome have been made by Wilkins and his associates, particularly Bongiovanni (Wilkins, Bongiovanni, Clayton, Grumbach, and van Wyk, 1955). Bartter, Albright,

FIG. 10.—Pre-pubertal virilism. Effect of corticotrophin, aldosterone, and cortisone. Note the determination of ketogenic steroids includes pregnanetriol, therefore corticoid metabolites measured by Reddy method (P.S.). The latter rises on cortisone therapy due to metabolites derived from it.

Forbes, Leaf, Dempsey, and Carroll (1951) were the first to suggest that there is basically a deficiency in adrenal corticoid synthesis in this condition, and this would theoretically lead to an increased circulation of corticotrophin. The latter has been demonstrated by Morris (1952) and by Sydnor, Kelley, Raile, Ely, and Sayers (1953). The deficiency in synthesis of hydrocortisone and other corticoids is partially due to failure of introduction of the hydroxyl group at position 21 (Dorfman, 1955). A high proportion of ketosteroid is often found with hydroxylation at position 11. Bongiovanni has also found that pregnanetriol is excreted in the urine in large amounts which, it seems likely, originate from 17-hydroxyprogesterone, as also probably does the increased excretion of 11-ketopregnenetriol reported by Finkelstein, von Euw, and Reichstein (1953) (Fig. 9). It is thought that the high secretion rate of corticotrophin stimulates the secretion of excessive adrenal androgen, a raised blood level of which, unlike that of hydrocortisone, does not inhibit further corticotrophin release.

These patients vary in their response to exogenous corticotrophin, but the response shown in Fig. 10 is typical. The corticoid metabolites have here been estimated by a modification of the method of Reddy *et al.* (1952) and show very little response to corticotrophin, whereas there is a distinct rise in ketosteroids from already excessively high levels. The urine of this patient also contained greatly increased amounts of pregnanetriol, the excretion of which was further raised by corticotrophin. The estimation of pregnanetriol is relatively simple and has appeared to be quite specific in this syndrome. It is, however, also included in the steroids estimated by the method of Norymberski *et al.* (1953), giving falsely high values for the level of corticoid metabolites. Wilkins and his group have observed a large series of these cases, and have found that cortisone, as suggested by Bartter *et al.* (1951) and especially if used early enough, has dramatic effects in alleviating the abnormalities. It also has a very powerful effect, as would be expected, on reducing

TABLE III.—Steroid Excretion and Response to Corticotrophin—Adult Hirsutism

Patient	Age	Summary	Resting (mg./day)		Response to Corticotrophin	
			Ketosteroid	Ketogenic Steroid	Max. Ketogenic Steroids (mg./day)	K.G.S./K.S. Ratio
1 F.S.	37	10 years' severe hirsutism accompanied by post-encephalitic changes from illness at age 7	20-27	10-4-13-1	27	0-3
2 L.C.	22	Hirsutism at puberty. Menorrhagia. Pseudomucinous cystadenoma removed at age 17, with one ovary. Histology of other ovary normal at 22. Other ovary had to be removed with uterus for menorrhagia. Urine oestrogen 13 µg./day after this	11-7-14-3 20-25	3-7-4-1 2-8-11-8	36 44	0-8 0-9

6 O.F.	25	Overweight and hirsute from after puberty. Severe acne	9-12	13-2-17-7	67	1-9
7 K.P.	26	Overweight 10 years, severely hirsute 4 years. Few purple striae. E.U.A. normal	17-25	9-3-9-7	75	1-4
8 M.L.	29	Severe hirsutism from puberty. E.U.A. normal				
9 J.B.	30	2 years' severe facial hirsutism. A mild case				

E.U.A. refers to examination of genital tract under anaesthesia.

the level of the ketosteroid output, and control of the dosage in this way is essential. It similarly depresses the excretion of pregnanetriol.

Post-pubertal Hirsutism

Patients suffering from post-pubertal hirsutism have been the subject of less fruitful research, and indeed are often grouped together under the term "idiopathic hirsutism." There is a striking incidence of the beginning of the disturbance at or soon after puberty, which is at a time when the adrenal cortex has assumed its adult pattern of secretion, especially with regard to ketosteroids (Mason and Engstrom, 1950). It is perhaps odd that they develop the degree of hirsutism that they often do, with little or no increase in their resting ketosteroid excretion. It has been shown that under conditions of increased stimulation with corticotrophin they are then capable of excreting amounts of ketosteroids relatively in excess of the normal. A group of nine patients have been studied.

The basal steroid levels in the urine and the data of response to corticotrophin for these patients are summarized in Table III. There is a general tendency for the ratio of the ketosteroid patterns to correlate with their clinical state, Case 1 being the most severe and Case 9 the mildest. There seems to be little relation between this ratio and the basal ketosteroid levels. Dr. Brooks, in our laboratory, has kindly carried out more detailed investigations of the ketosteroid patterns in three of the worst of these patients, using methods he has been developing for this purpose (Brooks, 1956). The β -ketosteroids represent largely purpose (Brooks, 1956). One of the most viril-dehydroepiandrosterone (Table IV). One of the most virilized individuals (Case 4) showed the highest basal level and, like Case 2, responded well to corticotrophin. The excretion of this substance in Case 1 was poor. The fraction of polar ketosteroids is particularly important, as it represents the ketosteroids with 11-ketone or hydroxyl groups. That they do not form a large proportion of the ketosteroid excretion

TABLE IV.—Ketosteroid Fractionation in Adult Hirsutism

Case	Total Ketosteroid (mg./day)	β -Fraction (mg./day)	Polar Ketosteroids (mg./day)
1 { Resting	20-4	0-9	2-7
1 { Corticotrophin	49-2	2-4	8-1
2 { Resting	14-3	2-6	6-5
2 { Corticotrophin	41-3	13-7	1-2
4 { Resting	12-1	5-6	4-0
4 { Corticotrophin	27-6	11-4	<0-1
Rheumatoid arthritis { Resting	11-4	2-9	3-7
Rheumatoid arthritis { Corticotrophin	18-5	4-0	
Prepubertal adrenogenital syndrome { Resting	107	12-1	33-6
Prepubertal adrenogenital syndrome { Corticotrophin	182	19-1	56-6

after stimulation with corticotrophin would therefore indicate that the larger part of the ketosteroids is not primarily derived indirectly as corticoid metabolites, but almost certainly by increased ketosteroid synthesis by the gland. The highest proportion of the total ketosteroid as polar ketosteroid after corticotrophin (19%) was found in Case 1. This was appreciably less than in the patient studied with prepubertal adrenogenital syndrome, whose corresponding figure was 31%. The comparison is similar in the case of the resting levels of the polar fraction.

TABLE V.—Pregnanetriol in Urine

	Before Corticotrophin (mg./day)	After Corticotrophin (mg./day)
Case 1. Hirsutism	1-5	8-2 (4)*

TABLE VI.—Comparison of Steroid Responses in Patients with Normal Adrenals and Those with Adult Hirsutism or Pre-pubertal Adrenogenital Syndrome

	Normal	Hirsutism	Adrenogenital Syndrome
Resting corticoid metabolites	Normal	Normal	Normal or low
" ketosteroids	"	Normal to high	High to very high
" 11-oxyketosteroids	"	Normal	Often high
" β -ketosteroids	"	Normal or high	Sometimes high
" pregnanetriol	"	Normal	High
Corticoid metabolites response to corticotrophin	Good	Good	Poor
Corticoid metabolites/ketosteroid response to corticotrophin	High	Low	Very low

The excretion of pregnanetriol in these patients is not very different from that found in other individuals (Table V), even after stimulation with corticotrophin. The highest level reached is that in Case 1, which is similar in magnitude to that in the patient with Cushing's syndrome. It cannot therefore be inferred that there is an abnormality in pregnanetriol excretion comparable to that in the pre-pubertal adrenogenital syndrome. Comparison of the hirsute group with normal individuals and the findings in the adrenogenital syndrome are summarized in Table VI.

enuresis, having a daily urine output of 12 litres, containing up to 400 g. of glucose. At the age of 9 he had had "poliomyelitis" and for some time had noticed blurring of vision. He was somnolent by day, but not sufficient to prevent his working. He had gynecomastia, sparse head and facial hair, but almost normal axillary and pubic hair. His external genitalia were small. Reduction of visual acuity accompanied bilateral papilloedema with numerous small circumscribed retinal haemorrhages. He had left-sided ptosis and signs suggesting old poliomyelitis in the left arm. His voluntary food consumption was equivalent to 7,000 calories daily.

FIG. 14.—Case J.G. Obesity and gynecomastia associated with chronic encephalitic lesion especially involving hypothalamic region.

The E.E.G. showed bilateral slow high-voltage activity, especially in the frontal regions, paroxysmal in nature. It was increased by overbreathing and stabilized by photic stimulation. Apart from what turned out to be a falsely positive ethyl iodophenyl-undecylate ventriculogram, suggesting a filling defect in the third ventricle, other neurological investigations were normal. The blood sugar was 300 mg. per 100 ml. and liver glycogen only 0.74%. There was never excess ketone in blood or urine. The blood sugar was unresponsive to adrenaline. F.S.H. was absent from urine. All epiphyses were united. After later control of the glycosuria with insulin he concentrated his urine to only S.G. 1014 by dehydration or with "pitressin." The B.M.R. was plus 15%, but thyroid uptake of ^{131}I was only 10%.

His response to corticotrophin (89754), both intramuscularly and intravenously, was poor and suggestive of hypopituitarism. At first he required 240 units of soluble insulin daily to control his glycosuria, with a reduction of urine volume to 2 litres. He was then put on a 2,000-calorie diet and given x-ray therapy to the infundibular area, whereupon his insulin requirement fell to 30 units daily. He was discharged on insulin and thyroid, but several months later returned with cerebellar symptoms and signs and died with hyperpyrexia.

At necropsy there were old encephalitic lesions of generalized nature, but specially involving the neighbourhood of the tuber cinereum and mammillary bodies (Fig. 15). There were extensive and more recent haemorrhagic lesions in the pons. The pituitary appeared normal; the thyroid showed vesicles filled with colloid and flattened epithelium (Fig. 16); the adrenals were small, and the fascicula was particularly narrow, with pronounced pigment granules in the inner zone and shrunken reticula; the testicles showed a considerable impairment of spermatogenesis with prominent Sertoli cells, and Leydig cells were reduced in number. Breast tissue showed considerable duct hyperplasia.

Harris (1955b) has carefully reviewed the evidence from experimental work on the hypothalamus and concludes that external stimuli to the anterior pituitary can pass by two pathways. The ordinary day-to-day stimuli are transmitted through nervous pathways, whereas stimuli can also pass by a direct metabolic mechanism. The animal experiments on which this conclusion is based are of two types: section of the pituitary stalk with care to avoid regeneration of the portal vessels, or stimulation of the various parts of the hypothalamic region and production of experimental lesions in this region. Thus stimulation of the posterior part of the hypothalamus in monkeys causes corticotrophin release (Porter, 1954). Pituitary stalk section need only lead to slight atrophy of the anterior pituitary and some atrophy of the adrenal cortex. It is reasonable to suppose that in our patient sufficient stimulation of the anterior pituitary remained by extrahypothalamic pathways to maintain the adrenal in its subnormal state of activity and to give the

somewhat reduced positive response to injected corticotrophin. The decreased uptake of ^{131}I in our patient closely follows Harris's (1955b) finding of reduced thyroid activity in the rabbit with pituitary stalk section.

With regard to gonadotrophin secretion, most experimental work has been done in female animals, but Benoit and Assenmacher (1953) found that isolation of the anterior pituitary of the duck caused decreased testicular function and atrophic changes. The changes in our patient were of partial degree and less severe than those often seen in anterior hypopituitarism (Howard, Sniffen, Simmons, and Albright, 1950). Similarly, the adrenal atrophy had not progressed to the degree often occurring in anterior

FIG. 15.—Case J.G. Typical encephalitic lesion adjacent to mammillary body. ($\times 280$.)

FIG. 16.—Case J.G. A. Quiescent thyroid. B. Testicle. Note the basement membrane, diminished spermatogenesis, prominent Sertoli cells, and reduction of interstitial cells. ($\times 110$.)

hypopituitarism (Sheehan and Summers, 1949). In a series of 60 cases showing endocrinological disturbances as a result of damage in the hypothalamic area meningo-encephalitic lesions were uncommon (Bauer, 1954). The most prominent change was alteration of sexual pattern, precocious puberty, or hypogonadism. In the latter group when tubero-infundibular lesions predominated, and patients with examined the pituitary was usually normal. Patients with encephalitis most resembling ours, but less completely investigated, are those of Moore and Cushing (1935) and of Ayala (1934). They both, however, had diabetes insipidus; in the former, irradiation of the region of the sella reduced the urine volume. In monkeys the hypothalamic nuclei are known to be sensitive to irradiation (Arnold, 1954).

Glycosuria is a rarity in such cases and ketosis seems to occur (Paton and Petch, 1954). Long (1940) reviewed the evidence, including that from experiments, that hypothalamic lesions cause glycosuria, and concluded that they do not permanently alter the control of blood glucose. He favoured the view that hypothalamic or brain-stem lesions cause disturbance via the sympathetic system and adrenal medulla. Our patient had no evidence of sympathetic overactivity, except possibly the small increase of basal metabolic rate. His history seemed to indicate the presence of polyuria due to glycosuria for a long period. The complete absence of ketosis, even with severe depletion of liver glycogen, still needs explanation.

Developing Ideas in Relation to Cushing's Syndrome

In typical cases the diagnosis of Cushing's syndrome is simple; in the causative type of adrenal cortical lesion the diagnosis may prove more difficult, and also in the less typical and related cases. It was only recently noticed how poor is the prognosis of the condition; of 32 patients, 17 were dead within five years (Plotz, Knowlton, and Ragan, 1952). In a study of a series of 40 patients, Soffer, Eisenberg, Iannoccone, and Gabrilove (1955) noted significant deviations from the classical form of obesity. Indeed, the facies may not always show the classical "moon" picture, but more nearly suggest benign obesity. The commonest abnormality, present in 80% of patients, is hypertension, which ultimately leads to irreversible systemic damage. The possible presence of a malignant tumour needs serious consideration before becoming inoperable or metastasizing. When appraising the views of our American colleagues it must be remembered that the occurrence of benign and malignant tumours is more frequent in North America than in Europe. Of 127 American cases, 40% had tumours (Sprague, 1953; Soffer *et al.*, 1955; Forsham *et al.*, 1955). European figures are more difficult to obtain, but the incidence in 57 cases appears to be about 7% (Luft, 1955; Querido, 1955).

It was once thought that the level of 17-ketosteroid excretion was a valuable sign (Forbes and Albright, 1951), but this is only sometimes true (Soffer *et al.*, 1955). The use of recent methods of assay of corticoids and their metabolites has been of help in the diagnosis of Cushing's syndrome, but not of the presence of tumours. In a series of 62 patients, 8 gave normal or doubtful values (Sprague, 1953; Soffer *et al.*, 1955). With a different technique Dustan *et al.* (1953) reported 8 out of 11 patients with normal values. It seems undoubted that a few patients with upper normal values will be found (Laidlaw *et al.*, 1955). It may, however, yet prove to be the case that an estimate of the free or unconjugated hydrocortisone and cortisone in the urine is of more definitive value (Gray, 1955; Cope and Harrison, 1955; see also Dustan *et al.*, 1953). Estimates of plasma corticoids and metabolites give a similar picture, and may be

FIG. 17.—Response in urine steroids of patients S.E. and N.R. with non-tumorous adrenal cortices in Cushing's syndrome to corticotrophin. A. Corticotrophin intramuscularly. B. Intravenously. (Compare Fig. 4.)

FIG. 18.—Responses of patient with Cushing's syndrome with non-tumorous gland. Failure of depression of steroids by 9α-fluorohydrocortisone, 10 mg. daily by mouth. Considerable increase in ketogenic steroid excretion after unilateral adrenalectomy (see text).

difficult to interpret because of the possibility of confusion with emotional factors (Bayliss, 1955).

An approach to the differentiation of malignant tumours from adrenal hyperplasia is the use of corticotrophin. Patients with overactive adrenals are very responsive (Fig. 17). Patient S. E. had adrenal hyperplasia and N. R. had adrenals of normal size but prominent zona fasciculata; both had pronounced Cushing's syndrome. Caution is needed in carrying out these tests, for cardiac failure may be precipitated. A rapid increase of blood corticoids or excretion of corticoid metabolites in patients of this type has also been noted by Burnett, Rukes, Kolb, and Forsham (1954) and by Laidlaw *et al.* (1955). The lability of the level of steroid excretion should be noted. In patient S. E. plasma hydrocortisone was 25 μ g. per 100 ml. and in N. R. values of 11 and 24 μ g. per 100 ml. were found.

On the other hand, the response of patients with adrenal cortical carcinoma to corticotrophin is said to be absent, on account of the autonomous nature of the tumour cells. This was not our experience in patient J. H. (Brooks, McSwiney, Mills, Prunty, Robertson, and Wood, 1956), who showed a significant rise of ketogenic steroids and ketosteroids with corticotrophin. The resting output of these steroids was high, but the plasma hydrocortisone was only 8 to 10 μ g. per 100 ml.

A second possible method of differentiation of tumour patients is that suggested by Venning, Pattee, McCall, and Browne (1952). The principle is to suppress cortical secretion of a non-tumorous gland by administration of a substance which will suppress corticotrophin secretion. Cortisone does this, but, since it also gives rise to significant quantities of corticoid metabolites, it is necessary to measure suppression of ketosteroids. This technique has been fairly successful in the hands of Jailer, Gold, and Wallace (1954), but cannot be regarded as very satisfactory (Wilkins, 1955). With the advent of 9 α -fluorohydrocortisone, which is active in very small amounts, the situation has theoretically changed (Thorn, Renold, Morse, Goldfien, and Reddy, 1955), as it produces insignificant amounts of measurable metabolites. Aldosterone is not powerful enough in its corticoid effects to suppress the anterior pituitary to a useful extent (Prunty, McSwiney, Mills, and Smith, 1954). Cope and Harrison (1955) have observed suppression of free hydrocortisone in the urine with 9 α -fluorohydrocortisone, but its effects in the hands of Nabarro and Walker (1955) have been variable. In Fig. 18 is seen its effects in patient N. R. No significant steroid suppression occurred.

Since the description by Conn (1955) of a patient with adrenal cortical tumour a new facet of the problem has appeared, and as many as 13 similar patients are now known (Conn and Louis, 1956; Brooks *et al.*, 1956). So far as can be determined at present, important features are hypertension, tendency to obesity, polyuria, and cramps with muscular weakness. These need not be present simultaneously. These patients also have low serum potassium levels and alkalosis. For many years these blood changes have interested the Mayo Clinic group, headed by E. J. Kepler; a recent survey of 83 patients with Cushing's syndrome has shown that 41% had alkalosis and 13% low serum potassium (Sprague and Power, 1953). These changes occurred in patients with both hyperplasia and tumour. An important additional biochemical finding in the group of atypical cases mentioned may be the presence of excess aldosterone in the urine. This can be present with normal corticoid metabolites and ketosteroids (Conn and Louis, 1956), or with elevation of these substances (Foye and Feichtmeir, 1955; Brooks *et al.*, 1956), or with an apparent increase of corticosterone (Mader and Iseri, 1955). Conn gave the unfortunate term "primary aldosteronism" to the condition to distinguish it from that state in which patients with subacute nephritis also excrete excessive aldosterone. Adrenal cortical tumours need not necessarily be present (Lancet, 1955; Conn and Louis, 1956), but adenomas are usual, and occasionally carcinoma (Foye and Feichtmeir, 1955; Brooks *et al.*, 1956). The exact relationship of aldosterone secretion to corticotrophin stimulation is not settled, but the pituitary hormone

does not appear to be essential (Gaunt, Renzi, and Chart, 1955; Falbriard, Muller, Neher, and Mach, 1955).

The lability of secretion of corticoid in these patients with Cushing's syndrome is also shown in the very pronounced rise in ketogenic steroids observed in response to unilateral adrenalectomy. From radiological evidence, I.V.P., and air insufflation it was thought likely that N. R. had a tumour of the left adrenal cortex. At operation it was found that the appearances were due to a large fibrofatty pad of tissue lying above the adrenal, which complicated the surgical procedure kindly carried out by Mr. R. H. O. B. Robinson. After the removal of this adrenal there was a sharp increase in ketogenic steroid excretion (Fig. 18) and the operation was followed by a severe sepsis of the area that was difficult to control. In addition there developed intractable haematemesis from large acute gastric ulcerations, from which the patient ultimately succumbed. This difficulty of healing has also been noted by Jepson *et al.* (1956) in a patient who did not have Cushing's syndrome but spontaneously responded in an exaggerated fashion with respect to the secretion of ketogenic steroids. The occurrence of spontaneous intestinal haemorrhage in Cushing's syndrome is apparently rare, Plotz *et al.* (1952) noting a death rate from this cause of less than 2%.

On the other hand, the occurrence of gastric bleeding in patients undergoing treatment with cortisone is quite well recognized. In Cushing's syndrome, where there is such lability of corticoid secretion, there may be risks in the post-operative period if only unilateral adrenalectomy is performed as a first-stage operation. The type of post-operative steroid response in this patient is also important. It resembles the response to corticotrophin, the ketogenic steroid:ketosteroid ratio being high, and is quite different from the response of the hirsute patient L. C. (Fig. 11).

Adiposity Resembling Cushing's Syndrome

Simpson (1951, 1953) made a study of a group of patients with obesity commencing in childhood who, he felt, had some form of altered adrenal cortical activity. Among the patients reviewed here several have had signs, particularly obesity and red striae, suggesting altered adrenal function (see L. D. and R. S. in Table VIII), but hypertension was mild or absent. Their response to corticotrophin does not show the pattern of Cushing's syndrome; indeed, in R. S. it was quite different. An extreme example is C. L., aged 18, who developed obesity at the age of 10; puberty was normal, but suddenly at 18 he developed very severe red lineae distensae (Fig. 19). He had a full plethoric face, a pre-diabetic sugar curve, and mild hypertension. His tallness seemed to be familial. X-ray studies, serum electrolytes, urinary ketosteroids, and ketogenic steroids were normal. Plasma hydrocortisone was 2.5 and 3.5 μ g.%. He showed a normal (not increased) response to corticotrophin (89754). He improved after pituitary irradiation and with reducing diet. We are inclined to agree with Simpson that there is an underlying abnormality of adrenal cortical function in these individuals which by present methods fails to be demonstrated. Such patients are not uncommon and their treatment remains a challenge.

FIG. 19.—Case C. L. Obesity.

In conclusion, it seems that when allowances are made for varying activity of corticotrophin preparations, and conditions are otherwise standardized, different patterns of response of the adrenal cortex may be discerned. In addition to the hyperactive response seen in certain patients with Cushing's syndrome there are those interesting ones with a low basal activity but potentially very responsive to stimulation. Some mechanism other than the enzymatic lesion of pre-pubertal virilism appears to control the relative production of corticoid and androgen, and this may be disturbed in varying conditions, including hirsutism.

The part played by central nervous control of the anterior pituitary through the hypothalamus must be acknowledged. Information on the interaction of hormones from other glands on the activity of the adrenal cortex is scanty and needs to be increased; probably the thyroid is particularly worthy of further study. The effects of metabolic derangement on the function of the central nervous system, including the mimicry of some manifestations of space-occupying lesions, is of practical importance. With the discovery of aldosterone the problem of differentiating the hormonal abnormalities in Cushing's syndrome and allied states has increased in complexity.

Summary

Relevant knowledge of compounds secreted by the adrenal cortex and their metabolism is reviewed. Experiments are discussed which give information about the action of corticotrophin in man. Difficulties in evaluating the response due to variations in the activity of different batches of corticotrophin are stressed. After making due allowance for these difficulties, it is possible to define a "spectrum" of response in individuals with various pathological entities. Particular attention is drawn to the response of patients with idiopathic hirsutism, and the effects are contrasted with those in hypopituitarism and normal childhood on the one hand, and in adrenal cortical virilism on the other. Comparisons are made between the effect of exogenous corticotrophin and the endogenous stimuli produced by surgical trauma.

A condition of "basal hypo-adrenal corticalism" is defined and its significance discussed. The possibility of synergic action between corticotrophin and a factor of synergic action between corticotrophin and a factor associated with growth hormone, gonadotrophins, and thyroid hormones is considered. There seems little doubt that thyroid hormones are of great importance in the responsiveness of the adrenals. Evidence concerning the existence of a potentiating factor to corticotrophin for the stimulation of adrenal androgens is shown to be worthy of consideration. A similarity in behaviour of certain adult male obese subjects to that of hirsute women is noted and contrasted with others bearing a superficial resemblance to patients with Cushing's syndrome.

Attention is drawn to clinical problems in relation to alterations of cerebral activity in patients with Addison's disease and hypopituitarism and to difficulties which arise when space-occupying intracerebral lesions may be present. A patient with long-standing encephalitis has been studied, with particular reference to the secondary endocrinological phenomena which ensued, and the significance of these is discussed. Recent advances and ideas in relation to the diagnostic problems in Cushing's syndrome and in patients with adrenal cortical tumours, particularly when hypocalcaemia and renal symptoms are present, are considered and supplemented with additional observations.

ADDENDUM.—Since this manuscript was prepared additional confirmatory evidence has been obtained in another

patient in support of the effects of tri-iodothyronine on corticotrophin stimulation in hypopituitarism.

I should like to thank those colleagues whose assistance made much of this work possible, and especially Drs. R. V. Brooks, B. E. Clayton, R. R. McSwiney, and I. H. Mills, and many house-physicians; Professor W. G. Barnard and his staff for assistance in morbid anatomy; Miss P. Seimssen and the nursing staff of Holden Metabolic Ward; and the many people who gave technical assistance. Lastly, my thanks are due to the Governors of St. Thomas's Hospital for some financial assistance from endowment funds.

EFFECTS OF HEAVY AND REPEATED MALARIAL INFECTIONS ON GAMBIAN INFANTS AND CHILDREN

EFFECTS OF ERYTHROCYTIC PARASITIZATION

BY

From the Medical Research Council Laboratories,
Gambia, British West Africa

Since 1947, when the Medical Research Council established its laboratories in the Gambia, many workers investigating the importance of non-parasitic diseases in the African population have found great difficulty in assessing the contribution to the general picture of the inevitable malarial infection. McGregor and Smith (1952) and Walters and Waterlow (1954) found the twin threads of parasitization and malnutrition exceedingly complex and difficult to unravel. In no section of the community is this complication more in evidence than in infancy and early childhood—when plasmodial infection is severe and almost universal. This paper describes the result of an investigation in the Sukuta area of the Gambia that was undertaken to determine precisely the effects, both immediate and long-term, of repeated and heavy malarial infections on infants and young children.

Sukuta is one of the principal villages in the Kombo St. Mary District of the Gambia, and as such it possesses

an infant welfare centre which serves the surrounding villages within a radius of 10 miles. It is the centre of a dominantly agricultural Mandinka community which depends for food largely upon the cereals that are grown in the rainy season. Maize and digitaria are produced in small quantities in the early part of the rains, while staple cereals—rice, sorghum, and millet (*pennisetum* spp.)—are raised in the latter part. Groundnuts are grown principally as a cash crop, but some 10% of the yield is consumed annually as food. Cattle are kept in considerable numbers, but as they are seldom killed they contribute little to village food supplies. Milk yields are low, and when the requirements of calves are satisfied little remains for human consumption. Fish is relatively abundant in the coastal region, and considerable quantities are eaten even in the more inland villages.

In the area under consideration malaria is hyper-endemic. Transmission declines in the dry months from December and May, when it becomes negligible, but rises dramatically with the onset of the rains in June, to reach a peak in October and November. *A. gambiae* is the dominant vector in the inland reaches, but in coastal villages associated with *Avicennia* mangrove swamps it is of secondary importance to *A. gambiae melas*. *P. falciparum* is by far the most commonly encountered parasite, but *P. malariae* and *P. ovale* are not infrequently seen.

In June, 1951, the investigation described here began with the creation of two experimental groups of newly born African infants at the Sukuta Infant Welfare Centre. The infants were assigned to either group by random selection. Infants in one group received 6 mg. of chloroquine base per kg. of body weight each week, while those in the other group received only a lactose placebo and were thereby maintained as controls. When each group contained 26 members no further infants were included. The sister in charge of the centre was advised to regard the experimental children as being in no way different from the other infants attending the clinic. If, in her opinion, an infant of the control series required antimalarial treatment, she was at complete liberty to administer any of the standard treatment courses that are used in Gambian dispensaries. Similarly, any non-malarious illness developing in members of either group had to be treated in accordance with her normal practice. An essential point of the experiment was that the established custom of infant-feeding in a rural Gambian community should not be modified: no supplements, such as skimmed milk, were therefore permitted.

When the children of the protected series reached the age of 2 years the weekly dosage level of 6 mg. of chloroquine base per kg. was discontinued and a flat rate of 150 mg. of base substituted. Both groups of children were regularly inspected and examined in the field, and in October, 1954, they were admitted to the research ward of the Medical Research Council's Laboratories at Fajara for detailed investigation and comparison. The methods used in the investigations and the results obtained are here reported.

First Investigation

Methods

Members of the two groups were visited weekly by a nursing sister who administered chloroquine to the protected and placebo to the unprotected series. The chloroquine, in powder form, was mixed in a teaspoon with water and care was taken to ensure that each infant swallowed its

dose. Vomiting was noted to be a frequent sequel to treatment in the protected infants, and the practice of observing each baby for 30 minutes after drug administration was instituted. If vomiting did not occur within that period satisfactory retention was assumed. If, however, it occurred the dosage was repeated. As members of the protected series grew older the frequency of the vomiting decreased until it was no longer necessary to continue the observation period.

Thick and thin blood films were taken from each infant at each weekly inspection. The thick films were subsequently stained by Field's rapid method and examined microscopically under 1/12 in. oil immersion lens, 100 consecutive fields of each being examined. Thin films were fixed in methyl alcohol and stained by Giemsa's method.

At monthly intervals the members of both series were examined by a medical officer and details of weight, diet, and colour of hair were recorded. The sizes of liver and spleen were found by palpation, and haemoglobin values, as assessed by the Dare haemoglobinometer, were noted.

Results

Extreme difficulty was encountered throughout the investigation in preserving the size of the experimental groups, and, although each had contained 26 members initially, by the autumn of 1954 the number had dwindled through death and change of domicile to 20 protected and 13 unprotected children. Moreover, by this time 3 of the 20 protected children had each experienced a single short attack of malaria. These attacks originated in the failure, despite many attempts, to continue weekly chloroquine dosage. Mothers without warning would depart, taking their children with them on visits to distant relatives. On their return such children were examined closely for evidence of malaria contracted in their lapse from treatment, and, initially, all infected ones were excluded from the protected series. Ultimately these children who were known to have been infected for only a short period were retained. The three children referred to above were known to have been infected for less than 10 days.

By October, 1952, before movement of the parents had reduced the size of the groups, one child of the protected series and five of the controls had died, thus producing group mortality rates of 3.8% and 19.2% respectively. The difference in these rates is not statistically significant. All deaths took place in the first 16 months of life. The precise cause of death (acute gastro-enteritis) could be established only in the case of the protected child. All the unprotected children who died were known to have been heavily infected with malaria immediately before death. From October, 1952, to November, 1954, no further deaths occurred, even in those whose regular drug prophylaxis had lapsed.

Analysis of the dietary notes kept throughout the investigation showed that supplements to breast milk were started on the average at 4½ months. These supplements comprised paps of the common local cereals—rice, sorghum, and

FIG. 1.—Average weight curves of protected and unprotected children during first three years of life.

millet. Weaning took place at the average age of 22 months, by which time the child was receiving a good mixed cereal diet with additions of meat and fish.

Fig. 1 expresses graphically the average weight curves of protected and unprotected children over the first three years of life. It will be noted that as age progresses and malaria infection becomes frequent the unprotected children lag behind their protected fellows. Nevertheless, at no time in the first three years is the weight difference statistically significant. By the end of the second year of life the unprotected children begin to make more rapid weight gains, and by the 36th month appear to have overtaken the protected children.

Figs. 2 and 3 contrast the weight development of a protected child with that of its control through successive wet and dry seasons. It is of interest to note that the subjects whose weights are recorded in Fig. 2 were homozygous (or uniovular) twin girls reared by their mother in identical circumstances.

Fig. 2.—Weight development of a protected child and of its control. These two children were homozygous twins.

Fig. 3.—Weight development of a protected child and of its control.

Fig. 4.—Mean Hb values of protected and unprotected children during first three years of life.

Both figures illustrate the tendency shown by all unprotected children to gain weight more slowly, and occasionally to lose weight in the wet malarious months than in the dry season.

Fig. 4 contrasts the mean haemoglobin values in children of both series from the end of the first month of life until the 36th month. The much lower level of the unprotected children will be noted.

In November, 1952, 25 protected children and 17 controls were examined. Table I contrasts the clinical findings.

TABLE I.—Clinical Findings (November, 1952)

	Protected Group	Unprotected Group
No. in group	25	17
Percentage with parasitaemia	0	100*
" " splenomegaly	0	88.3*
" " liver palpable below costal margin in mid-axillary line	4	88.3*
Percentage with hair dyspigmentation	32	53
Mean haemoglobin (g.%)	12.1 (S.D. 1.06)	9.5%* (S.D. 1.22)

* Values statistically significant.

Second Investigation

Methods

In October and November, 1954, 16 children of the protected series and 13 of the unprotected series were admitted to the ward of the Medical Research Council's Laboratories for detailed clinico-pathological investigation. Each child remained in hospital for five days, during which time liver biopsy was performed with the parents' sanction. Specimens of urine, stool, and blood from each child were examined in the following ways.

1. *Urine* was tested for specific gravity and the presence of protein, sugar, bile, blood, and casts.

2. *Stools*.—Microscopical examination of both fresh saline and salt-flotation preparations for protozoal and helminthic parasites. Densities of helminth ova were calculated by a modification of the Stoll technique.

3. *Blood*.—(a) Thick and thin films were examined for the presence of plasmodia. (b) Thick films, prepared at 11 p.m., were dehaemoglobinized, fixed in methyl alcohol, stained with haemalum, and examined for the presence of microfilariae. (c) Haemoglobin values were assessed, using the M.R.C. Grey Wedge photometer. In each case the mean of ten readings was taken. (d) Erythrocyte sedimentation rates were obtained by Wintrobe's method. (e) Packed cell volume was read after centrifuging for thirty minutes at 6,000 revolutions a minute. (f) Red- and white-cell enumeration was performed on a Neubauer "bright ruling" haemocytometer. (g) Sickling tests were made, employing the sealed cover-slip technique and using a 2% solution of sodium metabisulphite as a reducing agent. (h) Samples of serum were forwarded by air to the United Kingdom for various treponemal tests. (i) Total serum proteins were estimated by a semimicro-Kjeldahl method, using a selenium-sulphuric acid catalyst. For the estimation of serum albumin, serum globulin was precipitated by 25% sodium sulphate. The difference between total serum protein and serum albumin results was taken as the serum globulin value. Non-protein nitrogen was estimated separately after the serum had been deproteinized by a modified Folin-Wu tungstic acid reagent. (j) Electrophoresis of serum proteins was effected in a horizontal tank containing a barbiturate buffer (pH 8.6) to which a small quantity of fungicide (sodium salicylanilide) had been added. Serum (10–20 μ l.) was applied by coverslip to Whatman's No. 2 (chromatography) filter paper. A direct current (120 v.), obtained from a high-tension dry battery, was passed through the filter paper for 20–22 hours. Electrophoretograms were fixed by heat, stained with azocarmine "B" and "scanned" in a Joyce-Loebel densitometer.

Results

The results of the liver biopsy will be dealt with later in a separate publication. The detailed results of the other investigations are shown in Tables II–IX and Fig. 5.

All the children appeared fit and well, and no difference in physical agility or mental acuity could be detected between members of the two groups. The mean weight of protected children was slightly lower than that of the unprotected children, but the former were slightly taller (Table II).

No marked nutritional deficiencies were found in any child, and both groups were assessed as being in good nutritional condition (Table III).

All children of the unprotected series showed considerable enlargement of both liver and spleen (Table IV). In only two of the protected children could the liver be palpated below the costal margin in the mid-axillary line, and in only one child of this series could the spleen be felt. In this latter case splenic enlargement was small and the child was known to have experienced a short attack of malaria a few months before.

Examination of thick and thin blood films revealed that all the unprotected children were infected with malaria (Table V). In every instance the children were apyrexial, and the infection seemed to be completely asymptomatic. Parasite densities varied in individuals from 20 to 3,000 Parasite densities per 100 oil fields of thick blood films. The frequencies of infecting plasmodia were *P. falciparum* 100%, *P. malariae* 61.5%, and *P. ovale* 7.7%.

Examination of night films did not reveal the presence of microfilariae in the blood of any child. The incidence of infection with intestinal helminths was higher in the pro-

Total proteins	7.13 g. (S.D. 0.4429)	7.59 g. (S.D. 0.4309)
Albumin	3.92 g. (S.D. 0.5295)	3.83 g. (S.D. 0.3567)
Globulin	3.20 g. (S.D. 0.4017)	3.76 g. (S.D. 0.3640)
Non-protein nitrogen	20.85 mg. (S.D. 6.33)	19.07 mg. (S.D. 4.28)

tested series, but the density of these infections appeared to be greater in the unprotected children. The mean egg loads per gramme of faeces in protected and unprotected children respectively were: hookworm, 600 and 900; ascaris, 12,400 and 23,800; tapeworm, 1,600 and nil.

In only one case, that of an unprotected child, could any gross urinary abnormality be detected. This child showed a marked proteinuria (Esbach 1.125 g.%) but seemed physically fit and well and the N.P.N. value of her serum was within normal limits. No evidence of oedema could be detected on clinical examination. Microscopy of the uncentrifuged urinary deposit revealed both granular and hyaline casts, epithelial cells, and a few blood cells of both the red and white series. The blood of the child showed a fairly dense *P. malariae* infection, and while it is clear that the urinary condition could easily have been completely independent of this the possibility that it was a sequel to quartan malaria must be borne in mind.

While the mean haemoglobin concentration of each group showed practically no difference the mean erythrocyte concentration and the mean haematocrit value of the unprotected children were considerably lower than those of the protected series (Table VII). Both groups showed a degree of normocytic anaemia, that of the unprotected children being the greater. Erythrocyte sedimentation rates in the malarious children were much higher, despite the asymptomatic nature of the infections, than those of the non-malarious group.

In the serum of only one child, positive results were obtained in the Wassermann, cardiolipin Wassermann, Kahn, and treponemal immobilization tests. A positive pallida reaction was also obtained. This child was one of the two protected children in whom enlarged livers were palpated, and the possibility that luetic disease was responsible for the enlargement must be considered.

The mean total serum protein values, as determined by chemical estimation, were found to be approximately 0.5 g.% higher in the unprotected children (Table VIII). Fractionation of the serum proteins revealed that mean

albumin values for each group were almost identical but that the mean globulin value was higher in unprotected children. Non-protein nitrogen serum values were similar in both groups.

Fig. 5 shows the graphs obtained by "scanning" the electrophoretograms of an unprotected and a protected child. The strikingly high gamma-globulin fraction of the former will be noted.

When a pattern similar to the above had been prepared on standard graph paper for each child of both series it was cut out with scissors and weighed. A perpendicular to the baseline was then dropped from the lowest point of the trough between the curves representing the beta- and gamma-globulin fractions and, by cutting along this, the gamma portion of the pattern was severed from the remainder. This portion was then weighed and its weight as a percentage of the total graph calculated. In this way the mean serum gamma-globulin was estimated to be 24.43% (S.D. 5.74) of the mean total serum protein value in the unprotected children and 32.21% (S.D. 4.39) in the protected children. It is thus apparent, that the gamma-globulin content of the serum of the malarious children was almost one-third as great again as that of the non-malarious children.

It is unfortunate that the small size of each experimental group limited the value of the statistical analysis of results. Nevertheless we have thought that such analysis would prove helpful to the reader in assessing the relative importance of the difference between protected and unprotected children. Table IX therefore summarizes these differences in mean values observed, which were greater than twice the standard error of the difference. All other differences reported in this second investigation were less than twice this value.

TABLE IX.—Major Differences Detected Between the Protected and Unprotected Groups

	Difference Between Mean Values or Proportions of Groups	Standard Error	Difference Divided by Standard Error
E.S.R.	19.74	3.07	6.43

Height	1.33	0.65	2.04

Discussion

Before discussing the results observed in this investigation it must be remembered that chloroquine afforded the treated children protection only against the erythrocytic phases of the malaria parasite. It is known that the drug has no action on sporozoites or on the exo-erythrocytic phases of infection, and it must be assumed that sporozoite entry and subsequent exo-erythrocytic development occurred

normally in both groups, but that in the treated children no further parasitic growth took place. It is clear, therefore, that only the erythrocytic phases can be held responsible for the production of the differences observed between treated and untreated children.

From the above results one is led to deduce that malaria exerted its maximal effects in the first 18 months of life and that by the age of 3 years the unprotected children had developed a considerable immunity to the disease, as witnessed by their ability to live asymptotically with fairly dense parasitaemia. While the difference in the mortality rates of the two groups, which were of small size, was not statistically significant, and while the cause of death of the five unprotected children could not be ascertained, the possibility that comes to mind first, and cannot be excluded, is that the difference was related to the presence or absence of overt malaria infection.

Study of the weight curves of children of both groups indicates that acute clinical malaria tended to retard growth. This retardation did not appear to be in any way permanent, for when the malarious children had developed enough resistance to the noxious effects of the disease they rapidly regained lost ground and, despite the persistence of moderately severe parasitaemia, by the third year of life were just as heavy as their protected fellows. It should not be forgotten, however, that at this age the grossly enlarged livers and spleens of the malarious children must have contributed a disproportionate sum to the total body weight, whereas that of the protected children represented presumably normal body tissue.

These observations, coupled with the fact that no marked difference in the incidence of signs of specific nutritional deficiencies could be found between the groups at any time, suggest that in children to whom a good diet is available malaria exerts its main effect on growth not by appropriating nutrients that would otherwise be used in building body tissue but by limiting the food intake of the host through the anorexia that the clinical attack produces.

The differences observed in the mean haematological indices, of which the erythrocyte concentration and the packed cell volume alone are significantly reduced in the malarious group, appear to be entirely due to malaria. Hookworm infection cannot have contributed to these differences, for not only was the density of infection low in each group, but the incidence of ankylostomiasis was twice as high in the protected as in the unprotected children.

Wilson and Miles (1946) state that there is conflict in the evidence that malaria tends to give positive reactions in the Kahn and allied serological tests. In the present investigation no positive reaction to the tests employed was obtained in the sera of the unprotected children despite the fact that all were fairly heavily infected. These children were, however, asymptomatic, and it is possible that had they been febrile positive reactions might have been obtained.

Within recent years considerable interest has been focused upon the question of whether malaria causes substantial enlargement of the liver (Colbourne *et al.*, 1950; McGregor and Smith, 1952; Waddy, 1952; McGregor, 1954; Black, 1954, 1955). The results reported above demonstrate clearly that such is indeed the case. They also show that hepatomegaly is attributable to the erythrocytic cycle of the malaria parasite, and that the pre- and exoerythrocytic cycles within the liver do not appear to influence the overall size of that organ. In view of the good nutritional status of the members of both groups malnutrition may be discounted as an additional factor in the production of hepatomegaly in these children. From clinical examination of the children showing liver enlargement no evidence of hepatic dysfunction could be adduced. The mechanism of enlargement and the associated histological changes will be discussed in a subsequent communication.

Of particular interest are the differences observed in mean serum protein values. It will have been noted that, whereas mean albumin levels were similar in both groups, mean total protein and globulin values were much higher in the un-

protected children. Analysis of electrophoretic patterns indicated that this difference was located principally in the serum gamma-globulin fractions. The precise reason for the existence of a much higher gamma-globulin level in the serum of the malarious children is not known, but when the controlled nature of the investigation is considered it is clear that malaria must have been at least a closely related factor. Study of the literature relating to serum protein changes in malaria reveals that most communications describe observations made during the acute attack. Observers have reported a fall in serum albumin and a rise in serum globulin with an overall reduction in total serum proteins (Fulton and Macgregair, 1949). These changes are transient, and protein values revert to original levels soon after eradication of the infection. It is apparent that, hitherto, little information has been gathered on the cumulative effects on serum proteins of several years of repeated and heavy plasmodial infection.

It is possible that almost three years of continued irritation of the reticulo-endothelial systems of the unprotected children by the products of disintegration of parasitized erythrocytes may have stimulated the production of abnormally large quantities of gamma-globulin. If this is so the high values obtained in the malarious children are of no special significance, since they have their origin in a non-specific process. However, it is equally possible that these high values may be caused, at least in part, by the production of specific humoral antibodies to the erythrocytic phase of the infecting plasmodium. The observations of earlier workers justify this hypothesis. Sotiriades (1936) reported that whole blood from highly immune subjects produced beneficial results when injected into patients suffering from acute attacks of malaria, while Coggeshall and Kumm (1937) and Eaton (1938) demonstrated the presence of circulating antibodies in the sera of monkeys recently recovered from the malaria. At this juncture further speculation on the mechanism of the production of the serum protein variations recorded would be valueless, and additional investigations are clearly indicated.

The difference in the mean erythrocyte sedimentation rates of the protected and unprotected children must be regarded as a sequel to erythrocyte parasitization in the latter. The high mean rate observed in the treated group, however, is puzzling. As these children were all fit and well and presented no sign of disease save for a moderate degree of intestinal helminthic infection in some cases, one wonders what part the unsuppressed hepatic phases of malaria played in raising these sedimentation rates. McGregor and Deegan (1954) observed that the mean erythrocyte sedimentation rate in a group of fit and healthy Gambian adults, who must have experienced severe repeated malarial infection in infancy and childhood, was, by European standards, abnormally high. They postulated that a possible reason for this could be that Gambian adults possessed a plasma protein pattern which differed greatly from the accepted European normal. The results of this present investigation support that view and, further, incriminate malaria as a major factor in the production of the altered pattern.

The results of urinary examination and of the evaluation of serum non-protein nitrogen levels suggest that with one possible exception the prolonged heavy malaria infections experienced by the unprotected children caused no permanent impairment of kidney function. Even in the exceptional case the relationship of quartan malaria to proteinuria is obscure, and it is possible that the two conditions were completely independent.

After more than three years of continuous chloroquine dosage no evidence of drug toxicity was found in any protected subject. Throughout this period complete suppression of the erythrocytic cycle of malaria was achieved in every subject who received regular weekly treatment.

Summary

To assess the effects of repeated heavy erythrocytic infection in African infants and young children an investigation in a hyperendemic malarial district of the

Gambia began in 1951. Twenty-six infants were protected from birth by weekly doses of chloroquine base (6 mg. per kg. for the first two years and thereafter 150 mg.). A control group of equal size of unprotected infants from the same population was maintained. The established custom of infant feeding in a rural Gambian community was not modified. Members of both groups were examined regularly for three years.

The unprotected children once infected with malaria were observed to grow more slowly and to become much more anaemic than the protected children over the first two years. Mortality rates for protected and unprotected groups were 3.8% and 19.2% respectively, all deaths occurring in the first sixteen months. As increasing resistance to malaria was acquired the unprotected children made rapid growth progress.

In October–November, 1954, 16 protected and 13 unprotected children were admitted to hospital for detailed investigation and comparison. The mean weight of protected children at a mean age of 161.68 weeks was 464.50 oz. (13.167 kg.) and that of unprotected children at a mean age of 161.15 weeks was 466.15 oz. (13.214 kg.). The mean heights of protected and unprotected subjects were 35.82 in. (90.9 cm.) and 34.49 in. (87.6 cm.) respectively.

All unprotected children were found to exhibit malarial parasitaemia (plasmodial frequency being: falciparum 100%, malariae 61.5%, ovale 7.7%), but to be asymptomatic.

The nutritional status of members of both groups was assessed to be good, the incidence of deficiency signs in protected and unprotected children respectively being: skin changes 12.5% and 15.38%; bone changes 25% and 46.14%; mucosal changes 12.5% and 23.0%.

All unprotected children showed considerable hepatomegaly and splenomegaly, while 12.5% of protected children were found to have enlarged livers and 6.3% enlarged spleens.

Hookworm and ascaris ova were found in the stools of 68.8% of protected and 38.5% of unprotected children; the density of infection was greater in the unprotected group.

A marked proteinuria associated with a *P. malariae* parasitaemia was noted in a member of the unprotected group. No other gross urinary abnormality was detected in any child.

The differences detected in mean haematological indices between the protected and unprotected groups respectively were: E.S.R., 31.1 and 50.84; Hb, 11.28 and 10.88 g.%; R.B.C., 4,000,000 and 3,688,000; P.C.V., 34.37 and 31.96%; M.C.V. 86.25 and 86.92 cubic microns; M.C.H.C., 32.81 and 33.84%; W.B.C. 9,288 and 9,980; sickling trait, 12.5% and nil.

Chemical estimation of serum proteins showed the mean total serum protein (7.59 g.%) and mean globulin (3.76 g.%) values to be higher in unprotected than protected children (7.13 and 3.20 g.%). Mean albumin values were almost identical (3.92 g.% protected and 3.83 g.% unprotected), as were mean N.P.N. levels (20.85 mg. per 100 ml. protected and 19.07 mg. per 100 ml. unprotected). By filter paper electrophoresis the gamma-globulin fraction in unprotected children was found to be almost one-third greater than in protected children. The serum of only one subject, a protected child, yielded positive results in the Wassermann, cardiolipin Wassermann, Kahn, and treponemal immobilization tests.

The results are discussed and are considered to indicate that erythrocytic malaria in Gambian children exerts its main effects in the first two years of life, chiefly through the clinical illness produced by the acute attack. Malarious children, once they have acquired sufficient resistance to the noxious effects of clinical malaria, appear rapidly to make good lost ground despite the persistence of moderately dense parasitaemia. A consistent relationship between hepatomegaly and erythrocytic malaria is defined. The view is expressed that the serum protein changes observed in malarious children may in part be due to the formation of humoral antibodies.

We wish to thank Dr. S. H. O. Jones, Director of Medical Services, Gambia, for his assistance throughout this investigation; the nursing sisters of the Gambia Health Services and of the Medical Research Council for their invaluable and continuous co-operation; and Dr. I. N. O. Price, of the Public Health Laboratory Service, for conducting the serological tests reported in this paper.

STUDY OF TRANSFUSED PLATELETS IN A CASE OF CONGENITAL HYPOPLASTIC THROMBOCYTOPENIA

BY

A. DOYNE BELL, D.M., F.R.C.P.

J. W. MOLD, M.B., B.S.

R. A. M. OLIVER, B.M., B.Ch.

AND

SIDNEY SHAW, M.D.

Departments of Paediatrics and Clinical Pathology, Charing Cross Hospital

The following case of neonatal thrombocytopenia is of interest because of the rarity of the haematological disorder, which was apparently a primary aplasia of the megakaryocytes associated with a congenital skeletal defect of the forearms, and also because it was possible to give relatively large transfusions of platelets in view of the recipient's small blood volume. In the virtual absence of platelet production in the infant, the effectiveness and survival of these transfused platelets could be readily studied.

Case History

This child, a female, was born at term of the mother's second pregnancy. Its weight was 6 lb. 2 oz. (2,780 g.). The first pregnancy had miscarried at two months. Vaginal bleeding had occurred also in this pregnancy during the twelfth week. No consanguinity existed between the parents, who were in good health.

The infant was born with a deformity of both arms, due to the absence of both radii, resulting in diminutive forearms with abducted hands, but otherwise appeared healthy.

Progress was uneventful until the sixth week, when melaena occurred, immediately followed by the appearance of scattered petechiae and noticeable pallor. No drug with which blood dyscrasia could be associated had been given at any stage of the child's illness.

The infant was admitted to hospital on June 11, 1955, aged 6 weeks and weighing 7 lb. 7 oz. (3,370 g.). Nutrition and hydration were good. The child was alert and afebrile, but there was marked pallor with petechiae in the mouth and skin. The liver was palpable and enlarged. The spleen could be felt $\frac{1}{2}$ in. (2 cm.) below the costal margin. No lymphadenopathy was apparent. No other abnormality was found on physical examination. The urine was normal.

Investigations on Admission.—Hb, 5 g. per 100 ml.; white cells, 63,000 per c.mm., with a preponderance of granular cells and a marked shift to the left (for differential count, see Table I). The red cells showed frequent polychromatic forms and normoblasts. Blood group B, rhesus test positive (to anti-D), direct Coombs test negative. Platelet count

FIG. 1.—"Platelet transfusions" are indicated by arrows, and transfusions of stored blood by dotted arrows. The duration of a normal bleeding-time is shown by a continuous black line; where this is interrupted the bleeding-time was found to be longer than 10 minutes.

(Fonio's method), 3,600 per c.mm. Bleeding-time in excess of one hour. Clotting-time, clot retraction, and prothrombin times were within normal limits. Hess's test showed 15 petechiae in $\frac{1}{2}$ square inch (3.2 square cm.). Serum bilirubin, 0.4 mg. per 100 ml. Tibial marrow counts (Table I) showed a normoblastic hyperplasia, active leucopoiesis, and a striking absence of platelet precursors. Prolonged search of several films from each specimen failed to show any mature or early forms of megakaryocytes. A maternal blood count was normal, with a normal platelet count. The Wassermann reaction in the mother and child was negative.

After admission a tentative diagnosis of congenital hypoplastic thrombocytopenia was made, based on the absence of platelet precursors, the haematological condition being associated with skeletal abnormalities.

On June 14 a transfusion of stored blood was given. In spite of a satisfactory rise in haemoglobin there was no appreciable effect on the bleeding-time or the platelet count, and the stools continued to be heavily blood-stained. In view of the thrombocytopenia, platelet transfusions were given (for technique, see Appendix). The improvement on each occasion was striking but transitory (Table II). Clinically, there was fading of petechiae, and the stools changed from melaenic to normal. The increased number of circulating platelets persisted for as long as five days, while the bleeding-time and the capillary fragility were found to be normal for a longer period (see Fig. 1).

In addition to treatment with transfusion, cortisone was given by mouth. Therapy was begun with a dosage of 7.5 mg. daily, which was gradually increased to an ultimate dose of 24 mg. daily. Some control of the bleeding tendency appeared to be produced, as shown by improvement in tests of the bleeding-time and capillary fragility. There was no effect on the platelet count. In spite of anaemia the general condition of the child remained good, with satisfactory developmental progress (see Fig. 2, taken on October 11), and a slow weight gain from 7 lb. 7 oz. (3,370 g.) on admission to 14 lb. 3 oz. (6,435 g.) at death six months later.

After a poor response to two platelet transfusions, splenectomy was carried out on October 26. At operation the spleen was found to be slightly enlarged (weight 21 g.). Microscopy showed abundant splenic follicles with a simple pulp hyperplasia. There was no evidence of leukaemia, siderosis. As a pre-operative measure a particularly large platelet transfusion was given. There was no undue bleeding at the time of operation or during the post-operative period;

FIG. 2.—Showing the deformity of the forearms and degree of enlargement of the liver.

improvement was not maintained. Four days after an emergency transfusion of stored blood the haemorrhagic state became more marked; the infant developed signs of cerebral haemorrhage and died on December 2.

At necropsy an extensive cerebral haemorrhage was found. Absence of the radii was confirmed by dissection, no bony rudiment being demonstrable. Microscopy of the liver (weight 240 g.) showed small foci of haemopoietic tissue within the sinusoids. The lymph nodes generally were moderately enlarged, and microscopically showed similar haemopoiesis within the sinusoids. A sample of bone marrow taken three hours after death showed a hypercellular, actively normoblastic marrow. Megakaryocytes were not seen in these films, nor in subsequent bone-marrow sections. Small haemorrhages were present in the lungs, myocardium, meninges, and brain. The haemopoietic activity was considered to be in keeping with compensatory blood formation following continued bleeding.

Diagnosis

Thrombocytopenia in the neonate is an uncommon condition. A comprehensive review of such cases is given by Robson and Walker (1951). They classify congenital and neonatal thrombocytopenia into those cases in which there is a maternal history of purpura and those from normal mothers. In the latter category they distinguish transient idiopathic thrombocytopenic purpura, in which hyperplasia of the megakaryocytes is the usual finding, from other cases in which there is an aplasia of the megakaryocytes in the bone marrow. The earliest reference to this latter condition is that of Greenwald and Sherman (1929). Two further cases have been recorded (Landolt, 1948; Stefanini and Dameshek, 1955). In each of these cases the child had one or more congenital deformities associated with hypoplasia of the megakaryocytes. The case of Stefanini and Dameshek appears remarkably similar to our own, since the hypoplasia of the megakaryocytes was associated with a congenital absence of both radii.

It is significant in this case that the mother's blood picture was normal, and that she gave no history suggestive of a haemorrhagic diathesis. There was a history of threatened abortion at the second month. It is at about this time in intrauterine life that platelet production is thought to begin (Fruhling *et al.*, 1949). In addition, there was no evidence of secondary thrombocytopenia in the infant arising from such causes as acute infection, drugs, or leukaemia. The fall of haemoglobin associated with the presence of normoblasts in the peripheral blood raised the possibility of a haemolytic anaemia, which was excluded by the absence of jaundice, normal serum bilirubin, and the negative Coombs test. Aplastic anaemia associated with skeletal defects of the type described by Fanconi (1927) could be excluded by the bone-marrow findings, the high white cell count, and the absence of other features such as cutaneous pigmentation and microcephaly. It is suggested that this is a case of primary congenital aplasia of the megakaryocytes associated with other congenital deformities, as referred to by Hauser (1948).

Platelet Transfusion

Platelet transfusions may be given by a variety of techniques, all based on preventing platelets adhering to wettable surfaces. Duke (1910) reported the first successful platelet transfusion, but gave no details of his technique. Hirsch *et al.* (1950) succeeded in raising the platelet count of a case by using silicone-coated syringes and needles. Recently, with the development of plastic materials, it has been possible to use non-wettable tubing for continuous transfusion rather than the multiple-syringe technique used by Hirsch and Gardner (1952) and Stefanini and Dameshek (1953). The latter authors reviewed other methods of obtaining platelet suspensions. These included the use of dextran, the collection of platelets on columns of ion-exchange resin, or the centrifuging of blood at low temperatures to remove red and white cells. They concluded that the manipulations necessary for these methods so impaired the survival of platelets after transfusion that they defeated their own purpose. The method adopted here is both simple and convenient (see Appendix).

We confirm the striking decrease in haemorrhagic manifestations, bleeding-time, and capillary fragility which has been reported by other workers, notably Duke, Hirsch, and Dameshek. Besides the use of platelet transfusions in the present case, stored blood and cortisone were given (see Fig. 1). Stored blood did not have any appreciable effect on the haemorrhagic state or on the maintenance of haemoglobin. This is illustrated by the transfusion given initially and that given on August 6. After the latter transfusion the haemorrhagic diathesis became so marked, with generalized petechiae, bleeding gums, and the passage of bright red blood in the stools, that the haemoglobin fell from 18.5 to 8.5 g. per 100 ml. in three days. This state was arrested by a transfusion of fresh blood containing 490,000 platelets per c.mm., with an improvement of the capillary fragility to normal, and a reduction of the bleeding-time to within normal limits. These effects lasted for four days, after which no platelets could be found in the infant's blood. Eight such "platelet transfusions" were given, including three from a donor with a platelet count of approximately 1,000,000 per c.mm., followed by a similar improvement on each occasion. It can be seen from Fig. 1 that, irrespective of the number of platelets present in the infant's blood immediately following transfusion, the survival of significant numbers of transfused platelets in the circulation remained the same (from four to five days).

Some platelets presumably disappear during the first few hours, being used to control capillary haemorrhage. It is interesting to speculate on the mechanism for the removal of the remainder, since it has been observed by us, and by Mustard (1956), that platelets can be stored in acid citrate-dextrose mixtures at 4° C. for periods of at least three weeks. Tullis (1953) has shown that platelets can be stored in special media for longer periods than either red or white cells.

Blood containing 220,000 platelets per c.mm. at the time of transfusion, in which the platelets had a normal morphological appearance and staining properties in spite of storage in a siliconed container for four weeks, was used on November 24. No platelets were demonstrable in blood samples taken from the infant immediately after this transfusion. We conclude that platelets whose staining and morphological appearance are normal are not necessarily viable. For the administration of viable platelets, freshly taken blood is essential.

On each occasion that platelets were transfused, an estimate of the expected rise was made, based on the platelets present in the blood passing through the needle to the infant and the assessment of the infant's blood volume derived from its weight—reckoning a blood volume of 40 ml. per lb. (Russell, 1949). It was noticed that in the later transfusions the difference between the actual platelet count performed on the infant and the expected level was becoming greater. From Table II it can be seen that in the initial platelet transfusions yields of between 30 and 70% were

obtained. These figures are similar to those recorded by Hirsch and Gardner (1952). These yields fell to a level of only 10% prior to splenectomy. Following the transfusion on October 13 the platelet survival time became shortened, and subsequent studies revealed the presence of a platelet antibody. Serum taken on October 20 showed a titre of 1/16 with compatible platelets, and a sample taken terminally on December 2 showed a titre of 1/8, using the technique described by Stefanini *et al.* (1953).

The low titre of antibody in this case and its failure to rise in spite of repeated platelet transfusion might be accounted for by the immaturity of antibody-producing mechanisms in the neonatal period. Cortisone possibly also impaired antibody production. Unfortunately, antibody was not looked for in the serum on admission, but the clinical course and the persistence of thrombocytopenia and antibody make transplacental transfer of antibody from the mother extremely unlikely in this case.

Splenectomy was undertaken as a last resort, since after two months' treatment, including cortisone, there had been no sign of autogenous platelet production, and the frequency of transfusions was increasing. We were influenced also by the case reported by Stefanini and Dameshek (1955), in which splenectomy was followed by a rise in the platelet count to normal numbers. In the present case, although platelets returned in small numbers a fortnight after splenectomy, the improvement was only transitory.

Hirsch and Gardner (1952), in discussing the largest series of platelet transfusions recorded, pointed out that, of 42 transfusions given, only one failed to produce clinical improvement, and in this case there was no rise in platelets. We agree that haemorrhagic manifestations in states of thrombocytopenia can be dramatically arrested, but this effect is only transient, depending apparently upon the survival of the platelets. This method of treatment has the limitation that if repeated, especially in adults, sooner or later the platelet survival time becomes shorter owing to the production of a platelet antibody. We suggest that it is well worth while to administer fresh blood from siliconed containers through plastic tubing to cases with thrombocytopenia, in order to tide them over acute haemorrhagic episodes or operative procedures such as splenectomy.

Summary

A case of congenital hypoplastic thrombocytopenia associated with other congenital defects is described with post-mortem findings.

Similar cases are briefly reviewed and the differential diagnosis is considered.

The progress and treatment with platelet transfusions, cortisone, and splenectomy are described and discussed.

Repeated platelet transfusions have been found to be of value and a simple technique is outlined.

Information regarding the survival of platelets *in vivo* and *in vitro* following transfusion has been obtained.

The value and limitations of platelet transfusion are discussed.

APPENDIX: METHOD USED FOR PRESERVING PLATELETS

Blood for transfusion was taken from fasting donors with a wide-bore needle direct into a known volume of acid-citrate-dextrose solution in a siliconed glass bottle calibrated in cubic centimetres. The bottles were prepared by coating the inside with silicone fluid D.C. 550 diluted with ether 1 in 2. The bottles were rinsed with several changes of glass-distilled water, dried in the incubator, and sterilized by autoclaving at a pressure of 20 lb. per square inch (1.4 kg. per square cm.) for 30 minutes. The blood on each occasion was then administered within one hour by scalp-vein transfusion through a short length—about 2 feet (60 cm.)—of "polythene" tubing. Transfusions were given rapidly at the rate of 40–50 ml. an hour. By these methods it was anticipated that the loss of platelets in the transfer of blood from donor to recipient would be reduced to a minimum.

We thank Professor W. St. C. Symmers and Dr. J. Shore, of the Department of Morbid Anatomy, Charing Cross Hospital, for the histological and post-mortem reports on this case; Dr. David Stone for collaboration with the platelet transfusions; and Mrs. P. E. Rivers for technical assistance.

PULMONARY OEDEMA DUE TO
ANGIOCARDIOGRAPHY
TREATMENT WITH INTRAVENOUS
HYDROCORTISONE

BY

E. M. M. BESTERMAN, M.D., M.R.C.P.

J. C. LEONARD, M.D., M.R.C.P.

AND

PAUL WOOD, O.B.E., M.D., F.R.C.P.

From the National Heart Hospital, London, W.1

Serious reactions to contrast media containing iodine are a not uncommon sequel to angiocardiology. Dotter and Jackson (1950) reported 26 deaths out of a total of 6,824 investigations, an incidence of 0.38%. Respiratory difficulty, respiratory arrest, or pulmonary oedema occurred in 12 of the fatal cases. McAfee (1955) reported eight deaths in a series of 732 angiocardiology. He found that patients with primary pulmonary hypertension and pulmonary stenosis appeared to be especially liable to develop serious reaction. Two deaths were reported following selective angiocardiology: in one patient, with multiple pulmonary arteriovenous aneurysms, 35 ml. of a 70% solution of diodone was injected through a catheter in the right atrium; the patient died from acute pulmonary oedema after twenty-five minutes.

We report below the case-history of a patient who developed fulminating pulmonary oedema after the injection of sodium acetrizate into the pulmonary arteries.

Case Report

A man aged 39 had been well until a brief attack of unconsciousness during a strenuous game of football thirteen years previously. After this episode he became slightly breathless on exertion. He had a further syncopal attack, again precipitated by exertion, seven years ago. After a herniorrhaphy in January, 1955, he developed pulmonary infarction. There had been no other history of chest illness. He was admitted for investigation in November, 1955. On examination there were signs of pulmonary hypertension: a dominant "a" wave in the jugular pulse, an early ejection sound at the pulmonary area, and an accentuated pulmonary component of the second heart sound. The electrocardiogram showed right bundle-branch block. The chest x-ray picture showed moderate dilatation of the main branches of the pulmonary artery, with narrowing of the peripheral vessels.

The differential diagnosis included primary pulmonary hypertension, chronic thrombo-embolic pulmonary hypertension, and Eisenmenger's syndrome. Cardiac catheterization confirmed the presence of pulmonary hypertension. The pulmonary artery pressure was 90/20 mm. Hg, and the pulmonary vascular resistance was 10 units. The brachial arterial oxygen saturation was 91%. There was no direct or reversed shunt at any level. Selective angiocardiology was then performed to see whether any large pulmonary vessels were occluded. Promethazine hydrochloride, 25 mg., had been given one hour previously. A test dose of 1 ml. of sodium acetrizate was injected through the catheter into the pulmonary artery. As there was no reaction, 15 ml. was injected into the left pulmonary artery, and a film taken. Then 20 ml. was injected into the right pulmonary artery and a further film taken.

At 11.15 a.m., forty-five minutes after the injection, the patient complained of nausea, and became dyspnoeic and slightly cyanosed. He also coughed up small amounts of frothy blood-stained sputum. He was given 50 mg. of diphenhydramine hydrochloride by mouth, but his condition became steadily worse. By 12.30 p.m. he was very distressed and breathless, and fine crepitations due to acute pulmonary oedema were widespread. He was transferred to a "cardiac" bed, venous cuffs were applied to the thighs, and he was treated with morphine, adrenaline, aminophylline, and oxygen without benefit. At 2 p.m. 25 mg. of promethazine hydrochloride and 200 mg. of cortisone were given intramuscularly. Oxygen was bubbled through 45% ethyl alcohol in a fruitless attempt to reduce the frothiness of the sputum. His condition progressively deteriorated, and he developed signs of extreme peripheral vasoconstriction, with an unrecordable blood pressure. He became increasingly drowsy, and by 4 p.m. he was unrousable; his upper respiratory tract was choked with profuse frothy sputum which he was unable to expectorate. Death appeared to be imminent.

At this stage, laryngoscopy was performed by direct vision and a considerable amount of sputum aspirated; this brought slight improvement. An intravenous injection of 5 ml. of nikethamide caused the patient to recover consciousness and expectorate a large amount of frothy sputum. He then gradually relapsed into coma. Thirty minutes later, at 4.45 p.m., a further dose of nikethamide produced a similar result. Then from 5 to 6.30 p.m. he was given an intravenous infusion of 100 mg. of hydrocortisone (free alcohol) in 500 ml. of isotonic saline. During this time his condition steadily improved, his breathing became less distressed, and he recovered consciousness. There were fewer rales in his chest. When 5 ml. of nikethamide was given intravenously at 5.45 p.m. he produced much less sputum than after the previous doses. At 6.30 p.m. the hydrocortisone was stopped, and a slow drip infusion was continued with isotonic saline alone; 25 mg. of promethazine hydrochloride was given intramuscularly. At 10 p.m. pulmonary oedema recurred and responded again to the infusion of hydrocortisone, which was continued until 1.30 a.m. At 3 a.m. a second relapse occurred, and the signs of pulmonary oedema diminished within five minutes of starting the third hydrocortisone infusion. This was maintained for three hours, and thereafter his condition remained satisfactory.

Oral cortisone was subsequently given in gradually decreasing doses for nine days. During this time he was pyrexial, and developed signs of consolidation of the apical segment of the right lower lobe; this was confirmed by radiography, and attributed to pulmonary infarction.

Discussion

Of the 26 deaths reported by Dotter and Jackson (1950), sensitivity tests were performed in 19 cases and were negative. Yet the intravenous injection of 1 ml. of solution of diodone has itself caused death in four instances (Morgan, 1950; McAfee, 1955). In the present case, generalized pulmonary oedema must be attributed to a hypersensitivity reaction of

which no warning had been given from a preliminary test dose injected into the pulmonary artery. It is concluded that the administration of a test dose of contrast medium is an unreliable method of detecting hypersensitivity, and may in fact induce a false sense of security.

The treatment of the condition presented a difficult problem. As might have been expected, the methods of treatment applicable to pulmonary oedema occurring in left ventricular failure were ineffective here. Intravenous hydrocortisone, on the other hand, appeared to exert a specific and prolonged anti-allergic action in reducing pulmonary oedema. The antihistamine drugs proved of little value. Nikethamide was useful in reviving consciousness and the cough reflex so that fluid could be expectorated.

Intravenous hydrocortisone induced immediate improvement on three separate occasions, and undoubtedly saved this patient's life. Intramuscular cortisone, which was given initially, was presumably ineffective owing to poor absorption in the presence of severe peripheral vasoconstriction. The use of intravenous hydrocortisone in overwhelming allergic reactions is a rational therapeutic measure, and the present case history confirms its usefulness. Our experience indicates that the drug should be immediately at hand in all centres employing the intravenous injection of contrast media.

Summary

A case of gross pulmonary oedema following selective angiocardiology in a patient with primary or chronic thrombo-embolic pulmonary hypertension is reported. Recovery was clearly attributable to prolonged intravenous infusion of hydrocortisone. A test dose of sodium acetrizate failed to provide warning of hypersensitivity.

FREQUENCY IN THE FEMALE DUE TO URETHRO-TRIGONITIS CAUSED BY INTESTINAL INFECTION

BY

J. E. SEMPLE, F.R.C.S.

Surgeon to St. Paul's Hospital, London

In his Hunterian Lecture of 1933 Winsbury-White proved by means of injected animal specimens that infection of the genital organs in the female caused marked pathological changes in the urethra and trigone of the bladder. This fact had been readily accepted as occurring in the male as a result of the anatomical relation of the prostate to the bladder neck, but it was not recognized as occurring so readily in the female. By the routine use of a urethroscope, characteristic changes at the bladder neck were found to be invariably associated with disturbances of micturition.

This is the original work which established urethro-trigonitis as a clinical entity and the commonest condition found in female patients attending a urological clinic, but, as Winsbury-White (1947) states, chronic urethro-trigonal changes are not uncommon in women with healthy cervixes. And it is not uncommon even in patients who had had the genital organs removed some time prior to the onset of the urethro-trigonitis.

General Review of Urethro-trigonitis in the Female

In a review of female patients suffering from urethro-trigonitis and attending a urological clinic over the last seven

years it was found that the incidence of this condition was remarkably constant from year to year, varying only between 25 and 30% of the total female attendances of 453. The majority of cases occurred between the ages of 30 and 50, but it might occur in any of the age groups. The most common symptom was frequency of micturition, which was pronounced in 80% of the patients. Dysuria was present in 50%, as was urgency of micturition. In spite of the old teaching that residual urine is rare in the female, an intravenous pyelogram in all cases revealed that 66% of these cases had a definite volume of residual urine left after micturition. The laboratory reported that 16% of the catheter specimens taken as a routine contained pus cells and that organisms were present in only 12%, the predominant organism being *Bact. coli*. Winsbury-White states that urethro-trigonitis is a predisposing cause of *Bact. coli* infection of the urinary tract, and that it does not produce such an infection by itself but only by causing conditions which favour the onset of infection by reason of obstruction of the bladder neck. The diagnosis was made by routine examination with a urethroscope, and characteristic changes in the urethra and bladder neck were noted in every case. The cervix was examined as a routine, and an erosion or evidence of cervicitis was present in 66% of cases; of the remainder there was no evidence of genital infection.

In each case the internal sphincter was dilated as a result of the urethroscopic examination, and dilatation was repeated in accordance with Winsbury-White's method at not less than six-weekly intervals and to a dilatation not greater than F.28. In 25% treatment was speeded up by fulguration of the polypi and granulations and hillocks: 66% were cured and 28% much improved.

Urethro-trigonitis Not due to Infection of Genital Tract

There remain, therefore, 34% of cases in which no infection of the cervix or genital organs can be found to account for the pathological changes in the urethra and trigone.

In a number of patients an association between the large intestine and the neck of the bladder had been noticed: the first instance was that of a patient in whom an acute attack of diverticulitis of the sigmoid colon followed each dilatation of the urethra and in whom marked urethro-trigonal changes had been found on urethroscopy. On further inquiry the patient stated that when she had an attack of diverticulitis the symptoms of urethro-trigonitis were very much worse.

A frequent complaint in these patients is of discomfort and even pain in the left iliac fossa, which may be associated with some irregularity of the bowels. On abdominal palpation there is not infrequently definite tenderness over the sigmoid and pelvic colon, which may in some patients be palpable.

Out of 43 cases examined radiologically by means of a barium enema, 11 showed lesions of the large intestine which were closely related to symptoms of urethro-trigonitis verified by urethroscopy. Of the 11 cases, 8 showed numerous diverticula of the lower colon with radiographic appearances strongly suggesting inflammatory changes in the surrounding bowel. Two patients had been previously diagnosed as having diverticulitis with rigidity and thickening of the sigmoid colon. In one case a barium enema showed a carcinoma of the recto-sigmoid junction though there had been no initial symptoms suggesting a neoplasm of the bowel but only those of urethro-trigonitis.

Chronic constipation was not accepted as a likely cause of urethro-trigonitis, as it does not of itself produce inflammatory changes in the wall of the bowel; nor were lesions of the anal canal included as a cause, although on anatomical grounds there would seem to be no reason why they might not form a source of infection.

In the absence of animal experiments, which made Winsbury-White's work so conclusive, a study of the relationship of the lymphatics of the lower part of the large intestine with those surrounding the bladder neck, although

not showing such a close relationship as that of the cervix to the floor of the bladder, nevertheless shows a ready lymphatic connexion. This is well shown by Rouvière (1932), and there would seem to be no reason why infection should not spread from the lymphatics of one organ to those of the other, which would appear, on clinical grounds, to be the case.

The results of treatment of the bowel condition combined with that of the bladder neck go far to support this theory. Dilatation of the bladder neck and even fulguration of polypi and granulations have not produced very encouraging results in such cases, but when the lesion of the bowel is alleviated the urethro-trigonitis responds to treatment very much more readily. Thus the bladder neck was treated in exactly the same way as when the infection came from the cervix, care being taken not to irritate the urethra by too frequent dilatation—that is, not more than once every six weeks and usually at less frequent intervals.

Treatment of the bowel depends on the type of lesion and its extent. In the less extensive lesions, in which surgery is not called for, the institution of a low residual diet which does not irritate the mucosa of the bowel and limits fermentation, combined with regulation of bowel action by "petrolagar" with or without phenolphthalein, alone may give much improved results, but infection can be further limited by the administration of phthalylsulphathiazole in an initial dose of six 0.5-g. tablets followed by two tablets every six hours for fourteen days. This course can be repeated at fortnightly intervals until the infection has been greatly diminished. (In the more resistant cases an initial course of streptomycin and sulphaguanidine followed by phthalylsulphathiazole may be necessary.) As a result of this routine the symptoms of urethro-trigonitis were improved in each of the cases treated.

Summary

Symptoms of urethro-trigonitis were present in 25 to 30% of female patients attending an out-patient clinic, and this condition was verified by urethroscopy in which characteristic changes were found present at the bladder neck. These changes have been proved to arise from lesions of the cervix and genital tract, and were found in 66% of these cases. Of the remaining 34%, a third were found to have radiologically demonstrable lesions of the large intestine. Treatment of the intestinal infection, combined with dilatation and, where necessary, fulguration of the bladder neck, gives excellent results as compared with dilatation and fulguration alone.

The Ministry of Education on September 13 asked local education authorities to review their arrangements for providing primary and secondary education for children in hospital and to see that they are as comprehensive as possible. Though much has been done, the Ministry claims that "there are still some educable children in hospital for whom no provision has been made." This may be provided either by teachers visiting or by setting up hospital schools. In 1955 there were 120 hospital schools in England and Wales, with 6,476 children on the roll; 1,425 other children were receiving individual tuition. Where there is no hospital school or regular teaching group, the Ministry of Health has asked hospitals to inform education authorities about the admission of any child likely to remain in hospital who is yet well enough to have some lessons. The circular calls for a good supply of library books, commenting: "Reading matter given by well-intentioned visitors may not always be suitable or adequate."

ACCIDENTAL CARBON MONOXIDE POISONING

DANGERS OF INADEQUATE VENTILATION

BY

F. S. FIDDES, M.D.

Department of Forensic Medicine, University of Edinburgh

Of late there have been frequent expressions of concern at the increasing number of deaths from accidental coal-gas poisoning. A high proportion of such accidents are associated with various predisposing or contributory conditions in the victim, which have been described collectively as "the 4 D's of accidental carbon monoxide poisoning"—the decrepit, the diseased, the drugged, and the drunk. Others are caused by faulty appliances or by ill-advised amateur adaptations, and occasionally responsibility can be traced to defects in gas-pipes or joints which are actually outside the premises occupied by the victims.

The danger of coke braziers and coke-burning stoves is well known, but deaths still occur from these sources, through either ignorance or disregard of warnings. It is insufficiently appreciated, however, that even coal-burning stoves and fires may be dangerous in certain circumstances, and that gas-fires and other appliances, though free of defects in themselves, may also be a source of danger if the conditions do not ensure free and complete combustion of the coal-gas. The following cases, resulting in the deaths of three healthy adult males, illustrate the circumstances in which fatal poisoning from such sources may arise, and point to the need for a greater awareness of the potential danger.

Case 1

A man aged 50, employed as watchman on a building site, was in the way of spending part of the night asleep in a workmen's hut, and one morning he was found lying dead on the bunk with which the hut was fitted. The post-mortem appearances, external and internal, pointed to death from carbon monoxide poisoning, and the blood contained 55% carboxyhaemoglobin. There was no other significant finding at necropsy, apart from recent pleural adhesions over the left lung and older adhesions over the right lung. The man had recently resumed work after several weeks in hospital suffering from pneumonia.

The hut was of the wheeled type, adapted for towing, and the door at the rear was divided horizontally into two parts, upper and lower. There were two small windows, each capable of being opened. Inside the hut there was a fixed stove, with a chimney leading out through the roof. The capacity of the interior of the hut was approximately 600 cubic feet (17 cubic metres). On the night in question, which was very cold with a gusty wind blowing, both halves of the door had been closed and only one of the windows was slightly open. A fire had been burning in the stove, and this had apparently been well stoked before the man lay down to sleep. There was also an oil-lamp burning.

It was quite certain that no coke had been used in the stove, the only fuel available being coal of normal household quality. The stove and chimney were in good condition, without obvious defects. In these circumstances it was thought desirable to confirm the possibility of a lethal concentration of carbon monoxide having accumulated in the hut, and with this in view a fire of the same coal was lit in the stove and allowed to burn for about one and a half hours. The stove had previously been cleared of ashes and the fire burned freely. One window was slightly open. Samples were then taken of the flue (chimney) gases, with

the hut door open and closed, and also of the air above the stove, with the following results:

CO in flue gases (hut door open) 980 parts per million
CO in flue gases (hut door closed) 1,460 " " "
CO in air above stove (hut door closed) .. 310 " " "

The increase in the CO content of the flue gases on closing the door is marked, and clearly indicates inadequate ventilation, with consequent impaired combustion. The CO content of the air above the stove is significant, for, on the day of sampling, the down draught was only very slight and intermittent. It is obvious that with the door shut, and with frequent short periods of down-draught such as would occur in windy weather, a lethal concentration would accumulate quite rapidly in such a relatively small space. The time of exposure of any occupant would not require to be greatly prolonged before a fatal result ensued.

Cases 2 and 3

Two men, aged 31 and 32, booked lodgings for the night and retired to their bedroom about 9 p.m. In the morning the bedroom door was found locked, and, as no response was obtained to repeated knocking, entry was eventually obtained by a window, and the two men were found dead in bed. The gas-fire in the room was burning, apparently satisfactorily, but both men had died from carbon monoxide poisoning, the blood in each case showing a concentration of 72% carboxyhaemoglobin. The necropsy revealed no other feature of significance.

A washed nylon shirt and other garments were found hung up in front of the fire as if to dry, and it appeared that the fire had been lit by the men before retiring and had burned all night. The door of the room was fitted with a draught excluder, the window had been closed and the curtains were drawn. The capacity of the room was slightly less than 1,400 cubic feet (31 cubic metres) and the atmosphere in the room in the morning was very hot, dry, and oppressive, almost like an oven, although there was no strong or obvious smell of coal-gas.

The gas-fire stood in a tiled fireplace from which a long flue or chimney led to the exterior. There was some blackening of the tiles above the fire, and the chimney was found to be partially choked. The gas-fire consisted of seven elements or radiants, and, although these were broken in places, the flames appeared satisfactory and combustion complete. There was no defect in the gas-tubing or joints.

After the fire had been allowed to burn for about half an hour with the door and window closed, however, there was noticeable lengthening of the inner cones of the flames, indicating incomplete combustion. The sequence of events leading to the deaths was fairly certain. The exclusion of air entry into a room of small dimensions had resulted in insufficient oxygen for complete combustion, and the choked chimney had caused spilling of the products of incomplete combustion back into the room. Although the actual rise of CO concentration was not determined, it is obvious that a potentially lethal concentration would be quickly achieved in such a relatively small room, and the sleeping occupants would remain quite unaware of the increasing danger.

Conclusion

These fatal cases of accidental carbon monoxide poisoning provide a timely reminder of: (1) the danger of using stoves in confined spaces, even though these are in good order and fuelled with good quality coal, unless adequate positive ventilation is ensured at all times, whether the doors or windows be closed or not; and (2) the danger which may arise from gas-fires, even if these and their fittings are in perfect order and they appear to be burning satisfactorily, if there is not also adequate ventilation and extraction of the combustion products.

I am indebted to Dr. E. A. C. Chamberlain, of the Scientific Department of the Scottish Division of the National Coal Board,

for his co-operation in the investigation of Case 1 and for the results of the tests which he carried out in connexion therewith; and to Mr. David Beavis, Controller of the Edinburgh Division of the Scottish Gas Board, for the report of the investigation carried out by his department in connexion with the other two fatalities.

LOCAL HYDROCORTISONE FOR HUNNER'S ULCER OF THE BLADDER

PRELIMINARY REPORT

BY

J. H. JOHNSTON, F.R.C.S.

Senior Surgical Registrar, Liverpool Royal Infirmary

Local infiltration with hydrocortisone has been used effectively in the treatment of a variety of non-specific inflammatory and fibrotic processes. It appeared reasonable to expect that a similar resolution of focal inflammation with relief of symptoms would be produced by this means in cases of Hunner's ulcer of the bladder. Three patients with this condition have therefore been so treated.

Technique

The injection is carried out cystoscopically through a specially devised "needle" (see photograph). A size 0 hypodermic needle is filed through 1.5 cm. from its point

and lengthened by the interposition, between the two portions, of a size 5E ureteric catheter from which the eyelet end has been removed. The catheter is found to grip the needle securely, and there is no risk of the point becoming detached.

At cystoscopy, using an irrigating instrument and with the patient in the lithotomy position, the affected region of the bladder is identified. The needle, with a stylet in position almost to the point, is passed through the catheterizing or operating channel of the cystoscope and inserted into the bladder wall at or near the ulcer. An assistant is required to withdraw the stylet and inject about 0.5 ml. of hydrocortisone suspension. In all, 5 ml. containing 25 mg. of hydrocortisone per ml. is injected through several punctures into and around the involved area. Penetration of the bladder wall obliquely is found to minimize the tendency of the suspension to flow back from the puncture wound during the injection and after withdrawal of the needle. Ballooning of the vesical mucosa may be produced, but it is probably preferable to inject more deeply into the bladder muscle.

Results

The patients were women aged 63, 68, and 73 years, and were known cases of Hunner's ulcer of two, three, and six years' duration. Treatment by bladder distension under anaesthesia, zinc ionization, and vesical irrigation had formerly been carried out on many occasions. In January, 1956,

each one had one session of hydrocortisone therapy. All have shown marked symptomatic improvement which began a few days after the injection. In the case of the patient with the shortest history of the condition the result was dramatic. On admission to hospital she was passing urine every 30 to 45 minutes during the day and night. Other methods of treatment in the preceding two years had produced amelioration of symptoms for a few days only. For four months after the hydrocortisone injection she micturated every two to three hours during the day and once or twice at night. Recently there has been a gradual recurrence of the original complaint.

The total duration of the remission produced by hydrocortisone is not known, but it is to be expected that, when symptoms recur, further infiltration will again be effective, as is the case with other chronic inflammatory conditions. The results obtained with these patients would appear to justify a more extended trial of local hydrocortisone for Hunner's ulcer, especially in the early case before diffuse fibrosis has developed. Since this investigation began Schulte and Reynolds (1956) have reported satisfactory results of a similar technique using hydrocortisone and hyaluronidase.

I am grateful to Professor Charles Wells for his encouragement and for permission to carry out this procedure.

OBSERVATIONS ON THE FOOD HABITS OF MYOPIC CHILDREN

BY

PETER A. GARDINER, M.B., D.O.M.S.

Ophthalmologist, Miller and Barnett General Hospitals;
Research Fellow in Ophthalmology, Guy's Hospital

In the course of an inquiry into the development of myopia in children, which included questions about their diet, I was struck by the number of children who have rigid likes and dislikes of certain foods to the extent of consistently refusing some items.

The main sources of first-class protein are milk, cheese, meat, fish, and eggs. Over a period all the children attending a school clinic for refraction were asked whether they consistently refused one or more of these foods. The refusal to take milk as such or as a mainly milk drink was counted as an absolute refusal. It is interesting in this connexion to find a number of children who refuse their school milk—thereby providing others with a double or sometimes treble portion.

It was possible to divide the children into groups of myopes who were rapidly deteriorating, slowly deteriorating, or stationary. A fourth group consisted mainly of hypermetropes with a few emmetropes.

Results

Tables I, II, and III show that myopes are more fussy about some of their food than other children. This was noted as a generalization by Miller (1940), though not in rela-

TABLE I.—Refusals of Protein Sources

	Active Myopia Rate > 1 D per Annum		Active Myopia Rate 1 D per Annum		Stationary Myopia		Others	
	Boys	Girls	Boys	Girls	Boys	Girls	Boys	Girls
No. of refusals	9	26	42	59	27	49	73	76
Refusals per head	0.55	0.65	0.47	0.50	0.44	0.45	0.24	0.42

TABLE II.—Percentage of Children Refusing Protein Sources

	Myopes (264)	Others (149)
Refusal of milk	16%	5%
" " cheese	18%	14%
" " meat	3%	4%
" " fish	12%	8%
" " eggs	4%	2%

The percentage figures shown in the different categories are not mutually exclusive.

TABLE III.—Percentage of Children Refusing Two or More Sources

	Active Myopes	Stationary Myopes	Others
No. refusing two or more sources	136	128	149
Percentage refusing two or more sources	11	7	5

tion to these particular items. With increasing fussiness there is an increase in the activity of the myopia. The boys with highly active myopia show a refusal rate more than twice that of boys who are not myopic, and the girls a rate over 50% higher. Double refusals are twice as frequent amongst active myopes as amongst others.

That girls are more particular than boys about their food is well known, and in all these groups this is confirmed, though it is small in stationary and slowly deteriorating myopes. Though the rate of refusal is higher in girls than in boys in each group, it does not equal the rate of refusal for boys in the next group with a higher rate of myopic change.

Between the ages of 8 and 17 the refraction of girls changes more often than that of boys (Brown, 1938). My own figures agree substantially with this observation. The Chart shows the mean proportional changes in refraction per annum of male and female myopes aged 8 to 16. Between the ages of 9 and 13, and again between 14 and 16, myopia in girls increased at a faster rate than in boys.

Proportional change in refraction of myopes per annum.

The percentage refusing a particular source of protein do not provide any conclusive information. The most striking difference is in milk consumption. Over three times as many myopes refused milk as others.

Conclusion

It must not be concluded that myopia in children is associated dietetically exclusively with a different pattern of protein consumption, still less with a deficiency in the accepted sense of the word. There is evidence (to be published later) that other food factors are implicated, and in most individual cases the food pattern is in no way basically abnormal even though the myopia may be increasing rapidly.

Before coming to a conclusion on the exact significance of these findings, the unusual growth of myopes (Gardiner, 1954, 1955) must be linked with more detailed dietary intakes (to be published). None the less, the positive finding in this investigation is that myopic children are more particular about their sources of first-class protein than other children. There is an indication that this may be connected with their

myopia because girls are more prone to pick and choose than boys and because the more active the myopia the higher the rate of refusal per head.

Summary

The refusal rates of items of first-class protein are shown to be higher in myopic children than in other children.

It is debatable whether this is connected with their myopia.

Medical Memorandum

Dissecting Aortic Aneurysm Presenting as a Cerebral Catastrophe

It is a well-known fact that a dissecting aneurysm of the aorta can present in many guises, and neurological symptoms and signs are by no means rare. More commonly, however, it is the spinal cord and the pelvic nerve plexuses which are affected, and thus a flaccid paralysis involving one or both lower limbs is a more familiar picture in these patients.

The following case emphasizes that aortic aneurysm can closely mimic apoplexy or subarachnoid haemorrhage.

CASE REPORT

A collier aged 54 had enjoyed good health all his life until at 2 a.m. on September 30, 1954, while working on night shift in a coal-mine, he suddenly collapsed, became unconscious, and was admitted to hospital in deep coma. His blood pressure was 160/90 mm. Hg. The left pupil was larger than the right, all abdominal reflexes were absent, and there was a bilateral extensor plantar response. He had a left-sided hemiplegia, more marked in the face and arm than in the leg. The cerebrospinal fluid was clear, under normal pressure, contained 1 lymphocyte per c.mm., and 55 mg. of protein per 100 ml.; the globulin was slightly increased. Both the Wassermann reaction and the Lange colloidal gold curve were negative. Thirty-six hours after admission he regained consciousness, although weakness of his left arm and the left side of his face persisted for a further three days. By the evening of October 5 he felt much improved. At no time did he complain of any pain in his chest. At 10 p.m. he suddenly collapsed in bed and died almost instantaneously.

Necropsy Findings.—A dissecting aneurysm of the thoracic aorta was revealed. There were two large rents in the intima, measuring 17 and 10 mm. respectively, situated about 2 cm. above the aortic valve. From that point dissection had taken place upwards along the arch of the aorta as far as the origin of the left subclavian artery. The dissection had extended upwards into the innominate, the left common, and, to a less extent, the left subclavian artery. The innominate artery was partially, and the left common carotid artery almost completely, obstructed by prolapse of media and intima into the lumen of the vessel due to pressure of blood clot. Finally, dissection had also extended downwards and burst into the pericardial sac, which contained 600 ml. of partially clotted blood. There was widespread atheroma of the thoracic aorta with ulceration of the intima in two places. The heart showed a moderate degree of left ventricular hypertrophy, and there were numerous fatty plaques of atheroma in both coronary arteries. The abdominal aorta likewise contained atheromatous patches, but there was no ulceration. The lungs

and abdominal viscera were congested. The brain and meninges showed no demonstrable disease. A Kahn test of the blood obtained after death was negative.

COMMENT

Shennan (1934) produced a very comprehensive review of altogether 300 cases of aortic aneurysm, including 17 cases of his own. He quoted a total of nine cases with cerebral symptoms due to compression or thrombosis of one or both common carotid arteries. Since then several excellent papers have been published on the subject. Weisman and Adams (1944) described 11 cases of dissecting aneurysm with neurological complications. Most of these cases presented with a flaccid paralysis of one or both lower limbs due to occlusion of the common iliac arteries. Only one of their cases showed blockage of one of the carotid arteries; this patient had presented with mental confusion and dysphasia, but not hemiplegia. Baer and Goldburgh (1948) found hemiplegia due to occlusion of one of the common carotid arteries in 2 out of 44 cases of dissecting aneurysm. MacCuish (1953) described a patient who, like the present case, showed sudden coma and hemiplegia as the presenting features.

The comparative rarity of cerebral symptoms in these cases, though dissection commonly extends along the whole course of the aorta, is attributed by Weisman and Adams to the good collateral circulation produced by the circle of Willis. In the present case both the innominate and left carotid arteries were partially occluded; this may account for the severity of the cerebral signs. Partial recanalization of the innominate artery and establishment of a collateral circulation via the vertebral arteries may explain why our patient recovered consciousness and why his hemiplegia gradually wore off until eventually he died owing to rupture of the aneurysm into the pericardial sac.

Schnitker and Bayer (1944) seek the origin of dissecting aneurysm in a localized patch of medial degeneration and not in a primary defect of the intima, as is thought by many. The aetiology in the present case, however, was almost certainly atheromatous; the presence of plaques of atheroma in the aorta, the patient's age, and the negative serological tests all support this view.

A very unusual feature of the case under discussion was the complete absence of pain in the chest, which has been described as the first symptom in practically all the hitherto published cases. A correct ante-mortem diagnosis was thus rendered even more difficult in the present case.

My thanks are due to Dr. C. W. Healey, under whose care the patient was admitted.

C. GILES, M.D., B.Sc.,

Consultant Pathologist, City General Hospital, Stoke-on-Trent.

Two food taboos encountered by the East African Medical Survey during a survey of the dietary pattern in Kwimba District, Sukumaland, are described in the *Annual Report of the East African Council for Medical Research 1954-5*. Two series of observations were made during the survey, the first in August, September, and October, the second in March and April, on account of the seasonal rains. Dr. H. Trant led the team. The taboos concerned a "mud" fish and goats' milk. Dr. Trant notes: "The former is not eaten at all by women and the latter is used only for newborn babies as a first day's food. Very occasionally a small boy herding goats may take a drink of milk, but if this is known he is always held up to derision. One authority has suggested that this is really a 'snob' prohibition which came into common custom at the time when the people concerned started to own cattle."

Reviews

PATHOLOGY

An Introduction to Pathology. By G. Payling Wright, D.M., F.R.C.P. Second edition. (Pp. 636+xii; illustrated. 40s.) London, New York, Toronto: Longmans, Green and Co. 1954.

Pathology. By Peter A. Herbut. (Pp. 1,227; illustrated. £6.) London: Henry Kimpton. 1955.

The original purpose of Payling Wright's *Introduction to Pathology* was to revive an interest in the scientific study of the causation of disease, and the mechanisms which underlie disease processes, by employing the experimental disciplines of biology and physiology. Its first edition, published in 1950, has certainly engendered a keener perception of the scope and content of general pathology as an essential introduction to the study of human disease. A second impression appeared in 1951 and a third in 1952. The second edition, published in 1954, has been revised. It will be welcomed not only by the student as a reliable guide to the general principles of pathology, but also by his teachers, and it will be appreciated by all thoughtful clinicians. Many new references and illustrations have been included and two new chapters added. One of these deals with the origin and nature of allergy and the tissue changes which occur in hypersensitivity reactions. The other is concerned at a general explanatory level with the cell and tissue changes which are brought about by ionizing radiations. Reviewing this second edition provides the opportunity to comment on the author's ability to examine a mass of historical, clinical, and pathological evidence, discard the non-essentials, and frame a sound and valid generalization.

Professor Herbut's book is "an attempt to reduce an encyclopaedic amount of information to the confines of a single volume. To achieve this end a rather rigid pattern is necessarily followed throughout the text and the material is presented with little if any adornment." As there are 1,378 illustrations and 6 colour plates, and the price is £6 sterling, this absence of adornment clearly refers to the text, which is terse enough to be almost irritating.

"Pathology" for this author means the descriptive morbid anatomy and histology of human disease, and most of the text is concerned with this aspect of the subject. An exceptionally full but strictly factual account of the structural changes which accompany each disease is followed by a brief catalogue, with a profusion of commas, of its clinical signs and symptoms and of the diseases with which it may be confused. This method of parallel description, packed with detail on the anatomical side and far too brief on the clinical aspects, is claimed to provide "a bird's eye view of the disease as a whole" and is called clinico-pathological correlation.

Professor Herbut has certainly reduced "an encyclopaedic amount of information," but from the size of his book he appears almost to have succeeded in writing another encyclopaedia, which will be valuable as a work of reference for the busy hospital pathologist who is responsible for morbid anatomical and histological diagnosis. From this point of view the book has a place in pathological literature, and its publication will introduce some of us to an American morbid anatomist of wide experience and mature judgment. His approach is realistic and will instruct the student in the art of clinico-pathological diagnosis. In another sense it is dangerous, for it may leave him with the impression that the science of pathology is solely concerned with descriptive morbid anatomy. This criticism would have been met if the accounts of the morbid anatomy of specific diseases had been prefaced by a full explanatory introduction along the accepted lines of general pathology.

G. HADFIELD.

FERTILIZATION

Fertilization. By Lord Rothschild, G.M., Sc.D., F.R.S. (Pp. 170+ix; illustrated. 18s.) London: Methuen and Co. Ltd. New York: John Wiley and Sons Inc. 1956.

When it is realized that no book on fertilization has appeared for more than twenty-five years the significance of this small monograph, with its bibliography of some 400 references—most, of course, comparatively recent—at once becomes apparent. The further fact that it is written by one of the outstanding contributors to our knowledge of the subject makes this book something of an event for all students of fertilization. Of course, it is apt to be rather heavy going for anyone not specifically interested in the subject. After all, a whole book devoted to "the life of the egg from the attachment of the fertilizing spermatozoon to the fusion or apposition of the male and female pronuclei," which process, "except in mammalian eggs, usually takes a little less than one hour," is bound to go into the minutiae to a considerable extent, and these must be of very limited interest, except to the student of the subject. The latter, however, will find himself more than well served, not merely because this is the best and most extensive review of the subject he can have met, but because, unlike most modern reviews, this book expresses the writer's definite and very authoritative opinions on controversial matters. It also contains the novel feature of a list of experiments which Lord Rothschild thinks would be well worth while doing. The book includes chapters on the morphology of fertilization; sperm-egg interacting substances; the metabolism of eggs; metabolic, structural, and other changes at fertilization; polyspermy, bioelectric measurements, and the specificity of fertilization. Lord Rothschild apologizes—though he scarcely need do so—for the omission of such matters as androgenesis and gynogenesis, merogony and parthenogenesis. He has included, in addition to an excellent general index, an index of the names of plants and animals quoted—a most important feature in view of the confusion which has sometimes resulted from the failure of authors of papers on this subject to name accurately the species on which they were working. G. I. M. SWYER.

EAR, NOSE, AND THROAT DISEASES

Diseases of the Ear, Nose, and Throat. By William Wallace Morrison, M.D. Foreword by Arthur W. Proetz. Second edition. (Pp. 756+ix; illustrated. 84s.) Staples Press Ltd. 1956.

This somewhat lengthy book could be shortened with advantage by the omission of material which is now obsolete and historical, such as the description of Killian's operation on the frontal sinus, and also such unnecessary discussion of the definition and treatment (with figure) of synechia following operations on the nose. The arrangement of the subject-matter is rather haphazard; for example, new growths of the external meatus are sandwiched in between the various types of dermatitis affecting this region. The illustrations, 359 of them, are small and cramped and often difficult to interpret. Each section is prefaced by the appropriate anatomy and physiology, which, despite the criticism of some, would appear to be very desirable in view of the woeful ignorance of undergraduates on this particular subject. A useful list of references concludes each chapter. The section on sulphonamides and antibiotics is thoroughly up-to-date, and there is a further chapter devoted to headache and the neuralgias of the head and neck which will be read with interest and benefit. An account is given of the prophylaxis of the common cold, and, though this is interesting, the measures advocated are quite impractical. There is no mention of anosmia under the symptoms of choanal atresia, and pharyngeal diverticulum is apparently described under oesophageal diverticula, which is rather confusing. These are just two instances of matters which give grounds for criticism, but there are many more. There is a useful appendix of symptoms and of formulary. Of course there is much that is of value in a book of this size, and it will prove a useful addition as a work of reference. J. P. STEWART.

HYPOMETABOLISM

The basal metabolic rate (B.M.R.) is a measure of the metabolic response of the body tissues to thyroid hormone. A reduction in the B.M.R. below the lower limit of normal occurs in a number of conditions such as thyroid disorders, starvation and malnutrition from any cause, nephrosis and other conditions associated with generalized oedema, and some cases of schizophrenia. The lowered metabolism in oedematous states may be due to inclusion of the fluid retained in the oedematous tissues in the body-weight, from which the B.M.R. is calculated, and to diminished heat loss from the insulation provided by the fluid. In malnutrition the activity of the thyroid gland is reduced as a consequence of diminished secretion of thyrotrophic hormone from the pituitary. The cause of the hypometabolism in some cases of schizophrenia is less certain, but the fact that such patients can tolerate large doses of thyroid extract without any increase in B.M.R. or the development of the symptoms and signs of hyperthyroidism that would occur in a normal person suggests that the responsiveness of the tissues is inexplicably diminished. Hypometabolism due to diminished secretion of thyroid hormone is on rare occasions caused by an enzymic defect partially preventing the normal biosynthesis of hormone in the thyroid gland,¹⁻⁴ and the associated enlargement of the gland is a compensatory attempt to correct this deficiency. Although uncommon, and sometimes familial, these cases are of scientific importance because they give clues to the

chemical steps in the synthesis of thyroid hormone. More often hypometabolism due to diminished secretion of the thyroid hormone is secondary to a reduction in the amount of physiologically active thyroid tissue. This occurs in congenital athyrosis (cretinism), in juvenile myxoedema (the predominant manifestation at this age is failure of skeletal growth), idiopathic atrophy in adults (myxoedema), after removal of too much thyroid tissue or as a sequel to too much radio-iodine in the treatment of hyperthyroidism, as a temporary phenomenon in acute thyroiditis, in Hashimoto's struma lymphatosa (in which the thyroid gland is hard and often there are associated positive serum-flocculation reactions),⁵ and as a consequence of a reduction in the secretion of thyrotrophic hormone resulting from pituitary insufficiency from any cause. In all these conditions the symptoms and signs of hypothyroidism can be relieved with thyroid extract; experimental data indicate that the daily normal output of the adult thyroid gland is equivalent to about 3 gr. (0.2 g.) of thyroid extract.

The exact nature of the thyroid hormone is still uncertain. Formerly the only active iodinated substance in the plasma was thought to be L-thyroxine, and this was accepted as the thyroid hormone.⁶⁻⁸ Synthetic L-thyroxine has a metabolic activity such that 0.1 mg. is equivalent to about 1 gr. (65 mg.) of thyroid extract. Being a pure substance of known composition, it is preferred by some authorities to thyroid extract for the treatment of hypothyroidism. Recent chromatographic studies have detected other highly potent iodinated substances in thyroglobulin⁹ and in plasma.¹⁰⁻¹¹ The most important of these is L-triiodothyronine, which is perhaps the tissue-active form of thyroid hormone and is slowly liberated from the stable reservoir of thyroxine. Quantitatively L-triiodothyronine is at least five times as potent as L-thyroxine in the treatment of myxoedema¹²⁻¹³: it is much more rapid and transient in its effect, producing a rise in the B.M.R. within a few hours, whereas thyroxine takes at least five days to exert an effect. Apart from myxoedematous coma, where speed of action is essential, triiodothyronine has no apparent advantage over thyroxine in the treatment of hypothyroidism, and indeed the rapidity of its action makes it potentially more dangerous in patients with associated heart disease.

The diagnosis of adult myxoedema is usually easy if the possibility of the condition is remembered. Recognition of less severe degrees of hypothyroidism is more difficult. Symptoms usually comprise listlessness, lack of physical and mental energy, and vague arthritic and muscle pains. Physical findings include

in most cases a reduction in the size of the thyroid gland, dryness of the skin, and lack of sweating. Confirmation of the diagnosis is obtained most satisfactorily by measurement of the B.M.R., which is below the lower limit of normal, and by the electrocardiogram, which shows flat T-waves—both abnormalities being corrected by administration of thyroid extract, thyroxine, or triiodothyronine. In the past there has been a tendency to diagnose minor degrees of hypothyroidism without sufficient evidence; this has been particularly noticeable in the U.S.A., where many physicians have their own B.M.R. machine and patients commonly inquire about the level of their "basal."

Recently another possible variety of hypometabolism has been described by Freedberg and his co-workers as "nonmyxoedematous hypometabolism."¹⁴⁻¹⁵ Four male patients whose symptoms comprised lack of energy, fatigue, somnolence, nervousness, irritability, aching of the muscles and joints, sensitivity to cold, and diminished potency were found to have periorbital puffiness without other signs of myxoedema and a B.M.R. of -25%. Other measurements of thyroid function—serum protein-bound iodine, radio-iodine uptake, and serum cholesterol—were normal. These patients failed to respond to thyroid extract or L-thyroxine alone, but did so to large doses of L-triiodothyronine or to smaller doses in combination with thyroxine. The suggested explanations for these therapeutic results include a defect in the gastro-intestinal absorption of thyroid extract and thyroxine, failure at the tissue level to convert thyroxine to triiodothyronine, impaired permeability of the cells to thyroxine but not to triiodothyronine, and a deficiency in triiodothyronine, which may be necessary for the optimal utilization of thyroxine. Other explanations might lie in the potency of the thyroid extract used and in the dosage and duration of treatment with thyroxine. Pending the outcome of further investigations and confirmation of the present findings by other workers, it would be wise to keep an open mind on this type of hypometabolism. To administer, without further investigation, triiodothyronine to any patient who complains of some or all the symptoms outlined above is not in keeping with the best in modern medical practice and will only delay elucidation of the nature of this hypometabolic state. Many such patients will be suffering from psychoneurosis: at best triiodothyronine will then do no good; at worst it may serve to increase their difficulties by inducing palpitations or, as pointed out by Dr. H. E. S. Pearson¹⁶ in our correspondence columns last week, more serious cardiac trouble.

BROWN INDURATION OF LUNG

Pulmonary haemosiderosis, or brown induration of the lung, is well known to occur in cases of mitral stenosis accompanied by hypertrophy of the right ventricle. In this condition A. C. Lendrum and colleagues¹ described a focal distribution throughout the lungs of nodules consisting of four to twenty adjacent alveoli filled with siderocytes (macrophages engorged with haemosiderin). In addition, ferrous impregnation of the elastic tissue of the alveolar walls and small arteries results in fracture of the affected elastica, with giant-cell reaction, even to the extent of the development of giant-cell granulomata.² An identical picture may also be seen in patients with systemic hypertension who survive several attacks of left ventricular failure. Lendrum and colleagues¹ suggest that this type of pulmonary haemosiderosis is due to long-standing right ventricular preponderance, with resultant varicosity and repeated haemorrhages in the anastomoses between the bronchial and pulmonary circulations in the region of the respiratory bronchioles. Recently A. H. Cameron³ has described two cases of pulmonary haemosiderosis associated with bronchiectasis. Cor pulmonale and hyperplastic changes in the small vessels of the lung indicated that there had been pulmonary hypertension in both patients, and it is suggested that pulmonary hypertension and inflammatory vascular engorgement are the factors responsible for the haemorrhage from bronchiolar mucosa.

It is, perhaps, less widely known that a very similar pathological state may arise in young people who do not suffer from any preceding disease of the heart or lungs. To this has been given the name idiopathic pulmonary haemosiderosis (or essential brown induration of the lung). This condition bears no relationship to haemochromatosis, in which there is an abnormality of iron metabolism not present in pulmonary haemosiderosis. In 1948 W. G. Wyllie and others⁴ reviewed the pathological and clinical features of idiopathic pulmonary haemosiderosis as seen in 7 cases at the Hospital for Sick Children, Great Ormond Street, and in 17 cases culled from the literature. The histological appearances are the same as those seen in pulmonary haemosiderosis secondary

to heart disease, with this exception. Whereas in the latter the damage is focal because of haemorrhages in individual respiratory bronchioles, each related to a group of alveoli, in idiopathic pulmonary haemosiderosis the haemorrhage is intra-alveolar and diffusely spread throughout the lungs. The pathogenesis is unknown, but most workers have stressed the possibility of a primary defect of the elastic tissues of the walls of the small blood vessels and alveoli. The changes are slight to begin with and the clinical features appear insidiously. As larger parts of the lungs become affected, anoxaemia results in dyspnoea and cyanosis.

The condition, though sometimes seen in adult life,^{5,6} occurs mainly in children.⁴ There is no obvious hereditary tendency. The clinical course is episodic, and remissions of variable duration and completeness occur. The presenting signs are tachycardia and cyanosis associated with dyspnoea, pallor, fever, and, in some cases, jaundice. Cough and vomiting or abdominal pain are often troublesome. There may be signs of congestive cardiac failure such as cardiac enlargement, over-filling of the veins of the neck, gallop rhythm, and enlargement of the liver and spleen. Frank haemoptysis, an uncommon symptom in young children, has been a feature in most of the cases recorded. The test for occult blood in the faeces is often positive. A few rales and rhonchi may be heard over the lungs, but the paucity of physical signs contrasts sharply with the grossly abnormal x-ray appearances. These consist of a generalized mottling most pronounced towards the roots of the lungs. As the acute episode subsides a reticular pattern develops, which may clear completely between the earlier attacks. Lobar collapse may also occur. The blood shows a hypochromic anaemia, often severe, which may respond to iron. In addition, there are "pseudo-haemolytic" features such as a reticulocytosis, the presence of nucleated red cells in the blood films, slight jaundice, indirect positive van den Bergh reaction, excess urinary urobilinogen, and the presence of cold auto-agglutinins. Absence of methaemalbumin excludes intravascular haemolysis. The anaemia has been interpreted⁴ as the result of recurrent pulmonary haemorrhages, and the peculiar pseudo-haemolytic features are explained by the fact that the blood is not shed outside the body but within it—that is, into the lungs. The presence of cold auto-agglutinins may be an antibody response to the destruction of red blood cells within the lungs. Acute episodes may subside quickly or last for several months, but in the intervals the patient is debilitated, underweight, and easily made breathless. Ultimately clubbing of the fingers

develops. The prognosis is bad, and death results in due course from asphyxia and loss of blood.

The diagnosis is usually based on the characteristic radiographic appearances. The striking anaemia and the absence of distinctive physical signs over the lungs may lead to an erroneous diagnosis of iron-deficiency or haemolytic anaemia, but the presence of dyspnoea and cyanosis often associated with haemoptysis should indicate the need for a chest radiograph. The diagnosis may be confirmed by finding macrophages containing haemosiderin in the sputum, in stomach contents obtained by aspiration, or in material obtained by lung puncture.^{7,8} The diagnosis can be accepted only in the absence of an organic defect of the heart such as mitral stenosis. The x-ray appearances are closely similar to those seen in chronic miliary tuberculosis, xanthomatosis, Gaucher's lipoidosis, and sarcoidosis, which are excluded by appropriate investigations. It seems probable that some cases of miliary tuberculosis reported before the days of antibiotics to have improved spontaneously were really examples of idiopathic haemosiderosis.

Treatment has usually been confined to the administration of oxygen for anoxia and blood transfusion for anaemia. J. R. Browning and J. D. Houghton⁵ have reported benefit in one case from giving A.C.T.H. and cortisone.

LEUKAEMIA AND EXPOSURE TO X RAYS

The potential leukaemogenic nature of ionizing radiations is once again emphasized in a recent report by Dr. Alice Stewart and her colleagues,¹ whose findings suggest that exposure of children to x rays during their prenatal life may be an aetiological factor in the development of leukaemia in infancy and childhood. These workers studied the past histories of 547 children who had died from leukaemia or malignant disease in England before the age of 10 and during the years 1953 to 1955, comparing these with the histories of the same number of control children. They found an apparently significant excess of deaths from leukaemia, and also from other malignant diseases, among the children of mothers who had been subjected to x-ray examination of the abdomen during the relevant pregnancy. No similar excess of deaths was found among children who in the post-natal period had been subjected to diagnostic x-ray examination or to whom either sulphonamides or antibiotics had been administered. So far the histories of only about one-third of the children certified as dying from leukaemia or malignant disease during

the period in question have been reported upon, and when the final data are available the excess of deaths among children irradiated in prenatal life may well be different from that found at present. The preliminary findings, however, certainly appear to justify the authors' contention that prenatal irradiation may predispose children to the development of leukaemia or malignant disease during infancy and early childhood.

The report of Dr. Stewart and her colleagues follows closely upon that made by M. Faber² to the Fifth International Congress on Radiobiology, held in Stockholm last month, on the preliminary results of a study of the frequency of either diagnostic or therapeutic exposure to x rays in the histories of adult sufferers from various types of leukaemia. This work was based on the histories of cases of leukaemia recorded in the Danish Cancer Registry. In the belief that the incidence of chronic lymphatic leukaemia is not increased by exposure to x rays, Faber noted the differences in the frequency of a history of exposure to therapeutic or diagnostic x rays among patients with this form of leukaemia and those suffering from acute leukaemia or from chronic myeloid leukaemia. He found that a history of exposure to x rays was given with significantly greater frequency by patients with acute leukaemia or with chronic myeloid leukaemia than by those with chronic lymphatic leukaemia.

These studies of Faber and of Stewart and her colleagues suggest for the first time that the comparatively low doses of x rays received during diagnostic procedures may induce leukaemia. Prior to these publications evidence had accrued from other human studies that much larger doses of radiation than are used in x-ray diagnosis are leukaemogenic. The well-known facts from Hiroshima and Nagasaki have been supplemented by the results of a survey of the incidence of leukaemia among patients treated with x rays for ankylosing spondylitis, as reported by W. M. Court Brown and J. D. Abbatt,³ and recently more extensively by W. M. Court Brown and R. Doll in the report⁴ of the Medical Research Council's Committee on the Hazards to Man of Nuclear and Allied Radiations. Further, C. L. Simpson and her colleagues⁵ have reported an increased incidence of both leukaemia and cancer of the thyroid in children given mediastinal irradiation for thymic enlargement.

It can now be accepted without reserve that ionizing radiations can cause leukaemia in man. The nature

of the relationship between the incidence of leukaemia and the dose of radiation and, consequently, an understanding of the scale of risks involved remain to be discovered. It will be of the greatest importance to determine by direct observation, or to predict with some degree of confidence, whether a threshold dose of radiation exists below which exposure is not associated with an increased risk of inducing leukaemia. Court Brown and Doll⁴ thought that the possibility of very small doses of radiation having a leukaemogenic effect could not be ruled out; their further studies, as recently reported by Court Brown⁶ to the Sixth International Congress of Haematology at Boston, give added weight to the suggestion that over low ranges of dose there may be a simple proportional relationship between the incidence of leukaemia and the radiation dose. In such circumstances no threshold dose of radiation would exist. It may well be, however, that the foetus is more sensitive to the leukaemogenic effects of radiation than either the child or the adult.

The preliminary results reported by Faber and by Stewart and her colleagues are in keeping with the concept that low doses of radiation, such as are received during diagnostic procedures, may increase the probability of the development of leukaemia, but further studies will have to be undertaken to test this hypothesis and to establish it in a convincing manner or to repudiate it on sure grounds. In the meantime two precautionary steps can be taken. The first is to develop techniques of x-ray examination which will reduce as far as possible the amount of radiation received during any single exposure, and for this purpose more attention might well be paid to the use of image intensifiers. The second step was clearly stated by the Medical Research Council's committee,⁴ which concluded, so far as peacetime hazards were concerned, "that, as all such radiations are potentially dangerous, their use should be the subject of constant and close scrutiny, and that adequate justification should be required for their employment on however small a scale." The findings of Stewart and her colleagues reinforce this plea for "adequate justification" especially for an x-ray examination of the abdomen during pregnancy.

PAINLESS CARDIAC INFARCTION

The occurrence of cardiac infarction without pain continues to excite interest, and recently the circumstances in which it might occur were reviewed in these columns.¹ Patients may not complain of pain, because it is overshadowed by some other symptom, especially severe dyspnoea,² syncope due to heart block,³ or vomiting and acute circulatory failure. Rarely, arterial embolism

may indicate that cardiac infarction has occurred a few days earlier.⁴ Not infrequently, cardiac infarction presents as angina of effort⁵; H. L. Blumgart and his colleagues⁶ found evidence of old complete occlusion of at least one major coronary artery at necropsy in all cases of angina pectoris without valvular lesions or hypertension. However, undoubtedly some cases of cardiac infarction are symptomless. A low threshold to pain, altered perception of pain, slow infarction, and ischaemic destruction of nerve endings leading to analgesia have all been suggested as explanations.⁷⁻⁹ The pain of myocardial infarction is certainly due to cardiac ischaemia, and the speed of the infarction and the presence and number of available collateral vessels will influence the amount of pain which accompanies the occlusion. Thus the occurrence of a major coronary artery occlusion in the absence of collateral vessels is likely to be followed by intense ischaemia and severe pain,^{9,10} but when small areas of infarction occur in subjects with a collateral circulation the incidents may be "silent" until heart failure, arrhythmia, or sudden death occur, pain being absent or trivial.

In a recent paper W. Evans and G. C. Sutton¹¹ have drawn attention to this important problem in an investigation of 70 cases of painless infarction in 56 men and 14 women. They were careful to exclude the occurrence of pain by direct questioning of each patient soon after the onset of the illness, and to accept such symptoms as aching, sensations of pressure, "indigestion," and substernal discomfort as being equivalent to pain, and therefore necessitating exclusion from the series. Cardiographic evidence of infarction was insisted upon. In 26 of the 70 patients the absence of pain was associated with "restricted infarction," which the authors define as infarction which is limited in its distribution, and which gives rise to less obvious cardiographic changes which may escape detection unless carefully sought. Evans and Sutton believe that the absence of pain in this group was due not to the small size of the infarct but to the slowness of infarction, which in turn depends on the rate of arterial narrowing and the efficiency of the collateral circulation. In 21 of the 70 cases there was an auricular arrhythmia, usually fibrillation. Hypertension (associated with sinus rhythm in 9 and auricular fibrillation in 7) was present in 16 of the 70 cases. In 4 patients Stokes-Adams disease may have played a part in suppressing pain, while severe vomiting in two cases and cerebral embolism in one case could be considered as the equivalents of pain. The reason for the absence of pain in the group with auricular arrhythmias and hypertension is not entirely clear. Dyspnoea did not overshadow the pain, nor did heart failure play any part. Evans and Sutton considered the absence of

pain in the hypertensive patients to be due to the increase in myocardial muscle mass, which may determine a slower rate of myocardial necrosis following coronary occlusion. The part played by the arrhythmias in suppressing the pain is uncertain, and it would be of interest to know the incidence of auricular fibrillation in a comparable series of their patients with painful cardiac infarction. Certainly the onset of auricular fibrillation in older subjects may be the result of ischaemic heart disease, though cardiographic evidence of infarction is not always present.

Evans and Sutton have underlined the importance of not demanding a history of typical cardiac pain for the diagnosis of cardiac infarction, and of considering the possibility in patients who present with such signs and symptoms as acute dyspnoea, syncope, vomiting, and arterial embolism. The possibility of infarction should especially be borne in mind in older subjects with unexplained auricular fibrillation with or without hypertension.

ATTACK ON INSECTS

A few months ago we drew attention to the fact that in many parts of the world strains of insect pests are emerging which are resistant to insecticides.¹ There is some connexion between the intensity at which insecticides are applied and the speed at which resistance develops. In Britain, for example, where the climate does not foster insect pests so freely as in warmer climates, there are fewer cases of resistance, and the almost ubiquitous immunity of houseflies to D.D.T. and other chlorinated hydrocarbon insecticides has developed more slowly. While the problem of resistance is not restricted to pests of medical importance, there are more definite cases of this type than among the far more numerous agricultural insect pests. Apart from the housefly, which is almost everywhere resistant to D.D.T. and its analogues, body lice and bed bugs are resistant in a number of places, though rarely in Europe; four different strains of anophelines which are malaria vectors are resistant (in Greece, Java, Saudi Arabia, and the U.S.A.) and several strains of culicine mosquito. The housefly is in most places resistant to gamma B.H.C., chlordane, dieldrin, and like substances; the German cockroach is resistant to this group in parts of the U.S.A.; one anopheline malaria vector (in N. Nigeria) is resistant and so are several culicines. The housefly has been reported resistant to organo-phosphorus insecticides in Denmark, where these compounds have been widely used.²

Altogether, there have been reports of resistance of over 20 species of insects of importance in public health, though in a few cases the evidence is not completely substantiated.³ This is certainly disturbing, though the trouble is still localized for most of the insects concerned, and many of them show only one type of resistance so far. It is important to watch for the emergence of resistance and to counteract it if possible. The only feasible alternative reactions at present are to attempt

control by other than chemical methods or to change to different insecticides. The need for change has called attention to the prolific family of organo-phosphorus insecticides, to which only low levels of resistance have been recorded so far.² Several of them, now in use abroad, are no more dangerous to man than the chlorinated compounds; they include malathion, diazinon, chlorthion, "dipterex" and D.D.V.P. (apparently only the first is on the market in Britain). It must be admitted, however, that none of the known organo-phosphorus compounds has the long residual action of D.D.T. or dieldrin.

A possible line of defence against resistance which does not seem to have been adequately investigated is the combined use of insecticides of totally different types. Resistance is theoretically due to the survival (and breeding) of a few individual insects with abnormally high resistance to a particular type of poison. Addition of a different kind of poison might well prevent their survival.

RELAXIN

In many species, and especially in rodents, relaxation of the symphysis pubis occurs in late pregnancy. That this is under hormonal control was first shown in 1926 by F. L. Hisaw.¹ He called the substance responsible relaxin and detected it in the serum of pregnant rabbits. Subsequently, it has been shown to exist in several other pregnant mammals,²⁻⁴ and can be obtained from extracts of rabbit placenta and sow's corpora lutea.^{1,2,5} The substance is non-steroidal, and is thought to be a polypeptide, though no pure preparations have yet been made. Earlier doubts of the existence of such a substance, the effects of which, in guinea-pigs at least, could be reproduced by oestrogen and progesterone alone⁶⁻⁹ can no longer be entertained, since A. A. Abramowitz *et al.*¹⁰ have shown that 500 times the amount of relaxin necessary to produce a positive response in the guinea-pig was without either oestrogenic or progestational effect. Moreover, Hisaw *et al.*¹¹ further succeeded in differentiating the actions of

relaxin and progesterone and showed that the latter acts only by stimulating the secretion of relaxin itself. Though relaxation can be produced by oestrogen alone, the dose required to prime animals for the action of relaxin is small and without effect by itself. It remains possible, however, that relaxin acts as a potentiator of oestrogen, since it is ineffective in the absence of prior oestrogen treatment; but, if so, its action in so potentiating oestrogen must be very powerful.¹²

More recently interest has turned to the uterine relaxation which may follow administration of aqueous extracts of corpora lutea. This was first convincingly demonstrated on the guinea-pig uterus *in situ* by J. C. Krantz, H. H. Bryant, and C. J. Carr¹³ in 1950 and confirmed in 1953 by L. C. Felton, E. H. Frieden, and H. H. Bryant.¹⁴ These latter authors studied the chemical properties of the "uterine relaxing factor" (U.R.F.), found it to be a protein or polypeptide, and concluded that there was a close relationship between it and relaxin. Whether U.R.F. and relaxin are identical remains uncertain.

Clinical interest in these substances arises from two uses to which the uterine-relaxing property of extracts of sow's corpora lutea have been put—the treatment of dysmenorrhoea and of premature labour. G. S. Jones and F. Smith¹⁵ produced a report in 1954 on its use in the treatment of dysmenorrhoea; they showed that the active principle is not destroyed in the stomach and appears in the blood serum within 30 minutes after oral administration in human beings. In a series of 90 women who complained of dysmenorrhoea, symptoms were controlled by the treatment in 61, the results being regarded as sufficiently promising to warrant further trial. G. H. Rezek¹⁶ has also reported good results in a series of 298 patients, complete relief of symptoms being obtained in some 70% of cases within fifteen minutes following an initial oral dose of 3,000 "units." There were no undesirable effects.

Of no less interest are two reports on the use of U.R.F. in premature labour. J. T. Majewski and T. Jennings¹⁷ obtained good results in all but 4 of 21 patients in premature labour by giving 4,000 units initially, followed in one hour by 3,000 units, and thereafter 1,000 units hourly (all orally) until contractions ceased. E. Abramson and D. E. Reid¹⁸ treated by intramuscular injections five patients who went into premature labour between the 29th and 31st weeks. In each case the pregnancy continued until the 36th to 40th weeks, with the delivery of a normal infant. Finally, E. Eichner *et al.*¹⁹ made careful studies on the effects of intravenous and intramuscular injections of U.R.F. in labour and were able to modify and slow labour in all patients to whom adequate dosage could be given for over two hours before delivery. They further drew attention to the cervical softening which was induced by treatment in 30 of 39 patients and found that certain types of dystocia associated with disorganized contractions responded with normal labour and rapid delivery. It may not be too much to claim that the rather neglected "third ovarian hormone," as relaxin has been called, appears to have an interesting future in obstetrics and gynaecology.

THE CLINICAL PSYCHOLOGIST IN THE MENTAL HOSPITAL

BY

RALPH HETHERINGTON, Ph.D.

Senior Clinical Psychologist, Crichton Royal, Dumfries

The appearance of trained clinical psychologists in mental hospital practice is a comparatively recent phenomenon. It is therefore not surprising not only that many mental hospitals are still without psychologists but that those that do employ them are not all using them in the same way. Indeed, many medical men have but a sketchy notion of the training and capabilities of the clinical psychologist and are therefore not clear about what duties may properly be assigned to him. It is hoped that this article may make matters clearer by giving an account of how clinical psychologists are employed at the Crichton Royal, Dumfries, where the first psychologist was appointed twelve years ago.

Training of the Psychologist

Arrangements for the selection and training of clinical psychologists are set out in the Ministry of Health circular P.T.A. 39 and the appropriate covering memoranda.

No psychologist is now accepted for clinical training unless he has an honours degree in psychology. He is then required to gain a further three years' experience with mental patients, usually in a mental hospital, under the supervision of a senior psychologist, before he can be regarded as being fully trained. At the end of this time, if he is to be allowed to continue, he must gain a proficiency certificate from his employing authority. This period of hospital experience may be reduced if he has also received postgraduate training in clinical psychology in a university department. The psychologist, then, comes into the mental hospital with a background of academic knowledge of normal psychology, in contrast to the psychiatrist, who begins with a training in general medicine. Thus, whereas the psychiatrist is interested in eliciting symptoms which may lead him to diagnosis and so to treatment, the psychologist is concerned more with describing the patient in terms of personality traits of intelligence, temperament, and character. The psychiatrist's training has given him a knowledge of the abnormal, the deviant, and the pathological; whereas the psychologist's training has given him a knowledge of the normal range of human behaviour.

Work of the Psychologist

The work of the psychologist in the mental hospital may be classified under four heads: diagnosis, research, treatment, and teaching. It is unlikely that he will be able to give an equal amount of attention to each of these. All psychologists engage in a large amount of diagnostic interviewing and testing, which probably forms the major part of their work. The relative amount of time spent on research, treatment, and teaching depends on the psychologist himself and on the hospital in which he works. The man who is interested in research often does little or no treatment, and vice versa. As Sir Thomas Lewis (1930) pointed out, the research and clinical attitudes are not easily adopted by the same person concurrently. Whether or not the psychologist is called upon to teach depends on the presence in the hospital of medical officers training for their D.P.M. or of a school of nursing. Where psychology lectures are to be given the clinical psychologist is best fitted to give them.

Diagnosis.—The psychologist in his diagnostic work aims at providing information about a patient which will help the

psychiatrist to assess the nature of the illness. The tests he uses are based on scientific research and depend as little as possible on personal subjective impressions and as much as possible on objective measurement. The intellectual level of the patient, as well as signs of intellectual impairment or deterioration, is always an important factor, and the psychologist is equipped to make objective assessments of all these. Disorders of perception or thinking may give the first indications of a cerebral lesion or functional psychosis. These can be fairly easily demonstrated by test procedures. The various so-called "projective techniques," such as the Rorschach ink-blot test and Murray's thematic apperception test, give valuable information about a patient's personality. The former gives indications of how the patient operates: anxiously, depressively, obsessively, and so on; the latter yields information about his attitude and opinions with regard to his parents, death, violence, sex, and the like. Tests such as these not only help in diagnosis but are valuable research tools and often form a useful basis for psychotherapy.

Research.—So far as a psychologist has had training in scientific methods he is able to render valuable assistance in designing and in carrying out research projects; he can also give advice on scientific research in general. Since university courses in psychology usually include statistics, the psychologist is able to advise on statistical methods in medical research in the hospital. Recent psychological research at the Crichton Royal has included work on the effects of E.C.T. on memory and efficiency, the psychological changes in senile dementia, and the changes in attitude of alcoholics after treatment.

Treatment.—Not having a medical training, the psychologist does not, of course, undertake any of the physical treatments. He can, however, undertake the psychotherapy of suitable cases under the general supervision of the psychiatrist, who remains in charge of the case. As this form of treatment is very time-consuming, this part of the psychologist's work can be of great assistance to the psychiatrist. Since the former is never concerned with problems of administration, he tends to be regarded by the patient in a somewhat different light from either the psychiatrist or the nurse. Consequently it sometimes happens that the patient finds it easier to confide in the psychologist in the first instance. Some aspects of the patient's rehabilitation, too, are often more easily handled by the psychologist.

Teaching.—In lectures to medical officers training for their D.P.M. the psychologist should be able to supply the academic framework for the psychological knowledge necessary for the diploma, and in lectures to student nurses he should be able to relate psychological theory to practical issues on the ward. It is particularly necessary to encourage nurses to observe and understand themselves as a basis for understanding their patients.

Role of the Psychologist in the Hospital

There has been a tendency at some hospitals to use psychologists as "scientific medical auxiliaries," much in the same way as radiographers, E.E.G. recordists, or biochemists. In this case the psychologist is based on his own separate department, which he leaves only when it is necessary to visit the ward to test the patient. In some cases the patient may even be brought to the psychologist in his department. This arrangement has obvious limitations. The presence of the psychologist in the ward to see a patient on request may be interpreted by the latter as indicating a serious turn of events in his treatment. As the psychologist is a stranger to the patient, rapport has to be established before he can usefully begin to test the patient, and this often involves the need for prolonged reassurance and encouragement. On the other hand, if the psychologist is based on the ward and is there every day and all day, he soon becomes recognized as part of the ward team of doctors and nurses. Patients indeed come to accept the psychologist as one of the group

of people he sees regularly, concerned as a team in his day-to-day treatment. The psychologist is not then a strange expert called in for a special purpose but is a well-known figure with whom most of the patients have a talk some time or other. When the psychologist works in this way the value of the material he gains from the patient is greatly enhanced. The patient knows him and has come to trust him, and it is recognized in the ward that patients go and see him. Therefore there is no strain; there is no initial discussion to be undertaken with a patient before valuable material can be elicited.

Another way in which the part the psychologist plays on the ward can be useful has already been mentioned: whereas the doctor and nurse are inevitably in positions of authority, the psychologist is not so. He is not required, nor is it necessary, for him ever to give orders to the patient or to anybody else. His advice may often be sought, but he never assumes authority. This often provides opportunities for the patient to work out his problems when he needs some non-authoritarian figure to consult.

When a psychologist is based on a ward in the way that has just been described, the sphere of his work is inevitably restricted, as he will be available for work only on the ward in which he is based. On the other hand, the value of his work is so much enhanced, and the fullness and richness of the psychological material he obtains is so much increased, that there can be no doubt of the value of this system of working. Unless his efforts are concentrated on a single ward the potentialities of the psychologist in the mental hospital setting may not be fully realized and he may get so little done that is really worth while that his usefulness may begin to be doubted. On the other hand, if his potentialities are exploited by putting him on the ward, his usefulness will become apparent.

At a time when mental illness and neurosis are becoming major concerns in national life, the increasing employment of clinical psychologists in this way may play a part in meeting some of the difficulties which at the moment beset work in mental hospitals.

NORMAL AND ABNORMAL BONE SYMPOSIUM AT QUEEN'S COLLEGE, DUNDEE

[FROM A SPECIAL CORRESPONDENT]

The properties of bone, its growth and repair, and some of its clinical abnormalities were among the subjects discussed at a symposium and postgraduate lecture held at Queen's College, Dundee, on September 5. The Master of Queen's, Professor D. R. Dow, opened the meeting.

Breaking Stress

Professor G. H. BELL and Mrs. JEAN OLIVER (department of physiology, Queen's College) reported on the strength of bone in various pathological conditions. In Professor Bell's earlier studies it had been shown, they said, that the breaking stress of individual bones could be calculated from simple bending tests. The breaking stress was a measure of the quality of the bone material. In rats, while changes in the calcium intake might affect the size and therefore the strength of the bones, they did not alter the quality; similarly, pituitary, thyroid, and parathyroid hormones and oestrogens had little or no effect on bone quality. In rickets, however, the breaking stress was diminished in parallel with the reduction in the ash content of the bone, but apparently neither the bone's inorganic nor its organic constituents were altered. Recent studies with Mrs. Oliver on experimental lathyrism in rats had shown that in this condition bone quality was reduced even when there was no corresponding

change in the quantity or quality of the inorganic component. At the end of this contribution Mr. I. S. SMILLIE asked why the breaking stress of a bone—for example, the neck of the femur—was reduced in old age. No answer to this conundrum could be found. One suggestion was that the explanation might lie in some variation in the connective tissue.

Dr. J. W. SMITH and Professor R. WALMSLEY (department of anatomy, St. Salvator's College) then discussed fatigue in bone. Dr. SMITH said that, while stress fracture from repeated strains during normal activity was a well-known clinical entity, previously it had never been proved experimentally that bone could be fractured in this way. He then proceeded to describe experiments in which stress fractures had been induced, illustrating in a film the apparatus used. He had found that the breaking stress was directly related to the elasticity of the bone being tested, and that the stress and static loads were the same for any given piece of bone. His experiments had been on dead bone, and so did not take into account any remodelling that might occur in the living subject.

Professor WALMSLEY took the matter a stage further by describing research he had carried out to correlate the elasticity of a bone with the collagen arrangement in its haversian systems. By means of stained sections he demonstrated that the collagen in a haversian system is disposed in alternate circular and longitudinal layers. He had taken a horse's radius, where the anterior cortex is under tension and the posterior cortex under compression, and calculated Young's modulus of elasticity for these two sections of the cortex. Section of the anterior surface of the bone, where the figure for the modulus was relatively high, showed the longitudinal fibres to be most marked, whereas section of the posterior cortex, which had a much lower modulus figure, showed the circular fibres to predominate. In the ensuing discussion Professor P. LACROIX asked if the sections had been examined under polarized light. Professor WALMSLEY said the findings were the same as those demonstrated by staining. The mineral content of bone was increased on the side under compression, he added.

Growth and Repair

These aspects of the subject were discussed both in the symposium itself, where Mr. J. A. GILLESPIE (department of surgery, Queen's College) reported on his studies on the effect of nervous influences on bone growth, and in the open postgraduate lecture given after the symposium by Professor P. LACROIX (department of anatomy, Louvain), this year's praelector in the faculty of medicine at St. Andrews. Mr. GILLESPIE's experiments had led him to believe, he said, that neither the peripheral nor the autonomic nerves exerted any trophic action on bone. Nor did changes in blood flow to the limb alter the rate of growth. In a paralysed limb the quantity, not the quality, of the bone was affected. The basic rate of bone growth was due, he said, to the inherent growth energy of the cells of the epiphyseal plate and inner layer of the periosteum, and this basic rate was increased by the stimulus of muscle action. In his view the degree of muscle paralysis in a limb was directly related to the subsequent shortening. If maximum use was made of a paralysed limb, the shortening would be reduced to a minimum. However, Mr. G. MITCHELL (Edinburgh), speaking on the basis of preliminary clinical observations, did not think the degree of paralysis in poliomyelitis could be related to the limb shortening. But he thought the paralysis of muscles whose origins were close to a rapidly growing epiphysis was an important factor in leading to serious shortening of a limb, and Miss M. FORRESTER-BROWN (Edinburgh) agreed with him, citing paralysis of the gastrocnemius as an example.

Professor LACROIX began by reviewing his experiments on the induction of bone growth. In normal epiphyseal cartilage, he said, a layer of subperiosteal cartilage was laid down,

SIR,—In his article "Intracranial Aneurysm: A New Method of Surgical Treatment," Mr. J. E. M. Dutton (*Journal*, September 8, p. 585) makes a number of statements in connexion with the material used that are difficult to understand and may prove misleading.

(1) "So far the self-curing acrylic, methyl-methacrylate, has been found most suitable." Methyl-methacrylate monomer will polymerize *spontaneously*, but so slowly as to be useless for the purpose indicated. The so-called "self-curing" acrylic resins contain not only methyl-methacrylate but also chemical activator systems designed to bring about rapid polymerization without the application of heat. The chemical activator systems employed in various brands of self-curing resins vary widely in their properties, including the heat generated during polymerization, the degree of polymerization achieved, and their effects on the tissues. It would seem important to specify the type of self-curing resin employed.

(2) "Polymerization is complete in 15 to 20 minutes, and by that time the material has set quite firm." In a simple mixture of methyl-methacrylate monomer and polymer a "gel" or "dough" will be formed as a result of solution of the polymer powder in the monomer liquid, but unless the temperature is raised above about 60° C. no significant polymerization will occur.² If the material used by Mr. Dutton has set quite firm after 15 to 20 minutes, then presumably one of the chemically activated preparations is being used. However, the firm set does not indicate completion of polymerization; even after several hours as much as 1% of monomer may remain. This may be of importance when irritant effects come to be considered. If the material used is one which depends for its polymerization on benzoyl peroxide in the polymer powder, the proportion of residual monomer is likely to be even greater if the powder has been autoclaved, as advocated.

(3) "An acrylic compound was selected because . . . there is no shrinkage during polymerization. . . ." During polymerization methyl-methacrylate monomer undergoes a reduction in volume of approximately 21%. Of course, if the monomer is mixed with polymer powder, shrinkage of the mixture will be less than with monomer alone. This shrinkage may be within acceptable limits for a particular purpose, but there cannot be "no shrinkage."

(4) ". . . and there is neither clinical nor experimental evidence yet of any adverse local reaction to its presence." If, as I suspect, Mr. Dutton is using one of the chemically activated "self-curing" resins, then there is extensive evidence of their injurious effects on the tissues when used in certain other situations, even if there is no evidence of damage when used intracranially.³⁻¹⁵—I am, etc.,

London, W.C.1.

The Abuse of Antibiotics

SIR,—I am, in Stratford-on-Avon, sometimes privileged to look after visitors from across the Atlantic. It is most striking how many of them carry a comprehensive range of antibiotics as part of their luggage—sometimes with and sometimes without instructions on their use. Occasionally this modern form of travelling first-aid box has been the parting gift of some "well-wishing" family physician. Moreover, I do in fact find it is common practice for visiting Americans to have taken some form of antibiotic, usually oxytetracycline—be it for bowel infection, sore throat, common cold, or "chill"—before they call upon my services.

This seems to me one of the worst forms of the abuse of antibiotics. I cannot recall one instance of an antibiotic being correctly used by these self-treated patients. Either it was not indicated (which is practically synonymous with contraindicated), or, when indicated, the patient has been scared of using an adequate dosage. This is of course further evidence of the extent of the abuse of antibiotics. I would like to hope, however, that in this instance it has not arisen from any misunderstanding of the medical services, of antibiotics in particular, that are available to these very welcome guests to our country.—I am, etc.,

Stratford-on-Avon.

E. O. EVANS.

Medical Education

SIR,—I should like to draw further attention to a small item briefly mentioned in the valuable educational number of the *Journal* (September 1, p. 523), in point to the availability of annual summer schools abroad for British medical students, a benefit at present made use of by only a very small minority.

I have myself recently returned from one such course in Denmark, and in retrospect can appreciate something of the value obtained in observing the methods and ideas of another nation tackling fundamentally similar problems in both medical education and practice. In fact, I might go so far as to say that the informal discussions, the contrasts and comparisons, and the criticism, both objective and subjective, which inevitably mature in such a climate must surely play an integral part in the training of the "educated, thinking man" which the First World Conference on Medical Education appears to have agreed as being the aim of a Utopian teaching system.

The Danes fully realize the value of international contact at student level: a traditional scarcity of dissection material, which there is no attempt to remedy, enforces an annual exodus from the medical schools of Copenhagen and Aarhus during the summer vacation to a number of the other principal European universities, many reaching our own shores. To the Dane this is in fact a very definite stage in his education. Perhaps planners of the schooling of generations here to come might take yet one more note for future reference.—I am, etc.,

Oxford.

D. M. HILL.

SIR,—In your issue of September 1 (p. 494) I find in the article by Dr. A. Morgan Jones the following statement: "In the days of pre-scientific medicine it was natural to regard anatomy as the basis of pathology and medicine. . . . Further, anatomy was the basis of the surgeon's training. . . . All this has changed, and physiological knowledge has become the basis of medical diagnosis and treatment and even of surgery." Furthermore, he states that inclusion of anatomy on its present scale in the medical curriculum "is a dreadful and stultifying waste of time for the average doctor."

I strongly disagree with this; for one thing, how can you get physiological results without the basic knowledge of the anatomy of the part being worked upon, and even the elementary knowledge of the whereabouts of the gland or organ it is desired to investigate? Another point, take a simple injury to the ankle. I cannot imagine approaching this without a knowledge of anatomy.—I am, etc.,

Virginia Water, Surrey.

V. C. CAMERON.

Preventive Medicine and the Medical Student

SIR,—May I draw special attention to Dr. C. M. Fletcher's excellent article on the teaching of social and preventive medicine, and especially to the heading "Diagnosis and Management of Social Factors in Disease" (*Journal*, September 1, p. 497)?

He asks, quoting Professor Leslie Banks, "Why is this patient here and how could his illness have been prevented?" This question has been in the minds of many for

years. In 1919 Sir James Mackenzie established the Institute for Clinical Research "to investigate disease before the occurrence of any structural change in any organ of the body." Basing my knowledge on the inspection of Army recruits, civil appointments and insurance cases, inspection of school- and pre-school children, and from my experience as resident M.O. in several hospitals and as G.P. and M.O.H., I wrote in 1936,¹ "The investigation of disease in its early stages is one of the most valuable factors in prevention."

The medical curriculum has often been under review and criticism, and Dr. A. Morgan Jones (p. 494) goes so far as to write: "It is probable that the whole structure of the medical course should be reorganized." My contention is that the curriculum does not deal with prevention as a definite and distinct part of the final examination. The result is that the medical student is turned out pathologically minded and has not been trained so as to imbue a preventive-minded conscience.

I have very definite views on this. The Certificate of Public Health came to an end because it was not applied to the training of the medical student and was taken up only by the few interested in prevention.² I have advocated, and repeat without apology, that preventive medicine as a distinct subject should form part of the final examination and thus be placed on an equal footing with medicine, surgery, and obstetrics. Dr. Fletcher, referring to the recommendations of the General Medical Council, states: "A specialist in of the social and preventive medicine should be a member of the examining board." This specialist naturally should be a selected medical officer of health as the person skilled and engaged in this work in his official capacity. I have advocated that a medical officer of health should be included on the staffs of consultants in all teaching hospitals. There is a great opportunity here for teaching social and preventive medicine.³ This has been backed up by the Guillebaud Committee. As the Diploma of Public Health is one of the higher qualifications I suggest it would be more in keeping with the special nature of the duties of the medical officer of health that the D.P.H. should be renamed Doctor of Public Health, and thus give the M.O.H. equal status to other specialists with higher qualifications in their specialty gained in postgraduate study.

I submit that future students must be trained to be competent to deal with the preservation of the health as well as the diseases of the family.—I am, etc.,

Southport.

Is Tonsillectomy Necessary?

SIR,—I am grateful to Dr. John C. Ryle (*Journal*, September 8, p. 603) for drawing my attention to M.R.C. Special Report No. 227.¹ Its contents are indeed relevant to the problem of tonsillectomy. I fear Dr. Ryle did not have time to read the whole document, for if he had he would have noticed that on page 124 is to be found not only the answer to my question but also so excellent and fair a summing up of the whole matter that I beg leave to quote it in full.

"Summarizing our experience set out above, we may say that there is no evidence whatever that wholesale tonsillectomy [my italics] results in a diminished incidence of the infections under discussion. The argument may be put forward that, if tonsillectomized boys and girls had not undergone the operation, they might have suffered more severely than they did, and the effect of the operation was to render them at least as resistant to infection as their unoperated companions. Since we have no means of knowing what would have happened in these circumstances, this argument is unanswerable. There is some slight indication that the incidence of rheumatism, otitis media, and mastoid disease is actually higher in the tonsillectomized group, but here again we do not know whether it might have been even higher in these individuals if tonsillectomy had not been performed.

"Hitherto we have been dealing with all the available data at our disposal, irrespective of when the operation was performed. It was considered advisable to examine in detail the experience

of 364 boys in whom the tonsils were removed during school life, and for whom we had sickness records before and after operation. The details are set out in Table LVIII.

"It will be seen that for the nasopharyngeal group of infections, these boys before operation had an attack rate which was 8.7% greater than the expected rate obtained from the age-distribution and rates of all boarding schools combined. After tonsillectomy, however, the attack rate for nasopharyngeal infection was actually 0.5% less than the expected rate. Taking all sickness into account with regard to time lost, we find that this group of boys before operation lost one and a half days more than the average, but after operation they lost a quarter of a day less than the expected number. There is little doubt that in these boys the results of tonsillectomy appear to have been successful particularly in causing a diminished attack rate of nasopharyngeal infection, but it must be remembered that probably the majority of these operations were performed on the advice of school medical officers who selected their cases with care.

"Few to-day would encourage the retention of diseased or obstructive tonsils, or would cast doubt on the real value of the operation in properly selected cases as demonstrated above; but it is a little difficult to believe that among the mass of tonsillectomies performed to-day (1938) all subjects for operation are selected with true discrimination, and one cannot avoid the conclusion that there is a tendency for the operation to be performed as a routine prophylactic ritual for no particular reason and with no particular result."

I can only add the observation the unnecessary tonsillectomy still seems to be unnecessary and that necessary tonsillectomy still seems to be necessary.—I am, etc.,

London, S.E.26.

JOHN BURKINSHAW.

Gas Gangrene Risks

SIR,—Those who have had experience of war surgery will be critical of the views expressed by several correspondents blaming the presence of gas-forming organisms for the occurrence of gas gangrene in wounds. That this is not the direct cause has been proved repeatedly, since it is common to find such organisms in clinically healthy wounds. Simple facts are easily forgotten, but it will be calamitous if younger surgeons have to learn all over again the lessons of the last devastating war. The relation of pathogenic anaerobes to gas gangrene is straightforward: gas gangrene develops only in dead tissue. Hence the brilliant results following the teaching of Professor Trueta on correct wound excision, when war wounds remained clean after proper excision, even though wounds were teeming with these organisms.

Our theatres and tools should of course be as germ-free as possible, but even more important is the practice of correct surgical principles.—I am, etc.,

Swindon.

F. LOUIS.

Torsion of Spermatic Cord

SIR,—May I comment on recent papers and letters on the clinical features of torsion of the spermatic cord by Mr. J. A. Baty (*Journal*, May 5, p. 1014), Mr. R. Burkitt (*Journal*, August 11, p. 345), and Dr. D. G. Chambers (*Journal*, September 1, p. 552)? There seems to be some diversity of opinion, as stated or suggested by these authors, regarding the position of true testicular pain. Some years ago I demonstrated,¹ and I like to think logically and conclusively, that pain produced in the testis is invariably situated in the early embryonic position of the organ—about the level of the internal abdominal ring—and not in the scrotum. Why? A simple illusion, determined by anatomical structure and permanently fixed early in pre-natal life. Later migration by normal development—e.g., of testis, appendix, diaphragm, etc., or artificial displacement as in Aristotle's experiment (crossed fingers) and pedicle skin transplants—can neither destroy nor correct the illusion when the original innervation is maintained.

In this connexion (the common observation and fact that pain is frequently situated at a distance from the tissue in which it is produced or excited) one is somewhat surprised

and perturbed to note that in some medical schools (*not* St. Andrews) students still trot out McKenzie's theory—viscero-cutaneous reflex—as the explanation for these distant pains. One wonders who is responsible, physiologists or clinicians, for perpetuation of this illogical and fantastic view, which is akin to the widespread belief in ventriloquism. Both I should say are anatomical and physiological impossibilities, and deserve decent and honourable interment—R.I.P.

Mr. Burkitt, quoting O'Connor,² writes, "The condition [torsion of spermatic cord] is probably much commoner than is generally realized, most cases . . . never being diagnosed at all." This is probably true, the reason being, as suggested by Mr. Tom McNair, Edinburgh (personal communication), that the unknowledgeable clinician ignores the testis (and its cord) as a possible cause of low abdominal pain. Hence the removal of many normal appendices with no relief of symptoms. "Them's my sentiments" (W. M. Thackeray, *Vanity Fair*).—I am, etc.,

Dundee.

Rare Type of Anonychia

SIR,—We should be most grateful for an introduction to any family showing the dominant, inherited abnormality illustrated in the accompanying photograph. This condition is not seriously disabling except on those rare occasions when it is associated with ectrodactyly.

We have been making genetical linkage studies on a Rotherham family with this form of anonychia and more material is now required, so we hope that any practitioner who may have noticed the condition will communicate with us at the Galton Laboratory, University College, London, W.C.1.—We are, etc.,

London, W.C.1.

Inhaled Foreign Bodies

SIR,—Mr. C. L. N. Robinson and Dr. W. W. Mushin (*Journal*, August 11, p. 324) have rightly drawn attention to this important subject. As they say, foreign bodies are liable to inhalation, particularly by young children.

In 1954 I published an account in the *Journal* (January 16, 1954, p. 125) of three children who had inhaled radio-translucent foreign bodies. In this account and in an annotation on the subject in the same issue (p. 144) the importance of bronchoscopy in the search for foreign bodies was stressed. In the last two years I have seen five more children who had inhaled radiotranslucent foreign bodies. In three of these the initial episode had been forgotten. All five presented with respiratory disorders ranging from "a slight wheeze" to signs of advanced lung sepsis that had not responded to chemotherapy. In one the chest x-ray was normal, though full inspiratory and expiratory films were impossible owing to the child's age. All had inhaled

nuts, which were removed at bronchoscopy. In four they were peanuts, which seem to have a peculiar fascination for children and are presumably easily inhaled on account of their small size.

If a child is alleged to have "swallowed something down the wrong way" or, with something in its mouth, to have choked, gagged, or coughed, no effort should be spared to locate a foreign body by all methods, including bronchoscopy. Similarly, if a respiratory disorder in a child has not responded to usual treatment, even if a parent cannot remember any choking episode, the possible presence of a foreign body should not be overlooked.—I am, etc.,

Derby.

BERNARD M. LAURANCE.

Shoe-fitting

SIR,—While agreeing with Dr. W. G. Booth (August 25, p. 479) on the uselessness of the shoe-fitting fluoroscope, the need for trained shoe-fitters, and the high incidence of hallux valgus in teen-age girls, I cannot agree that this deformity is caused primarily by bad fitting of footwear. Bad fitting means the selection of the wrong footwear and therefore implies that correct footwear is available. This is not the case. Hallux valgus is caused by wearing wrongly designed footwear—footwear that causes angulation of the hallux at the metatarso-phalangeal joint.

If a 16-year-old girl with undeformed feet stands erect with her bare feet together, the big toes are in contact all along their inner border. When correctly shod the toes should be accommodated in exactly the same position. Footwear that cause the toes to point outwards cause deformity. My own work¹ has shown that slight deviations from the normal are important and can cause deformity. These principles of design are accepted by all the leading manufacturers of children's footwear. Shoes with straight inner borders are available in many makes in small sizes, but they are very rare in the late teen-age styles. One well-known brand of children's footwear shows a variation of nearly twenty degrees between the early and late teen-age styles, but all carry the same trade-mark and sales publicity. Correctly designed footwear for the adolescent and the adult is virtually unobtainable.

Why then do manufacturers depart from the principles of good design in teen-age styles? No reason is given, but, as the trend is most marked in girls' footwear, it seems that preparation for fashion footwear plays a large part. Fashion footwear is the trade's best money-maker, and this type of footwear is designed without regard for the shape or function of the foot and invariably deforms. For example, "low-cut shoes of 'court' type are necessarily deforming, for the pointed toe is essential to its security."

To-day 75% of the girls leaving school have acquired hallux valgus because their shoes are badly designed and could never be correctly fitted. All hallux valgus is preventable, but first we must secure an adequate supply of correctly designed footwear, for until then neither shoe-fitter nor parent can play their part.—I am, etc.,

London, S.E.15.

Recurrence of Tetanus

SIR,—A Tamil girl, aged 3 years, was admitted to hospital on November 4, 1955, with a history of inability to open her mouth for three days, and generalized spasms, which had occurred several times a day for two days. There was a history of discharge from the right ear for one week.

On examination there was trismus, a risus sardonicus, and opisthotonos. No abnormality was found in the heart or lungs. The abdomen was tense. A diagnosis of tetanus was made and an intramuscular injection of 100,000 international units (1950) of tetanus antitoxin given on admission. Sedation was accomplished by the use of rectal paraldehyde and chloral by mouth. Elixir mephenezin and penicillin

were also given, while chloramphenicol drops were instilled into the ear. The discharge from the ear was negative for *Cl. tetani* on culture. The antitoxin was repeated in a dose of 30,000 units once daily for three days, commencing the day after admission. The child was discharged after seventeen days.

She was readmitted on March 8, 1956, with a history of generalized spasms, with inability to open her mouth, from the previous evening. The mother also mentioned that a discharge from the child's ear had been noticed three days previously. She had been in good health previous to this. On examination all the signs of tetanus were found. No discharge from the ears was seen. 100,000 units of antitoxin was given on admission, and 40,000 on the day following. In addition the usual treatment was given. The discharge from the ear was negative for *Cl. tetani* on culture. The child was discharged 20 days after admission. The child was seen again on August 28, 1956. She was found to be in good health, with no residual stiffness.

I must thank Dr. Stanley Silva for permission to report this case.—I am, etc.,

Colombo.

TREVOR PHILLIPS.

Swaphook Tenotomy

SIR,—I was asked to visit a lady who had walked into a woodshed and trod on a sickle. On examination I noticed a neatly placed half-inch (1.3-cm.) transverse cut one inch (2.5 cm.) above the back of the os calcis. The calf muscles on the same side looked preternaturally athletic, while at the classical point where Mrs. Achilles had grabbed her infant son my finger and thumb could be opposed by nothing more substantial than two layers of skin; and through this skin, by pushing it forward, one could palpate quite easily the back of the ankle-joint. Needless to add, my patient was unable to plantar-flex her foot. She received expert surgical treatment (not from me, of course), but it took all of six months to undo the damage done by that swaphook tenotomy. Now, however, I am glad to write she has made a complete recovery and is still on my list (N.H.S.).—I am, etc.,

Buxted, Sussex.

W. R. E. HARRISON.

Soya Flour in Infantile Eczema

SIR,—Dr. B. Isserlin's letter (*Journal*, September 1, p. 553) raises the question of an easy source of supply of soya flour. Soya Foods Ltd. supply a full-fat processed soya flour under the name "soyolk," which can be easily converted into soya bean milk. "One of the best methods to make soya milk from soyolk is to scald in boiling water in the proportion of 1 cup of soyolk to 5 cups of water, cool and strain through fine cheese cloth. The white opaque liquid is soya bean milk" (extract from leaflet).—I am, etc.,

London, N.W.10.

FELIX S. BESSER.

Old Students of University College London

SIR,—I should be grateful if you would grant me a little space in your columns to try and make contact with old students of University College London, of whom we calculate there must be some 30,000 either in this country or overseas. Unfortunately, we have got records of the careers and up-to-date addresses of only a very small proportion of this number. The college authorities are anxious to get in touch with old students, to invite them when possible to appropriate college functions, and on occasion to seek their advice. It is only when some honour, public appearance, or other matter is recorded in the press that the college can add to its records of the individual concerned.

The college authorities hope that old students will write, even just a postcard, to the secretary of University College London, Gower Street, London, W.C.1, giving their addresses, dates at college, and subjects studied, and will keep the secretary informed of changes of address.—I am, etc.,

London, W.C.1.

IFOR EVANS.

Obituary

S. D. RHIND, M.C., M.B., F.R.C.S., F.R.A.C.S.

Mr. S. D. Rhind, consulting surgeon to the Wellington Hospital, New Zealand, and a former editor of the *New Zealand Medical Journal*, died recently after an illness of several months' duration. He was 62 years of age.

Sydney Devenish Rhind was born at Christchurch in 1894, but was educated in England. From Berkhamsted School he went on to St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1916. He entered the New Zealand Medical Corps immediately after qualification, and served with the 1st New Zealand Expeditionary Force. In 1918 he was awarded the Military Cross. After demobilization he returned to St. George's, where he held a number of house appointments, and graduated M.B., B.S. from London University in 1922. In the following year he was admitted a Fellow of the Royal College of Surgeons of England. He was elected a Fellow of the Royal Australasian College of Surgeons in 1937.

In 1924 Rhind went back to New Zealand and became assistant surgeon at the Wellington Hospital; later he was appointed full surgeon and ultimately consulting surgeon. For many years he was senior surgeon of the hospital, where he took a particular interest in the teaching of final-year students. He was appointed editor of the *New Zealand Medical Journal* in 1934, in succession to Sir James Elliott, under whom he had been assistant editor for three years. He occupied the editorial chair until 1939, when Dr. J. O. Mercer became editor. Rhind was an energetic editor and was responsible for a number of improvements in the *New Zealand Medical Journal* in the matter of both content and format. A member of the B.M.A. for nearly forty years, he was chairman of the Wellington Division in 1937-8; honorary secretary of the New Zealand Branch from 1940 to 1944; president of the Branch from 1945 to 1947; and in 1946 he returned to England to attend the Annual Representative Meeting as representative of the Branch. He married Miss Vera Anderson in 1924 and had two daughters.

Dr. J. R. SLESSOR died with tragic and startling suddenness on June 3 at the age of 48. He was taken ill while attending a patient and died within a few hours. The elder son of Dr. R. A. Slessor, with whom he was in partnership, James Runcieman Slessor was born at Fraserburgh on March 2, 1908, and received his medical training at Aberdeen University, where he graduated M.B., Ch.B. in 1930. After holding resident appointments at the Royal Cornwall Infirmary, Truro, he became a ship surgeon for about two years. Before settling in practice with his father at Fraserburgh in 1938, he worked for several years as a locumtenent in carefully selected practices in many different parts of England and Scotland. This and his sea experiences were undoubtedly to his great advantage, for very few had such a full knowledge of cities and men as he had. During the second world war he served with the R.A.F., mostly overseas in North Africa and Malta, holding the rank of squadron leader. After his return, besides being engaged in a very busy practice, he took a great interest in the affairs of his native town, being a member of the local school management committee. A keen sportsman, he was a past captain of the local golf club. From the beginning of the National Health Service he was a member and vice-chairman of North Aberdeenshire hospitals board of management. Greatly interested in the welfare of ex-Service men, the work

he did for the Fraserburgh branch of the British Legion, of which he was chairman, was monumental. These were not all the interests of his very full and helpful life, and certain of his medical neighbours will miss, but remember with gratitude, his wonderful companionship on several long motor tours abroad. Dr. Slessor was a widower—his wife, a daughter of a Birmingham medical practitioner having died in 1948—and he is survived by a son and two daughters.—J. C. W.

Dr. H. C. WRIGHT, who was in general practice at Newcastle-upon-Tyne for many years, died on August 28 at the age of 68. Henry Cecil Wright was born on February 10, 1888, and studied medicine at Manchester University, qualifying L.M.S.S.A. in 1913. After qualification he held resident appointments in hospitals in Macclesfield and elsewhere. Shortly after the first world war he settled in practice in Newcastle-upon-Tyne and was for many years in partnership with the late Dr. J. E. Basham. He soon built up a large practice and became very popular, for he was a good doctor of the old school and inspired confidence in his patients. One of the kindest and friendliest of men, he had a keen sense of humour and a genial, disarming smile. He was an active member of the British Medical Association and was elected to serve as chairman of the Newcastle Division in 1932-3. He was also an active member and secretary of the Medical Institute in Newcastle for many years. Dr. Wright took a great interest in football and cricket, especially the latter, which he played well himself in his younger days. Latterly he had taken up bowls. His passing has left a void which will be hard to fill and he will be missed by a host of friends and patients.—J. H. B.

Dr. JOHN L. GAMMIE, junior depute medical officer of health for the City of Edinburgh, died suddenly on August 30 at the age of 52. He studied medicine at Aberdeen University, graduating M.B., Ch.B. in 1926 and two years later obtaining the D.P.H. with distinction. After graduation he held house appointments at Aberdeen Royal Infirmary, Woodend Hospital, Aberdeen, and the Aberdeen City Fever Hospital, returning to Woodend Hospital in 1930 as senior resident medical officer after a period in general practice in Aberdeenshire. He joined the Edinburgh public health department in 1932 as senior medical officer and depute tuberculosis officer, and was appointed junior depute medical officer of health for the city in 1937. On the outbreak of the second world war he willingly undertook the duties of medical officer in charge of the Edinburgh civil defence casualty service. He was appointed, in 1946, a part-time lecturer in the department of public health and social medicine of the University of Edinburgh, and he also held the post of lecturer in health education to the Moray House Training College for Teachers. As depute medical officer of health he made a particular study of environmental hygiene and infectious disease control and was frequently consulted by family doctors throughout the city.

H. E. S. writes: The sudden death of John Gammie has come as a rude shock to his many friends. He was a man with outstanding gifts of mind, and his wide knowledge of medicine and of affairs in general, together with a pawky Aberdonian wit, made him a clear, informative, and interesting lecturer and speaker and a most agreeable and entertaining companion and colleague. To those who knew him best, however, he will always be remembered as a loyal friend who inspired feelings of affection and regard of an unusual degree and depth. His personal qualities were not always revealed on short acquaintance, but all who worked with him were quick to recognize his generous nature and kindness of heart. Not many, however, knew of the help and service he gave quietly and unobtrusively to those who came to him in trouble or difficulty. For them he never spared himself in time, thought, or material assistance, and not a few present in the large congregation gathered to pay their last respects must have looked back with deep gratitude to the help and guidance given them by John Gammie when things seemed dark and hopeless.

Two colleagues write: With the untimely death of John Gammie, Edinburgh has lost a well-known personality and his colleagues a good comrade. At first meeting John Gammie's brusque, abrupt manner may have been something of a barrier to closer acquaintance, but those who came into more frequent contact with him learnt to appreciate what lay under the surface—kindliness, friendliness, a sense of humour, and a willingness to help. In his professional work he applied to every problem clarity of insight and common sense, and though he was ready to listen to others his decisions were his own and he carried them out in a practical way with his feet firmly on the ground. As a university teacher he was a clear and interesting lecturer and was equally effective with a lay audience, especially an audience of young people, for John Gammie had the "common touch." His knowledge and experience were great, both in the clinical and in the administrative fields of public health, and his interest was not confined to his profession alone. He had a considerable appreciation of the arts, particularly of literature, and his gift of quotation from the poets often surprised his acquaintances. His colleagues will miss him, and their sympathy goes out in full measure to his wife and young son.

Medico-Legal

DEATH AFTER STABBING

HOSPITAL TREATMENT VINDICATED

A committee of inquiry has found that "exemplary" treatment was given at the Hull Royal Infirmary to Walter Beaumont, aged 27, after he had been stabbed by James Clinton, aged 21, a member of the U.S. Air Force. The Leeds Regional Hospital Board has accepted the committee's report and expressed full confidence in the Infirmary's medical and nursing staff.

On July 25 Clinton was convicted of the murder of Beaumont by stabbing him in the stomach. On August 21 the Court of Criminal Appeal quashed the conviction after exercising its power, rarely used, to hear fresh evidence.¹ Between the conviction and the appeal a doctor who had observed Beaumont's treatment in hospital communicated to Clinton's legal advisers his view that the bronchopneumonia from which Beaumont died resulted not from the stab wound but from the administration of tetracycline after the patient had shown himself to be intolerant to it, and from the injection of excessive amounts of fluid. At the appeal Dr. Keith Simpson, pathologist, London, and Mr. Guy Blackburn, surgeon, London, gave evidence in support of this view.

The Leeds Regional Hospital Board therefore set up a committee of inquiry, with three independent medical assessors, to inquire into Beaumont's case. The assessors were Professor J. H. Biggart, professor of pathology and dean of the faculty of medicine, Queen's University of Belfast, Professor J. Bruce, regius professor of clinical surgery, University of Edinburgh, and Dr. F. M. Parsons, assistant director of the Medical Research Council's surgical research unit, General Infirmary, Leeds. The following members of the medical staff from the Hull Royal Infirmary attended when the committee met on September 5: Mr. P. Walton, consultant surgeon, Mr. M. A. Morkos, surgical registrar, and Dr. A. J. Shillitoe, consultant pathologist.

The report of the medical assessors is as follows:

Report of Assessors

"At the invitation of the Leeds Regional Hospital Board, we attended an inquiry into the management and the circumstances connected with the death of Beaumont in Hull Infirmary on May 12, 1956. We were afforded every opportunity of perusing the case records, and statements of those

¹ *British Medical Journal*, September 1, p. 556.

concerned in the care of this patient, and of discussing all aspects of this patient's treatment and death with the appropriate medical attendants. We were greatly impressed by the frankness of those discussions, and the readiness with which all our questions were carefully and scrupulously answered. We also had the advantage of examining the material and the histological preparations pertaining to the autopsy. We consider, therefore, that all the relevant evidence was placed at our disposal.

"Before enunciating the observations we wish to make, we want to place on record our opinion that Beaumont's treatment at Hull Infirmary was exemplary, and in particular, we wish to pay a tribute to the care and devotion shown by the surgical registrar, Mr. Morkos, who, at Mr. Walton's request, moved into residence in the hospital and stayed there, scarcely leaving the patient's side from the time his post-operative state took an obviously serious course.

"From our scrutiny of the post-mortem material and of the case records, we are able to make the following observations:

"(1) There is histological evidence of severe damage to the kidney tubules (lower nephron nephrosis), which could only have originated soon after his injury, and was sufficient to have resulted in death.

"(2) The autopsy showed extensive pulmonary lesions. These were septic in type, and vascular and perivascular in situation, indicating that they had resulted from the transport of small infected clots. The lesions contained coccal organisms, and there is no evidence of the presence of fungi or yeasts such as are sometimes seen in patients treated with antibiotics.

"(3) Early meningitis was demonstrable at autopsy, and we regard this as further evidence of a blood-borne infection.

"(4) Death was hastened by the development of a catastrophic post-operative enteritis. We have carefully considered the relationship of this to the administration of terramycin. We are aware that this complication sometimes arises in patients treated with terramycin and other broad spectrum antibiotics, but in these cases the cause of enteritis can be established as due to antibiotic-resistant staphylococci rather than to any inherently poisonous property of the drugs. In the present case, the culture of the stools failed to yield staphylococci, and we must therefore regard the cause of the enteritis as an open question, since a similar and fulminating enteritis sometimes occurs after operations, especially on the abdomen, without any antibiotic therapy. In one view, the latter type of post-operative enteritis is the sequel to a period of low blood pressure, and the occurrence of hypotensive lesions in the kidney lends support to such a possible explanation in this case.

"(5) The use of terramycin initially in Beaumont's case was in our opinion not incorrect, and there is good evidence of its value in the treatment of peritonitis. Its withdrawal at the onset of diarrhoea was correct. By this time, the patient had developed a fulminating gastro-enteritis as well as chest lesions, and these did not respond to penicillin. It was possibly unwise of the resident surgical officer to resort again to terramycin; but since there was reasonable doubt about the cause of the enteritis, and there was reasonable doubt about the cause of the enteritis, and since the patient was gravely ill and febrile despite the administration of penicillin, the renewal of terramycin therapy was not stration of penicillin, the renewal of terramycin therapy was not unreasonable and certainly not blameworthy. In any event, the small quantity of terramycin which was then administered had no influence of any kind on the outcome of the case. We believe, in fact, that before the second course was started, the patient's state was irreversible.

"(6) It seems to us that the management of the fluid-electrolyte state should be considered in relation to three periods of the man's illness.

(a) In the pre-operative and operative period, the management of the fluid-electrolyte situation in our opinion was adequate.

(b) In the early post-operative phase, the control of the fluid therapy was appropriate.

(c) In the late post-operative period, following the development of severe enteritis complicated by serious renal impairment and by lung infection, a highly complicated biochemical disturbance developed. The fluid loss from the bowel was enormous and resulted in profound dehydration, one evidence of which, apart from the careful clinical observations of Mr. Morkos, was the concentration of haemoglobin in the blood (114%). As soon as possible Mr. Morkos enlisted the aid of the hospital biochemist, who thereafter performed daily estimations on which the day-to-day administration of fluids was based. The amount of fluid administered may appear

large to those unfamiliar with the management of severe gastro-enteritis or cholera, which this man's diarrhoea resembled. It was perhaps fortunate that Mr. Morkos had had some experience of the treatment of cholera, and had the courage to apply this experience in the management of this extremely difficult case. That the amount of fluid given was in no way excessive is borne out by the absence at autopsy of the usual findings of overhydration, as, for example, oedema of the lungs, fluid in the serous cavities, or generalized dropsy.

"It is our impression that Beaumont was on the point of death on the fifth post-operative day when, in view of the gravity of his condition, a surgeon of Mr. Walton's experience found it necessary to advise the police authorities to take a dying deposition. The fact that he survived for a further three days was due, in our opinion, to the energetic and competent measures adopted by the staff of the hospital. In the event, and in the light of all the evidence, however, this man's life was unsavable and his death was not in any way attributable to the treatment he received in hospital."

Full Vindication

The medical members of the Board present, after hearing the report of the assessors, endorsed it without reservation. In the opinion of the members present at the inquiry the report provided a full vindication of the staff of the Hull Royal Infirmary, and they requested that the following should be made known to the Board:

"(1) Whilst a patient at the Hull Royal Infirmary, the deceased man was treated by a medical team consisting of a consultant surgeon, a surgical registrar, a resident surgical officer, and a house-man. The direct responsibility for the patient at all times vested in the consultant surgeon. Three days before the patient died, the surgical registrar, a Fellow of the Royal College of Surgeons, voluntarily agreed to leave his home and family in Hull and to take up residence at the Infirmary in order that he could give the most constant and close attention to the patient, thus removing all onus of responsibility from the more junior members of the medical team.

"(2) In addition to the normal nursing staff on duty in the ward a special nurse was assigned to the patient, who was under constant nursing attention up to the time of his death."

Vital Statistics

Week Ending September 8

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 253, whooping-cough 2,315, diphtheria 4, measles 1,092, acute pneumonia 171, acute poliomyelitis 105, dysentery 330, paratyphoid fever 8, and typhoid fever 15.

Infectious Diseases

A further fall was reported in the incidence of infectious diseases in England and Wales during the week ending September 1. The decreases in the number of notifications included 484 for measles, from 1,866 to 1,382, 233 for whooping-cough, from 2,515 to 2,282, 75 for dysentery, from 379 to 304, 53 for acute poliomyelitis, from 177 to 124, and 27 for food-poisoning, from 247 to 220.

The largest falls in the incidence of measles were 56 in Staffordshire, from 76 to 20, 46 in Cornwall, from 111 to 65, and 44 in Norfolk, from 71 to 27. The largest decrease in the incidence of whooping-cough was 34 in Durham, from 110 to 76. Five cases of diphtheria were notified, being 4 more than in the preceding week. 246 cases of scarlet fever were notified, 1 more than in the preceding week, and there were no large fluctuations in the local returns.

The number of notifications of dysentery was the lowest for two years. The largest returns were Lancashire 59 (Liverpool C.B. 16), London 33, Yorkshire West Riding 33 (Leeds C.B. 14), and Middlesex 20.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 1 (No. 35) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Melanocyte-stimulating Hormone.—In a letter to the September 5 issue of the *Journal of the American Chemical Society* Professor C. H. LI and his colleagues at the hormone research laboratory at California University report the isolation of pure melanocyte-stimulating hormone (intermedin) from the posterior lobe of pigs' pituitary glands. They also report the hormone's structural formula: it is a peptide consisting of 18 amino-acids, with a minimum molecular weight of 2,177. In their formula, Professor Li and his colleagues point out, one sequence of seven amino-acids in it "also occurs, identically, in all the corticotrophins that have been studied hitherto." This, they suggest, in all probability explains the intrinsic melanocyte-stimulating activity of pure corticotrophin preparations. In the corticotrophin molecule, they continue, "this central sequence apparently acquires, by virtue of a different specific order of amino-acids on each side of it, an adrenal-stimulating activity as well."

25th Anniversary at Welsh National School of Medicine.—Next month the Welsh National School of Medicine is celebrating the 25th anniversary of the granting of its charter in 1931. This constituted the Welsh National School of Medicine, in its present form, as the clinical school of the University of Wales. On October 12 Professor JETHRO GOUGH, professor of pathology in the School and director of the Institute of Pathology, himself a past student of the School, will deliver the opening address of the session to the students. This is a break with tradition to mark the occasion, as the speaker is usually a visitor. In the evening there will be an anniversary dinner at the City Hall. On October 12 and 13 all the departments of the School and the preclinical departments at University College will be open to past students and visitors. Special exhibitions are being arranged in the departments. If any past students of the Welsh National School of Medicine wish to attend the dinner, and have not so far received an invitation, they should communicate at once with the Secretary of the School, Mr. F. DODSWORTH, at 34, Newport Road, Cardiff.

"Student's Guide to London."—The National Union of Students has produced a first-rate guide for the 10,000 new students arriving in London this year. A limited number of copies are available to others, at 2s. net, from the N.U.S., 3, Endsleigh Street, London, W.C.1. The guide gives advice on such practical topics as lodgings and travelling in London, how to make the money go round, vacation work, and where to find inexpensive food and entertainment, the latter ranging from a visit to the House of Commons, sport, or the theatre, to jazz and drinking clubs. Much else of value to the student—and his elders—is included, both serious and gay. Thanks to the generous support of advertisers, the guide is free to the new students for whom it is primarily intended.

Cruelty to Children.—The scale of operation in Britain of the National Society for the Prevention of Cruelty to the Children may not be generally appreciated. During the year ended February 29, 1956, the society dealt with 36,697 cases involving 98,277 children, of whom about 43% were under school age. The types of case were: neglect (22,097), assault or ill-treatment (3,624), moral danger and immoral offences (805), "beyond control" (524), abandonment (67), "exposure or causing to beg" (47), unregistered foster children (39); in addition aid or advice was sought in 9,494 cases. The society relatively seldom prosecuted: only 840 cases were prosecuted or brought before Juvenile Courts, whereas nearly 35,000 cases were dealt with by warning or advice. In its annual report the society draws attention to two problems of particular importance: the failure to report known cases, and the widespread existence of mental cruelty to children. "In almost every bad case which we handle,"

states the society, "it is borne in upon us that someone must have known what was happening but failed to speak and so connived at the continuance of sufferings which could have been prevented. To meet this worrying problem we proclaim as widely as possible that the society never divulges the names of its informants unless malice is proved." Mental cruelty is stated to pose probably the greatest current problem confronting those working for the happiness and welfare of children. Anyone knowing of a child who is being ill-used or neglected; or who is being denied necessary medical treatment through the negligence of its parents; or of a parent who is worried about any matter concerning his or her children and needs advice, is asked by the society to communicate with the director, N.S.P.C.C., Victory House, Leicester Square, London, W.C.2 (Telephone: Gerrard 2774), or with any of the society's local offices. All further steps are then taken by the society.

Queen's University, Belfast.—Dr. J. G. GIBSON, senior lecturer in psychiatry at the London University Institute of Psychiatry, has been appointed to the newly created Chair of Mental Health at Queen's University, Belfast. Dr. Gibson graduated M.B., B.Ch. at Belfast in 1942, proceeding M.D. in 1947. He obtained the M.R.C.P. (London) in 1949, and the D.P.M. (England) in 1954. Among his appointments he has held posts as assistant resident in psychiatry at the Massachusetts General Hospital, Boston, and teaching fellow in psychiatry at the Harvard Medical School. Dr. Gibson is also honorary consultant at the Bethlem Royal and Maudsley Hospitals. Dr. I. J. CARRÉ, medical registrar at the Children's Hospital, Birmingham, has been appointed to a lectureship in child health at Queen's University.

Chair of Pathology at Dalhousie.—Dr. W. A. TAYLOR, formerly lecturer in the department of pathology at Glasgow University, has been appointed to the Chair of Pathology at Dalhousie University, Halifax, Nova Scotia, and director of the pathology division of the Nova Scotia Department of Public Health. After graduating B.Sc. at Glasgow University with first-class honours in physiology in 1942, Dr. Taylor was elected to a Rockefeller studentship in America. On his way there he was torpedoed off Newfoundland and set ashore by a corvette at Halifax. In America he spent a year at Stanford University Medical School, San Francisco, and two years at Cornell University, New York. On his return to Glasgow in 1945 he graduated in medicine, and joined the staff of the university pathology department at the Western Infirmary, where he remained until March, 1955, when he left to become associate professor at Dalhousie.

Contact with Poland.—At the request of the Polish Ministry of Health the British Council has arranged for Sir ROBERT MACINTOSH, Nuffield Professor of Anaesthetics at Oxford, and Professor IAN AIRD, director of the surgical unit at the Postgraduate Medical School of London, to visit Poland next month. This is the first visit of its kind to Poland for some years. Sir Robert Macintosh will arrive there on October 6, after a three-weeks visit to Moscow at the invitation of the Medical Academy and the Soviet Ministry of Health, to be the guest of the Polish College of Surgeons until October 18. He will be joined by Professor Aird on October 19, and they will then lecture for ten days in Warsaw. An exhibition of British medical books and periodicals will be shown in Warsaw during their visit.

W.H.O. Regional Director for Europe.—Dr. P. J. J. VAN DE CALSEYDE, director-general of health at the Belgian Ministry of Health, was nominated by the World Health Organization's regional committee for Europe on September 12 for the office of regional director for Europe. This post fell vacant on the death of Dr. NORMAN D. BEGG last May.

Good-bye to the Sanitary Inspector.—For the last time sanitary inspectors met this week at their association's annual conference, this year at Bournemouth, under their old title.

By the Sanitary Inspectors (Change of Designation) Act, 1956, which took effect last month, their title has been changed to Public Health Inspector.

Memorial to James Bridie.—At the Glasgow Citizens' Theatre on September 17 Mr. J. B. PRIESTLEY unveiled a bronze plaque in memory of JAMES BRIDIE (Dr. O. H. MAJOR), the Glasgow physician and playwright, who founded the theatre. The ceremony was presided over by Dr. T. J. HONEYMAN, and the playwright's son, Dr. RONALD MAJOR, also a physician in Glasgow, proposed the vote of thanks.

Ciba Foundation.—Sir RUSSELL BRAIN, President of the Royal College of Physicians, has been appointed a trustee of the Ciba Foundation.

Visiting Professor at Birmingham.—Professor WALTER BAUER, Sterling professor of clinical medicine at Harvard, and physician-in-chief at the Massachusetts General Hospital, will be visiting professor of medicine at Birmingham University during October.

Dr. Nora Wattie, principal child welfare medical officer of Glasgow Corporation, was elected president of the Royal Sanitary Association of Scotland at the association's annual meeting in Montrose on September 17.

COMING EVENTS

Ministry of Supply.—Medical Services Exhibition, illustrating aspects of occupational health as applied at the Ministry's research and other establishments, will be held at the Pillar Hall, Board of Trade/Air Ministry Building, Whitehall, London, S.W.1, September 24–28, from 10 a.m. to 6 a.m.

Middlesex Hospital Medical School.—Annual dinner for past and present students will be on September 28 at 7 for 7.30 p.m. at the Savoy Hotel. Mr. F. W. ROQUES will be in the chair. The usual "Refresher Course" for past students will be held from September 28 to 30. Details from the medical school secretary, Middlesex Hospital, London, W.1.

Royal College of Obstetricians and Gynaecologists.—An admission ceremony will be held on September 28 at 3.30 p.m. in the College House, 58, Queen Anne Street, London, W.1, when Viscount NUFFIELD and Lord WEEKS (formerly Sir Ronald Weeks) will be admitted to the Honorary Fellowship of the College.

National Smoke Abatement Society.—Annual conference at Southport, October 3–5. Sir HUGH BEAVER will deliver the Des Vœux memorial lecture on "Clean Air: The Next Step." Details from the society, Palace Chambers, Bridge Street, London, S.W.1.

Mongolism.—A meeting to discuss current research on mongolism will be held at the Fountain Hospital, Tooting Grove, London, S.W.17, on October 3 at 5.30 p.m. The speakers will be Professor L. S. PENROSE, F.R.S., Dr. C. O. CARTER, and Dr. U. MTTWOCH. All interested are invited.

Association of Clinical Pathologists.—Fifty-seventh general meeting will be held at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, October 4–6. On October 6 there will be a joint meeting with the Association of Clinical Biochemists. The dinner (25s.) will take place on October 5. Details from Dr. J. N. CUMINGS, National Hospital, Queen Square, London, W.C.1.

London County Medical Society.—A meeting of the Society will be held at 5.30 p.m. on October 4 at the County Hall, Westminster Bridge, London, S.E.1. The society will be addressed by Sir CLEMENT PRICE THOMAS, and his subject will be "Carcinoma of the Lung." Members of the Association of Industrial Medical Officers, the Middlesex County Medical Society, and members of the London Divisions of the B.M.A. are invited.

Institute of Diseases of the Chest.—Clinical demonstrations arranged will be held in the lecture room of the Insti-

tute, Brompton, London, S.W.3, on Fridays at 5 p.m., from October 5 to December 14. Open, without fee, to medical practitioners.

Yorkshire Association of Graduates of Glasgow University.—Annual dinner at the Great Northern Hotel, Leeds, October 6 at 7.30 p.m. Details from Mr. J. WISHART, F.R.C.S.Ed., 33, Manor Row, Bradford, 1.

NEW ISSUES

Archives of Disease in Childhood.—The new issue (Vol. 31, No. 158) is now available. The contents include:

FREE DIETS IN THE TREATMENT OF DIABETIC CHILDREN. Constance C. Forsyth and W. W. Payne.
A CLINICAL AND BIOCHEMICAL STUDY OF GALACTOSAEMIA. G. M. Komtrower, V. Schwarz, A. Holzel, and L. Goldberg.
ADDISON'S DISEASE IN INFANCY. Alan Williams and M. J. Robinson.
FIBROCYSTIC DISEASE OF THE PANCREAS IN AN ADOLESCENT WITH MINIMAL PULMONARY INVOLVEMENT. R. C. King.
ACUTE PANCREATITIS IN CHILDHOOD. Edwin Haigh.
SYMPTOMATIC PANCREATIC HETEROTOPIA OF THE PYLORUS ASSOCIATED WITH BILATERAL RENAL CORTICAL NECROSIS IN AN INFANT. R. J. Kernohan and J. Edgar Morison.
PATENT DUCTUS ARTERIOSUS. J. D. Hay and O. C. Ward.
HYDROCEPHALUS ASSOCIATED WITH OBLITERATION OF THE LONGITUDINAL SINUS. J. L. Emery and R. B. Zachary.
CONGENITAL FACTOR VII DEFICIENCY. H. B. W. Greig, H. C. Falcke, M. Simon, and H. Cohen.
HAEMOLYTIC DISEASE OF THE NEWBORN DUE TO ANTI-DUFFY (Fy^a). J. B. Baker, David Grewar, Marion Lewis, Hiroko Ayukawa, and Bruce Chown.
THE INTELLIGENCE OF CHILDREN WITH CLEFT PALATE. R. S. Illingworth and L. B. Birch.
A PATHOLOGICAL STUDY OF FIVE CASES OF PYELONEPHRITIS IN THE NEWBORN. K. A. Porter and M. McC. Giles.
THE MORBID ANATOMY OF INFANTILE MALNUTRITION IN CAPE TOWN. J. A. H. Campbell.
ACUTE NECROTISING RHEUMATIC ARTERITIS IN A CHILD. A. T. Sandison.
LEAD POISONING IN CHILDHOOD TREATED BY THE SUBCUTANEOUS ADMINISTRATION OF A CHELATING AGENT. N. V. O'Donoghue.
A CASE OF ATRESIA OF THE LARYNX. N. E. Rankin and I. R. Mendelson.
INTRATHECAL ISONIAZID IN TUBERCULOUS MENINGITIS. P. N. Swift.
BOOK REVIEWS.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, September 24

LONDON UNIVERSITY.—At Royal Free Hospital School of Medicine, 5.15 p.m., special university lecture in physiology by Professor J. H. Comroe (Pennsylvania): Pulmonary Function: Tests and Interpretation.

Tuesday, September 25

LONDON UNIVERSITY.—At Royal Free Hospital School of Medicine, 5.15 p.m., special university lecture in physiology by Professor J. H. Comroe (Pennsylvania): Pulmonary Function: Tests and Interpretation.

Wednesday, September 26

HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m., Professor Hans Selye (Montreal): Recent Progress in the Study of Stress.

Thursday, September 27

ROYAL NORTHERN HOSPITAL.—2.45 p.m., Dr. E. C. O. Jewsbury: General Practitioner and Epilepsy.
SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Horton Hospital, Epsom, 8 p.m., Freud Centenary Meeting. Address by Dr. E. G. Glover.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cantwell.—On September 7, 1956, at the Hammersmith Hospital, London, W., to Patricia, wife of Dr. R. J. Cantwell, a daughter—Shirley Margaret. Cleary.—On April 11, 1956, at the Mater Private Hospital, Sydney, Australia, to Thérèse (formerly Dunne), wife of Michael F. Cleary, M.B., B.Ch., B.A.O., a daughter—Pauline Mary Thérèse.
Price.—On September 7, 1956, at City Hospital, St. Albans, Herts, to Elizabeth (formerly Jones), wife of Dr. John Harding Price, a son.
Swan.—On September 11, 1956, at Jessop Hospital for Women, Sheffield, to Harold and Elisabeth Swan, a son.

DEATHS

Fitch.—On September 2, 1956, at Ambleside, Arthur Alfred Fitch, M.R.C.S., L.R.C.P., aged 69.
Leathes.—On September 14, at Montreux, Switzerland, John Beresford Leathes D.Sc., M.B., F.R.C.P., F.R.C.S., F.R.S., aged 91.
Sinnott.—On September 4, 1956, Malcolm Bernard Gathorne Sinnott, M.B., Ch.B., D.P.H., of Wayside, Barkerend Road, Bradford.
Waterhouse.—On September 1, 1956, at Oxford, Amyas Theodore Waterhouse, M.D., of Boar's Hill Hotel, Oxford, aged 83.
Welsh.—On September 6, 1956, at 20, Bellevue Road, Prestwick, Ayrshire, James Kennedy Welsh, M.B., Ch.B., late of 5, Mayfield Gardens, Edinburgh.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Threatened Abortion and the Foetus

Q.—Have any studies been carried out on the morbidity and mortality of infants surviving threatened abortion compared with those of infants whose intrauterine life has been uneventful? Do the former group show a higher incidence of congenital malformations, mental defects, or neonatal morbidity and mortality?

A.—There is a voluminous literature on this subject, but all the statistics are confused if only because different standards are taken for the diagnosis of threatened abortion. Thus, estimates of the frequency of this complication vary from 4% to 26% of all pregnancies, and figures can be selected to substantiate any thesis. A general conclusion, however, is that the chance of a deformed child is not increased in pregnancies which continue after abortion has threatened, and the treatment of threatened abortion has not raised the incidence of malformations—which again is variously estimated as occurring amongst 0.47% to 4.9% of babies born after 28 weeks, according to different classifications.

As regards other foetal risks, it might be expected that the incidence of placenta praevia, accidental antepartum haemorrhage, and premature labour would be increased in cases of threatened abortion. Here again there is no proof, and one study shows that the risk of premature labour is no higher than 2%—which is lower than the accepted overall incidence. By and large it may be concluded that when threatened abortion is a sign of foetal abnormality, and when the amount of placental separation is enough to damage the foetus, the pregnancy does not continue whatever treatment is applied. The very fact that the pregnancy survives the disturbance is a sign that all is well, and the chance of a normal healthy child resulting is said to be not less than 98.5%.

Immunization in Pregnancy

Q.—(1) What immunization is advised for a pregnant woman going to the Tropics (Sumatra)? (2) If she delays her journey until after her child is born, what immunization will the infant require? (3) Are there any strong reasons for advising the latter course, on the grounds that immunization might harm the foetus in utero?

A.—A pregnant woman proceeding to Sumatra would legally be required to be protected against smallpox and to have a valid certificate of vaccination issued within the preceding three years. Such protection is also required for persons of all ages, so that a newly born child would require vaccination before proceeding overseas. There are no strong reasons for advising postponement of the journey on the grounds that immunization against smallpox might harm the foetus in utero.

Though not legally enforced, persons proceeding overseas are advised in their own interest to be protected against enteric fever. There is no evidence that inoculation of a pregnant woman with T.A.B. is likely to harm the foetus, but if it is feared that this might happen no immunization difficulties would arise from postponing the inoculation. It is inadvisable to give enteric vaccination to those aged less than one year.

Protection against yellow fever is not required for those entering Sumatra, but, if any part of tropical Africa, or other

region in which yellow fever is endemic, is to be visited en route, yellow fever vaccination would be legally required. In that case infants and persons of all ages would have to be in possession of a valid certificate of yellow fever vaccination; again there is no available evidence that vaccination of a pregnant woman would harm the foetus in utero.

There is, however, always a slight risk that any illness or fever no matter how mild or transient might adversely affect pregnancy in the early months, and this risk, though minimal, would be more particularly expected in primary vaccination against smallpox. If the person concerned is unwilling to accept the risk it would be necessary to postpone the vaccinations and therefore the journey until after the first few months of pregnancy.

Crops of Styes

Q.—What treatment is advised for a child with recurrent styes who is sensitive to penicillin eye ointment? How can further attacks be prevented?

A.—Children who are otherwise in excellent health may suffer from a crop of styes without any evident provocation, just as they may from time to time break out into successive boils on other parts of the body. In most cases the crop will spontaneously come to an end, and all the sooner if over-treatment of a particular stye is avoided. Hot fomentations, incisions, and plucking of eyelashes are all to be deplored; nor are antibiotics and elaborate chemotherapy needed. When once a stye has begun, it will run its course in a few days, and seldom needs any treatment except gentle cleansing away of any discharge that may issue from it. If styes keep on recurring in spite of good general health, then a course of antistaphylococcal vaccine may be tried. It is useless to pretend that this remedy always succeeds, but results have been encouraging. Stock vaccine is generally considered to be as effective as an autogenous preparation.

Diet before Glucose Tolerance Test

Q.—When a patient is found to be suffering from glycosuria, it is nearly always necessary to ask for a glucose tolerance test. It is said to be important that the patient should not restrict his diet before the test. Why should this be so?

A.—It is not nearly always necessary to ask for a glucose tolerance test when a patient is found to be suffering from glycosuria. A glucose tolerance test is very rarely required for the diagnosis of diabetes.¹ It has been known for nearly a century that a reduced carbohydrate diet impairs carbohydrate tolerance in dogs. If a glucose tolerance test is performed while the patient is on a low carbohydrate diet the test will reveal impaired glucose tolerance whether diabetes is present or not. The precise mechanism of this is still a subject of research.

¹ *Clinical Pathology in General Practice*, 1955. B.M.A., London.

Salt-water Swimming-pool

Q.—I prefer swimming in salt water, so I propose to add salt to a private swimming-pool to make the water as near sea-water as possible. What variety of salt and what concentration are advised? Will the salt prevent algae growing and mosquito larvae breeding?

A.—The simulation of sea-water is a most difficult task: this will be appreciated when it is realized that out of some eighty-odd elements known to man over thirty have been isolated from sea-water samples. The commoner salts found in water (in grammes per litre) are: sodium chloride (27), magnesium chloride (3.8), magnesium sulphate (1.6), calcium sulphate (1.25), potassium sulphate (0.8), calcium carbonate (0.12), and magnesium bromide (0.076). The salinity of average sea-water varies from about 4 to 6%. In Britain (for example, at Preston Pans, Scotland) sea-water is evaporated

for commercial purposes. If contact were made with a commercial chemical firm, no doubt crude sea-water salt could be obtained. The salt would, of course, be lost each time the pool was drained.

Green algae occur only in fresh water. These can be dealt with by copper sulphate. Sea-water is subject to infestation by blue-black algae, which will not respond to the application of copper sulphate. The blue-black variety are very tenacious and are difficult to remove even by physical means. The growth of such algae and the breeding of mosquito larvae could best be tackled by the fitting of a suitable circulating filtering and chlorinating plant, preferably one making use of break-point chlorination. Such a plant will almost certainly be necessary if the water is to remain sweet and usable, as, apart from the problems mentioned by the questioner, other difficulties will be met, such as the presence of spores which require free chlorine for their control.

Severe Reaction to Penicillin

Q.—Following an injection of 900,000 units of procaine penicillin an Indian child of 10 months with early bronchopneumonia developed urticaria of the legs the same evening. By the next day the legs were tensely oedematous and purpuric, and urticaria was still present. The condition deteriorated, and eventually both feet developed dry gangrene and fell off at the ankle-joints. Two other infants of about the same age received the same dose of procaine penicillin from the same vial without mishap. What is the explanation of this extreme reaction? Is there any treatment that might help in such a case? Have similar cases been recorded in the literature?

A.—I do not know of any such very severe reaction to procaine penicillin, but certainly similar reactions have been recorded in the literature. Harkavy¹ mentions necrotizing purpuric lesions as a sensitivity response to penicillin. Many others have recorded their belief that polyarteritis nodosa can occur as a sensitivity reaction, and Schmid² records gangrene which was apparently associated with neither purpura nor polyarteritis nodosa. It seems very probable that this was a sensitivity response, and it is just possible that treatment at the stage when urticaria only was seen might have averted the eventual gangrene.

Medical Treatment of Cholecystitis

Q.—What dietary and other treatment is recommended in elderly patients with cholecystitis for whom operation is contraindicated? Have there been any recent advances in the medical management of such cases?

A.—An acute cholecystitis may be treated initially medically, and, indeed, there is one school that believes this to be the method of choice. The patient is put to bed, pethidine and atropine are given for pain, constant gastric suction may be necessary for repeated vomiting, and hydration is maintained, if necessary, by intravenous fluids. Antibiotics may not be of much benefit in the early stages, for acute cholecystitis so often results from chemical irritation due to bile retained when the cystic duct is obstructed by a gallstone. Bacterial invasion, however, is apt to follow, and tetracyclines should be given in full doses. If symptoms fail to subside in 2 to 3 days, if the right upper quadrant mass increases, and if the white blood count exceeds 20,000 per c.mm. gangrene and perforation are imminent. In spite of age and poor general condition operation should then be seriously considered, as the mortality from these complications is about 50%.

There have been few advances in the medical management of chronic cholecystitis, and when symptoms are sufficiently severe and cholecystography confirms the condition the gall-bladder should be removed. Medical measures include correction of obesity and a bland diet avoiding heavy, greasy meals and cooked fats. The functional state of the

gall-bladder determines dietary fat intake; if it is non-functioning, a low-fat diet is advisable. If cholecystography, however, demonstrates atony, a normal-fat diet can be recommended and even reinforced by such cholagogues as olive oil, 1 fl. oz. (28 ml.) three times a day, or magnesium sulphate, 60 gr. (4 g.) each morning.

Septic Tanks

Q.—On what principles do septic tanks work? Have septic tanks been superseded in rural areas where there are no sewers?

A.—The purification of sewage in a septic tank is due to the action of anaerobic bacteria which attack the sewage and break down the proteins. The process is referred to as anaerobic liquefaction and is followed by aerobic nitrification, in which the nitrogen-containing by-products of the protein breakdown are converted into harmless nitrites and nitrates. This second process is carried out by passing the septic tank effluent over a filter consisting of broken stones. The method has not been superseded in rural areas.

Exclusion of Sugar from Diets for Obesity

Q.—Why is sugar excluded from diets for obesity? I was taught that it burned up the fat.

A.—Sugar as such is usually excluded from reducing diets because of its high calorie value in relation to its volume (stomach-filling quality). Other carbohydrate foods, such as vegetables, with relatively more bulk than calorie value are allowed, the carbohydrate in them being turned to sugar by the digestive processes. This amount of sugar is enough to play its metabolic part in the burning up of the surplus fat of obese persons.

NOTES AND COMMENTS

Diets for Coeliac Disease and Steatorrhoea.—Dr. L. H. LAMPITT, D.Sc. (Director and Chief Chemist, J. Lyons and Company Ltd.), writes: Our attention has been drawn to the statement in the *British Medical Journal* on diets for coeliac disease and steatorrhoea ("Any Questions?" April 21, p. 937), and in particular to the last paragraph of that statement, which reads: "Only some proprietary foods are suitable for inclusion in the diet. The following are among those known to be gluten-free: . . ." The list which follows concludes with a reference to two brands of ice-cream, from which we think the assumption may readily be that other ice-creams are not or might not be suitable for inclusion in a coeliac diet. We write to inform you that our own ice-cream is entirely free from gluten, and we therefore ask you to correct your statement by including also Lyons's ice-cream.

Corrections.—We regret that Dr. C. B. L. Hart's initials were wrongly printed in the list of references on p. 568 in the *Journal* of September 8.

In the Educational Number, under "Medical Service of the L.C.C." (September 1, p. 536), two erroneous figures appeared in the scales of salaries for medical officers. The maximum of the higher salary scale for divisional medical officers of the London County Council is £2,270 (not £2,370), and for principal medical officers and psychiatrist (whole-time) it is also £2,270 (not £2,570). It would also be more accurate to speak of a deputy divisional medical officer as "serving" in a division instead of "living" in it.

AN ASSOCIATION BETWEEN BLOOD GROUP A AND PERNICIOUS ANAEMIA

A COLLECTIVE SERIES FROM A NUMBER OF CENTRES*

For several years studies on pernicious anaemia have been in progress at the centres contributing to this report. The nature and purposes of the studies vary, but in all of them the ABO blood groups of the patients have been determined. Realizing that with so rare a disease it would be unlikely that any single centre could obtain enough data within any reasonable time for testing the existence of blood-group associations, we decided to compare our data and pool the results. This was done nearly a year ago, when we discovered that the combined data pointed fairly strongly to a higher incidence of pernicious anaemia in persons of group A than in those of group O. Though we had hoped to build up a larger total, we think that a brief interim account should now be given, setting out the evidence for the association with blood group A and postponing a more detailed analysis till later. It is to be hoped that others will be able to supplement the data and either confirm or disprove a finding for which, however, the evidence is tolerably strong.

It is interesting that Buchanan and Higley (1921) gave results for no fewer than 457 cases of pernicious anaemia. In retrospect the percentage frequencies of O and A—41.4 and 44.2 respectively—do suggest an excess of group A. Their own statement covering all the diseases studied was, however: "There is no relationship between blood groups and any disease in which sufficient data are available to justify a conclusion."

Results

The basic data are given in Table I. In London and Glasgow there seemed to be large differences between different hospitals. This is very striking if the figures for the Southern General Hospital and the Royal Infirmary at Glasgow are compared. Lest real heterogeneity should be obscured, the data from hospitals in these areas have been

* This report is an analysis of studies made by the following workers: I. Aird, H. H. Bental, and J. Bingham (Department of Surgery, Postgraduate Medical School of London, Hammersmith Hospital); E. K. Blackburn, Mary S. Mackay, and H. T. Swan (Department of Haematology, Royal Infirmary, Sheffield); Sheila T. Callender and M. A. Denborough (Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford); E. H. Hemmsted (Royal Berkshire Hospital, Reading); D. P. Mollin, Barbara Anderson, John Selwyn (Department of Haematology, Postgraduate Medical School of London); D. N. Phear and G. A. Gresham (Department of Pathology, Addenbrooke's Hospital and University of Cambridge); Joan S. Sneath (Blood Group Research Unit, Lister Institute, London); C. C. Ungley (Royal Victoria Infirmary, Newcastle); John Wallace (Western Scotland Blood Transfusion Service, Glasgow); J. S. Adams (Department of Medicine, Royal Infirmary, Glasgow); and J. Buchanan and G. H. Shaw (Southern General Hospital, Glasgow). The data supplied have been analysed by J. A. Fraser Roberts (Burden Mental Research Department, Stoke Park Colony, Bristol, and London School of Hygiene and Tropical Medicine).

kept separate so far as possible. In London the fairly large series for Hammersmith and the Kingston General Hospital are both high in A, the remainder showing no excess. The remainder consist of several very small series, which have been added together. Seven results from Birmingham, which has very much the same ABO frequencies as London, have also been added.

Except for Sheffield the control series used have all been described in previous publications: those for London and Newcastle by Aird, Bental, Mehigan, and Roberts (1954); for Oxford by McConnell, Pyke, and Roberts (1956); for

TABLE I.—Basic Data

	Pernicious Anaemia				Controls			
	O	A	B	AB	O	A	B	AB
London:					4,578	4,219	890	313
Hammersmith . . .	48	75	7	4				
Kingston . . .	23	42	1	2				
Composite* . . .	19	18	4	1				
Oxford . . .	112	120	18	8	2,888	2,839	557	208
Cambridge . . .	51	49	8	2	1,571	1,501	255	111
Sheffield . . .	47	58	10	8	1,451	1,318	249	93
Newcastle . . .	55	45	7	2	6,598	5,261	1,321	392
Glasgow:					3,177	1,906	637	178
Southern General . . .	63	35	9	3				
Royal Infirmary . . .	72	61	22	5				
Total . . .	490	503	86	35				

* This composite number includes 7 patients obtained from the records of Birmingham United Hospitals in the course of the survey of another disease, and the remainder of the group comprise 35 patients suffering from pernicious anaemia who have presented, since the collection of data was begun, at Balham Hospital, the Central Middlesex Hospital, the North Middlesex Hospital and Whips Cross Hospital.

TABLE II.—Summary of Group Frequencies in Patients and Controls (including Copenhagen)

	Pernicious Anaemia		Corresponding Weighted Controls (%)
	No.	%	
O	534	43.6	47.2
A	550	44.9	40.3
B	100	8.2	9.3
AB	41	3.3	3.2
Total	1,225		

Cambridge by Bennett and Walker (1956); for Glasgow by Peebles Brown, Melrose, and Wallace (1956). The control series for Sheffield was kindly provided by the Nuffield Blood Group Centre of the Royal Anthropological Institute; it is based on a count of consecutively registered blood donors.

For the analysis we have added a series of 111 cases from Copenhagen, as recorded by Køster, Sindrup, and Seale (1955). It is useful to be able to include additional published series, but in this instance it is especially important that the Copenhagen figures should be added, because they lower the significance of our finding. The Copenhagen figures

for pernicious anaemia are: O, 44; A, 47; B, 14; AB, 6; and for the corresponding controls: O, 5,804; A, 6,299; B, 1,557; AB, 644.

A brief summary of the findings is given in Table II. The percentage group frequencies for the controls are based on figures weighted according to the numbers of patients drawn from each area. It will be seen that in the disease series as compared with the controls A is increased and O and B are both reduced, though, of course, the number with B is very small.

The method of analysis is that of Woolf (1955). It is rather similar to that used by Aird *et al.* (1954), but the work is carried out in terms of relative incidences instead of differences in proportions. It is natural to think of diseases in terms of incidence, and the results come out in a form which has a direct and simple meaning. For example, from Table I, the Sheffield results show 47 with O and 58 with A in the disease series, compared with 1,451 and 1,318 respectively in the controls. Thus the relative incidence of pernicious anaemia in persons of group A, as compared with persons of group O, is simply $(58 \times 1,451) \div (47 \times 1,318) = 1.3586$. Woolf's method also has the advantage that series drawn from populations with very different gene frequencies can readily be combined. When such differences are not very large, as in this country, the two methods give closely similar results, but this would not necessarily be so if data from different parts of the world were being compared. The method of combining areas in the analysis is the same.

Table III gives the relative incidence and χ^2 for groups A and O.

TABLE III.—Relative Incidence of Pernicious Anaemia in Persons of Group A Compared with its Incidence in Persons of Group O

	Relative Incidence	χ^2
London:		
Hammersmith	1.70	8.05
Kingston	1.98	6.90
Composite	1.03	0.01
Oxford	1.09	0.41
Cambridge	1.01	0.00
Sheffield	1.36	2.35
Newcastle	1.03	0.02
Glasgow:		
Southern General ..	0.93	0.13
Royal Infirmary ..	1.41	3.83
Copenhagen	0.98	0.01
		21.71

The combined weighted relative mean incidence of pernicious anaemia in persons of group A is 1.20 compared with 1 in group O. The total χ^2 of 21.71 is partitioned as follows:

	D. of F.	χ^2	P
Difference from unity	1	8.84	0.0029
Heterogeneity	9	12.87	0.17

Thus the probability of getting so great a departure from equality by chance is 1/340.

There is no evidence of any heterogeneity. Although the results look so different for the different series, ranging from an incidence in Group A at Kingston Hospital which is practically double that in group O to an actual slight excess in group O at the Southern General Hospital, Glasgow, and also at Copenhagen, such fluctuations are only to be expected with samples of this size.

Group A is also increased as against group B. If A is compared with O and B added together, the analysis shows:

	D. of F.	χ^2	P
Difference from unity	1	10.63	0.0011
Heterogeneity	9	15.28	0.087
Total	10	25.91	

The probability of getting so great a difference by chance is thus reduced to 1/900, and once again the 10 areas are not significantly heterogeneous at the 5% level.

Further analysis must await more detailed comparisons, we hope on larger numbers. For the moment we simply give

in Table IV a brief comparison by sexes, which shows that the excess of A appears in both. This refers to the British data only, as the Copenhagen figures were not broken down by sex. The differences in the control figures are due to the differing proportion of men and women at the various centres.

TABLE IV.—Comparison of Sexes. Totals for British Series

	Men			Women		
	Pernicious Anaemia		Corresponding Weighted Controls	Pernicious Anaemia		Corresponding Weighted Controls
	No.	%		No.	%	
O	167	42.7	47.4	323	44.7	48.0
A	180	46.0	40.4	323	44.7	39.7
B	34	8.7	9.0	52	7.2	9.2
AB	10	2.6	3.1	25	3.4	3.1
Total	391			723		

Summary

The combination of data from a number of centres shows with fairly high significance that pernicious anaemia is commoner in persons of Group A than in persons of Group O, and also perhaps, though the numbers are small, than in persons of group B. The greater incidence in group A appears in both sexes.

One of the authors (J. Bingham) has been in receipt of a personal grant and a grant for secretarial expenses from the British Empire Cancer Campaign. The Glasgow contributors wish to acknowledge the help they received from Professor L. J. Davis, Glasgow Royal Infirmary, and from Dr. E. G. Oastler and Dr. L. D. W. Scott, Southern General Hospital, Glasgow, and wish to thank them for access to patients in these two institutions. They also wish to acknowledge the assistance they received from Dr. I. A. Cook, Southern General Hospital, Glasgow.

In the recently published Annual Report of the General Board of Control for Scotland for the year 1955 (H.M.S.O., price 1s. 6d.), it is stated that more people are seeking psychiatric help at an earlier stage of mental illness. During 1955 the total number of patients under treatment for mental illness in Scotland was 21,242, 80 fewer than at the end of 1954, but the number admitted to hospital was 9,168, 657 more than in 1954. Of that number 2,583 were certified patients and 6,585 were voluntary patients, the latter figure being an increase of 723 over the previous year. On the other hand, the number of discharges both of certified and of voluntary patients increased substantially, the figures being 1,481 and 5,718 respectively. 241 patients were allowed out on probation from mental hospitals during the year: of these, 123 were discharged at the end of their probation period, 95 were sent back to institutions, 22 were transferred to guardianship in private dwellings, and 3 died. Seven deaths occurred from suicide among hospital patients and 52 died as a result of accidents. The total number of certified mental defectives was 8,065, or 207 more than at the end of 1954. Of that number 5,513 were patients in institutions and 2,552 were under guardianship. The Board comments that all but one of the mental hospitals in Scotland were built more than 50 years ago, but much is being done to make these institutions more cheerful.

ABO BLOOD GROUPS AND SECRETOR CHARACTER IN DUODENAL ULCER

POPULATION AND SIBSHIP STUDIES

PART I. ABO BLOOD GROUPS IN DUODENAL ULCER

In a previous paper (Clarke *et al.*, 1955) we showed in a survey of 1,665 peptic ulcer cases drawn from three Liverpool hospitals that there was a great increase in blood group O in patients with duodenal ulcer compared with controls; in gastric ulcer, on the other hand, the ABO distribution was normal. The investigations had been prompted by the earlier paper of Aird *et al.* (1954), which demonstrated, in three other English centres, a marked increase in blood group O in both duodenal and gastric ulcer compared with controls. The high frequency of group O in peptic ulcer has also been reported by workers in Portugal (Lessa and Alarcão, 1949), Scotland (Peebles Brown *et al.*, 1956), Denmark (Køster *et al.*, 1955), Norway (Westlund and Heistø, 1955), and the U.S.A. (Buckwalter *et al.*, 1956; Mayr and Diamond, 1956).

Our next interest in the matter was to consider whether this association between group O and duodenal ulcer was causal—that is, due to a direct or pleiotropic effect of the O gene—or, alternatively, coincidental. Penrose (1939) pointed out that because a blood group appeared to be associated with a disease a causal connection should not necessarily be assumed. He instanced the finding of Henwerden and Boele-Nijland (1930) in Holland, in which an apparent association between dark hair and blood group B was due simply to the presence of a racial group (in this case Dutch East Indian) in the general student population being investigated. Penrose therefore suggested that we should carry out a study of the blood groups of duodenal ulcer patients and their sibs, the main point being to obtain a control which could not be criticized on the ground that it was not from the same stratum of the population as the ulcer patients. In all previous surveys, our own included, the controls had either been blood donors or hospital patients with other diseases. In an analysis of sibships such as we have carried out the unaffected sibs act as controls and any question of racial stratification is avoided. Furthermore, Penrose suggested that, if possession of blood group O were indeed a cause of duodenal ulcer, the association should show up more clearly in sibships, where

variability due to differences in environment and genetic constitution is reduced compared with the general population.

Methods

Between 1954 and 1956 293 sibships have been collected. The propositi were either obtained from hospital records or referred to us by general practitioners at the request of the local Research Committee of the College of General Practitioners. In every case an accurate diagnosis had been made, the clinical findings being confirmed either radiologically or at operation.

The sibs were obtained through the propositi and were interviewed in order to assess their duodenal ulcer status and ABO blood group. Where there was doubt about the scoring an x-ray examination of the gastro-intestinal tract was carried out if possible, but there remain a few sibs in whom the diagnosis rests on the history only.

The sibs were scored as follows: 1=no dyspepsia; 2=atypical dyspepsia not suggestive of ulcer; 3=typical symptoms of ulcer; 4=a firm radiological diagnosis of ulcer; and 5=macroscopic evidence of ulcer. For the purpose of analysis 1 and 2 have been considered as "no ulcer," and 3, 4, and 5 as "ulcer." The ABO blood grouping was done by the macroscopic slide technique, using potent anti-A and anti-B sera.

The sibship data are too extensive to be given in full in this paper, but a selected sample is shown in Table I. The full data will be supplied on request to anyone wishing to use them, and a copy has been deposited in the archives of the Galton Laboratory, University College, London. It will be seen that secretor character is also given in Table I; this is dealt with in Part II.

TABLE I.—Selected Sample of Sib Data

* Twins.

In this country about 78% of the population are secretors and 22% non-secretors, the percentages being the same in each of the ABO blood groups. Race and Sanger (1950) pointed out the marked biological difference between those people who do and those who do not secrete their antigens, and suggested that there might be selective differences between them. It occurred to one of us (Sheppard, 1953) that if this were so the differences might be particularly important in diseases of the gastro-intestinal tract, as the concentration of antigen is particularly high in saliva and gastric juice. We therefore decided to investigate the secretor character of duodenal ulcer patients, and the findings have been compared with two types of control. Firstly, we have obtained a series of unrelated duodenal ulcer cases and compared their secretor character with controls taken from the general population. Secondly, we have investigated the secretor character of the individuals in the sibships referred to in Part I.

Method of Collection of Material

All secretor tests were carried out by one of us (R. B. McC.) on saliva, specimens being obtained from 514 patients from four hospitals in the Liverpool region. The clinical diagnosis of duodenal ulcer was always confirmed, either by macroscopic or by definite radiological evidence. The control series consisted of students, soldiers, and nurses. In the sibships the method of collection of the individuals was as described in Part I. The two investigations are not completely independent, as 189 *propositi* of the sibships are also included in the series of 514 unrelated patients.

Technique of Secretor Tests

The tests were carried out on specimens of saliva which had been placed in a boiling-water bath for ten minutes within one hour of collection and then stored frozen solid. The technique used was of an agglutination-inhibition type in which dilutions of saliva were mixed with antiserum and then the appropriate red cells added. In non-secretors the antiserum is not affected and agglutination takes place.

In the early part of the investigation the specimens of saliva of individuals of groups A and B were tested with anti-A and anti-B sera respectively, and eel serum was used for testing the saliva of those of group O. It was found, however, that eel serum is an unsatisfactory anti-H, as the saliva of an appreciable number of secretors (at least 10%) contains so little of the H-substance which inhibits eel serum that it can be detected (Ceppellini, 1955a) only by using three volumes of neat saliva to one volume of eel serum. Some group O persons were therefore erroneously scored as non-secretors because equal volumes of saliva dilutions and eel serum were used in our technique (see Table VI).

A study was therefore made with an extract of the seeds of *Ulex europaeus* to assess its value as a source of anti-H. The investigations confirmed the opinion of Boyd and Shapleigh (1954) that a *Ulex* extract is suitable for testing the secretor character not only of group O persons but also those of groups A, B, and AB. Thus specimens of saliva from 205 people of groups A, B, and AB were tested with a *Ulex* extract as well as with anti-A and anti-B sera, and all those containing A- or B-substance were found also to contain a significant titre of the H-substance which inhibits *Ulex* extract. However, the saliva specimens from groups B and AB secretors usually inhibited *Ulex* extract to lower titres than did those of groups O and A secretors. All those scored as non-secretors with anti-A and anti-B sera were also non-secretors when tested with *Ulex* extract.

The separation of individuals into secretors and non-secretors by the use of calibrated *Ulex* extract was found to be so reliable that this technique has been used in the later stages of the investigation whatever the ABO group; however, where a person of group A, B, or AB has been scored a non-secretor with *Ulex* extract, the scoring has always been confirmed by testing also with anti-A and anti-B

TABLE VI.—Results of Secretor Tests in 514 Duodenal Ulcer Patients and in 491 Controls

Blood Group	Secretor Character	Males		Females	
		Controls	Duodenal Ulcers	Controls	Duodenal Ulcers
O (<i>Ulex</i> extract)	Sec.	91	135	43	31
	Non-sec.	25	77	17	22
A	Sec.	123	106	51	12
	Non-sec.	38	41	20	12
B	Sec.	37	28	14	9
	Non-sec.	12	17	4	3
AB	Sec.	9	12	4	1
	Non-sec.	0	7	3	1
Total		335	423	156	91
O (eel serum)	Sec.	102	113	45	14
	Non-sec.	48	87	30	23

serum. The use of *Ulex* extract in the testing of all salivas has the advantage that an error in ABO blood grouping cannot lead to mis-scoring as a non-secretor.

The series of 514 duodenal ulcer patients and 491 controls reported and analysed in this paper were tested with *Ulex* extract if of group O and with anti-A, anti-B, and/or *Ulex* extract if of groups A, B, or AB. In the sibship investigation all the group O individuals in sibships 120-293 were tested with *Ulex* extract, but those in sibships 1-119 with eel serum. The results of the tests in 237 group O patients and 225 group O controls when eel serum was used have been reported (McConnell, 1956). They are included in Table VI in order to show the degree of error with this technique, but they are not used in the analyses in this paper.

Secretor Character in Duodenal Ulcer Compared with General Population Controls

Table VI shows the results of the secretor tests in 514 duodenal ulcer patients and in 491 controls, and Table VII shows these results for group O and for groups A, B, and AB combined, expressed as percentages. It will be seen that there are higher proportions of non-secretors in the patients than in the controls. Statistical tests on these data are given in Table VIII. There is no heterogeneity among the male controls or among the female controls with respect to the frequency of non-secretors among those with different blood groups. In the tests, persons of group AB were combined with those of group B because of the small number, so that the χ^2 has two degrees of freedom. Because of the absence of heterogeneity, the ratio of secretor

TABLE VII.—Percentages of Non-secretors in 514 Duodenal Ulcer Patients and in 491 Controls

	Males		Females	
	Controls	Duodenal Ulcers	Controls	Duodenal Ulcers
Group O: Non-sec.	21.55%	36.32%	28.33%	41.51%
Groups A, B, and AB: Non-sec.	22.83%	30.81%	28.12%	42.11%
Non-sec. in all groups	22.39%	33.57%	28.21%	41.76%

TABLE VIII.—Analysis of Secretor Data in 514 Duodenal Ulcer Patients and in 491 Controls

Comparison of Non-secretor Frequency in	Degrees of Freedom	χ^2 for Heterogeneity	P
Groups O, A, and B + AB male controls	2	0.28	>0.80
O, A, and B + AB female controls	2	0.00	>0.99
Male controls—female controls	1	1.96	>0.10
Groups O, A, and B + AB ulcers (males)	2	3.29	>0.10
O, A, and B + AB ulcers (females)	2	1.67	>0.30
Males with ulcers—females with ulcers	1	2.21	>0.10
All ulcers—all controls	1	13.97	<0.001

to non-secretor among all male controls was compared with that among all females, and again there was no heterogeneity. The same procedure was followed for the duodenal ulcer cases, and again it was found that there was no heterogeneity and that consequently the male and female data from all blood groups could be combined. A test was then made between the frequency of the two classes among the controls and among people with duodenal ulcer. The resulting χ^2 was 13.971, giving a significance level of less than 0.001.

We also investigated the question of heterogeneity within the data with respect to diagnosis and source of the samples of saliva. Table IX shows a breakdown of the duodenal

TABLE IX.—Duodenal Ulcer Data Subdivided with Respect to Diagnosis and Source of Saliva Samples

ulcer data into those diagnosed macroscopically and those in which the diagnosis was based on radiological evidence. Table IX also shows the secretor character of the cases in which the samples were obtained at the David Lewis Northern Hospital, compared with those collected elsewhere, and brought to the David Lewis Northern Hospital for storage and testing. The reason for this subdivision is that there might be a deterioration in the antigen content in those samples of saliva collected from outlying hospitals, for there would then be a greater time interval between collection and storage at -20°C , thus giving an apparently high frequency of non-secretors. Analysis shows that there is no heterogeneity for either of these factors.

In these data there is therefore a very marked association between non-secretion and the presence of duodenal ulcer when the general population is used as a control.

Secretor Character within Sibships

In 262 of the duodenal ulcer sibships the secretor character of the individuals has been tested, and these data have been examined to see if the association of ulcer with non-secretion is also found within families. The results in the total of *propositi* and affected and unaffected sibs of the sibships 120 onwards (tested with *Ulex* extract, see below) are shown in Table X. It will be seen that the proportion of non-secretors in the unaffected sibs is less than that in the *propositi* and the affected sibs, but it is considerably higher than that found in the general population. For the same reasons as those given in Part I an analysis has been made of the 89 sibships which segregate for ulcer and for non-secretors, taking each family separately as described in the Appendix to Part I. The result, given in Table XI, shows that there is a significant association between duodenal

secretors is again greater than the expected, though on the small numbers involved the difference does not reach the significance level of 0.05. However, it supports the conclusion of an association between ulcer and non-secretion based on the *propositi* analysis (Table XI).

These sibship results cannot be accepted as they stand without consideration of the fact that there has been mis-scoring of both ulcer patients and unaffected sibs of group O in sibships 1-119, due to the use of eel serum. It is, in fact, in these early sibships that the association appears to be most pronounced, but this is not confined to sibships with members who are group O. Three considerations militate against the suggestion that mis-scoring of group O secretors as non-secretors is responsible for the association found between duodenal ulcer and non-secretion in the sibships.

1. There is no apparent association between duodenal ulcer and blood group O in the sib data, the *propositi* and unaffected sibs having about the same group O frequency; therefore the error in technique should apply equally to the *propositi* and to the unaffected sibs and there should be no bias in favour of the *propositi* being non-secretors.

2. A comparison between group O sibs in which secretor character was scored using *Ulex* extract and those where

eel serum was used shows that both methods give an excess of non-secretors among the people with duodenal ulcer, as compared with their unaffected sib controls.

3. If all families segregating for group O are excluded—because it is only in such families that a bias is likely to occur—the association between duodenal ulcer and non-secretion is still found. Thus in families in which all members are group O and in which eel serum was used one gets an expected number of non-secretor propositi of 7.50 and an observed value of 10. A similar difference is found in all other families non-segregating for group O, including group O families scored with *Ulex* extract, but excluding all scored with eel serum. Here the expected value is 20.30 and the observed 29, the difference being $+8.7 \pm 3.174$ ($P < 0.01$). The data therefore do not support the view that the association found between non-secretion and duodenal ulcer is due to the faulty technique, for a significant result is obtained after excluding the families tested with eel serum and those segregating for group O.

Discussion

The observed association between non-secretion and duodenal ulcer might be accounted for in at least three ways.

1. *Racial Stratification*.—The arguments are similar to those in Part I concerning the association of group O with duodenal ulcer. It is possible that there is a strain high in duodenal ulcer and high in non-secretion imperfectly mixed with the general population, and that this accounts for the association; the secretor sibship data, however, contradict this view. Moreover, an ethnological explanation seems even more unlikely here than in the case of group O, because the non-secretor frequency in different European populations has been found to vary much less than do the ABO blood-group frequencies.

2. *An Effect of the Disease*.—It is possible that the disease itself affects the amount of blood-group substance secreted, so that the phenotype is changed to non-secretor in some ulcer patients who had been weak secretors. This hypothesis is testable by investigating the patients' Lewis blood groups, as these are very unlikely to be affected by the disease. Non-secretors of ABH are usually $Le(a+)$, and mis-scoring would be suspected if a higher proportion of the ulcer non-secretors are found to be $Le(a-)$ than that found in non-secretors of the general population. The proportion of non-secretors who are $Le(a-)$ found in previous population surveys has varied from 1 in 48 (Race and Sanger, 1954), to 2 in 59 (Grubb and Morgan, 1949), to 11 in 94 (Ceppellini, 1955b), but in this country the expected frequency would be about 7% (Race, 1956). In 82 ulcer patients scored as non-secretor the red cells were tested for Le^a (Table XIII), and 8 (9.76%) of them were $Le(a-)$.

TABLE XIII.—Result of Tests with Anti- Le^a Serum in 82 Non-secretor Duodenal Ulcer Patients

ABO Group	Males		Females	
	$Le(a+)$	$Le(a-)$	$Le(a+)$	$Le(a-)$
O	33	3	10	4
A	18	0	4	1
B	7	0	2	0

The saliva of the 8 $Le(a-)$ patients did not inhibit anti- Le^a serum.

The proportion of $Le(a-)$ in the males (4.92%) is in good agreement with the expected, but in the females it is very much higher (23.81%). This difference, however, between the $Le(a-)$ rate in male and female non-secretor patients is not quite significant ($P=0.13$). It can be concluded from these data with some degree of confidence that the difference found between the non-secretor rate of male ulcer patients and the controls is not due to a change of phenotype, and probably this conclusion is also true in the females.

3. *A Causal Relationship*.—It is possible that the genes controlling secretion are affecting the susceptibility of the indi-

vidual to duodenal ulceration, making non-secretors more liable to the disease, and we feel that our data give some support to this view. The concentration of blood-group substances is higher in saliva and gastric juice than in most other body fluids, a circumstance which is not likely to be fortuitous; and it is perhaps not surprising, therefore, that a selective effect has been found with a condition of the upper gastrointestinal tract. It is of interest that Pasternak *et al.* (1955) have found easily detectable amounts of B-like substance in the gastric mucosa of guinea-pigs but not in the mucosa of other parts of their gastro-intestinal tract.

The mechanism responsible for a relationship between duodenal ulceration and non-secretion might depend on the mucopolysaccharide nature of the ABH substances secreted, causing them to have a protective action on the mucosa of the gastro-intestinal tract, as suggested by Aird *et al.* (1954). Aird (1955) also put forward the hypothesis that the relationship between blood group O and duodenal ulcer might be due to the A, B, and H substances conferring different degrees of protection against ulcerogenic agents, H-substance giving less protection than A and B substances. If this were so, one would expect to find a particularly high proportion of non-secretors in the ulcer patients of groups A, B, and AB. In our data, however, the percentage of non-secretors in the ulcer patients is rather higher, though not significantly so, in those of group O (total, 37.2%—males, 36.3%; females, 41.5%) than in those of the other ABO groups (total, 32.5%—males, 30.8%; females, 42.1%). This finding does not support Aird's attractive hypothesis, but rather suggests that group O non-secretors may be the individuals most liable to ulcer. The question of a possible protective action might be answered by more information than we have at present on the titre of antigens secreted, and it would also be valuable to know what proportion of the total gastric mucin is made up of blood-group antigens.

When considering the amount of protection which the secretion of blood-group antigens may confer on an individual, the Lewis system as well as the ABH substances must be taken into account. Le^a and Le^b substances are the only antigens, other than the ABH, which have been found on red cells and which are also known to be secreted in large amounts in body fluids, and Le^a substance, at least, has similar physical and chemical properties to the ABH substances (Annisson and Morgan, 1952). The method of their inheritance is of some importance; the ability or inability to produce and secrete them is apparently determined by alleles at a locus which is not linked with the locus for ABH secretions nor with the ABO blood group locus (Ceppellini, 1955b), and since the two secretion characters therefore segregate independently there is the same proportion of non-secretors of Le^a in ABH secretors as in ABH non-secretors.

The interrelationship of the ABH and Lewis systems is also of importance, and according to Ceppellini is as follows: Le^a substance is the primary product of a dominant gene Le , and in ABH non-secretors it is present as such both in secretions and on red cells. Le^b substance is probably derived from interaction between the gene Le and the gene for ABH secretion (Se). The Le^a activity which is found in the secretions (but not on the red cells) of the ABH secretors who show the phenotype ($Le(a-b+)$) on the red cells could be either an unmodified residue of the primary Lewis substance or a manifestation of cross-reactivity between anti- Le^a sera and Le^b substance. Individuals without the gene Le ($le le$) have neither Le^a nor Le^b specificity on the red cells; their saliva when tested with anti- Le^a and with "specific" anti- Le^b sera also appears to be devoid of any Lewis specificity; however, many anti- Le^b sera ("H-cross-reacting" variety, according to Ceppellini) are inhibited by the saliva of all ABH secretors and thus simulate the presence of Le^b specificity.

There are therefore four main secretor types (Ceppellini, 1955a), and they might have differential protection from duodenal ulcer (Table XIV). If it is assumed that the ABH

TABLE XIV

Genotype	Red Cells Phenotype	Antigens in Saliva			Approximate Percentage in Population	Possible Protection
		ABH	Le^a	Le^b		
ABH Secretor : Lewis Locus						
$sese$: Le	$Le(a+b-)$	—	++	—	20	++
Se : Le	$Le(a-b+)$	++	+	+	70	+++
Se : $lele$	$Le(a-b-)$	++	—	—	8	++
$sese$: $lele$	$Le(a-b-)$	—	—	—	2	0

and Lewis substances give about equal degrees of protection, and that the presence of the gene Le does not influence the amount of ABH substances secreted, it will be seen from the last column in Table XIV that there will be an excess of non-secretors of ABH among people with duodenal ulcer, as about 90% of the secretors of ABH will be twice as well protected as any other individuals in the population. Only the fourth type of person, being a non-secretor of both ABH and Lewis substances, is completely without the hypothetical protection, and this type might be expected to be particularly prone to duodenal ulcer and therefore found more commonly in patients than in normals.

Clearly the next step should be to investigate in detail the Lewis secretor character of duodenal ulcer patients and controls, using both anti- Le^a and anti- Le^b sera. The data which we have on this subject are inconclusive, and all that can be reported at present is that in 82 ABH non-secretor patients we find eight non-secretors of Le^a (Table XIII). The only available data on secretion of Le^a in normal people with which to compare this finding are those of Grubb (1951) and Ceppellini (1955b), who found respectively 9.8% and 11.78% of non-secretors of Le^a . Our result is therefore in good agreement with the expected, but it will be seen from Table XIII that in the males there are less than the expected (4.9%), whilst in the females there is a considerable excess (23.8%) of those people who are completely without a hypothetical protective action of the blood-group substance.

In conclusion we feel that an unequivocal answer to the nature of the association between non-secretion and duodenal ulcer which we have demonstrated must await further investigation. We are continuing the study, and with the method of analysis used sibship data from various regions can readily be incorporated with those reported here.

SUMMARY

Part I

Recent work has suggested an association between blood group O and duodenal ulcer in several areas of Europe and in the U.S.A. The finding has been obtained by comparing the blood groups of ulcer patients with a control series of unaffected people living in the same area. Such controls can be unsatisfactory in that a population of mixed origin may contain elements with a high frequency both of group O and of duodenal ulcer without the two being causally connected. Sibship studies where the unaffected sibs act as controls are not subject to this criticism.

Data are presented for 293 duodenal ulcer sibships. An analysis of these gives no evidence to support the hypothesis that a group O individual is more likely to have a duodenal ulcer than are his A, B, or AB sibs.

This result could be regarded as evidence in support of the suggestion that the previously found association was due to racial stratification within the populations concerned. There are, however, considerable objections to this explanation, and an alternative, that the findings are due to a maternal effect, is discussed.

Part II

The ability to secrete ABO blood group antigens in body fluids is an inherited character, and it seemed possible that secretors and non-secretors might have different susceptibilities to duodenal ulcer. We have therefore investigated the secretor character in the saliva of 514 unrelated duodenal ulcer patients and compared the results with those of 491 controls from the general population.

This analysis shows that there is a significantly higher proportion of non-secretors in the duodenal ulcer patients (35.0%) than in the controls (24.2%). This difference is found in both males and females of each of the ABO blood groups and in both macroscopically and radiologically diagnosed cases. These data suggest that non-secretor individuals may be about 45% more likely to develop duodenal ulcer than are secretors.

For the same reason as in the association between group O and duodenal ulcer, sibship studies have been carried out, and the results in 262 families suggest that the relationship between non-secretion and duodenal ulcer may hold within families.

The possibility that the ABO and Lewis antigens may confer some protection against duodenal ulceration by virtue of their mucoid character is discussed.

We are indebted to Professor L. S. Penrose for suggesting the sibship investigation and for his advice during the work. Our thanks are also due to Dr. R. Ceppellini, Lord Cohen of Birkenhead, Dr. E. B. Ford, Dr. J. A. Fraser Roberts, and Dr. C. A. B. Smith for advice on various aspects of the work and for their comments on this paper. Antisera were kindly given us by Dr. A. E. Mourant and Dr. J. Ruffié. The co-operation of the Merseyside Branch of the College of General Practitioners and its Research Committee, under the chairmanship of Dr. K. M. Cobban and Dr. W. P. O'Regan respectively, was of great assistance, and we are grateful to the many practitioners and house-physicians who helped in the collection of data.

The work has been carried out with the aid of a grant from the Medical Research Committee of the United Liverpool Hospitals. One of us (P.M.S.) is grateful to the Nuffield Foundation for their support, and during the latter part of the work one of us (R.B.McC.) has been in receipt of a personal grant from the Medical Research Council.

The work has been greatly expedited by the untiring efforts of our research assistant, Miss Sheila M. Manning, who collected much of the material both in hospitals and in the homes of relatives, and whose ability and tact in handling reluctant sibs were invaluable.

OBSERVATIONS ON THE AETIOLOGY
OF CHOLELITHIASIS

BY

GABRIEL HORN, M.B., Ch.B., B.Sc.

From the Department of Medical Statistics,
University of Birmingham

It is generally taught that cholelithiasis occurs characteristically in females who are "fat, forty, and fertile." This description implies that obese multiparous women who are approaching the climacteric are especially prone to gall-stone formation; if valid, therefore, it may lead to a more precise definition of the aetiology of gall-stones—for example, in terms of endocrine disturbances affecting this group of the population.

There have been several investigations into the incidence of biliary calculi among post-mortem specimens (Gross, 1929; Cleland, 1953; Joske *et al.*, 1954), but the results have little significance to the clinician who is concerned with the occurrence of stones in living patients. Nor do such studies in themselves throw much light on the aetiology of gall-stones. Griffin and Smith (1954) carried out a limited survey of the age and sex distribution of patients with cholecystitis. Their conclusions, however, are not necessarily applicable to patients suffering from cholelithiasis.

The present investigation was undertaken as a preliminary attempt to test the validity of the above-mentioned aphorism by comparing the age, sex, fertility, height, and weight distributions of a number of patients presenting with symptoms of cholelithiasis (subsequently confirmed radiologically or at operation) with the supposed distributions in the population at risk. It was found possible to collect complete and accurate data on only a limited number (783) of patients, but it is evident that if the "fair, fat, and forty" epigram is valid, either as a diagnostic aid or for heuristic purposes, it should be suggestively demonstrated by such a sample of unselected cases. An analysis was also made of the incidence of gall-stones among a group of post-mortem cases.

Data were derived from the records of patients suffering from cholelithiasis who entered the Queen Elizabeth and General Hospitals, Birmingham, between August, 1950, and December, 1954. It was not possible to delineate the exact population at risk, since some patients entering the hospitals live outside Birmingham, and some Birmingham patients are treated in other hospitals. We have therefore defined the *related incidence* in each age and sex group as the ratio of the number of cases in

each group to the population of Great Britain in the corresponding group (Census 1951, 1% sample). Our related incidence is therefore expressed as the number of cases in each group per million of the population of Great Britain of corresponding age group and sex. The Census gives no information concerning the parity distribution of women beyond the age of 49. This information was extracted from the *Report on the Family Census of 1946* (1954); the related incidence of married women with gall-stones in each age and parity group is thus expressed per 100 of the estimated population of married women in Great Britain in the corresponding group.

Records of all post-mortem examinations conducted at the hospitals between 1946 and 1954, inclusive, were also scrutinized and all cases noted in which calculi were found in the biliary tract. These data were related to the age and sex distribution of the total population examined after death at the two hospitals during the same period.

Clinical Material

1. Influence of Age and Sex on Related Incidence of Cholelithiasis

A total of 822 patients (163 male, and 659 female) suffering from cholelithiasis were admitted during the period. Of these, 39 were not included in the analysis because the age was not known (6), the marital status was not known (14), or because they were divorced or living apart (19). This left 783 cases (150 male, 633 female).

It may be seen from Table I and Fig. 1 that the disease occurred earlier and had a higher frequency in females than in males for all age groups. The related incidence was highest among females in the age group 50-59 and in males of the 70-79 group. The interval between the date of onset of symptoms and the date at which medical aid is sought is not known, but may be appreciable. It is possible, therefore, that Fig. 1 will describe the age and sex distribution of a population older than they were at the time they first experienced symptoms.

FIG. 1.—Related incidence of gall-stones by age and sex.

Biliary calculi were found with consistently greater frequency in single females than males. These findings lend support to the view (Robertson and Dochat, 1944) that factors related to child-bearing are insufficient to account for the sex differences in the incidence of the disease.

2. Fertility

The fertility—that is, number of live-born children—of married women with cholelithiasis was calculated and related to a sample of the population of Great Britain described in the *Report on the Family Census of 1946*. Up to the age of 40 women with gall-stones had rather more children and beyond this age rather fewer children than in the sample (Fig. 2). The period 40-49 appears to be a time of transition. Cholelithiasis occurred more often in married women with children than in nulliparae up to the age of 50 (Fig. 3). After this age gall-stones occurred with greater frequency among the childless than among parous women. The fifth decade is the period during which most women experience the menopause, so that the years before 50 may be designated "pre-menopausal" and those beyond 50 "post-menopausal."

FIG. 2.—Married women according to age and average number of live-born children.

FIG. 3.—Related incidence of cholelithiasis among married nulliparae and married parous women according to age.

FIG. 4.—Related incidence of cholelithiasis among married women according to age and parity.

50, "post-menopausal." There is a marked difference in the distribution of gall-stones among married women of the post-menopausal years compared with married women of the pre-menopausal years. These differences are also shown in Fig. 4, where data for married women are broken down according to age and number of live-born children. Up to the age of 50 the frequency of gall-stones increases with parity. Among older age groups a reversal takes place, so that cholelithiasis decreases in frequency with parity. Once again the period of 40-49 (the menopausal years) appears to be a time of transition.

Gall-stones occurred with consistently greater frequency in married than in single women (Table I). The related incidence of the disease in widows, who for some part of their lives will have lived with their spouse, lies closer to that of married than to that of single women. The question arises whether the difference between married and single women is wholly accounted for by factors related to child-bearing, for among married women there is a definite relationship between parity and the incidence of biliary calculi. The related incidence of the disease among single women was thus compared with that for married nulliparae (Table II). Since the Family Census data did not include

TABLE II.—Related Incidence of Cholelithiasis in Single Women and in Married Nulliparae

Age	Numbers		Related Incidence	
	Single	Married Nulliparae	Single	Married Nulliparae
20-29	3	2	2.3	2.9
30-39	4	5	7.8	11.5
40-49	9	13	16.1	24.9
Ages 20-49	16	20	6.9	12.1

single women, numbers were related to the distribution by age and marital state of the female population of Great Britain according to the Census of 1951. Unfortunately, the Census gives data on married nulliparae to the age of 49 only. Up to this age, though numbers are small, the direction of trends is constant and shows that gall-stones occurred with greater frequency in married nulliparae than in single women.

The results enumerated above suggest that among women both the marital state alone and the factors related to or consequent upon child-bearing may be of aetiological significance in the development of gall-stones.

Data for males are very few and there is no unequivocal relationship between the incidence of gall-stones and the marital state (Table I).

3. Weight and Height

A two-months sample of women entering hospital with cholelithiasis was reviewed for height and weight measurements, since these data were not recorded in the main group of clinical material. Measurements taken from the 20 patients in the sample were compared with those of a sample of the general population measured by Kemsley (1950). Since the subjects of Kemsley's survey were measured fully dressed, 6 lb. (2.7 kg.) in weight and 1½ in. (3.8 cm.) in height were added, as suggested by Kemsley, to the clinical data, which had been recorded from women who wore no footwear and were clad only in night attire.

The linear regression of height on age was calculated by the method of least squares for our own sample and compared with Kemsley's data (Fig. 5). The curves run closely together. There is no reason to suppose, therefore, that the heights of the patients differ from those of the general population.

The curve of quadratic type fitted to the age/weight data by Kemsley is shown in Fig. 6. The scatter of weight against age was plotted for our data, and a curve of the same order was fitted. It is evident from Fig. 6: (a) that below the age of 50 the women in our sample were almost without exception

heavier, and an average of approximately 25 lb. (11.3 kg.) heavier, than the average for women of comparable age in Kemsley's population; (b) that over the age of 50 there was no preponderance of heavier-than-average women in our population. These findings are also expressed by the curve fitted to our data, which is widely separate from that for Kemsley's data for ages below 50 and close at ages above 50.

Since the distributions of heights of the two populations are closely similar, the generalization which follows is that it seems probable that, below the age of approximately 50,

Fig. 5.—Cholelithiasis. Age/height curve of 20 female patients.

Fig. 6.—Cholelithiasis. Age/weight curve of 20 female patients.

women with biliary calculi are on the average more obese than women of comparable age in a sample of the general population. It would of course be desirable to verify this by examination of the weight/age distribution of a larger sample of cholelithiasis patients; but our results are particularly suggestive (a) in that they show a marked difference in the weight/age distribution before and after 50 years as compared with the estimated distribution for the

population; and (b) in the magnitude of the apparent difference for earlier age groups.

Lowe and Gibson (1955) have shown that at corresponding ages married women with children are heavier than those without. Before the sixth decade gall-stones were more frequent among married women with children than among married nulliparae (Fig. 3). After the menopause the reverse is true. The weight curves thus follow the direction which might have been anticipated on the basis of Lowe and Gibson's report.

Post-mortem Material

The records of all post-mortem examinations (3,523 males, 2,176 females) performed at the Queen Elizabeth and General Hospitals, Birmingham, during 1946-54, inclusive were examined. All specimens in which gall-stones were discovered (492) were recorded according to age and sex and related to the distribution by age and sex of all necropsy cases examined at the two hospitals during the same period (Table III). The bias introduced by the preponderance of

necropsies on male subjects was therefore eliminated. No information was available concerning marital state or parity.

Gall-stones were divided into two groups. Those cases in which the stones were found impacted, or in which other pathological features were noted in the biliary tract, were referred to as "symptomatic" stones, since symptoms referable to the gall-bladder were likely to have been present during life (Table IV). The term "asymptomatic" was used to refer to those calculi found in biliary tracts in which no coexisting pathology was apparent and which were unlikely, therefore, to have given rise to symptoms during life (Table V).

It was found (Fig. 7) that in both sexes the incidence of biliary calculi increases with age and is highest in the oldest age group (80-89). In this group stones occur almost as frequently in men as in women, but below this age among women consistently more than men. Fig. 8 shows that in both sexes gall-stones of the asymptomatic variety are more frequent in each age group than those of the symptomatic variety.

If the information derived from post-mortem material be combined with that from the clinical material, a more

accurate description of the distribution of gall-stones among a living population may be obtained than from consideration of either set of data alone. Thus gall-stones which occur in hospital patients produce symptoms, and in this sense are symptomatic. They do not, however, contribute to the symptomatic post-mortem group, since symptom-producing cholelithiasis is usually treated by cholecystectomy. If such patients come to the post-mortem room at all they are without a gall-bladder. Thus a case that certainly had symptoms will not be included among the post-mortem symptomatic group. The latter will therefore be inordinately small, and would be an inaccurate index of the frequency of cholelithiasis among a living population. This is particularly true of the younger age groups, when

Other Not known	7		55		5		2		2		3	

On the other hand, excretion may not occur so effectively in men, as a consequence of which there is a low frequency of gall-stones and a high incidence of atherosclerosis. After the menopause sex differences in cholesterol metabolism may gradually diminish. At this time the frequency of gall-stones and that of atherosclerosis in the two sexes converge. Consistent with this view is the finding that in females the concentration of serum cholesterol increases slowly to equal that of the males by the seventh decade (Jones *et al.*, 1951).

The types of stones found in the biliary tract of post-mortem specimens are classified in Table VI into mixed,

FIG. 9.—Post-mortem material. Percentage of males in each age group.

FIG. 10.—Hospital patients with cholelithiasis. Percentage of males in each age group.

pigment, and cholesterol. In each sex the mixed type of stone occurred with greatest frequency, the pigment type next, and the cholesterol stone least. The proportion of mixed stones in gall-bladders showing additional pathology ("symptomatic") was higher than in gall-bladders without additional pathology ("asymptomatic"). These findings suggest that an infected biliary tract is associated with an increased incidence of biliary calculi of the mixed variety. Furthermore, amongst the symptomatic group the proportion of mixed stones in females is substantially higher than in males. This state of affairs may be due to a higher frequency of gall-bladder infection in women than men.

Unfortunately no information is available concerning the frequency of the various types of stones present in diseased gall-bladders of living patients.

Discussion

The aphorism "fat, forty, fertile, and female" may describe a certain patient, but it does not describe the "typical" patient suffering from cholelithiasis. The use of the dictum is thus undesirable, since it tends to focus attention on a small group of those affected by the condition.

Some of the findings of the present study warrant further comment. First, however, it is necessary to remark briefly on two of the factors contributing to the formation of gall-stones, factors which appear to be of particular significance to the discussion which follows. It is generally accepted that biliary calculi may be produced (1) consequent on an increased excretion into the gall-bladder of cholesterol, and its subsequent precipitation out of solution; and (2) following infection of the gall-bladder (Cappell, 1951).

During the years of the menopause and immediately following it, great changes take place in the endocrine system. The ovaries gradually become atrophic (Engle, 1955), ovulation ceases, and the cyclic production of oestrogens and progesterone no longer takes place. These hormones appear to exert some influence on the blood cholesterol (Okey and Boyden, 1927); both are steroid compounds, the basic structure of which is the cholesterol molecule (Pincus *et al.*, 1955). Andrews *et al.* (1932) state that cholesterol-containing stones make up a large majority of all human gall-stones. It is not impossible, therefore, that the changing endocrine balance expresses a modification of cholesterol metabolism which is related in some way to the high incidence of biliary calculi in women during the immediately post-menopausal years. Furthermore, Pincus *et al.* have shown that the average androgen outputs of men and women converge in the later decades, when the output of oestrogens in women is actually lower than in men. Thus in the older age groups hormonal differences between the sexes become less clearly defined. These changes may be one of the factors responsible for the diminishing sex differences in the frequency of stones in the older age groups, and may also account for the relationship which has been suggested between gall-stone formation and atherosclerosis.

There are other factors, however, which must be considered in the possible relationship between endocrine metabolism and gall-stone formation. During pregnancy the ureters dilate. One of the causes of this dilatation is ascribed by Stuermer (1947) to the relaxing effect of the follicular and corpus luteum hormones on the smooth-muscle component of the wall of the ureters. The muscle of the bile ducts and gall-bladder are involuntary. Under the influence of the female sex hormones the muscle may relax, the biliary passages dilate, and the duodenal contents or pancreatic secretions regurgitate into the gall-bladder and there promote conditions favourable to the formation of calculi. In this connexion it may be significant that there is a higher proportion of mixed stones and hence, probably, a higher proportion of infection in the gall-bladders of women than of men.

It is difficult to account for the change in the incidence of gall-stones which occurs among married women after the menopausal years. The fact that the change occurs so abruptly is strongly suggestive of a relation with the climacteric, though the nature of this relation, if any, is by no means obvious.

It is concluded that the frequency of gall-stones increases with age in both sexes, but that among women these trends are modified by factors operating in and related to the child-bearing period.

Summary

An investigation was made into the incidence of gall-stones among hospital patients and post-mortem material.

Among hospital patients the related incidence was highest in females of the 50-59 age group and in males

AETIOLOGY OF GRAVES'S DISEASE IN RELATION TO RECENT EXPERIMENTAL FINDINGS

BY

Emotional Trauma and Graves's Disease

The occurrence of hyperthyroidism following a severe fright was first reported by Parry in 1825, when he described the condition that was later to be called Graves's disease. Ever since this first account innumerable papers describing the condition have confirmed the frequency with which emotional or psychological upsets precede the onset of thyrotoxicosis. The French school of Charcot (1859), Trousseau (1867), and others believed the disease to be nervous in origin, either a form of hysteria or associated with a definite but undetermined lesion. Such further publications as those of Crawford (1897), Marañón (1921), Deutsch (1923), Lewis (1925), Bram (1927), Moschowitz (1930), Goodall and Rogers (1933), and many others afford evidence of the relation between psychic trauma and the onset of the hyperthyroid state.

More recent work has been devoted to the type of individual and type of disturbance likely to be associated with thyrotoxicosis. Lidz and Whitehorn (1950) have described the type of patient in whom Graves's disease occurs as one highly dependent on interpersonal relationships for his security. This relationship is often familial, such as that of a daughter to mother or a mother to child. There is little latitude for adaptability, and the patient feels abject and helpless without such symbiotic relationship. These patients react in a highly emotional or exaggerated fashion to the disruption, or threat of disruption, of such a relationship. It is this type of emotional stress which threatens their security that is apt to precipitate Graves's disease.

It has been stated that the incidence of Graves's disease declines in times of economic depression, and it is possible that such social conditions bind families into closer-knit units. On the other hand, however, it is clear that emotional stress does not result in Graves's disease in a high proportion of the population. The aerial bombardment of large towns and cities during the last war did not appear to increase the incidence of thyrotoxicosis, though in some Scandinavian countries subject to occupation thyrotoxicosis is said to have reached epidemic proportions (see discussion following the paper of Lidz and Whitehorn, 1950). If emotional stress is an aetiological factor of importance, as seems likely, it is not the sole factor underlying the onset of the disease.

In view of the possible relationship between the central nervous system and thyroid activity, it became of interest to see the effect of prolonged (one to seven days) electrical stimulation of the hypothalamus on thyroid activity.

of the 70-79 age group. The frequency was higher in women than in men for all ages, though the differences were very small in the 80-89 group. At ages below 50 gall-stones were more frequent in married women without children than in single women, and more frequent in married women with children than in married nulliparae. Beyond the age of 49 the related incidence was higher in married nulliparae than in married women with children.

It was argued that by combining data from clinical and post-mortem material a more accurate description of the distribution of gall-stones in the living population could be obtained than from consideration of either set of data alone. It was found that gall-stones increase in frequency with age, but that in females after the sixth decade and males after the eighth there is a high proportion of "silent" stones.

It is concluded that, in women, age changes in the incidence of cholelithiasis are modified by factors operating in and related to the child-bearing period.

In the years following the female climacteric, sex differences in the incidence of cholelithiasis appear to diminish until there are virtually no differences in the oldest age group.

At ages under 50, women with gall-stones were heavier than normal women of a comparable age and height. After 50, differences in weight were no longer apparent.

Analysis of stones found at necropsy showed the mixed type to be most frequent, the pigment type next, and the cholesterol type least frequent in both sexes.

Comparisons were drawn between the incidence of gall-stones and of atherosclerosis. Prior to the menopause there is a sex difference in cholesterol metabolism. It is suggested that this difference is expressed in women by a high frequency of cholelithiasis and a low frequency of atherosclerosis, whilst the reverse occurs in men. After the menopause, when hormonal differences between the two sexes become less clearly defined, the pathways of cholesterol metabolism may converge and so account for the diminishing sex differences in the related incidence of gall-stones and atherosclerosis among the older age groups.

My thanks are due to Professor Lancelot Hogben, F.R.S., Dr. R. G. Record, and Dr. R. H. Cawley for their interest in this work; to Dr. Wallis Taylor for his assistance with the statistical analysis of the data; and to Professor J. W. Orr for allowing access to the post-mortem records.

Electrical Stimulation of Hypothalamus, Thyrotrophic Secretion by Anterior Pituitary Gland, and Thyroid Activity in the Normal Animal

Few reports in the literature describe the effects of electrical stimulation of the hypothalamus on the thyroid gland. Green and Harris (unpublished, quoted by Harris, 1955) saw no increase in the oxygen consumption of rabbits following prolonged stimulation of the hypothalamus, but drew no conclusions from these data owing to the limitations of the method for measuring metabolic rate in rabbits. Colfer (1949) observed histological signs of increased thyroid activity in rats and rabbits after four one-hour periods of hypothalamic stimulation on each of two days.

In a recent study Harris and Woods (unpublished) have employed the method of remote control (de Groot and Harris, 1950) of electrical stimulation as applied to various regions of the hypothalamus and pituitary gland, and the ^{131}I output method (Brown-Grant, von Euler, Harris, and Reichlin, 1954) for indicating changes in thyroid function. These techniques permit (a) electrical stimulation to be applied to the unanaesthetized and unrestrained animal for long periods (usually 48 hours), and (b) continuous observation of thyroid activity to be made over an interval of 10 to 14 days. Out of 35 experiments on 22 rabbits in which the electrode was situated in some part of the hypothalamus or pituitary gland, stimulation resulted in thyroid inhibition in 20, no change in thyroid activity in 14, and a questionable result in one case. In one further animal a definite increase in thyroid activity occurred on two occasions. Since thyroid acceleration was observed in only 2 out of 37 experiments it was felt possible that some other factor was inhibiting or masking the effects of an increased secretion of thyrotrophic hormone in these experiments. One possibility appeared to be that the secretion of the adrenocorticotrophic hormone and excitation of the adrenal cortex known to follow such hypothalamic stimulation prevented in some way the pituitary secretion of T.S.H.

Effect of Adrenal Steroids on Thyroid Activity

It is now well established that electrical stimulation of the tuber cinereum elicits increased discharge of corticotrophin from the anterior pituitary gland and a rise in the concentration of the adrenal cortical steroids in the blood (de Groot and Harris, 1950; Hume and Wittenstein, 1950; Porter, 1953, 1954). The effect of the injection of corticotrophin or adrenal steroids on thyroid activity has been studied by many workers using different criteria for assessing such activity. A depression of ^{131}I uptake by the thyroid gland has been found to follow administration of corticotrophin or cortisone to man (see Hill, Reiss, Forsham, and Thorn, 1950; Berson and Yalow, 1952; Kuhl and Ziff, 1952), rabbit (Myant, 1953), and rat (Money, Krantz, Fager, Kirschner, and Rawson, 1951; Perry, 1951; Albert, Tenney, and Ford, 1952; Verzar and Vidovic, 1952; Migeon, Gardner, Crigler, and Wilkins, 1952). A similar depression of thyroid activity following the administration of corticotrophin and cortisone has been shown in the rat (Brown-Grant, 1955, 1956) and rabbit (Myant, 1953; Brown-Grant, Harris, and Reichlin, 1954; Brown-Grant, 1956) using the ^{131}I output method.

That the inhibition of the thyroid following the injection of corticotrophin is due to adrenal activation is shown by the fact that corticotrophin injection in cases of Addison's disease (Hill *et al.*, 1950) or into adrenalectomized rats (Brown-Grant, 1956) is without effect on thyroid function. It is also of interest that injection of both corticosterone and hydrocortisone (which are known to be secreted by the rabbit adrenal cortex) inhibit the release of radioactive hormone from the rabbit thyroid (Brown-Grant, 1956).

It is probable that the adrenal steroids affect thyroid activity by suppressing the secretion of thyrotrophic hormone from the anterior pituitary, since cortisone was found not to influence the response of the thyroid gland of the hypophysectomized rabbit to injection of T.S.H. (Brown-Grant, Harris, and Reichlin, 1954).

Electrical Stimulation of the Hypothalamus and Thyroid Activity in the Adrenalectomized Animal

In view of the above data the effect of electrical stimulation of the tuber cinereum on thyroid activity was investigated in adrenalectomized rabbits maintained on constant daily doses of cortisone. Fourteen such rabbits have been studied (Harris and Woods, unpublished), using the techniques mentioned above. Electrical stimulation evoked a marked and consistent increase in thyroid activity in 20 experiments on 10 animals (though previous to adrenalectomy these animals had shown thyroid inhibition in 10 experiments and no change in thyroid activity in five experiments). Ten experiments in the other four animals showed no observable change in thyroid function on eight occasions, an inhibition on one occasion, and a questionable result on one occasion. The precise location of the region stimulated in the various animals has not yet been determined by histological study, but the radiographic evidence suggests that it is stimulation of the median eminence of the tuber cinereum which results in increased thyroid activity.

During five experiments on four rabbits in which increased thyroid activity was observed from measurements of the thyroidal radio-iodine, estimations of the plasma radio-activity revealed a marked increase (up to $\times 3\frac{1}{2}$) during the period of stimulation. It is significant that hypothalamic stimulation could maintain an increased level of thyroid activity even in the presence of a high concentration of thyroid hormone in the blood. Five out of the 10 rabbits that showed a marked acceleration of thyroid activity during stimulation eventually died, suddenly and unexpectedly, while being stimulated.

In view of the striking difference in the results obtained in normal and adrenalectomized animals, it is of interest to consider the data regarding adrenal cortical function in Graves's disease.

Adrenal Cortical Function in Graves's Disease

An important relationship between the adrenal cortex and Graves's disease has been suspected for many years. Boyd (1944) states: "The more carefully the matter is studied the more clearly does an underlying relationship become evident between three such apparently different conditions as exophthalmic goitre, status lymphaticus, and Addison's disease." In 1921 Marine and Baumann reported increased heat production, increased respiratory exchange, and a symptom-complex resembling exophthalmic goitre following removal or damage to the adrenal glands in rabbits. Marine (1930) pointed out that thyrotoxicosis in the human is often associated with signs of adrenal cortical underactivity (lymphoid hyperplasia and a large thymus) and a small adrenal cortex. LeCompte (1949) measured the width of the adrenal cortex in cases of Graves's disease and found a significant narrowing of the cortex in such cases. The onset of Graves's disease has been noted to follow x-ray damage to the adrenal cortex in the human (Oppenheimer, 1937), and the incidence of thyrotoxicosis has been reported to be ten times greater in patients suffering from Addison's disease than in normals (Frederickson, 1951).

The techniques developed for estimating adrenal cortical activity during life have shown that in hyperthyroidism the urinary excretion of 17-ketosteroids may be low (Fraser, Forbes, Albright, Sulkowitch, and Reifenstein, 1941; Shadaksharappa, Calloway, Kyle, and Keeton, 1951; Corvilain, 1953), the excretion of reducing steroids may be normal or slightly increased (Shadaksharappa *et al.*, 1951; Talbot, Wood, Worcester, Christo, Campbell, and Zygmontowicz, 1951), and the urinary formaldehydogenic steroids are decreased (Daughaday, Jaffe, and Williams, 1948). In the study of Daughaday *et al.* (1948) serial studies of a patient showed that a severe exacerbation of the thyrotoxic state was accompanied by a fall in the excretion of formaldehydogenic steroids.

In a more recent study (Levin and Daughaday, 1955) the excretion of urinary 17-ketosteroids and 17-hydroxysteroids

was found to be within the normal range in hyperthyroidism. The surprising feature of these data is that urinary excretion of adrenal steroids is not greatly increased in Graves's disease, for the administration of exogenous thyroxine is known to result in adrenal hypertrophy (Wallach and Reineke, 1949; and others), an increased excretion of 17-ketosteroids in the guinea-pig (Levin and Daughaday, 1955), and an increased excretion of 17-ketosteroids in man (Corvilain, 1953). Also the emotional and physical state of a patient with thyrotoxicosis would appear to afford a strong stimulus for adrenal cortical hyperactivity. It is probable, then, that there is a relative, if not an absolute, degree of adrenal cortical hypoactivity in this condition.

General Conclusions

A comparison may be drawn between (1) the findings of Harris and Woods (unpublished) that electrical stimulation of the tuber cinereum of the hypothalamus in the normal rabbit results in inhibition of, or no change in, thyroid activity (rarely thyroid acceleration), whereas the identical procedure in the same animals after adrenalectomy results in a consistent and marked increase in thyroid function; and (2) the clinical observations relating emotional stress and relative adrenal insufficiency with the state of thyrotoxicosis.

In a patient with Graves's disease it is possible that some stressful stimulus has resulted in decreased adrenocortical activity and increased thyroid activity. Such a response would seem to be the reverse of that which occurs in the normal individual. In support of this view is the clinical evidence of Hill *et al.* (1950) that corticotrophin administration may induce remission in early cases of thyrotoxicosis.

Summary

It has been found that electrical stimulation of the hypothalamus rarely elicits increased secretion of thyrotrophic hormone in rabbits with intact adrenal glands. Prior to adrenalectomy increased thyroid activity was observed in only one rabbit out of 22 during electrical stimulation of the hypothalamus. In 35 experiments on 21 such rabbits thyroid activity was either unchanged or actually decreased.

After bilateral adrenalectomy, performed on 14 of the 22 rabbits, hypothalamic stimulation consistently elicited a marked increase in thyroid activity in 20 experiments on 10 rabbits.

Thyroid activity was estimated by measuring the rate of release of ^{131}I from the thyroid and the blood concentration of P.B. ^{131}I . Electrical stimulation of the brain was carried out in unanaesthetized and unrestrained rabbits by the remote control method.

These results seem to be of interest with respect to the aetiology of Graves's disease, since: (1) there is a probable relationship between psychological trauma and the onset or exacerbation of the state of hyperthyroidism; and (2) numerous clinical reports suggest that either a relative or an absolute adrenal insufficiency is a concomitant of Graves's disease.

It is felt that investigation of the effects of corticotrophin administration in early, previously untreated cases of Graves's disease would be of interest.

PREFRONTAL LEUCOTOMY

VIEWS OF PATIENTS AND THEIR RELATIVES

BY

ALICK ELITHORN, M.D., M.R.C.P., D.P.M.

AND

ELIOT SLATER M.D., F.R.C.P., D.P.M.

From the Department of Psychological Medicine and the Neurological Research Unit of the Medical Research Council, the National Hospital for Nervous Diseases, Queen Square, London

Recent correspondence in the *Lancet* and the *British Medical Journal* has shown that there are still widely diverging views on the value of leucotomy in the treatment of mental disorders. Critics object either that the deleterious effects of the operation are insufficiently appreciated and outweigh trivial symptomatic improvements if such occur, or that if beneficial results are obtained then they are in some ill-specified way not ethically justifiable. Thus it has been stated that all the surveys which show favourable results have been published by those who are emotionally prejudiced in favour of this treatment (Allen, 1955); and that the majority of surgeons do not know how badly their operations turn out (Standley, 1955; Atkinson, 1956). Winnicott (1956) has said that even if he were convinced that a leucotomy could be good he would still believe it was bad; and he has observed that many of his patients have a deep fear of leucotomy. Hardenberg (1956) confirms this finding, adding that the fear may be so deep that it can be unearthed only with difficulty. Tow (1956) attributes much of this fear to scare articles in the lay press.

Published reports of results, for reasons of space, commonly confine themselves to overall assessments made by the authors and such objective observations as rates of discharge from hospital and proportions of patients at work. However, these are not always found convincing, and it can be and is argued that leucotomy represents some form of degradation. Better for the

patient, it is claimed, that he should continue indefinitely an incapacitating battle with pathological ideas and emotions than that he should resign himself to becoming a diminished personality, the struggle abandoned, in a socially tolerated role. Overall assessments have a subjective aspect. Subjectivity in the judgment of results obtained is not to be excluded altogether, and there is some advantage in seeing what emerges if we change the judge. In the material which follows we have excluded all consideration of our own views of what has happened to our patients, and report solely what the patients themselves and their relatives think.

Material and Method

The subjects of the present analysis are all the patients from the public wards of the National Hospital who were leucotomized there before June, 1954, together with those patients from the private wards with whom one of us (E.S.) was clinically concerned. Two patients transferred to the Radcliffe Infirmary for cingulectomy by the late Sir Hugh Cairns have also been included. The great majority of these patients have attended, with their relatives, at regular intervals at a follow-up clinic, where consistent efforts at the greatest attainable degree of rehabilitation have been made. In addition, home visits have been made by the psychiatric social worker in nearly all cases, and contacts have been established with the disablement rehabilitation officers and employers. The assessments which are the basis of this paper have been obtained at the follow-up clinic or in the patients' homes. The diagnoses have been intractable pain (22 cases), excessive emotional reactions to physical symptoms such as tinnitus or involuntary movements (19 cases), chronic anxiety or tension states (36 cases), endogenous depression (21 cases), and schizophrenia (5 cases). There was a total of 46 standard and 57 modified operations. The average lapse of time between the operation and the taking of the assessments was 31 months, the shortest time being six months and the longest 104 months.

In making these formal assessments a modified "open-ended" interview technique was used. Each patient was asked the same six questions: (1) Whether the operation had helped him and, if so, how? (2) Which symptoms had improved (or) had any symptoms improved? (3) Which symptoms had not improved? (4) Had he noticed any bad effects? (5) Had he noticed any change in personality? (6) Was he glad that he had had the operation, did he regret it, or was he undecided? (This last question was arranged as a five-point scale: see Table I.) Free spontaneous elaboration of answers under all these heads was invited.

The relative was asked whether the operation had relieved the patient, which symptoms were relieved, and which had not, whether any bad effects could be reported; and he was asked to assess the value of the operation to the patient on a five-point scale from much improved to much worse (see Table I). He was further asked whether, with his present knowledge, he would in similar circumstances again give consent. And, finally, he was asked about the social consequences of the operation, how it had affected his own life and his relationship with the patient. After these questions both patient and relative were taken through the complete range of pre-operative symptoms and disabilities to ascertain their present standing.

Results

Of the original 118 patients who fall into this series, five died as a direct consequence of the operation; one other patient failed to survive six months, dying of an intercurrent cerebral accident; four others died of natural causes before the assessment was made, and one committed suicide. Of the remaining 107 cases, the assessment has been mislaid in two cases, was made to a questionnaire since abandoned in one, and was blocked by a relative in a fourth, the husband maintaining that post-operative improvement had been brought about by spiritual means. The data provided by the residual 103 patients (96% of the survivors) are presented in

Relatives' Opinion	Patients' Opinion					Totals
	Very Glad	Definitely Glad	Indeterminate	Regrets	Great Mistake	
Great improvement	23	14	4	—	—	41
Some ..	6	10	10	5	—	31
Little change ..	1	3	4	2	—	10
Slightly worse ..	—	1	2	1	1	5
Much ..	—	1	2	1	2	6
None available ..	3	4	1	2	—	10
Total ..	33	33	23	11	3	103

Table I. The views of a close relative or friend, obtained at a formal assessment interview, are available for 93, or 90%. In the 10 remaining cases no relative with adequate knowledge was available in four, the assessment has either not yet been made or has been mislaid in four, and in two cases the patient has requested us not to contact relatives.

Table I shows a marked but not complete agreement between patient and relative on the value of the operation. Rather surprisingly, considering that leucotomy is supposed to produce personality changes of an antisocial type, the relatives were more favourably impressed than the patients. Of the patients, 65% were glad they had had the operation, 32% very glad; of the relatives, 78% thought there had been improvement, 45% that there had been great improvement. Disagreement between patient and relative is clearly, in part at least, due to the fact that they were required to answer rather different questions. However, in the 72 cases where the relatives thought there was improvement the patient regretted the operation in only five, and in the 66 cases where the patient was glad to have had it relatives thought they were worse in only two.

At the time when these interviews were being conducted our predilections were more for modified operations than for standard ones. If the interview had any suggestive effect in eliciting favourable reports (which we do not believe), then this effect should be greater in the reports of patients who had had modified operations than in those who had had standard ones. Actually, the latter group of patients gave the more favourable answers (39 "glad," 3 "indeterminate," 4 "regret," as against 27, 20, 10). The reports of relatives also tended to favour standard rather than modified operations.

Personality Changes, Bad Effects, and Social Adjustment

Of our 103 patients, 46 denied both that there had been any bad effect and that there had been any personality change of any kind; 14 denied any bad effects but claimed that there had been personality changes which were regarded as beneficial; 11 others, also denying bad effects, said that there had been personality changes which they felt were unfortunate. The remaining 32 patients all reported bad effects—15 with unwelcome changes of personality, 16 with no such change, 1 with a favourable change. In all, 43 patients reported either bad effects or an unwelcome change of personality, or both.

Bad effects, apart from personality change, are not of a very impressive kind: eight patients reported an increase in one or more of their symptoms, six complained of pains or unpleasant sensations in eyes or head which they attributed to the operation, one patient complained of fits, one of frequency of micturition, one of depersonalization and difficulty in making decisions, one that the certification which had followed operation meant that he would not be able to emigrate.

Among personality changes the most common complaints, with numbers reporting them, were: increased irritability (12), emotional flatness (11), lack of energy or laziness (7), intellectual impairment (6), tactlessness (5), loss of self-assertiveness (3), decreased ability to mix socially (3), lack of personal tidiness (2), lack of self-confidence (1). One woman claimed she was now able to assert her ideas more than before. Unfortunately these were Christian principles

relating to the status of coloured people, and she asserted them at bridge parties in South Africa. Since this embarrassed her husband, and she herself regretted it, the tendency has been recorded as a personality deficit under the heading of tactlessness. Another woman, after the operation less preoccupied with her own symptoms, now complained of greater sensitivity to those of others, her husband's uncouth eating habits particularly distressing her. A handful of other patients had complaints which they had difficulty in characterizing, or which do not fall under any of the main headings.

Fifteen patients, when asked about personality changes, said that there had been such changes, but of a beneficial kind; only one of these patients thought that there had also been some bad effect. These favourable changes are mostly classifiable as increased stability of affect and a reduced liability to unpleasant emotional reactions. Increased self-confidence, increased confidence in others, increase of energy, initiative, and of interests are also mentioned. A patient who had had several years of orthodox psycho-analysis claimed that the operation had made him more adult and less narcissistic.

As might be expected, bad effects following the operation were more readily and more often recognized by the relatives than by the patients; nevertheless there was fairly good agreement. There was also close agreement in the kinds of bad effect reported, and the list quoted above provided by the patients is duplicated by the relatives, with somewhat increased numbers (see Table II). Irritability,

TABLE II.—Incidence of Certain Defects in 93 Cases

Nature of Defect	Report by Either Relative or Patient	Report by Relative	Report by Patient
Irritability	30	25	12
Lack of energy, laziness	15	12	6
Emotional flatness	23	15*	11
Intellectual or memory defect	12	7	8†
Tactlessness	13	11	5

* Includes two cases where the reduction in emotional responsiveness was regarded by the patient as an asset.
† Includes one case in which the patient did not regard this impairment of his powers of memory as a deficit, since they were reduced from phenomenal to normal.

lack of energy or laziness, and tactlessness were reported by the relatives twice as often as they were mentioned by the patients; though sometimes they were reported by the patients and not by the relatives. Although emotional flatness was reported more frequently by the relatives, they were patients were in general aware of this defect, and they were actually more sensitive to defects of memory and intellect than the relatives.

In addition to the above, relatives also reported, in individual cases, fits, frequency of micturition, difficulty in finding words, selfishness, restlessness, excitability, and an increasing interest in sex. The relatives reported some bad effects in 59% of the cases in which a standard leucotomy had been performed, and in 53% of those in which the operation was a modified one.

When asked about the effects of the operation on the personal relationship between informant and patient, 45 relatives replied that this had improved, 28 that there was no significant change, and 20 that there had been a deterioration. In these 20 cases irritability was reported in 15, lack of energy in 7, tactlessness in 4, emotional flatness in 4, and memory or intellectual impairment in 3. Irritability was by far the most ominous change and the one most likely to be associated with social deterioration.

Discussion

The aim of this paper is to present the solicited but unselected testimony of patients and their relatives about leucotomy. Of the 103 patients available at the time of the inquiry only three regarded their operation as a great mistake. Eleven others regretted having had it, but in

five of these cases the relative reported definite improvement, and in two more they said that the patient was no worse.

It is not appropriate here to raise the question of how far these results may justify the operation on certified patients without their consent. In the present series the operation was carried out only on the request of the patients themselves. It is clear from their replies to the questionnaire that they would, in the majority of cases, now regard any psychiatrist who had previously advised them against the operation as having been mistaken. On the other hand, they would regard with scepticism Pippard's (1955) statement that "positively undesirable changes" occurred in only 2 of a series of 114 cases treated by modified leucotomy.

There is an unfortunate tendency in the literature either to disregard favourable personality changes or to confuse personality changes of any kind with bad effects. Changes of personality that are regarded as favourable by patients and relatives are not uncommon, and may be independent of symptomatic changes. They may well be brought about by more than one mechanism. Thus Pippard (1955), in his series, reports a favourable change in energy output in seven patients, and attributes it to the removal of hampering symptoms. It might as easily be the case that an increase in energy, perhaps analogous to the increase in appetite often noticed after operation, has, through the activation of basic emotional drives and the arousal of normal interests, provided a primary contribution to the alleviation of symptoms. We argue all too easily that damage to tissues which appear normal under the microscope can produce nothing but defects, and that then, if symptomatic improvements occur, some defect must be called on to account for them. Surely the fact that leucotomy is a crude therapeutic weapon, and that unnecessary and unwanted changes are often produced by it, should not blind us to the observation that occasionally it may produce effects which are wholly beneficial.

Few will doubt that the incidence of personality defects is larger with more extensive operations than it is with modified ones (Meyer and Beck, 1954; Pippard, 1955). In the present series patients and relatives detected bad effects with approximately the same frequency in the standard and the modified series. Since those who had a full leucotomy made better symptomatic improvements than those who had only a partial operation, it would seem that, if the result obtained is generally good, side-effects may not only appear less important or less bad but also may actually be less readily detected. Any particular change of personality cannot be regarded as good or bad in itself, though there are some changes, such as irritability, whose effects are nearly always bad. With most changes of personality there are both good and bad sides to its effects; all that is observationally possible is to say whether the patient as a whole has benefited or has suffered. Even this is a question which can only be answered in a defined context. There are patients who consider themselves better and are considered worse by their relatives, and a more numerous group to which the opposite applies. By what standards are we to say that one opinion is right and the other wrong?

Summary

A series of 103 patients have been asked for their views about the value to them of a leucotomy-type operation: 66 were glad to have had the operation, 11 regretted it, and 3 thought it had been a great mistake; 23 were neither glad nor sorry that they had had the operation.

The views of 93 relatives were also obtained: 72 thought the patient was better off, 11 thought the patient was worse, 10 thought it had made little difference.

Unwelcome changes were reported by the patients in 43 cases and by the relatives in 51 cases.

In the present series a good result was reported much more often with a standard operation than with a

In seven cases the disease was so advanced that even laparotomy could not be advised; if these are excluded the operability rate rises to over 70%. Eight cases might be open to question: those where inoperability was judged on the fixity of the growth and the presence of enlarged glands, both of which conditions may be inflammatory and not due to growth. When these are the only contraindications to resection it is well worth removing the growth if at all possible.

Elective Surgery: Resection

Colon.—In this series 178 resections were performed for carcinoma of the colon; the operative measures used are shown in Table VI. The use of a Paul-Mikulicz operation

TABLE VI.—*Resection for Carcinoma of Colon*

		1945-50	1950-5
Right colon (71)	End-to-end	20	50
	Paul-Mikulicz	1	0
Left colon (50)	End-to-end	6	23
	Associated bowel drainage	(3)	(11)
Sigmoid colon (57)	Paul-Mikulicz	12	9
	Hartman's operation	8	35
	Associated bowel drainage	(4)	(15)
	Paul-Mikulicz	8	3
	Hartman's operation	1	2

on the right colon has never been popular in this country because of the small-intestinal fistula. The figures suggest that it is now less frequently used in the remainder of the colon. Excluding the right colon, end-to-end resection without bowel drainage was used in only 39 cases (36.4%). This figure seems low, but it was associated with a group in which 20.2% of all patients with colonic growths were admitted in acute obstruction.

Rectum and Recto-Sigmoid (Table VII).—The standard radical operation for these cases was some form of combined excision. Anterior resection was used for certain growths in the upper rectum and recto-sigmoid, while perineal resection and Hartman's operation were occasionally used for frail patients.

TABLE VII.—*Resection for Rectal and Recto-sigmoid Carcinoma (417)*

No.	1945-50	1950-5
Operable (palliative operations included)	178	239
Perineal resection	128 (71.9%)	186 (77.8%)
Hartman's operation	5 (2.8%)	5 (2.1%)
Anterior resection	33	52
Abdomino-perineal	64 (4.4%)	88 (36.8%)
Synchronous combined	14 (4.4%)	33 (13.8%)
Perineo-abdominal	7	2
Pelvic exenteration	—	4 (1.7%)
Operative mortality	7.8%	7.5%

The frequency with which *anterior resection* has been used—85 out of 314 resections (27%)—is rather higher than it would normally be for purely rectal growths and is due to the inclusion of recto-sigmoid growths in this group. Those selected for anterior resection should be early growths, not of high malignancy, at least 10 cm. from the anal verge, 5 cm. above the reflection of the peritoneum in the pouch of Douglas, and ensuring that a clear margin of bowel 5 cm. in length can be removed below the growth. There were no deaths among these 85 operations, and this has reduced the overall mortality rate: if these cases are excluded the mortality rises by 3%. The figures in this series suggest that while the abdomino-perineal operation is still in common use the *synchronous combined operation* is gaining in favour. The overall mortality of the abdomino-perineal operation was 7.9% and that of the synchronous combined operation 14.9%, but in the last five-year period both operations had the same operative mortality—9%. *Pelvic exenteration* was used on four patients with one death.

Operative Mortality

Colon.—Resection was performed on 178 patients with 18 deaths (Table VIII), a mortality of 10.1%.

Rectum and Recto-Sigmoid.—Resection was performed on 314 patients with 24 deaths (7.6%).

TABLE VIII.—*Causes of Post-operative Deaths*

Colon	Rectum
Peritonitis	4
Pulmonary embolus	4
Shock	2
Cardiac failure	2

	2
	2
	2
	1

In the three hospitals concerned in this series, pre- and post-operative exercises were routine throughout the greater part of this ten-year period, yet it is interesting to note that fatal pulmonary embolus equalled peritonitis as the most common cause of death.

Recurrence

Among patients dying from recurrence after resection there were 145 in whom necropsy or other evidence was sufficient to indicate the main metastases at death. Only a limited number were submitted to necropsy, and while the recurrence rate for the liver may be overestimated it will certainly be underestimated for the lungs, adrenals, skeleton, and lymph nodes. Brown and Warren (1938), in a series of necropsies on cases of rectal cancer, found hepatic metastases in 34%, pulmonary in 22%, adrenal in 11%, and occasional metastases in sacrum, spine, thyroid, and brain. In the present series the percentage of those dying from recurrence with liver metastases was 50.5% for the rectum and 48% for the colon, with pulmonary metastases 13.2% for the rectum and 6% for the colon, and with skeletal metastases 17.6% for the rectum and 2% for the colon; metastases also occurred in the brain and spinal cord, adrenals, lymph nodes, and kidneys. There were two cases of "A" rectal growths (Dukes's (1944) classification) treated by combined excision where metastases occurred in the brain and spinal cord at intervals of five and eight years after operation. Skeletal metastases and those in the brain and spinal cord were more frequent with rectal than colonic growths, and it is reasonable to explain this on the more likely involvement of the paravertebral venous plexus by rectal growths. Many writers have stressed the frequency with which excised growths show venous invasion and the influence which this has on prognosis. The frequency with which blood-borne metastases contribute to the patient's death is undoubted.

Evidence, at death, of peritoneal recurrence was present in 33% of rectal cases and in 39.6% of colonic cases, and these figures were not materially altered by the exclusion of "C" cases (Dukes's classification).

Recurrence at the anastomotic site occurred in 6 out of 85 cases of rectal cancer treated by anterior resection (7%) and is believed to have occurred in 15 out of 178 cases of colonic resection (8.4%). It is believed that the figures for the rectal cases are accurate and that all such recurrences are included, but for the colonic cases the evidence is less certain and the local recurrence rate may be higher. The importance of post-operative supervision after anterior resection is shown by the fact that five recurrences were treated by combined excision and that two of these patients were alive and free from recurrence six and six and a half years after the second operation. The remaining anastomotic recurrence had followed a palliative operation.

Survival After Colonic Resection

Although there are 297 colonic growths in the series, only 77 remain to be considered when from the total are deducted those inoperable cases, operative deaths, and (the largest deduction) those cases operated upon less than five years ago. The figures, which include palliative resection, show an overall five-year survival rate of 57.1%, with a high level of 68.6% for B cases and 34.6% for C cases (Table IX). If the figures are broken down into groups it is found that growths in the sigmoid colon have the lowest survival rate. This is in keeping with other findings, for of the 114 cases of sigmoid carcinoma in this series 28.9% were admitted with acute obstruction, 10.4% with general or local peritonitis, and 6.1% with a vesico-colic fistula, and the operability

TABLE IX.—*Colonic Resection. Five-year Survival Rate (five years elapsed since operation). Palliative Resections Included; Three Untraced Cases not Included*

Group	Operation Survivors	Died in Less Than 5 Years	Survived 5 Years
A	—	—	—
B	51	16	35 (68.6%)
C	26	17	9 (34.6%)
Total	77	33	44 (57.1%)

Two patients died of recurrence after five years.

rate was only 50%, the lowest of any group. One could sum up the outlook for carcinoma of the colon in this series, which I believe to be fairly representative, as follows: of every 100 patients admitted to hospital, including all cases, the 60 will have a resection, 6 will die from operation, and of the remaining 54, 31 will survive five years. A few of those (two cases in this series) surviving five years will subsequently die of recurrence. In a series reported by Colcock (1947) 13.6% of the five-year survivors died of recurrence in the next five years.

It is interesting to compare these results with those of Grinnell (1953) in a larger series from the Presbyterian Hospital, New York, consisting of 890 colon and 777 rectal growths over the years 1916 to 1945 inclusive. In the colon the five-year survival rate of all cases admitted rose from 5.9% for the period 1916-20 to 32% for 1936-40, but in 1941-5 it dropped to 30.8%. Unlike my own series, Grinnell found the worst prognosis to be in growths of the hepatic flexure, which he attributed to early invasion of the liver and duodenum. As regards lymphatic involvement, he found a 67.9% five-year survival rate for curative colon resection when no glands were involved and 36.7% of those with metastases. In the present series the figures are 68.6% and 34.6%, but all operations, including palliative resections, are included. Broder's grading on growth histology has not been applied to these figures, but it has always been shown that the degree of differentiation influences prognosis.

Survival After Rectal and Recto-Sigmoid Resection

Out of 314 cases, 162 survivors of this operation had been operated upon more than five years ago. The proportion of C cases is less than is usual in a series of rectal growths, and it is likely that fuller dissection might have placed some of the B cases in the C group. The figures, which include all palliative resections, show an overall five-year survival rate of 47.5%, with a high level of 78.2% for A cases and 28.8% for C cases (Table X). Taken with the operability rate

TABLE X.—*Rectal and Recto-sigmoid Resections. Five-year Survival Rate (five years elapsed since operation). All Operations, Palliative Resections Included. Four Untraced Cases not Included*

Group	Operation Survivors	Died in Less Than 5 Years	Survived 5 Years
A	23	5	18 (78.2%)
B	87	43	44 (50.5%)
C	52	37	15 (28.8%)
Total	162	85	77 (47.5%)

Three patients died of recurrence after five years.

and mortality rate they suggest that of every 100 patients admitted to hospital with carcinoma of the rectum, 75 will have a resection, 6 will die from operation, and of the remaining 69, 33 will survive five years. This figure is slightly better than that for carcinoma of the colon. Dukes (1944) quotes a figure of approximately 40% of the total entry at St. Mark's Hospital surviving five years after operation, but it is probable that general hospital beds are more likely to receive the frankly inoperable case. In Grinnell's series the five-year survival rate for all cases of carcinoma of the rectum admitted to hospital rose from 17.5% for the period 1916-20 to 32.7% for 1936-40, but in 1941-5 it dropped to 28.6%. These comparisons suggest that though the numbers in this series are small the picture they present of the disease is

probably a fair one. Private patients comprised over 40% of all cases in Grinnell's series and under 10% in the present series.

Survival After Combined Excision and After Anterior Resection

The after-results of cases treated by combined excision and by anterior resection are compared in Table XI, which shows that in this series the results of anterior resection were better than those of combined excision in all groups. Because of the small numbers, C cases show better results than B. Waugh, Block, and Gage (1955), from the Mayo Clinic, have

TABLE XI.—*Five-year Survival Rate after Combined Excision and After Anterior Resection (five years elapsed since operation)*

Group	Operation Survivors	Died in Less Than 5 Years	Survived 5 Years
<i>Combined Excision</i>			
A	12	4	8 (66.6%)
B	56	28	28 (50.0%)
C	36	28	8 (22.2%)
Total	104	60	44 (42.3%)
<i>Anterior Resection</i>			
A	10	1	9 (90%)
B	27	12	15 (55.5%)
C	9	3	6 (66.6%)
Total	46	16	30 (65.2%)

reviewed a series of 625 cases of rectal cancer treated by three procedures: combined resection, combined resection with sphincter preservation (an operation in which continuity is restored by perineal anastomosis), and anterior resection. They quote a five-year survival rate of 65.6% for anterior resection, 53% for the combined resection with sphincter preservation, and 51.6% for combined resection. While the five-year survival rate for anterior resection is the same, that for combined operations compares favourably with the figures in the present series.

The figures for anterior resection should not occasion any surprise: they are only to be expected. If radical restorative operations such as anterior resection are practised only on properly selected cases their results should be better than those of combined excision. Anterior resection should be chosen for a high rectal growth, and we know that, however treated, this type of growth has a better prognosis; it should be chosen for an early growth—and this has a better prognosis; and it should be chosen for a growth of low malignancy, again a factor for better prognosis. While I remain an advocate of the operation of anterior resection I do not think we should be unduly influenced by figures. However well selected, a patient treated by anterior resection will retain a slight risk of recurrence which would not be present had the whole rectum been removed. As against this must be set the advantage of retaining an anal orifice, and an operative mortality rate which is lower than that of combined excision.

Conclusions

In this series 20.2% of cases of carcinoma of the colon were not admitted to hospital until suffering from acute obstruction.

The mortality of the patient admitted in obstruction was approximately twice that of an elective resection when unobstructed.

Simple decompressive measures appeared to carry the lowest mortality in obstruction.

If all cases of the disease are included it is difficult to achieve a high operability rate in carcinoma of the colon or of the rectum.

End-to-end resection with associated bowel drainage was favoured for the colon; some form of combined resection for the rectum.

re used when complete skin cover is required for the orsum or for the palm. The skin of the abdomen is often used in young children for cover of the fingers: because of the extreme difficulty of effecting immobilization it is divisible to raise a much larger flap than is necessary and partially tube it. This will allow of movement of the hand in the abdomen and reduce the risk of traction on the recipient area.

Thumb.—Skin cover for the thumb can be obtained by any of the methods previously described, with the exception of the thenar flap. Local flaps can be used to cover the terminal phalanx, a similar method to that used in cross-finger flaps, described below. In the same way a skin flap from the dorsum of the hand can be used to cover the flexor aspect of the proximal phalanx. When possible, it is preferable to use local skin flaps, as the skin is of good quality for weight-bearing surface on the hand, and it develops a higher degree of sensation than skin transported from a distance. An example of this is a patient who lost the skin from the flexor aspect of his thumb, exposing tendon and necessitating full-thickness skin cover. The defect was closed by a flap elevated from the dorsum of the hand, turned through 90 degrees, and inset into the flexor aspect of the thumb. The flap was detached after 14 days.

Middle and Proximal Phalanges of the Fingers.—Skin loss over the flexor aspects of the middle and proximal phalanges of the fingers may be repaired by flaps from the abdomen, chest, or arm; but, ideally, cover is provided from the dorsum of the contiguous finger by the cross-finger flap method. Fig. 6 shows the stages of the operation. An example is the case of a patient who burned her right middle finger. The area of skin loss exposing the long flexor tendon and the digital nerve was covered with a flap raised from the dorsum of the ring finger and turned through 180 degrees. The donor area on the ring finger was covered with a Wolfe graft from the left breast. It is possible to inset this flap only when the fingers are flexed owing to the disparity in length of any two fingers.

Degloving Injury of the Palm and Dorsum

This type of injury, which is not uncommon in industrial accidents, is a shearing effect often caused by catching the hand in rollers or in a press. The entire dorsum, palm, or both surfaces may be turned back on a distally based flap. Should this flap carry with it the venous plexus, as it often does, then it will become cyanosed within a few hours and the arterial blood supply will inevitably fail. At the time of injury the flap may appear viable, as in fact it is, with a good colour and a freely bleeding edge. An immediate decision to excise the flap and cover the raw area with a graft or a flap, according to whether the tendons are exposed or not, is not an easy one to make. Most surgeons will stitch the flap back and review in 24 hours, and exposed tendons will not suffer from this delay should the flap fail to survive. It should be emphasized, however,

that undue delay is unwarrantable, as infection is common under necrotic skin, and this not only jeopardizes the survival of deep structures but adds greatly to the post-traumatic fibrosis.

The next case is an example of the degloving type of injury involving the palm of the hand. This patient caught his hand in rollers, and the whole palm from the wrist crease to the base of the fingers had been turned back on a distally based flap. This flap was of good colour and had a freely bleeding edge. It was stitched back. Twenty-four hours later the flap was cyanosed, and it was therefore removed, the defect being covered by an abdominal flap. Where whole-thickness skin cover by a viable flap method is required, whether for the dorsum or the palm, the donor site of choice is the abdomen. An alternative procedure rarely used for the dorsum of the hand is the tunnel flap (see Fig. 7). This method is mentioned merely to discard it. It has no advantages over the single-based flap and has many disadvantages. With the patient fully anaesthetized the flap will appear to accommodate itself to the defect by compression of the abdominal wall. When tone recovers, however, the flap becomes taut over the hand and the tension is taken on the suture lines with subsequent necrosis, spreading towards the centre of the flap.

Degloving Injuries of the Hand and Fingers

In degloving injuries of the fingers complete replacement with abdominal flaps or tubes cannot be expected to give the patient a normal digit. There is, inevitably, some loss in joint mobility, and the skin covering is a poor substitute for normal hand skin. It does, however, provide the patient with a means to grip and even pick up small objects, and is therefore superior to any other reconstruction. The patient presented under this heading caught his hand in rollers. The dorsum of the hand was degloved and all the fingers stripped of skin cover. The middle and ring fingers were fractured and fit only for amputation. Two flaps were elevated from the abdomen, tubed, and slid over the index and little fingers. The dorsum of the hand was covered with a free graft. The end-result is shown (Fig. 8). After replacement of the pulp with a free graft the thumb was functionally normal. This patient can now grip and pick up small objects.

Reconstruction of the Thumb

The position the thumb holds in the function of the hand is unique. Not only is it the key opposition element, but its weight-bearing surface is requisite in all composite movements. Loss of any part of the thumb constitutes a serious disability, and the methods used for its repair and reconstruction are dependent upon the amount of tissue loss. The provision of skin cover for the terminal phalanx has been discussed, and loss of less than half of this phalanx does not justify more radical procedures. Loss of

the terminal phalanx can, to some extent, be compensated for by apparent lengthening, a procedure known as phalangization, whereby the thumb web is deepened and the defect so created lined by a free graft. When the terminal loss of the thumb is of such an extent that it no longer reaches the level of the second cleft, then additional length should be provided to attain this level.

There are three commonly used methods for adding length to the thumb, each dependent on the degree of tissue loss:

FIG. 8

FIG. 9

(1) the chapeau flap of Gillies, (2) the tube pedicle and bone graft, and (3) pollicization. The preservation of normal skin with normal sensation in the thumb adds greatly to its functional place in the hand, and for this reason the chapeau flap is the method of choice where the additional length required does not exceed $\frac{1}{2}$ in. (2 cm.). It is essential, however, that minimal terminal scar should be present; otherwise necrosis will supervene and lead to loss of the bone graft. The following is an example of the chapeau flap. This patient, operated upon by Mr. Rainsford Mowlem, lost the terminal phalanx of his thumb while working a circular saw. A curved incision was made around the base of the thumb and the skin dissected off, superficial to the venous plexus, until it could be slid over the end of the bone, attached only to the first cleft. An autogenous bone graft of the desired length was fixed to the end of the bone and the skin replaced. A skin defect created at the base of the thumb was made good by a free graft. Fig. 9 shows the hand before and after operation.

In cases where the loss in length exceeds that of the terminal phalanx, a simple opposition post constructed by a tube pedicle and bone graft adds considerably to the function of the hand. The patient should be warned that for the first six months after reconstruction the skin is anaesthetic and should be protected against excessive heat and cold. Thereafter, a degree of sensation is present which is sufficient to protect the area from injury. Fig. 10 shows the hand of a patient who lost his thumb and three fingers. A tube pedicle from the right side of the abdomen was grafted on to the hand. After the pedicle had been detached

from the abdomen it was opened and an iliac bone graft inserted into the stump of his metacarpal. With his little finger and reconstructed thumb he was able to grip and resume his pre-accident occupation of gardening. The end-result is shown.

Pollicization

Where the thumb has been amputated down to near the base of the metacarpal, pollicization of the index finger must be given serious consideration. The hand with four fingers but without a thumb is a poor functional unit compared with a thumb and three fingers. This procedure has been fully dealt with by Cuthbert (1949). In those cases where the trauma to the hand has at the same time damaged the index finger, pollicization is the method of choice.

An example of this is the case of a boy who caught his hand in a lathe. The thumb had been amputated through the base of the metacarpal. The proximal phalanx of the index was left; but the skin was beyond repair. An immediate abdominal flap was utilized to repair the defect in the first instance (see Fig. 11). Later the index was pollicized. A flap from the dorsum of the hand was elevated and the interosseous muscle between the index and middle metacarpals was split. The second metacarpal was sectioned near its base. An incision was then made in the palm and the artery to the middle finger isolated and divided; the digital nerve was then split proximally. The deep transverse ligament and the adductor pollicis were divided; the index was then rendered freely mobile. The second metacarpal was wired to the base of the first. The extensor tendon to the index was sutured

to the extensor pollicis, and the dorsal flap was wrapped around the pollicized digit so as to give good local skin cover on the flexor aspect. The defect on the dorsum of the hand was covered by a free graft. Fig. 12 shows the end-result.

FIG. 10

FIG. 4

FIG. 5

FIG. 6

FIG. 7

At a later date the pollicized digit should be provided with an opponens tendon transplant, as there is a marked tendency for the digit to take up a position of adduction deformity. This deformity has been corrected and both opposition and abduction have been much improved in the case described. This addition to the method of pollicization has proved to be an advance on the earlier technique used.

Major Hand Reconstruction

In injuries of the hand where all the digits have been lost, the objective is the provision of a forceps type of hand by lengthening one or two metacarpals with bone

FIG. 11

FIG. 12

grafts covered by flaps or tubes of skin, and the reduction of the intervening metacarpal remnants. These two rays can be motivated by tendon transplantation to provide a simple means of opening and closing the forceps to enable the patient to grip. The provision of a mobile wrist-joint is of first importance in the functional end-result of this type of hand, and every effort should be made to achieve this by early active movements. It is interesting to observe how children with congenital absence of the fingers and a normal wrist-joint can adapt the palm and the dorsum of the hand to a surprising degree of usefulness.

Multiple Injuries

Damage to the hand, particularly in industrial accidents, may be associated with injuries to bone and soft tissues proximal to the wrist, whose immediate treatment and functional recovery are problems inseparable from those of the hand. Two cases are presented to illustrate these points.

One patient caught his arm in a cement mixer. In addition to a severe hand injury he had, in the same arm, a fracture of the lower end of the radius and a dislocation of the elbow. The dislocation was reduced, the fracture of the forearm plated, one finger amputated, and the other repaired. He recovered full function and returned to his pre-accident occupation.

In this type of case it is not only desirable to effect a one-stage repair, it is equally desirable to initiate composite movements of the entire limb in its rehabilitation.

The other patient caught his hand in an automatic die-casting machine with spikes. There was skin loss on the dorsum and palmar aspects of the hand associated with comminuted fracture of the lower end of the radius. There was a large area of skin loss on the dorsum of the wrist, exposing the fracture. The hand was repaired by free grafting, the radius was plated, and an abdominal flap was elevated and inset into the forearm to cover the plated bone. All areas healed without complication.

Summary and Conclusions

An attempt has here been made to illustrate accepted methods of using skin cover to repair injuries of the hand, the aim being to limit the loss of tissues that may affect the functional end-result. Primary skin cover reduces the incidence of infection and preserves deeper structures which would not normally remain viable if exposed. At the same time as the skin cover is provided, the underlying structures are rearranged so as to place them in the optimal position for the reconstructive phase. The stages of hand repair present a composite picture, each one being related to and dependent upon the other. Each stage must be consolidated by maximal functional recovery before proceeding to the next.

Transported skin must be toughened up and rendered freely mobile, tendons and nerves allowed to unite and function, joints activated, and the hand integrated into the synergic mechanism of the whole upper limb.

Throughout treatment, rehabilitation by those experienced in the care of damaged hands can do much to establish new cerebral patterns to compensate for loss or limitation of movement. Undesirable defence mechanisms and trick movements can be corrected and avoided by careful re-education as the stages of reconstruction proceed. In the end the patient should be left, not with a useless monument to the technical skill of the surgeon, but with a functional unit patterned on a conception of his primary requirements—earning a living and the performance of his usual daily tasks.

I wish to thank Mr. Rainsford Mowlem for his help and encouragement in this field of surgery, and in the preparation of this paper. I also thank Miss Farmer, of Rookdown House, Basingstoke, and Miss Walker, of the Photographic Department, Mount Vernon Hospital.

RENAL VEIN THROMBOSIS WITH NEPHROTIC SYNDROME AND RENAL FAILURE

BY

W. BRUMFITT, M.B., M.R.C.P.

AND

W. O'BRIEN, M.D., M.R.C.P.

From the Cambridge Military Hospital and Southern
Command (Leishman) Laboratory, Aldershot

Acute thrombosis of renal veins with renal infarction was first described by Rayer (1837-41). It may be either "primary" or, more commonly, a complication of dehydration, and is seen in infants. It presents as acute renal failure with anuria or oliguria, haematuria, and renal enlargement; it is usually rapidly fatal (Barenberg *et al.*, 1941).

A subacute or chronic thrombosis of the renal veins resulting clinically in nephrotic syndrome is a less common condition. Shattock (1913) described a case in which oedema of the legs and abdomen occurred in a 24-year-old medical student after he had run in a 120-yards race, during the whole of which he held his breath. Albuminuria persisted until death 25 years later. At necropsy the inferior vena cava was found to be converted into a flat impervious ribbon extending from the point of entry of the hepatic veins to below the renal veins. Both renal veins were occluded at their point of entry into the inferior vena cava. Derow *et al.* (1939) described a case of inferior vena caval, portal, and renal thrombosis in a 15-year-old boy who had the features of a nephrotic syndrome without renal failure and who died after six months' observation following an attack of acute gastro-enteritis. Fishberg (1939) described the case of a patient with migrating phlebitis who subsequently developed a nephrotic syndrome. At post-mortem examination canalization of thrombi of the inferior vena cava and renal veins was found. More recently Blainey *et al.* (1954) described three cases, in one of which thrombosis of the inferior vena cava and renal veins had resulted in typical nephrotic syndrome. This patient had a raised blood urea and died from pneumonia after one year's observation. Milne (1954) reports a case of intrarenal vein thrombosis in a patient with nephrotic syndrome who died following pneumococcal peritonitis.

A case is described below in which the nephrotic syndrome, with later progressive renal failure, was apparently due to a primary thrombosis of renal branch veins within the substance of the kidneys unaccompanied by thrombosis or occlusion of the main renal veins or the inferior vena cava.

Case History

The patient, a retired Army officer aged 57, leading an extremely active life, consulted his doctor on June 12, 1954, as he had noticed a sudden swelling of his legs and face. He had been playing tennis frequently, and the last game he had been on the day before symptoms appeared. He had had no previous illnesses of note, but had had a bullet wound of his left loin in 1917. He was admitted to the Cambridge Military Hospital on June 20, and was found to have severe pitting oedema of the legs and oedema of the face, whilst his urine was loaded with protein. The blood pressure was 150/90 mm. Hg and there were no other abnormal signs.

Investigations.—Urine: protein, 20 g. per litre (albumin 62%, globulin 38%); the deposit showed a moderate num-

ber of granular casts and red cells with a few epithelial cells. Serum proteins: total 4.1 g. per 100 ml. (albumin 30.2%, globulin 69.8%—alpha one 3.1%, alpha two 31.2%, beta 11.3%, gamma 24.2%). Apart from a somewhat higher gamma globulin the electrophoretic pattern was similar to that quoted by Squire (1953) as being associated with nephrosis. Oedema fluid protein, total 0.6 g. per 100 ml. (albumin 33.6%, globulin 66.4%). Blood urea, 30 mg. per 100 ml. Blood cholesterol, 400 mg. per 100 ml. X-ray film of chest and E.C.G.: N.A.D.

For the first few days after admission he was given a low-protein diet with 30 oz. (852 ml.) of fluid intake daily. On this regime his urine output fell rapidly from over 50 oz. (1,420 ml.) to 10 oz. (284 ml.) a day, and his plasma albumin dropped to 0.7 g. per 100 ml. He was then given a high-protein diet with restriction of sodium to less than 0.5 g. daily, his fluid intake being maintained at 30 oz. (852 ml.) daily. This was followed by a continued diuresis reaching 90 oz. (2,556 ml.) a day one month later. It was necessary to raise the fluid intake to 40 oz. (1,136 ml.) and then to 50 oz. (1,420 ml.) daily, as he suffered from thirst. The plasma albumin climbed gradually to 1.8 g. per 100 ml. and he lost a considerable amount of his oedema. From July 29 his high urinary output began to drop slowly. On August 5 his output was 60 oz. (1,704 ml.) a day and his intake 50 oz. (1,420 ml.), but his blood urea, which had previously shown only a slight elevation, rose to 120 mg. per 100 ml. His blood cholesterol at this time was 550 mg. per 100 ml.; serum sodium, 140 mEq/l., and serum chloride 90 mEq/l. From then onwards his urinary output fell slowly but steadily and the blood urea rose progressively. Towards the end of August he became drowsy and developed intractable hiccup. He sank gradually into a uraemic state and died on September 5.

During all this time he had continued to pass large quantities of protein in his urine (20-45 g. per litre). Red cells and granular casts were continually present. Towards the end of his illness pus cells appeared in the urine in increasing numbers. No organisms were seen in the Gram films, and urine culture was sterile. Blood urea readings were: June 25, 30 mg. per 100 ml.; July 1, 46 mg.; July 11, 50 mg.; July 24, 59 mg.; August 7, 120 mg.; August 12, 160 mg.; August 19, 186 mg.; August 26, 200 mg.; August 31, 215 mg.

The blood pressure remained approximately the same throughout the illness.

Necropsy Findings.—The kidneys were pale and much enlarged (right 250 g., left 235 g.) (Fig. 1). Numerous stellate veins could be seen through the capsule. The capsules stripped with ease, leaving a smooth, pale surface with reddish mottling. The pelves, ureters, and bladder showed no lesions. The renal veins and inferior vena cava contained no thrombus and were of normal appearance. However, there was thrombosis of several of the major renal branch veins and multiple thromboses of the arcuate veins. Apart from the latter findings the macroscopical appearance of the kidney suggested subacute glomerulonephritis (Ellis Type II).

FIG. 1.—Hemisection of the right kidney.

Microscopical Examination of Kidneys.—The glomeruli were normal and the basement membrane showed no thickening or other lesions. Many of the convoluted tubules were dilated and the lumina contained large numbers of polymorphs, debris, and eosinophilic fluid. Gram's stain failed to demonstrate the presence of organisms. The dilated tubules were lined with atrophic epithelium. No regeneration of epithelium was present, and the appearances suggested a chronic tubular atrophy (Fig. 2). The collecting tubules were normal. The interstitial tissue was fibrotic and oedematous, there being a patchy infiltration by lymphocytes and polymorphs. Examination of the pelvis of the kidney revealed the presence of multiple intrarenal branch vein thrombi. Many of the thrombi showed organization and recanalization (Fig. 3).

FIG. 2.—Dilated convoluted tubules containing either large quantities of pus or eosinophilic fluid. Note increase of interstitial tissue. (Periodic acid Schiff.)

FIG. 3.—Branch of the renal vein within pelvis of kidney to show thrombus undergoing organization and recanalization. (H. and E.)

Discussion

This case differs from previously reported cases in that the nephrotic syndrome occurred in an adult, associated with renal vein thrombosis and occlusion which was wholly within the substance of the kidney. Furthermore, there is discrepancy between the findings of apparently typical "large white kidney" and the histological features. Chronic glomerulonephritis, amyloid disease, pyelonephritis, and eclampsia have been reported as having been complicated by multiple thrombi in the main and medium-sized branches of the renal veins resulting in acute terminal uraemia (Vilk, 1940). Bilateral renal vein thrombosis in a youth of 18 without involvement of the inferior vena cava was reported by Miller *et al.* (1954) and was associated with polyarteritis nodosa. However, in the case which we have described no associated disease was found. The case of thrombosis of main renal vein tributaries reported by Milne (1954) was in a boy of 7 who had a typical nephrotic syndrome. The thrombi were undergoing organization, and it was concluded that these could have dated from the onset of the disease. The histology of the kidney was not discussed.

In children renal vein thrombosis may be secondary to dehydration or it may be "primary" (Barenberg *et al.*, 1941; Sandblom, 1948; Zuelzer *et al.*, 1951). Thrombosis usually begins in the arcuate and interlobular veins, although even smaller veins may be involved (Morison, 1945). Moreover, in children, when the inferior vena cava is thrombosed there is evidence that the thrombus starts in the small veins of the kidney and extends from there into the renal vein and inferior vena cava (Kobernick *et al.*, 1951). It is common in these cases to find associated thrombosis in other vessels, suggesting that the thrombosis may be the expression of a systemic factor whether it be haemoconcentration, blood slowing, damage to the endothelial wall, or other cause (Zuelzer *et al.*, 1951; Becker, 1954). In our case thrombosis involving other organs was not found. In view of the organization and recanalization of many of the thrombi and the rapid course of illness it is likely that multiple renal branch vein thrombosis was present at the onset of the illness and did not constitute a terminal event. It is suggested that the high pressure in the tributaries of the renal vein produced by the presence of thrombi resulted in a heavy proteinuria and thus, ultimately, to a fully developed nephrotic syndrome. It has been shown experimentally in dogs that gradual progressive obstruction of the renal vein after unilateral nephrectomy results in persistent albuminuria with apparently normal renal function (Rowntree *et al.*, 1913).

Histological examination did not reveal glomerular lesions, and it must be assumed that protein escaped from the glomeruli in the absence of obvious structural changes. Corcoran (1952) draws attention to the fact that in a normal kidney up to 10 mg. of protein a minute may escape from the glomeruli: under normal circumstances this is all absorbed by the proximal tubules. In this case the presence of gross proteinuria is explained by the increased escape of protein from the glomeruli accompanied by considerable failure of tubular reabsorption due to the presence of chronic tubular atrophy (Fig. 2).

It is interesting that Shattock's case followed a period of acute exertion, as did this case. It is known that such exercise may cause proteinuria or even haematuria, and that the mechanism appears to be decreased renal blood flow accompanied by slowing of the renal circulation (Covian and Rehberg, 1937; Barclay *et al.*, 1947). It would seem possible that in the present case the thrombus occurred or extended during a period of severe exercise (not necessarily the last game of tennis), and that this was the precipitating cause.

Summary

A case of intrarenal branch vein thrombosis associated with nephrotic syndrome is described. The possibility that the nephrotic syndrome was secondary to the multiple thrombosis is discussed.

We are grateful to Captain T. Freeman, R.A.M.C., for carrying out the electrophoretic studies, and to Colonel R. Spicer for permission to publish the case.

SMOKE IN A LONDON DIESEL BUS GARAGE

AN INTERIM REPORT

BY

B. T. COMMINS, M.Sc., A.R.I.C.

R. E. WALLER, B.Sc.

AND

P. J. LAWTHORP, M.B., M.R.C.P.

Medical Research Council, Group for Research on Atmospheric Pollution, St. Bartholomew's Hospital, London

Exhaust products from motor vehicles are known to be potentially harmful to man in that they contain substances which, if inhaled in sufficiently high concentrations, are noxious. Much is known of the composition of vehicle exhausts, but such analytical data, though essential, are of limited toxicological value unless the degree of dilution in the ambient air is known. No practical assessment of the potential danger is possible without knowing what man is likely to breathe. The highest concentrations of exhaust products to which men are regularly exposed probably occur in garages, and we are at present studying air pollution in one of London Transport Executive's garages for diesel buses. This study is being supplemented by extensive analyses of exhaust products of various diesel vehicles under different running conditions on the L.T.E. test track at Chiswick. Our work is being done in the closest co-operation with London Transport Executive, which has offered us every facility for the investigations.

Our efforts have been directed initially to the study of diesel exhausts as a matter of urgency in view of recent suggestions that, because 3:4-benzpyrene has been found in soot from diesel engines, they might be at least partly responsible for the rise in the incidence of lung cancer. It is with this urgency in mind that we have prepared an interim report of our findings with respect to smoke and benzpyrene; a detailed account of our findings with respect to all suspect pollutants will be published later.

Site of the Investigation

In consultation with the London Transport Executive, the garage at Merton, S.W.19, was selected for a pilot study. It is one of the executive's older garages, situated about seven miles S.W. of Charing Cross in a fairly densely populated area with some factories near by. Nearly 200 buses are parked there every night, and most of them have the same type of 6-cylinder 9.6-litre diesel engine. Ventilation of the garage is by natural draught (through the length of the garage) and at present no extractor fan is in use. Most buses leave the garage in the early morning, and at this time a lacrimatory mist is produced for short periods as groups of buses are started up. The effect is most marked on cold mornings and is worst in the "annex," a poorly ventilated section adjoining the main garage. Some buses return for periods during the day, and all finally come back during the evening. At this time buses are left by their drivers in the mouth of the garage and are moved on, generally within a few minutes, for re-fuelling, washing, and ally parking. These manoeuvres involve several short bursts of acceleration with periods of idling in between, and, when a number of buses are running at once, smoke haze is visible.

Methods

The main object of this pilot survey was to determine the concentration and composition of smoke inside the garage. It was desirable to sample the air at sites where pollution was highest, and it was essential to take simultaneous samples of the air outside the garage, as there was likely

to be an appreciable amount of smoke from general urban sources. That the sampling sites we selected were indeed those with the highest concentration of smoke was later confirmed by direct experiment. The first survey was made on the night of April 18/19. It was cold and misty, and there was much town smoke in the air. It was later felt that the high levels of ordinary urban pollution on this occasion might have obscured any contribution made by the buses to the benzpyrene content of the garage air, and a second survey was therefore made on the night of June 21/22, when there was very little town smoke. This night was mild and there was some light rain. Exactly the same procedure was followed each time.

The nights were divided into four periods, during which the air inside and outside the garage was sampled continuously. The first two simultaneous samples were taken between 6 p.m. and 11 p.m., during which period buses were coming in a few at a time to be re-fuelled and washed at intervals. The second period was from 11 p.m. to 1 a.m., when there was maximum activity and greater pollution; buses were coming in almost continuously, and fuelling and washing were in progress most of the time. During the third period, from 1 a.m. to 5 a.m., there was no vehicular activity. In the fourth period, from 5 a.m. to 7 a.m., buses were being started up, and on the first occasion some were run for a few minutes before leaving the garage. The first three indoor samples were taken at one of the fuelling points, and the fourth in the annex. All four outdoor samples were taken on a flat roof adjacent to the garage.

Samples were obtained by drawing air at a rate of about 40 cu. ft. (1.13 cu.m.)/min. through weighed sheets of glass-fibre filter-paper. Between 20 and 430 mg. of smoke was collected on each filter, and in Table I these amounts are expressed as milligrams per cubic metre of air sampled. Each filter was extracted for several hours with cyclohexane, and the yellowish solution obtained analysed for polycyclic hydrocarbons by a modification of the method described by Cooper (1954).

Results

Determinations were made of the amounts of anthracene, pyrene, fluoranthene, 1:2-benzanthracene, 1:2-benzpyrene, 3:4-benzpyrene, and 1:12-benzperylene in each extract, and in some cases there was enough material to allow two determinations to be made on aliquot parts. In Table I, the amounts of 3:4-benzpyrene are expressed as micrograms per cubic metre of air sampled. Results are arranged in pairs, so that comparison can be made between the concentrations inside and outside the garage at any given time.

Concentration of Smoke and 3:4-Benzpyrene at Merton Garage

Period	Site	April 18-19		June 21-22	
		Smoke mg./m. ³	3:4-benzpyrene* µg./m. ³	Smoke mg./m. ³	3:4-benzpyrene µg./m. ³
(1) 6-11 p.m.	Garage	1.81	0.28	0.81	0.027
	Outside	0.92	0.34	0.24	0.015
(2) 11 p.m.-1 a.m.	Garage	3.04	0.46	1.44	0.026
	Outside	1.46	0.47	0.23	0.014
(3) 1-5 a.m.	Garage	0.77	0.21	0.21	0.011
	Outside	0.66	0.24	0.18	0.018
(4) 5-7 "	Annex	1.72	0.27	0.48	0.005
	Outside	0.55	0.20	0.14	0.006

* Mean of two estimations.

Discussion

To interpret the results it is necessary to assume that in the absence of pollution by buses the concentration of smoke inside the garage would be the same as that outside, and that it would contain similar amounts of 3:4-benzpyrene. That this is approximately so is borne out by the similar smoke concentrations found between 1 and 5 a.m., when all buses were parked. The slight differences in the concentration of 3:4-benzpyrene at that time could be due to chance. At all other times the concentration of smoke was much higher in the garage than outside, and it seems

reasonable to attribute the excess to exhaust smoke. The greatest difference noted between the concentrations of smoke inside and outside was about 1.6 mg./cubic metre, and this represents a 100% increase over the outside level. However, despite these considerable differences in the total amount of smoke, the amount of 3:4-benzpyrene in the garage remained virtually the same as outside. The estimations are not accurate enough for the detection of small differences in benzpyrene content, and the results from the first night are consistent with a hypothesis of no difference between the benzpyrene concentration of the air inside and outside the garage at any time. The results from the second night, when there was very much less smoke outside the garage, suggest that the buses might have added a small amount of benzpyrene to the garage air, an amount of perhaps the same order as that existing outside. As each figure is based on a single estimation only, these small differences cannot be established with any degree of certainty, but it is certain that the concentration of 3:4-benzpyrene does not rise in proportion with the concentration of smoke. It is also clear, by comparing results on the two nights, that any contribution of 3:4-benzpyrene by the buses is negligible in comparison with the fluctuations which may arise from the varying levels of smoke outside. The smoke from the buses must then contain little, if any, 3:4-benzpyrene, and certainly less than coal smoke.

These findings have been supported by the results of experiments carried out on individual buses running round a test track at London Transport's Chiswick works. No 3:4-benzpyrene has been detected in the exhaust smoke from several buses in average condition, but in samples from others small amounts have been found. In all cases the proportion of 3:4-benzpyrene in the smoke has been smaller than that found in coal smoke, and experiments are continuing in order to determine the conditions under which it is emitted. Kotin, Falk, and Thomas (1955) found no 3:4-benzpyrene in the exhaust smoke from a diesel engine operating efficiently, but they found considerable quantities under conditions of inefficient operation. It is important to note that London Transport derate all their engines by 10% in order to reduce the possibility of heavy smoke emission, and they also ensure, by a carefully arranged maintenance routine, that they are kept in excellent mechanical order.

Summary

Measurements have been made of the concentration of smoke and its associated 3:4-benzpyrene in the air inside and outside a London bus garage. Whilst the concentration of smoke is greatly increased when the buses are running in the garage, there is little difference in the concentration of 3:4-benzpyrene. It is concluded that the exhaust smoke from these buses contains little, if any, 3:4-benzpyrene, and this conclusion is supported by the results of experiments carried out on individual buses. Small quantities of 3:4-benzpyrene have been found in the exhaust smoke from certain buses, and experiments are continuing in order to determine the conditions under which it is emitted.

ADDENDUM.—Since this report was written, analyses of further samples of smoke, including quadruplicate determinations of 3:4-benzpyrene, have been completed. These results, together with the determinations of other polycyclic hydrocarbons, confirm the conclusions reached in this interim report and will be published later in full. The experiments reported here are to be repeated in the near future at another garage housing buses powered by engines of a different make.

Miss P. M. Harrison, B.Sc., of this group, carried out most of the analyses reported here. We are indebted to the London Transport Executive for providing facilities for this investigation.

Medical Memoranda

Intra-arterial Thiopentone Injection in a Patient with Anomalous Forearm Vessels

The dangers of intra-arterial injection of thiopentone have been amply recorded in medical journals and textbooks of anaesthesia, yet cases still occur in which the drug is given into an artery, not because of ignorance on the part of the operator but often because what is believed to be a vein happens, in fact, to be an anomalous artery. The following case illustrates this point.

CASE HISTORY

A fit young man aged 24 was admitted to hospital for removal of a ganglion on his left wrist. To induce anaesthesia, a light rubber tourniquet was placed around the right arm proximal to the cubital fossa and a prominent subcutaneous vessel in the fossa was entered with the needle. Blood spurted into the syringe, the tourniquet was released, and a test injection of 2 ml. of 5% solution of thiopentone was made. Immediately the patient complained of pain at the injection site and tried to withdraw his arm, and the distal half of his forearm and hand noticeably blanched. The radial pulse disappeared. The needle was withdrawn, and during the next two to three minutes the colour of the skin and the radial pulse returned to normal.

Similar procedures were carried out on a vessel on the radial side of the cubital fossa and then on one on the ulnar side, at the junction of upper and middle thirds of the forearm. In these, only 0.5 ml. of solution was injected, and the reaction, although similar to the first, was less severe.

The patient was anaesthetized with ethyl chloride and ether, and suffered no ill effects from his experience.

At first it was thought that he was in some way abnormally sensitive to the drug, but careful examination of his right arm showed that the distal 3 in. (7.5 cm.) of the brachial artery, the proximal 3 in. (7.5 cm.) of the radial, and the proximal two-thirds of the ulnar artery were all superficial, as shown in the diagram. The numbers indicate the three injection sites.

COMMENT

There is little doubt that superficial arteries in the upper limb are relatively common. Cohen (1948) emphasizes their frequency and the dangers inherent in their non-recognition. Dubreuil-Chambardel (1926) found 90 in 500 subjects, about 50% bilateral; and he cites Testut, who found an incidence of 12.5%, and Ancel, who had an incidence of 15.9%.

Out of 481 limbs, Quain (1894) found 64 high divisions of the brachial artery at various levels upwards to the lower border of the axilla; the radial artery was the branch prematurely separated in 75%, but sometimes the ulnar artery, and more rarely a vas aberrans which joins one of the forearm arteries.

McCormack, Cauldwell, and Anson (1953) found 18.5% of 750 limbs with major variations in brachial or ante-brachial patterns, the commonest (15.45%) being a high origin of the radial artery. A high radial origin associated with an unusual course of the ulnar artery occurred in 1.9%, and a superficial brachial artery forming a common trunk for radial and ulnar arteries in 1.27%.

This patient had the common radio-ulnar trunk. Characteristically there is a high or low origin of a common trunk

from the axillary or brachial artery respectively; this is superficial in the cubital fossa, where it divides into radial and ulnar branches which remain superficial, the former in the proximal third and the latter in the proximal two-thirds of the forearm.

Ileo-colic Intussusception after Appendicectomy

Ileo-colic intussusception following appendicectomy is a rare condition. Cleland (1953) reviewed the five recorded cases, and added a sixth. In a further case, here reported, the intussusception occurred within two weeks of operation for acute appendicitis.

CASE REPORT

A lance-corporal aged 19 was admitted to hospital on January 26, 1954, with a typical history of acute appendicitis. Appendicectomy was performed through a gridiron incision; the appendix, lying in the pelvic position, was incised; the appendix, lying in the pelvic position, was incised; the appendix, lying in the pelvic position, was incised. The acutely inflamed throughout the whole of its extent. The stump was invaginated with a purse-string suture, and the caecum and proximal part of the ascending colon were noticed to be abnormally mobile.

Post-operative progress was satisfactory until the evening of the fourth day, when he complained of a vague central abdominal pain, which recurred several times throughout the day. On the fifth day the pains became increasingly severe, were colicky in nature, and were localized to the left iliac fossa. He had developed anorexia and had not vomited. His bowels were opened normally twice early in the day; no mucus or blood was seen, but after the second bowel action he passed no flatus up to the time of his second operation. His general condition was good, pulse 80, and temperature 99° F. (37.2° C.). He had tenderness, with guarding, over the right half of the abdomen and normal gut sounds were heard. Rectal examination showed no mass high up in the pelvis. Urine examination showed no abnormality; his total white-cell count was 12,000 per c.cm., with 82% polymorphonuclear leucocytes; and a straight x-ray examination of the abdomen in the standing position revealed no conclusive abnormality.

During the evening of the fifth day after operation his condition deteriorated. He began to vomit, and his pulse rate rose to 120 and his temperature to 100.2° F. (37.9° C.). The pains became less severe and less frequent. The tenderness and guarding had spread to the epigastrium and the left hypochondrium. No mass was palpable. Intestinal obstruction due to an intussusception was tentatively diagnosed and operation advised. Under anaesthesia an elongated mass lying transversely in the epigastrium could be felt.

Laparotomy was performed through a right lower paramedian incision. There was an intussusception of the terminal 9 in. (23 cm.) of the ileum and the caecum into the ascending colon and transverse colon, almost to the splenic flexure. This was fairly easily reduced except for the caecum, which had formed the apex of the intussusception. The caecum was finally reduced manually, accompanied by a few small spurts of pus from the oedematous and inflamed site of the invaginated appendix stump. The caecum and the proximal part of the ascending colon were quite mobile and had a short mesentery. The site of the appendix stump was infected, with flakes of pus covering the serosa, but the wall of the caecum appeared quite viable. The capillary oozing was controlled with hot packs; the caecum was dusted with penicillin powder and replaced in the abdomen. The wound was closed in layers and the peritoneum drained.

The patient was placed on a five-day course of intramuscular crystalline penicillin, 200,000 units six-hourly, and streptomycin, 0.5 g. twice a day. Intravenous infusion and

gastric aspiration were continued for three days. On the third day after his second operation he was well enough to take fluids by mouth and to get up. He continued to make satisfactory progress, and by the tenth day was quite fit and awaiting his sick leave.

DISCUSSION

The cases reported by Rouquette (1914), Brodersen (1930), Schaaff (1933), Roesgen (1943), Ingelrans *et al.* (1947), and Cleland (1953) were of intussusception occurring in the immediate post-operative period following appendicectomy for acute appendicitis. In all of these the site of the invaginated stump of the appendix had formed the apex of the intussusception. The reports recorded either state definitely or infer that the stump had been invaginated, and the case described here is no exception. The advisability of invaginating the stump is questionable. Since invagination is such a frequent procedure, the rarity of the intussusception seems unusual if this is the cause.

Mayo (1934) quotes his pathologist, who had found a pocket of pus at the site of the invaginated appendix stump in cases in which appendicectomy had been performed in combination with another surgical procedure and death had occurred within 21 days. It seems likely that it is the oedematous inflamed wall of the caecum, sometimes with small abscess formation, which may act as the apex of the intussusception, not the invaginated stump of the appendix.

There is, however, another factor—that of failure of the third stage of rotation of the mid-gut, with the resulting mobile caecum and ascending colon. Forshall (1953) states that a fixed caecum is unlikely to intussuscept. Aird (1949) is more definite in claiming that ileo-caecal intussusception cannot occur unless the caecum and ascending colon are mobile and provided with a mesentery. Intussusception of the vermiform appendix with subsequent ileo-colic intussusception is a much more common occurrence than ileo-colic intussusception following appendicectomy, and McSwain (1941) collected 81 published cases. He added a personal case in which the patient had an ileo-colic intussusception originating from partial intussusception of the appendix. At operation the intussusception was reduced and the appendix removed. This appendicectomy was followed by a recurrence of the ileo-colic intussusception three months after operation. The caecum and ascending colon were extremely mobile and possessed a long mesentery.

In the case presented the patient exhibited two important aetiological factors—namely, an inflamed oedematous wall of the caecum, forming a mass at the site of the invaginated appendix stump, and a mobile caecum and ascending colon with a mesentery.

It seems reasonable, therefore, to suppose that the intussusception would not have occurred unless the congenital abnormality were present together with the inflammatory mass in the caecal wall. If this were not so, ileo-colic intussusception following appendicectomy would occur much more often than it does.

It is usually considered unnecessary to perform any fixation of the intestines after reduction of an intussusception in a child. If, however, a mobile caecum with a mesentery is found at appendicectomy, ileo-colic intussusception may be prevented by attaching the caecum to the lateral abdominal wall by means of sutures.

I wish to thank Colonel A. G. D. Whyte, consultant surgeon, B.A.O.R., for his assistance and encouragement in preparing this report.

Reviews

DRIED B.C.G. VACCINE

Dried B.C.G. Vaccine. By Yoji Obayashi, M.D. (Pp. 220; illustrated. 25s., \$5.00, or Sw. Fr. 15.) Geneva: World Health Organization. 1955.

The World Health Organization is engaged in tuberculosis control campaigns all over the world, in which B.C.G. vaccines play a leading part. One of the most important problems met with is that of the transport of liquid B.C.G. vaccine over long distances, for the vaccine is very labile and rapidly loses potency, particularly in hot climates. Of great importance is the fact that because of its instability the vaccine has to be used before many of the tests can be performed which should be included if the absolute safety of the vaccine is to be ensured. Much work has been done in many countries in an effort to produce a more stable vaccine; the most hopeful project at the moment would seem to be the freeze-dried vaccine on which the Japanese have been concentrating for some years. As much of the information they have gathered is not readily obtainable by workers in the West, W.H.O. has published this monograph in the hope that the findings reported will be of general interest to all concerned with the problems of B.C.G. vaccinations. Only those who have actually worked on the problem will appreciate the enormous amount of work which is recorded in the 212 pages of this monograph, reporting as it does the results of numerous viability counts, animal experiments, and human inoculations.

As a result of their experiments the Japanese favour a vaccine prepared as follows. The bacilli are grown on Sauton's medium and harvested in the late logarithmic phase of growth. They are then suspended in 1.25% saccharose. Freeze drying is carried out in a chamber in which the ampoules of vaccine are prefrozen to between -15° and -20° C. During drying the water vapour is sublimed on to a condenser refrigerated to -40° C. The drying time is approximately seven hours, when the residual moisture content should be between 1 and 3%. The vaccine is finally sealed *in vacuo*, neither nitrogen nor dry air proving satisfactory for final packing. By this procedure a vaccine possessing about 40% of its original viability and having a stability vastly superior to that of the liquid vaccine is obtained, though, as the author states, "it has not yet been developed to the point where it can be safely preserved at room temperature in summer."

This book should certainly be in the hands of all those working on this problem. There are a number of points on which they would like further information; many of the tables are somewhat obscure, and the book suffers from the common disadvantage of those concerned with rapidly expanding subjects by being already out-of-date at the time of publication. In a personal communication Dr. Obayashi has informed me that they have now greatly improved on the 40% survival reported in this book.

R. I. N. GREAVES.

THERAPEUTIC HYPNOTISM

Hypnosis and its Therapeutic Applications. Edited by Roy M. Dorcus, Ph.D. (Twelve sections plus a 14-page index. 56s. 6d.) London, New York, and Toronto: Blakiston Division, McGraw-Hill Book Company Inc. 1956.

This is in many respects an outstanding contribution to the literature of hypnosis. Based on a series of postgraduate lectures delivered at the University of California in 1952, it covers the theoretical, experimental, and therapeutic aspects of the subject. A temperate discussion of theories regarding the nature of hypnotic phenomena is followed by a description of various methods of induction, a study of the control of sensory and perceptive functions by hypnosis, an account of its physiological effects and influence on learning and habit-formation, and some notes on the genuineness of hypnotic phenomena. The clinical sections are rather meagre in content, but include chapters on the uses of hypnosis in differential diagnosis; on symptom-formation

control and the control of pain; on the applications of hypnosis in general hospital practice, dentistry, and "supportive therapy"; and on methods of "hypno-analysis."

Psychiatrists will note, with, it is to be hoped, some chagrin, that the volume is the work of seven Ph.D.s and a dental surgeon. And although it might well have been enriched with contributions from medical hypnotists and possibly illumined by commentaries and paraphrases from a psychoanalyst versed in the techniques of hypnosis, it is a good example of team-work on a subject that calls for the attention of both clinical and laboratory psychologists. The most ambitious, though the most obscurely written, chapter is by a laboratory psychologist, Sarbin, on the physiological effects of hypnotic stimulation. Produced by an eclectic team, the book states the therapeutic claims of hypnosis with a becoming modesty which might well be copied by other sorts of psychotherapist. Incidentally, the theory of hypnosis most generally favoured by the writers is that of "role-taking," a psychological concept which would be more illuminating if the unconscious origins of identification and dramatization were more fully explored. (Compare, for example, the factor of "suitability for plastic representation" noted by Freud in his *Interpretation of Dreams*.) Fortunately the authors are not dogmatic even on this point, and the reader is left to form his own impressions, which doubtless will be determined by his own theoretical predilections.

EDWARD GLOVER.

A.M.A. SCIENTIFIC EXHIBITS

A.M.A. Scientific Exhibits, 1955. Sponsored by the Council on Scientific Assembly, American Medical Association. (Pp. 784+xiv; illustrated. \$20.00.) New York: Grune and Stratton. 1955.

At each Annual Meeting the American Medical Association stages a gigantic scientific exhibition which is the envy of all other associations. The five days of the meeting are all too short to examine the 300 or so exhibits and to attend the many other events. In 1955, for the first time, the A.M.A. has attempted to record in book form some of the exhibits, so that the many who are unable to be present may study them carefully at leisure. In the preface Dr. Thomas G. Hull, the organizing genius of the scientific meeting, claims with justification that this exhibition offers the finest medical postgraduate course in the world. These 800 pages give a complete photographic record of about one-third of the exhibits, from which one cannot fail to learn much of current medical research and practice in the U.S.A. This volume, however, serves another and possibly more important purpose, as a record of methods of medical illustration. In fact it could almost be a textbook on the subject, showing the varying techniques of display. It is of interest to note how use has been made of the best in the methods of artists in many different media. Apart from the orthodox artist, architect, sculptor, or photographer, there are examples of the methods of the window-dressers of Fifth Avenue, the strip cartoonist of the "comic," the arresting work of the commercial poster artist and the slogan writer, to mention but a few.

As a reference volume this is a "must" for any hospital or medical school department of medical illustration. Those preparing material for scientific exhibitions will be inspired by its pages, and saved a great deal of time in deciding on the methods to adopt. Two constructive suggestions are offered for subsequent volumes. As some of the best exhibits depend on colour for their effect, in future there should be a few colour plates, even at the cost of cutting down the number of exhibits recorded. In addition, as the whole exhibition is an attraction in itself as much as the individual items, it is submitted that there is a place for a few pictures of the whole exhibition in action, showing the bustling, viewing crowds, the discussions between the viewers and exhibitors, and, for those who have a special interest in such matters, plans of the general layout and details of grouping, lighting technique, and construction of booths.

The A.M.A. is to be congratulated on producing this magnificent volume, and it is to be hoped that it heralds a long series.

BLOOD GROUPS AND DISEASES

The suggestion that particular blood groups, especially those of the ABO system, may be associated with particular diseases has recurred in the literature since about 1920. Apart from the investigations into haemolytic disease of the newborn, which is in a separate class and does not concern us here, most of the earlier studies failed to yield conclusive positive results, some because the diseases chosen for investigation had little or no connexion with blood groups, but others because they were planned on too small a scale or because of diagnostic or classificatory defects. It is now known, however, that some of them, though they were ignored at the time, did lead to correct and important conclusions.

More recently, in 1951, D. Struthers¹ showed that among infants in Glasgow dying of bronchopneumonia the frequency of blood group A was higher than it was among the general population. Then in 1953 I. Aird, H. H. Bentall, and J. A. Fraser Roberts² demonstrated a highly significant excess of persons of group A among sufferers from carcinoma of the stomach, which means that among all persons of group A a higher proportion have the disease than among persons of other groups. Their paper is of outstanding importance, not only because of the conclusions themselves, but because, by showing that definite positive conclusions could be reached in such investigations, it encouraged many other workers to enter the field; it set, moreover, an admirable diagnostic and statistical standard which most of these workers have followed. Beyond the confirmation and consolidation of existing knowledge, work carried out since 1953 has been directed to two main objects—the discovery of other diseases associated with blood groups, and the elucidation of the nature of such associations. It was very soon shown³ that an excessive proportion of sufferers from peptic ulcer were of group O, and subsequently⁴ that such an excess, though present in gastric ulcer, was much more marked in duodenal ulcer. A significant excess of group A has now been established⁵ among sufferers

from diabetes mellitus. For some diseases, notably carcinoma of the lung,^{3,6} it has been shown that there is virtually no connexion with the ABO blood groups, while for others, such as carcinoma of the colon and rectum,³ suggestive results have been obtained but the numbers of patients investigated have been inadequate to establish a significant excess of one blood group. Most of the work hitherto published has been carried out in Great Britain and based on the British population. Workers in this country may therefore feel a legitimate satisfaction in having opened up this important new field of research and in their great achievements in it.

The virtual restriction of investigations to one relatively homogeneous population has, however, been in many ways a disadvantage and has made it unnecessarily difficult to elucidate the nature of the connexion between a given blood group and a particular disease. Whenever such a connexion has been established two principal hypotheses must be considered in order to account for it. One is that the presence of a particular blood-group gene or antigen somehow increases susceptibility to the disease or fails to give protection from it. The other is that there are present in the population separate strains, of different historical origin and intermarrying little if at all, one characterized by high frequencies both of the blood group and of the disease, and another by low frequencies of both. If it could be shown that the same connexion was present in a number of populations of varying origin and in different countries, it would be most unlikely that it resulted from the coexistence of the same two racial strains in each of the countries. Already the results which are beginning to be obtained in countries outside Britain for a number of diseases are confirming the relations found here and so tending to disprove the hypothesis of separate strains.

This week the *Journal* contains two important contributions to the subject. A co-operative study reported in our opening pages by many workers in a number of different centres in Britain shows pernicious anaemia to be 20% commoner in persons of group A than in those of other blood groups. The numbers of patients examined is still small, and it is to be hoped that further investigations will be carried out and published. This study is a model of co-operation; in the case of a relatively rare disease, or when the effect of the blood groups, though real, is slight, it is only by means of such co-operation that we can hope to reach satisfactory conclusions. In view of the known connexion between pernicious anaemia and carcinoma of the stomach, it is satisfactory to find that the associations with the blood groups are similar in the two diseases.

heaps that are poorly made and not mixed. There are no recorded cases of disease arising from the use of habitation waste in agriculture in Great Britain.³

Under anaerobic conditions less nitrogen is required for composting because less carbon is oxidized completely. The temperature does not rise so rapidly or to the same maxima in anaerobic heaps, and pathogens are destroyed under these conditions more slowly than in composts that are turned frequently. The methane produced under these conditions, which are similar to those obtaining in the digestion of sewage sludge, can be stored in small gas cylinders and used on farms or in villages. One metric ton of organic waste yields about 50-70 cubic metres of methane, and about two cubic metres are required per day for cooking for an average family.

The duration of composting in aerobic heaps depends on the moisture content, particle size of the material, and the efficiency of mixing and aeration, all of which can be controlled, and also on the composition of the materials used, which is variable. When the carbon-nitrogen ratio is initially less than about 20 to 1, composting for a few days gives a product which can be safely applied to crops. If the final carbon-nitrogen ratio is greater than about 15 to 1, however, there is a risk that nitrogen in the soil will be utilized to decompose carbon compounds in the compost, and this can result in a serious check to plant growth. In general, the longer composts are stored the greater the amount of nitrogen they release for crop growth; in commercial composting for horticulture, storage may be for 8-12 months, but this is seldom possible when habitation wastes are composted in municipal plants, when storage is usually limited to 2-3 months. The approximate composition of composts prepared from habitation wastes, and of farmyard manure, is as follows:

Materials Composted	Moisture Content	% Dry Matter			
		N	P ₂ O ₅	K ₂ O	Ash
Garbage and refuse (U.S.A.)	—	1.4	1.1	0.8	37
Sewage sludge and town refuse (U.K.)	40-50	1.0	0.9	—	70
Refuse (Holland)	20-35	0.4-0.5	0.4-0.5	0.4	75-80
Farmyard manure	74	2.2	1.6	2.0	36

Composts from town refuse have a lower nutrient content than farmyard manure, and have given lower yields in field trials, particularly under wartime conditions when efficient sorting removed much of the organic material for feeding pigs.³

The quantities of nutrients and organic matter in town refuse are small compared with the amounts of inorganic fertilizers or farmyard manure used in Great Britain. The Zuckerman Report⁴ concluded that town refuse collected annually in this country contains

about 25,000 tons each of nitrogen, P₂O₅, and K₂O, but that over three-quarters of these nutrients were present in fine dust which it would not be economical to compost. This report also showed that about 700,000 tons of compost could be made annually by composting household wastes with sewage sludge; the estimated nitrogen content was about 4,500 tons, which is, however, only about 2% of the total nitrogen used each year in inorganic fertilizers. Although composting household refuse and sewage sludge by local authorities appears uneconomical in Great Britain, and would not conserve significant amounts of plant nutrients, it has been suggested that agricultural wastes and sewage sludge could usefully be composted where local conditions are favourable, and this is done at several plants in Britain. The efficient conservation of the nutrients in sewage effluent, in which at present 60,000 tons of nitrogen and large but unknown quantities of potassium salts are discharged annually into the sea, appears to be more important economically in this country than the recovery of the nutrients in town wastes.

RESPONSE TO LEUCOTOMY

A preference for an empirical rather than a theoretical outlook is traditionally supposed to mark the British character, and there are those who would argue that in psychiatry it is a preference that bears fruit. In this country psychiatrists probably concern themselves with philosophical issues less than do their colleagues overseas. One result of this has been the greater development and application of physical therapies than elsewhere, and the most radical of these, leucotomy, must by now have been performed about 15,000 times in Britain. While for many years the correspondence columns of this and other journals have contained discussions on the ethical pros and cons of this operation, general practitioners and psychiatrists have gone on steadily recommending it for suitable patients simply because it so often helps them when all else has failed. In an article published at p. 739 of the *Journal* this week Drs. Alick Elithorn and Eliot Slater show what a high proportion of patients can be helped by this operation, especially when selection of cases is very carefully carried out, as it is at the National Hospital, Queen Square. But if too full a cut is made, or patients are badly selected, the results will not always be so pleasing. Moreover, this particular series included only five schizophrenic patients, and some of the deleterious effects attributed to leucotomy in the past arose from leaving a patient with a schizophrenic illness too long untreated, so that emotional dilapidation from the illness itself was added to any undesirable effects of the operation.

Before this irreversible measure is carried out every other means of treatment should of course have been tried. Some patients do well on the new chemical tranquillizers, and they should always be given a trial before operation

is finally considered, but there is not yet any convincing evidence for recent suggestions that these drugs have done away with the need for either full or modified leucotomies. Most schizophrenic patients should generally be left for at least two years and be given all other forms of treatment, alone or in combination, before the operation is seriously thought of; in cases of neurosis and depression an even longer period of illness should be allowed. Many neurotic illnesses turn out to be atypical depressions and the patient recovers spontaneously after a year or two of waiting; and most neurotic illnesses have high remission rates whatever the type of treatment given. Again, it should be borne in mind that the result is the personality before illness the better the result is likely to be from the operation. Only when chronicity really appears to be present in either a neurotic or psychotic illness, and when all other treatments have been tried and failed, and when the patient is suffering from severe anxiety or from much unrelieved agitation and tortured self-concern, should the issue come to decision; then Elithorn and Slater's article shows that many patients will be grateful rather than critical after the operation.

Though Elithorn and Slater's paper does not mention the particular types of modified leucotomy performed on the patients in their group, the operation varies considerably in the hands of different surgeons. Some now feel strongly that modified operations, when thoroughly severing the tracts in the lower medial quadrants of the frontal lobes, are to be preferred to the full operation even in some cases of schizophrenia, and practically always in the neuroses and depressions. This seems to be a sound view, even though the personality deficits of the full operation were not found to cause complaint by patients or relatives in Elithorn and Slater's group so much as is sometimes reported by other workers. If necessary a second and fuller operation can always be done, but nothing can undo the effects of too extensive a cut done in the first instance. Undoubtedly when the modified operations come into more general use many of the remaining objections to this means of relieving intolerable mental suffering will diminish. Elithorn and Slater do well to state: "Surely the fact that leucotomy is a crude therapeutic weapon, and that unnecessary and unwanted changes are often produced by it, should not blind us to the observation that occasionally it may produce effects which are wholly beneficial." It is to be hoped that such an opinion now coming from the National Hospital and the neurological research unit of the Medical Research Council will do much to stop scare stories about this operation, for these not only can cause much unnecessary distress to patients and relatives, but may even stop a patient from having the only treatment which offers any hope at present of ameliorating a chronic and intractable mental illness.

BALLISTOCARDIOGRAPHY

The first ballistocardiogram was recorded nearly eighty years ago by J. W. Gordon,¹ who used a light bed suspended by ropes from the ceiling to record the movement imparted to the body by the heart and circulation.

J. S. Haldane and his colleagues² used a form of ballistocardiograph in order to determine the effect of altitude on cardiac output on the Pike's Peak expedition, their apparatus consisting of a plank supported on cork piles. Later other workers³⁻⁵ became interested in this field of investigation, and finally I. Starr⁶ in 1939 described his high-frequency instrument and developed the theory, technique, and clinical application of ballistocardiography.

Three main types of ballistocardiograph are used today. These are the Starr table, with a natural frequency of 10 cycles per second or higher; the Nickerson⁷ table with a frequency of 1.5 cycles; and the simpler Dock⁸ type of ballistocardiograph, which records the motion of the subject as he moves back and forth on a rigid table. The deflections of the normal ballistocardiogram were named by Starr according to the letters of the alphabet, H, I, J, K, L, M, N. The genesis of these deflections is still debated, though the H wave is believed to be due at least in part to the forces of atrial contraction and the J wave to forces resulting from ejection of blood into the aorta and pulmonary artery. While ballistocardiography is usually confined to recording the longitudinal movements of the body, three-dimensional ballistocardiograms have also been recorded,^{9,10} the record being named the vectorballistocardiogram.

The main clinical problems to which ballistocardiography has been applied have been the estimation of the cardiac output and the diagnosis of ischaemic heart disease. Both Starr¹¹ and J. L. Nickerson¹² have devised formulae for calculating the cardiac output, but these have not so far proved sufficiently accurate under varying circumstances and in the presence of different heart diseases to be of practical value. B. M. Baker and colleagues¹³ in a study of 110 patients found that in the presence of ischaemic heart disease both the ballistocardiogram and the electrocardiogram were usually abnormal, but that in certain cases the ballistocardiogram alone was abnormal and hence might be a useful test. More recently L. Brotmacher,¹⁴ using a Dock type of ballistocardiogram, has reviewed the criteria for the normal ballistocardiogram, but his conclusions about its practical clinical value were guarded. Although ballistocardiography and electrocardiography were invented at about the same time toward the end of the last century, their development has been unequal; while electrocardiography has become an essential method of investigation, ballistocardiography remains at present primarily a research process.

EXPERIMENTS ON CONVICT VOLUNTEERS

Two medical research projects this year in which convict volunteers have collaborated are of special interest: the first, at the Ohio State Penitentiary, because of the nature of the experiments—the grafting of live human cancer cells into the volunteers; and the second, which is being carried out under the aegis of the Union of South Africa's Department of Nutrition, because it is the first example in that country of this use of convicts. Moreover, the fact of using convicts at all in medical research is in itself a debated question. In America a code of ethical rules governing the conduct of such research is believed to be already in existence.

By courtesy of the bodies responsible for these two investigations we are able to give details of how the volunteers were obtained, the safeguards adopted, and the practice with regard to incentives, as well as some information about the experiments themselves.

Research at Ohio State Penitentiary

The Ohio State Penitentiary has a tradition for helping in medical research. Thus, when the Sloan-Kettering Institute for Cancer Research, New York, and the Department of Medical Research of the Ohio State University College of Medicine needed human volunteers to further their work on the immunology of cancer, they turned for help to the Warden of the Penitentiary, Warden RALPH W. ALVIS. Experiments at the Sloan-Kettering Institute had already shown that transplanted cancer cells would grow slowly, remaining localized, when injected subcutaneously into patients with cancer who had volunteered for this. With the approval of the Warden, and the director of the Ohio Department of Mental Hygiene, Dr. JOHN D. PORTERFIELD, the following notice, signed by the medical director of the prison hospital, Dr. RICHARD H. BROOKS, appeared in the May 19 issue of the *Ohio Penitentiary News*. The *News* is a weekly newspaper written and published by the prisoners which is offered for delivery anywhere in the United States at 50 cents per annum.

"CANCER RESEARCH VOLUNTEERS NEEDED"

"For many years there has existed, one of many puzzling phenomena in the growth of cancer cells that still needs an answer; is still unsolved. Live cancer cells can be transferred from one individual to another. In the person who has cancer, the cancer cells will live and grow. In the person who has no cancer in his body, all of the transferred cells will die, eventually, after a short period of growth. It is this part of the problem that requires some further observation and study. Just how the normal individual who does not have cancer can kill off the transplanted 'Foreign' cancer cells, is the present important problem. So far, in past experiments, all attempts at growing one person's cancer cells in another individual, who does not have cancer, have ultimately failed. This is so, definitely, as far as we know now, that if transplanted cells do not grow, when injected into another person, it follows, that the injected person does not have cancer. If the cells do grow, it would indicate that the person injected probably does have a hidden or lurking cancerous growth, somewhere in his body.

"With the approval of Doctor Porterfield, Warden Alvis, and myself, the Sloan-Kettering Research Institute of N.Y.C. and the Department of Medical Research of the O.S.U. College of Medicine, are prepared to further study this problem, on volunteer inmates of the Ohio Penitentiary. The study will be directly supervised by Dr. Charles A. Doan, Director of Medical Research, College of Medicine, Ohio State University.

"The study would consist of the injection of live cancer cells (taken from some person who has a cancer) that have been kept alive in test-tubes, into both forearms of the volunteer—by direct needle injection under the skin. At the end of a two-week period, one of the injection sites would be entirely removed by a surgical excision of the injected area. The injection site in the other forearm would be observed for an—as yet—undetermined period of time, and then later be surgically removed. The

study of these skin biopsies—it is hoped—would bring forth some information on how the normal or non-cancerous individual's body-reaction goes about its normal process of 'killing-off' these foreign cancer cells that have been transplanted into it.

"The only hospitalization required would be for overnight stays, following the biopsies (surgical excision of the injected areas).

"Inmates with any type of known illness (diabetes, quiescent T.B., syphilis, osteomyelitis, peptic ulcer, heart trouble, high blood-pressure, etc.) would be acceptable as volunteers for cancer research.

"Men eligible for transfer to one of the Branch Camps, or assignment to another institution such as LPF, MCI, would also be acceptable.

"Approximately twenty (25) five volunteers will be utilized in this project.

"Any one interested in volunteering for research on our yet most baffling problem of our age, are requested to send a 'kite' to Warden Alvis."

Volunteers were asked to sign, in the presence of two witnesses, an authority provided by the Ohio State University, at the foot of which it was stated: "The organizations involved in this study agree to pay for any and all medical care, special treatment, biopsies, etc., that may be necessary in connection with this study." The authority was in these words:

"I, of the Ohio Penitentiary, and being of the age of 21 years or more, hereby volunteer myself freely and of my own will as a subject of experimentation in connection with a study of cancer, to be carried out under the joint supervision of the Division of Medical Research, College of Medicine, the Ohio State University, and the Sloan-Kettering Institute for Cancer Research of New York City.

"This study, as it has been explained to me, is intended to determine whether or not presumed live cancer cells can be successfully transplanted, indirectly, from one individual to another. I have been told that the cancer cells will be transplanted to my body by means of direct needle injection under my skin. I further understand that if the cancer transplant is successful that its existence will be observed for an indefinite period (whether I am still an inmate of the Ohio Penitentiary or not or am transferred to one of its branches). Further, I will readily agree to submit to a surgical excision of the involved area at any time or to a biopsy of adjacent (nearby) areas of my body upon the request of the principal investigators, Doctors Charles A. Doan, Alice E. Moore, and Chester M. Southam, or their associates. It is expected that if the transplant survives that the entire growth will be entirely removed. From time to time a sample of my blood will be drawn for analysis during this study.

"I also hereby agree that I will not donate any of my blood to the American Red Cross for transfusion until a release for same is obtained."

As a result of this appeal, the Warden received applications from 130 of the 3,800 convicts in the penitentiary. They formed, apparently, a fair cross-section of the inmates, including "some lifers as well as long- and short-time prisoners." The Warden is quoted in the *News* (of June 6) as saying that about 40% of those who applied added reasons for their volunteering, a majority stating that members of their families had died or were suffering from cancer; a few saying they had been "blanks all their lives" and welcomed the opportunity to do something useful; and some that they were grateful for what the prison regime had done for them, one specifying the education he had received there. The authorities offered no incentives to the volunteers. Indeed, most of the convicts in their applications made it clear that they understood there were to be no special privileges or prerogatives granted as a result of their volunteering. Fourteen of the volunteers were chosen for inoculation.

The story is carried a stage further in the July 7 issue of the *News*, which prints an extract from a report in the *Columbus Citizen*. This records that the 14 volunteers were inoculated subcutaneously in each forearm with the cancer cells on June 14, and that two weeks later "a section surrounding the injection was removed from one forearm of

each man." The report ends: "The fourteen participants, who have been given daily physical checks since the injections, include four lifers, four statutory offenders, four serving time for burglary and larceny, and two forgers. They have been working at their regularly assigned prison jobs since the start of the cancer research project. Biopsies of the injections on their forearms will be taken at a later date yet to be determined."

South African Project

In South Africa a working group from the National Nutrition Research Institute of the Council for Scientific and Industrial Research, operating under the aegis of the Union Department of Nutrition, is investigating the effects of variations in dietary fat in two groups of volunteer prisoners, one consisting of 20 European males and the other of 20 Bantu males. All the volunteers are serving long sentences. The original sponsor of the investigation and leader of the research team is Dr. P. J. KLOPPERS. The research stems from the current interest in the part played by fat intake and racial factors in coronary disease.

Although this is the first occasion on which convict volunteers in South Africa have been used for medical research, no special legislation was necessary. Arrangements were made by mutual agreement between the State Departments of Prisons and Nutrition, with the Council for Scientific and Industrial Research undertaking the laboratory aspects of the investigation. The project is reported to have the sanction of Mr. C. R. SWART, the Minister of Justice. No restriction has so far been placed on the type of investigation the working group may carry out. The only condition is that both the nature and aim of the experiment should be fully explained to, understood by, and voluntarily agreed to by each prisoner taking part. No prisoner, it is stated, "will necessarily be pardoned of part of his sentence merely by taking part in the experiment, while on the other hand again no prisoner will be penalized should he at any stage of the investigation desire to withdraw, with or without satisfactory reasons." The working group is also sworn to secrecy regarding the use of "photographs, family and personal histories, experimental findings, etc.," in writing up the work. Code numbers are being used to prevent the volunteers' identification.

There are no direct incentives to volunteering, but certain indirect ones are noted by the working group: "They [the volunteers] can of course look forward to changes (mostly for the good) in a rather monotonous diet, like the incorporation at some stages of the work of more highly satisfying fats of animal origin (e.g., butter), also eggs and so forth; the getting together for group talks by members of the working team; and in the case especially of the Bantu volunteers some extra cigarettes or tobacco."

The aim of the research is to throw light on the role of the diet, and in particular its fat content, in the aetiology of coronary thrombosis. The investigators hope to evaluate the relative importance of such factors as race and family history, and whether the consumption of unsaturated fats instead of saturated fats, or the presence of some other feature in the unrefined Bantu diet, affects blood cholesterol levels or the liability to thrombosis. The present cholesterol levels of both the Bantus and the Europeans in the prison diets are known each to contain 18% of fat. After investigation are known each to contain 18% of fat. After stabilization at this level both diets will be altered so that the consumption of saturated fats is increased to 40%, the diets being kept isocaloric by the withdrawal of carbohydrates. Again after stabilization, the Bantus will then be placed on the European diet with 40% of saturated fats. (The Europeans' diet remains unchanged.) After further stabilization, diets of both groups will be changed only in so far as the saturated fats will be replaced by unsaturated fats. Next both groups return to their own basic diets, but now containing 40% of unsaturated fat. Finally, each group goes back to its own original diet. The groups are

matched for age, and each group has a control group of 10 prisoners of the same race whose prison diet will not be altered. During the whole period, full clinical and laboratory investigations are being undertaken, including a full personal and dietary history and an attempt to assess the degree of "maleness" of each subject. This research has now been in progress for several months, and the results are awaited with interest.

PROGRESS IN BLOOD TRANSFUSION
INTERNATIONAL CONGRESS IN BOSTON

[FROM A SPECIAL CORRESPONDENT]

Advances in the technique of platelet transfusion, briefly noted in our issue of September 15 (p. 656), formed the main talking point at the International Society of Blood Transfusion's sixth congress in Boston this month. The congress was held in conjunction with the annual meeting of the American Association of Blood Banks from September 1 to 5, immediately after the congress of the International Society of Haematology (see *Journal*, September 15, p. 655). Dr. I. S. RAVDIN and Dr. J. J. GRIFFITHS presided.

Plastic Equipment in Transfusion

The work on platelet transfusion was presented by Dr. J. L. TULLIS and his colleagues from Boston. It was only the use of plastic bags and tubing and siliconed needles that made it possible. Dr. Tullis uses the Cohn automatic blood-fractionator to separate blood into red cells, plasma, and platelets. He then washes the platelets and resuspends them in gelatin. After freezing, they can be preserved for months. Dr. M. STEFANINI and Dr. E. KLEIN (Brighton, Mass.), and others, use the new plastic apparatus described by Dr. C. W. WALTER and manufactured by Fenwal; with this it is possible for any laboratory to prepare, *ex tempore*, packed cells, plasma, and concentrated suspensions of platelets without exposing the blood to any risk of contamination and without any waste; it will now be possible, for the first time, for any large hospital to prepare fresh frozen plasma and platelet suspensions. On first inspection this seems to be one of the greatest technical advances in transfusion since the introduction of blood banks, and one must hope that before long the equipment will be available for trial in Britain. If the quality of the plastic can be maintained, it may even prove advantageous to replace our glass bottles entirely by this plastic equipment.

Blood Groups and Antibodies

At the joint meeting with the International Society of Haematology on the first day of the Congress, a series of new discoveries in blood groups was announced: new alleles at the Ss locus (S^u , previously labelled U) by Dr. T. J. GREENWALT (Milwaukee); at Kk (Kell) by Dr. F. H. ALLEN, Jr. (Boston); at ABO (B^w) by Dr. P. LEVINE and Dr. M. J. CELANO (Raritan, N.J.). Dr. RUTH SANGER (London) showed that P, p, and Jay form a system similar to A_1 , A_2 , and O, for anti-Jay agglutinates all bloods containing P or p. Dr. M. SHAPIRO (Johannesburg) reviewed the MNS system, which now includes M,N,Ss,U (now S^u), Henshaw, and Hunter. The Rhesus system has been further complicated: the anti-V serum related to Rh was further studied by Dr. E. R. GIBLET and Dr. A. J. MOTULSKY (Seattle); Dr. H. H. GUNSON and Dr. W. L. DONOHUE (Toronto) described the phenotype C^wD-/C^wD- ; while Dr. R. E. ROSENFELD (New York) described an anti-D antibody, found in the serum of an Rh-positive woman, which agglutinated all Rh-positive cells except her own; absorption studies indicated that this subject lacked some component of the D-antigen mosaic. Indeed, all the blood-group systems are becoming more complicated. In the Rhesus system the hypothesis of

a one-to-one correspondence between genes and antigens seems now to have become inadequate, however fruitful it may have been in the past. There is clear evidence that the D antigen at least is composed of a mosaic of receptors or groups with antigenic specificity, and the only way of retaining the original hypothesis would be further to subdivide the D locus into yet more closely linked or inseparable sub-genes. Fortunately, however, these complexities are not often clinically important, though they may be of the utmost genetic and serological significance. These new discoveries may eventually necessitate some revision of the nomenclature.

Dr. J. V. DACIE (London), Dr. M. CUTBUSH (London), and Dr. J. H. VAUGHAN and Dr. M. V. WALLER (Richmond, Virginia) have studied the antibodies which behave as if they were composed of alpha and beta globulins—i.e., the “non-gamma-globulin” antibodies. These are nearly all cold antibodies, and their reaction in the anti-globulin test is due to absorption of the C₁, C₂, and C₄ components of complement on the sensitized cells. Antibodies to Lewis, H, A and B, P, Tj^a, Fy^a, and some Kell, M, and N antibodies, are of this type, and will not be detected if stale or inactivated serum is used in the test unless fresh complement is added. Dr. F. STRATTON (Manchester) underlined the importance of this for the Le^a antibody which is often a factor in transfusion reactions.

SOCIETY OF MEDICAL OFFICERS OF HEALTH

In his presidential address to the Society of Medical Officers of Health on September 20, Dr. J. D. KERSHAW, M.O.H. of Colchester, took a peep into the future. He was concerned not so much with the future shape of the public health service as with how its officers could make the most of their chances. Their Society, said Dr. Kershaw, was a community of true equality, which recognized that each member, whatever his status and seniority, could contribute something to the common pool. Apart from internal complacency and disunity, only three things could impede their progress: bureaucracy, hierarchy, and authority.

Bureaucracy, Hierarchy, and Authority

All these influences were at large. Perhaps at close quarters they were not very easily recognized. As an international Civil Servant with the United Nations, he had seen bureaucracy and hierarchy carried toward their awful conclusion. In a task with desperate urgency it had been distressing and infuriating to see how procedure caused delay and frustration, and rigidity robbed expert skills and knowledge of their effect. Back in England, his joy at the free air of public health was tempered by seeing the early symptoms of those diseases he had just encountered abroad at an advanced stage. “I urge,” said Dr. Kershaw, “that we examine our public health bureaucracy.” Public health was now and always would be a matter of helping people to live successfully. Flexibility and humanity were absolutely essential, whether for the helper or the helped.

It was the move towards bigger units which had also taken them toward a hierarchic administration, and close to hierarchy ran authority—“Father knows best” or, perhaps worse, “Father knew best.” It was well to remember that the newest recruit brought to his work a fresh viewpoint. He was every bit as likely to have something to contribute as an elder statesman.

Positive Health

In public health they were now moving out of an era centred on the development of the personal health service

into a search for positive health in its widest sense. A hundred years ago clinicians, by and large, had neither interest in nor time for preventive work. Public health workers had had to strike out into this field alone, and the evil effects of that cleavage between prevention and treatment were still only too apparent to-day. At all costs a similar schism in the field of mental health must now be avoided.

It was inevitable that psychiatric knowledge should have developed through the study of the diseased mind, but experience of mental illness did not inevitably lead to an understanding of mental health. It was unfortunate, too, that psychopathology exerted such a fascination on mankind as a whole. The human being who never in his life did or said anything that would not pass through the meshes of the psychiatrist's sieve was a rare creature and a poor one. Cranks and eccentrics were as important to the working of society as to that of the motor-car. A psychiatry that would stigmatize originality and individuality as signs of maladjustment could bring about as dangerous and deadening a uniformity as mass-advertising and political indoctrination. But there were welcome signs that, while one wing of psychiatry was moving rapidly in that direction, the other was seeing more than a glimpse of reality. It had been a psychiatrist who recently defined mental health as “a matter of getting on with people.” But, whatever the definition, the prevention of mental ill-health was largely a social matter. It was in the home, the school, or the place of work or recreation rather than by the couch-side that positive achievements would be made.

A second great problem of the times was the care of the ageing. There was no part of medicine where clinicians were becoming more social-minded or where there was greater scope for co-operation. “I want to see,” said Dr. Kershaw, “the people who care for the aged outside meeting and getting to know their charges while they are still in hospital.” The health visitor in particular should be a welcome guest and colleague in the wards. Another problem was the care of the handicapped. It was worth remembering in this connexion that whether a disability was or was not a handicap depended very largely on circumstances. And circumstances could be changed and modified. Help could be given in the planning of these people's lives, in reducing their risk of ill-luck and facilitating their opportunities. These three examples—the fields of mental health, geriatrics, and the handicapped—said Dr. Kershaw in conclusion, illustrated the new challenge: the future's outstanding needs were social rather than medical, and this applied to all the major problems they now faced.

OCCUPATIONAL HEALTH

MACKENZIE INDUSTRIAL HEALTH LECTURE

Dr. R. S. F. SCHILLING, reader in occupational health at the London School of Hygiene and Tropical Medicine and president of the Association of Industrial Medical Officers, gave the sixth Mackenzie Industrial Health Lecture at B.M.A. House on September 25. His subject was “Assessing the Health of the Industrial Worker.” The lecture, which is sponsored by the B.M.A. in conjunction with the Association of Industrial Medical Officers, was open to all interested in industrial medicine. The chair was taken by Dr. ALEXANDER HALL, President of the B.M.A.

Dr. Schilling reviewed the usefulness and reliability of such indices of industrial health as occupational mortality statistics, sickness-absence rates, records of treatment, and the results of field surveys, stressing some of the pitfalls. In the past, said the lecturer, industrial medicine was restricted to problems of industrial disease. “To-day the research

worker and the doctor in industry are expected to assess the extent to which many physical and psychological factors influence health.”

Mortality and Morbidity Rates

Occupational mortality rates were still of great value. Within the last ten years they had revealed or confirmed risks of lung cancer in arsenic, asbestos, and gas workers, and supported the hypothesis that the physically active in work get less coronary heart disease than the inactive. But they could mislead, indicating non-existent hazards or failing to show important ones. The Registrar-General's data were not sufficiently detailed to indicate certain hazards, such as the risk of those exposed to benzol and its compounds dying of aplastic anaemia, leukaemia, and liver necrosis, or dyestuff workers of bladder tumours.

Many occupational diseases might be revealed by sickness-absence rates, but such statistics were beset with difficulties. Recorded sickness in industry was dependent not only upon the pathological condition but upon many other factors—such as the nature of the employment, whether wages were paid during absence, and the method of recording. All these factors must be taken into account when comparing sickness statistics between one industry, factory, or occupation and another. Selective recruitment and discharge might also be important. But analyses in which these various factors were accounted for had been invaluable. Treatment records were also used to assess occupational health, but they might not be a reliable index of minor accidents and illnesses. Whether or not a worker reported for treatment depended on many things. Some made light of minor ailments. Others made the most of them. Distances from the ambulance room, the personality of the nurse, possible loss of wages, and so on might all influence the worker's decision to attend for treatment.

Field Surveys

Higher mortality and morbidity rates might only point to occupational hazards. Subsequently field surveys might be needed to show the extent and nature of the risk. In field surveys persons might be examined clinically, by set questionnaires, or by interview. In this type of work there were difficulties which did not arise in the statistical analysis of mortality and morbidity data. Little or nothing could be done without the co-operation of the population or a sample of it. If a minority refused to be seen or was not available, those who were seen might not be representative. A low lapse rate was usually achieved only by hard and painstaking preparation in gaining the support of the workers, their unions, and their employers. There were also important problems of error in observing clinical signs, in reading radiographs, in taking histories of symptoms, and so on. Much that was recorded might be unreliable, and the validity of the observations and answers given to questions had to be tested before the data could be used. If these difficulties were overcome, the field survey could be a valuable instrument of research. Although the field survey was useful in investigating diseases with a relatively high prevalence, it was of less value where the occupational risk was low, because so many workers had to be seen to get conclusive results.

Conclusion

But if one accepted the World Health Organization's definition of health as a state of physical, mental, and social well-being, and not merely the absence of disease, said Dr. Schilling in conclusion, then freedom from occupational disease could only be one component of occupational health. Conditions of lighting, atmospheric temperature, hours of work, the length of working spells, and so on clearly influenced well-being. In addition there were psychological factors: the worker should be suited to his job, both physically and mentally, and he should be able

to feel that he was making a useful contribution to the community. All these aspects had to be taken into account in the assessment of occupational health.

MEDICAL DEFENCE UNION

The annual meeting of the Medical Defence Union was held at the Birmingham Medical School on September 18. The president, Dr. S. COCHRANE SHANKS, gave an address on “Medical Litigation, Past and Present.” The situation could be summed up in a sentence, he said: “In the olden days there wasn't very much; now there is a great deal.” After a graceful reference to the presidency of Mr. Lawson Tait (1887-93), a leading Birmingham surgeon, and to the Union's early history, Dr. Shanks turned to the present. Of all the claims now made against members only a third were justified, he said, in that the Union either settled out of court or lost in court. In the other two-thirds the case was won in court or abandoned by the plaintiff. But, as in 80% of the court cases the plaintiff received legal aid, costs were usually not recovered even if the result was favourable. In two cases successfully defended recently the Union's costs had been more than £10,000, none of which had been recoverable. Defence societies, however, were not merely insurance companies. Their first object was to defend the character and interests of members. An insurance company took the cheapest way out. Time and again the Union had fought and won a case when it would have been cheaper to settle. Disputes between doctors were often referred to the Union and were usually settled informally and amicably. Sometimes they were settled by an arbitrator appointed by the council. It was the Union's rule not to support one member against another, though in one or two really difficult cases legal assistance had been provided to both parties.

Under the recent Medical Act, continued Dr. Shanks, divorce proceedings where a doctor was the co-respondent and the respondent his patient, if proved, were referred automatically to the G.M.C., which had to accept the verdict of the divorce court. To meet this situation, in selected cases the Union would undertake a member's defence in the actual divorce proceedings. This, however, was not automatic, and depended on the merits of the case in question. Dr. Shanks concluded his address by giving some examples of the types of case brought against doctors for negligence.

Annual Report

The annual report records that on July 17, 1956, membership of the M.D.U. stood at 43,219, of whom 7,698 were women. During 1955 the Union handled 2,348 cases, a similar volume of work to that in 1954. During the year Dr. PHILIP ADDISON was promoted to deputy secretary, under the secretary of the Union, Dr. ROBERT FORBES.

Under the heading “Practising illegally” the report draws attention to the large number of doctors whose names have been erased from the *Medical Register* because they have failed to answer inquiries as to their address from the G.M.C. Doctors are urged to check their position by inspecting the current *Register*. Other subjects discussed in the report include: the Coroners Rules, 1955; Witnesses Allowances Regulations, 1955; Dentists Act, 1956; medical reports to officials; blood transfusions; accidents in hospitals; “informing the patient”; professional secrecy; the Central Legal Office at St. Andrew's House, Edinburgh; disputed accounts; disclosure of information to the police; inquests; and the infringement of copyright—this last concerning an article in the *British Medical Journal* which, without permission, was reproduced in full in a popular magazine. The treasurer, Dr. HENRY ROBINSON, reports that, after deficits in current expenditure in the two preceding years, 1955 showed a surplus of £8,714, more than enough to cover the combined deficits. The total funds of the Union now amount to £171,522.

Correspondence

Breath-holding Test

SIR,—Tests for the quick assessment of cardiac and respiratory function are now being replaced by more elaborate investigations, such as the maximum breathing capacity and bronchspirometry. However, a test still used by many anaesthetists is the so-called Sebrasez breath-holding test, in which the time a person can hold his breath after a maximum inspiration is measured and anything over 25 seconds is regarded as normal. During the last four years I have been holding a pre-operative clinic at which I have seen patients for assessing their fitness for major surgery, and besides a full clinical examination of the heart and lungs I have carried out this breath-holding test. Having performed this test on just over 1,000 patients I am not satisfied that it gives any more information than the knowledge of a patient's everyday activities.

I thought it would be interesting to know how and why Sebrasez—whoever he might be—came to describe this test and what value he placed upon it. This led to the remarkable discovery that no such man as Sebrasez ever lived, and with the help of the Medical School librarian—Mrs. L. Sargeant—I finally traced the origin of this test.

In 1902 Dr. Jean Sabrazès, a Bordeaux physician who died in 1943, wrote in the *Gazette Hebdomadaire des Sciences Médicales de Bordeaux* a short note on "La durée maxima de la pause apnéique volontaire."¹ Here he describes his test in detail and emphasizes that the time measured is that during which a patient can hold his breath after a normal expiration *not* preceded by a forced inspiration; he states that the average figure for a normal person is 20–25 seconds. In other words, you ask the patient to see how long he can prolong the normal pause that follows expiration. This is, of course, quite different from holding the breath after a maximum inspiration. To illustrate this difference I carried out tests on a group of medical students and nurses and found the following:

	Average Age	Average Vital Capacity	S1	S2
Nurses	20 years	3,200 cu.cm.	42 sec.	19 sec.
Medical students	22 "	4,200 "	60 "	30 "

S1=Breath-holding after a maximum inspiration. S2=Breath-holding after a normal expiration.

It will be seen that a normal person can hold his breath for approximately twice as long after a maximum inspiration as after a normal expiration.

It seems hard that, only 54 years after a test is described, not only has the originator's name been mutilated but his test wrongly described and performed. I believe that the original test can be of value, and some interesting work was done by H. S. Ruth² in 1926, who showed that, in a series of 52 poor-risk patients, two-thirds of the deaths occurred in those cases with subnormal breath-holding ability—he, of course, was using the originally described test. Ruth also says that in cardiac cases if the breath-holding test is normal then circulatory depression is not likely to be encountered during anaesthesia. Woodbridge³ makes the same point when he states that a normal result in patients with heart disease is significant, but unfortunately he was not using the original test.

I have written this letter mainly to show how important it is to refer to original articles and not be satisfied with later references which may have become distorted. I hope also that this test of suspended respiration, as it was called by Gilbert Fitz-Patrick,⁴ will be reintroduced as a test of real value in assessing anaesthetic risk.

My thanks are due to Mrs. Sargeant, who finally found a copy of the Bordeaux gazette referred to at Bristol Medical School, and to the authorities at Bristol who allowed me to make a photostat copy of the original article by Dr. Jean Sabrazès.—I am, etc.,

King's College Hospital, S.E.1.

Steroid Anaesthetics

SIR,—As one of the experimenters mentioned in your excellent annotation on steroid anaesthesia (*Journal*, September 8, p. 594), I would like to comment on your statement that "hydroxydione is not an anaesthetic in the true sense of the word, but rather is a non-analgesic hypnotic." When a towel-clip is applied to the skin during the sleep produced by pentobarbitone (or other similar barbiturates) or bromethol in basal-anaesthetic doses the subject instantly rouses sufficiently to try and rid himself of the painful stimulus—he may even moan or cry out. With hexobarbitone or hydroxydione ("viadril") there would be slight movement at most, while with thiopentone there would be no movement if the dosage were adequate. To produce a lack of movement under such stimulation poisonous doses of pentobarbitone or bromethol would have to be used—i.e., sufficient to depress the respiration and circulation to dangerous levels. Thus it would appear that pentobarbitone and

bromethol are the true "non-analgesic hypnotics" when given in safe doses and that hexobarbitone, hydroxydione, and thiopentone come into another category—i.e., the analgesic-hypnotics, with thiopentone admittedly exhibiting a greater measure of analgesia than the other two. As hydroxydione depresses the throat and pulmonary reflexes instead of stimulating them, as do hexobarbitone and thiopentone, its slight deficiency in analgesic properties is amply compensated. The proof of the pudding is, of course, in the eating. Hydroxydione has been proved as an adequate alternative to thiopentone; a few anaesthetists still use hexobarbitone, but, so far as I know, no one uses pentobarbitone for this purpose. Thus, hydroxydione cannot be classed with the true "non-analgesic hypnotics." The accompanying block-diagram, which compares certain analgesics, hypnotics, and intravenous anaesthetics, is intended to illustrate my argument.—I am, etc.,

Asphyxia Due to Faulty Apparatus

SIR,—About three years ago I had a similar experience to that of Dr. W. N. Rollason (*Journal*, September 15, p. 658). I was giving an anaesthetic to a rather fat woman for a hysterectomy and passed a nasotracheal tube by blind intubation. The tube passed easily at the first attempt and expired air could be felt coming out of the Cobb's adapter. On connecting this to the gas machine, however, the lungs could not be inflated, although the patient's efforts to expire increased the size of the rebreathing bag. I was completely baffled and could only think that an acute bronchospasm had occurred. For this reason I was reluctant to remove the tube, but finally did so, with the gratifying result that the obstruction was immediately relieved. A second tube was passed and the narcosis proceeded without further incident.

On examination it was found that the Cobb's adapter contained a bakelite spigot used to close the inflating tube of the pneumatic cushion of a facepiece, and the shoulder

of this spigot acted as a perfect non-return valve. It transpired that some spare spigots had been stored in the box containing Cobb's adapters. Some of the flimsy chains securing the caps had broken so that several of the adapters had open ends into one of which a spigot had entered unnoticed. The moral is never to take anything for granted.—I am, etc.,

Respiratory Sign of First-plane Anaesthesia

SIR,—I am most grateful to Dr. V. T. Baxter (*Journal*, September 15, p. 658) for drawing my attention to the late Dr. J. U. Human's "sign of subcostal effort," in a textbook with which I regret I have previously been unfamiliar.¹ On the whole, I think that Human's title is a better one than mine ("modified cough"), since, as Dr. Baxter quite rightly points out, it can be and usually is apparent, even in the absence of a respiratory irritant—for example, thiopentone—prior to induction of anaesthesia by a sequence involving ether, or other stimulating agent. That this is a sign *per se* of ascending anaesthesia, however, I cannot agree, except in so far as any sign belonging to a certain level of anaesthesia will become apparent when that level is attained, either ascending or descending through the "planes."

Such a valuable respiratory sign in anaesthesia deserves better recognition, and Dr. Baxter will have done just service to the memory of a shrewd observer if Human's "sign of subcostal effort" finds its way into some of our standard textbooks for students of anaesthesia.—I am, etc.,

London, W.2.

Medical Education

SIR,—I was most interested in Dr. J. K. Paterson's scheme for the education of the complete doctor (*Journal*, September 1, p. 513), but, having followed its pattern up to the stage of clinical finals, I would like to suggest that there is an element of unrealism about it. *Tempus fugit*; and by my calculation the youngest doctor to step off the top rung of his ladder would be in his thirties. True, for the last two years he would have earned his living as a useful member of society, but could the State be expected to finance its future doctors to the age of 28? Furthermore, during the two "combative years" which Dr. Paterson advocates after leaving school these embryos will have lived alongside married men; can they all be expected to eschew marriage till 28? If not, who should pay? How can these objections be met? Is it not a poor outlook if two years of combative training are to be regarded as a *sine qua non* of manhood? There are ample opportunities to further this aspect of education in enterprising use of university vacations and in the three years of postgraduate training.

In your leading article (p. 519) you discuss the struggle for a synthesis in the university medical curriculum between fact accumulation and broader training of the mind. I suggest that Oxford has largely found that synthesis. Fact accumulation is essential as a foundation for clear thinking and sound medical judgment, and the preclinical student can satisfy this essential in eight hours of the day. For the remainder of the time he may enlarge his "manhood" by indulging in a variety of activities, mental and physical, in a non-medical environment, and one college at least insists admirably on its medical students writing periodical essays on cultural topics.—I am, etc.,

Oxford.

JOHN B. WILLIAMS.

Virilism with Mental Symptoms

SIR,—I should like to make a slight correction to my letter (*Journal*, September 8, p. 604) on the treatment of psychoses associated with virilism by adrenalectomy. I overlooked the fact that Dr. Raymond Greene and his asso-

ciates¹ published a successful case in 1945, and Soffer² reported the cure of a paranoid psychotic after her adrenal had been removed in 1948. Thus Dr. E. A. Bennet's case (*Journal*, August 25, p. 478) is the fifth in which cure of a psychosis has resulted after adrenalectomy.

Cases to be successful should be chosen for operation with considerable care. The criteria of suitability are that the patient should preferably be under 35 years of age; there should be definite adrenogenital virilism, which should have occurred synchronously with the psychosis. Signs of homosexuality such as a desire to wear male clothing, etc., are of good prognosis for the success of the operation.

It is interesting that cortisone has produced psychoses in some people,³ and the oxidation products of adrenaline—adrenochrome and adrenoxine—are believed by Heirman⁴ to act as hallucinogens. Obviously the adrenal gland is more important to psychiatrists than they have realized in the past.—I am, etc.,

Abuse of Antibiotics

SIR,—I was interested in Dr. A. Fry's outcry (*Journal*, September 1, p. 551) against the abuse of antibiotics, which I should like to second. But why look so far afield as the Continent for an example? The following is a quotation from a note I received recently with a baby sent up by a general practitioner to a London casualty department: "This baby has had a febrile illness lasting one week, in spite of sulphonamide therapy. Would you kindly see and advise?" If this were an isolated example of hit-and-miss medicine it would be laughable, but it is not. The only unusual feature of the case is that the doctor had prescribed the humble sulphonamide and not one of the more exotic—and more dangerous—antibiotics.—I am, etc.,

London, N.11.

JOAN M. CURTIS.

Drugs with Similar Names

SIR,—Can nothing be done to stem the spate of more and more drugs with similar-sounding names but widely different? Even if one can find the formula, that often conveys little to one's mind of what is what.

My post this morning contains literature about "penbenemid" and "pentoxylon," and not long ago a chemist gave one of my patients "thyroidex" instead of "theodrox" (luckily she had had them before and knew they were not the same). It seems to me that the situation is not only chaotic but dangerous. We doctors can so easily make a mistake, and it is becoming impossible for the chemist to be the extra check on the prescription.—I am, etc.,

Potters Bar, Middx.

A. MARY ALLAN.

Medical Evidence at Inquests

SIR,—Dr. F. M. Rose's letter (*Journal*, August 11, p. 356) on the question of the consultation of the family doctor by the coroner reminds me of three of my own cases.

In the first, my evidence almost certainly would have shown that the patient intended to commit suicide; so I was glad not to be called. In the second case, I arrived at the mortuary punctually but only just in time to persuade the pathologist to examine the neck; here he found a fracture-dislocation, which was the actual cause of death instead of the hypothetical one which he was going to present to the coroner. In the third, I learnt subsequently that the patient had died soon after his admission to hospital and that the staff had felt unable to give a certificate. The pathologist had been equally at a loss. I felt sure that it was a case of Landry's acute ascending paralysis, and I was very disappointed that no examination had been made of the spinal cord.

I hope that I shall not be accused of libel when I suggest that if the coroner can satisfy himself that the death has not been due to someone's carelessness or crime he is not particularly interested in the precise diagnosis. Whether this is a safe or desirable attitude to take is another question.—I am, etc.,

Beckenham, Kent.

W. MAXWELL PENNY.

Coronary Artery Disease

SIR,—In a letter in the *Journal* for July 14 (p. 98) Professor Ancel Keys discusses certain factors in the aetiology of coronary thrombosis. The low incidence of this disease in Africans is coupled with dietary factors. I wonder if Professor Keys would be interested in my experience as an anaesthetist whose patients are largely of African descent. In the last four and a half years over 17,500 anaesthetics have been given in the main operating theatres of the University College Hospital of the West Indies, and during that time only one proved case of pulmonary embolus occurred. Another suspected instance in a patient was not proved, as the woman recovered and the signs were equivocal. Nygaard *et al.*^{1,2} report an incidence of 1% after operation, and McCartney³ attributes 5% of all post-operative deaths to it. I would be interested to know whether anaesthetists in other tropical countries have had the same experience.—I am, etc.,

Jamaica.

Speech Therapy

SIR,—In a recent article in *The Times* speech therapy was called a young science dating from the first world war, but Dr. Neil Arnott wrote on this subject in 1828, Dr. James Hunt in 1854, and Dr. Wyllie in 1894. What is of much greater importance, with speech therapy recognized as an auxiliary medical service, is its rapid expansion in the last ten years from 260 members to more than 800, and its wider scope, which now includes correction of slurred s's and l's, speech re-education after brain injuries, cleft palate, and stammering.

As the majority of students are trained by public grants, with a large wastage through marriage, the value of their work should be assessed, for it seems that too much time is spent on correction of slurred consonants which would correct themselves, while stammerers are not having the help they need. I put forward their case because the great majority of them are far above the average in intelligence, so it is because of their potential value to the community that I ask for treatment more suitable for them. A stammering boy of 12 should be treated by a man, not by a young woman, for this reason. At that age or very soon after most boys are attracted by a girl some eight years older than themselves; it is the normal "bridge" between mother and sweetheart, a perfectly healthy phase, but to expect a teen-age boy to benefit from treatment for his stammer given by a pretty girl of 22 indicates ignorance of a normal phase, and, in addition, many boys at this age resent being bossed by a woman. Most boys feel this and sensible mothers accept it.

If it is really important to correct slurred s's, which are actually taught by some elocutionists and are no deterrent from employment, judging by many broadcasting ladies, it should not be a three years' training at a cost of between £160 and £245. When I was in charge at Guy's I never saw backward speakers more than once, when I explained the mistake and saw the child make the right sound, but I did not waste further time on them; schoolteachers or the parents could follow up my advice. But they could not do what I was there to do—the correction of cleft palates

and stammerers. By saving time on backward speakers I was able to increase the time available for the stammerers from 62½% to 75%.

In teaching speech sounds to spastic children the greatest care is needed; it is easier to start them stammering than to improve them. Take the sentence "What a pity it is that people do not take more trouble to speak clearly and distinctly." Spoken slowly, those 17 words of 23 syllables take 5 seconds, but they entail 60 muscular adjustments—that is, 10 per second—a lot to ask from a spastic. Simple consonant correction for infants could be done after a short training; for stammerers men are needed. But if women must be used, they should be older women with grown-up or teen-age sons. It is extremely difficult to be really conscientious about wasting time when working by paid sessions, but for the future reputation of speech therapy a sense of comparative values should be maintained.—I am, etc.,

London, N.W.1.

H. ST. JOHN RUMSEY.

Non-specific Ulcers

SIR,—The condition described by Dr. S. H. Wydel (*Journal*, September 1, p. 553) appears to be "pyoderma gangrenosum" or "dermatitis gangrenosa infantum," possibly due to a strain of *Staphylococcus pyogenes* resistant to most antibiotics and even to "topical" applications of an effective disinfectant. The thin paper-like scar that follows inordinately slow healing is rather characteristic; also the initial "blister"-like lesion. The differential diagnosis includes tropical ulcer and the cutaneous gangrene of Meleney.

Treatment is always difficult and requires much patience. Some cases, when first seen, have already had treatment with corrosive substances which increase the gangrenous area, make the lesion look "clean" and dry, and make an effective bacteriological examination of the exudate almost impossible. Cortisone has been recommended for some cases. The condition of the patient should be "built up" with good food—including milk if possible—luxur quantities of vitamin C, the vitamin B complex, and vitamin A. Cortisone may be effective when one of the underlying conditions is "necrotizing vasculitis." It is necessary to make conditions in the wound as near optimum for healing as possible; too profuse granulations may be controlled by restrained sprinkling with fine potassium permanganate powder; this application provides oxygen and has a disinfectant action. Sterile petroleum jelly can then be applied liberally, covered with sterile petroleum jelly gauze, and the whole encased in a few turns of plaster-of-Paris bandage or other strong "meddle-proof" outer covering. The whole application may be changed at weekly intervals or after ten days; more frequent changes should be avoided unless definitely indicated. The "pansement spécifique" of Dickson Wright is of undoubted value.—I am, etc.,

Epping, Essex

Summer Time and Duodenal Ulcer

SIR,—When summer time ends many people will be taking their meals one hour later than formerly. The majority may have stomachs which can or will become accustomed to this change, but those with duodenal ulceration are prone to recurrence every year at this season.

If it were possible to warn such patients to take their meals earlier than usual for a limited period much suffering might be avoided and the waiting time for barium meal examinations not extended.—I am, etc.,

Bristol.

J. V. SPARKS.

Longer Holidays

SIR,—I am concerned by the increasing number of patients who attend surgery with anxiety and tension states and with symptoms of psychosomatic illness. Many of them are physically and mentally exhausted not only by the ever-increasing tempo of modern life but in large measure because of the inadequate annual holiday period, which appears to average about two weeks. The demands of industry to-day surely deserve at least one month's holiday per year for everyone. With increased relaxation, health and efficiency must improve and the pressure on our psychiatric clinics would almost certainly be reduced.—I am, etc.,

Dorridge, Warwicks.

G. A. POWELL-TUCK.

Shoe-stretcher for Bunions

SIR,—Having recently become afflicted with a bunion through wearing shoes bought while on leave in the United Kingdom and subsequently using them in Malaya, I was rather disappointed to find that a new pair of shoes specially made by a local Chinese shoemaker were still very uncomfortable even after stretching on an instrument that reminded me of Kollman's urethral dilator.

I decided to make a wooden gadget on the principle of the mouth gag, in which pressure applied to the handles opens the jaws. I made a wooden last from 1½ in. (3 cm.) thick hardwood, roughly the shape and size of the foot from the proximal interphalangeal joints to within 2 in. (5 cm.) of the heel. A V-shaped wedge about 4 in. (10 cm.) deep and 1 in. (2.5 cm.) wide was then cut out at the heel end and a similar V piece in front so

as to divide the last, as illustrated, into two. A tuberosity to correspond with the bunion and little toe can be raised on the last with some padding, held in position by adhesive strapping. The divided last can be easily positioned in the shoe, pressure being applied transversely to the proximal ends by a carpenter's G cramp from outside the shoe, the leather being protected by suitable padding. The pressure should be increased by turning the cramp screw at intervals, and thus great pressure can be applied in an outward direction to the leather that presses on the bunion and little toe. A wet compress should be applied to soften the leather for the first 24 hours and then the leather should be allowed to dry out for another 24 hours in the stretched position.

I am not aware if this device is well known, but it is cheap and effective and should be of interest to bunion sufferers who dread wearing new shoes. Needless to say, it is important, even in men's shoes, to have low heels.—I am, etc.,

Malacca, Malaya.

J. E. MCMAHON.

Paediatric Anaesthesia

SIR,—I read with interest Dr. John Bullough's letter (*Journal*, August 11, p. 360). I would endorse his division of children into three main groups from the anaesthetist's point of view, but as far as premedication and anaesthesia for guillotine tonsillectomy are concerned I do not feel that rectal or intravenous thiopentone are to be favoured, as depression of reflexes and nightmare states can follow the former, and post-operative delirium does in a substantial proportion of cases follow the latter.

I have tried methylpentynol in the full dosage recommended for premedication in these children, and more recently "pacatal" in a dosage of 25 mg. per stone (6.4 kg.) body-weight, but neither has proved as effective as syrup of chloral in a dosage of gr. 5 (0.3 g.) per stone (6.4 kg.) body-weight. Since its introduction into medicine in 1869 chloral hydrate has stood the test of time. It is one of the cheapest and most effective sedatives. To-day it receives none of the prominence in medical literature and drug advertising accorded the barbiturates and the tranquillizers, but in my view it is the drug by which the claims for the others should be judged.—I am, etc.,

Hull.

W. N. ROLLASON.

Apartheid in Blood Transfusions

SIR,—May I be permitted, please, to correct a misleading impression which your readers might gain from Dr. R. A. A. R. Lawrence's letter (*Journal*, August 11, p. 356)?

Voluntary blood donors of the Capetown blood transfusion service were overwhelmingly of the white racial group and were bled for emergency transfusions at the Somerset Hospital, which is exclusively for non-white patients. Donors were naturally entitled to refuse permission to any particular doctor to carry out the bleeding. Members of the hospital staff were entrusted with this duty only after having been certified as competent to carry it out.

I leave it to the good sense of your readers to decide whether the profession, whose concern it was to maintain the supply of donors and of blood, would have been wise to interfere with this privilege vested with the individual donor.—I am, etc.,

Capetown.

J. H. L. SHAPIRO.

Amnion Implantation in Peripheral Vascular Disease

SIR,—Mr. E. Troensegaard-Hansen reported on 40 cases of peripheral vascular disease treated by amnion implantation (*Journal*, August 4, p. 262). It might be of interest to report briefly on another patient successfully treated by this method.

A man, aged 58 in January, 1956, complained of pain in both calves after walking short distances. He had cold cyanosed feet and barely perceptible dorsalis pedis pulses. He derived no benefit from peripheral vasodilators and finally was compelled to halt seven times in the half-mile level walk from the station, and then to take a bus up the final steep hill to his home. On May 8, 1956, Mr. Troensegaard-Hansen did an amnion implant in his left thigh; three days later he was able to walk half a mile without pain.

Now, four months after the implant, he can walk two miles without discomfort, and no longer finds it necessary to ride up the final steep furlong.—I am, etc.,

Arundel, Sussex.

J. N. WARREN.

"Old Elthamians 13; U.C.H. 8"

SIR,—As an Old Elthamian and for several years a regular O.E. 1st XV player, I was surprised to see a reference to the above rugby result in the excellent paper by Drs. W. D. M. Paton and Hannah Steinberg on ganglion block in human subjects (*Journal*, September 15, p. 622).

I cannot agree with the inference that this result was due to loss of prowess at sport following the administration of 25 mg. of hexamethonium bromide. Perhaps U.C.H. might find it profitable to use dextro-amphetamine sulphate in their next class experiment. They might then find that they are still missing putts on the 18th green and still losing to the Old Elthamians.—I am, etc.,

Sudcup, Kent.

R. A. HARLOW.

Obituary

J. B. LEATHES, D.Sc., B.M., B.Ch., F.R.C.P.
F.R.C.S., F.R.S.

Professor J. B. Leathes, emeritus professor of physiology in the University of Sheffield, died at Montreux on September 14. He was 91 years of age.

John Beresford Leathes was born in London on November 5, 1864, the son of the Rev. Stanley Leathes, D.D. From Winchester, where he was a scholar, he went up to New College, Oxford. Although a classical scholar, he decided to qualify in medicine and completed his clinical training at Guy's Hospital, graduating B.M., B.Ch. in 1893. In the following year he took the F.R.C.S. In those days it was in Germany rather than in America that young men sought experience abroad, and Leathes worked under Drechsel and Schmiedeberg from 1895 to 1897. Returning to England, he was appointed lecturer in physiology at St. Thomas's Hospital, where he remained until 1909, when he was appointed professor of pathological chemistry in Toronto. He had also for some years before this been a member of the staff of the

[Lafayette, Ltd.]

department of pathological chemistry at the Lister Institute. On the outbreak of war in 1914, feeling that his services were required at home, he resigned his chair and returned to England. Just at this time the chair of physiology in Sheffield became vacant, and Leathes was approached by the then vice-chancellor, H. A. L. Fisher, who had known him at Oxford, and he accepted the chair at Sheffield. He occupied this post from 1915 until he retired in 1933 at the age of 69. The fact that he had then already passed by some years the normal retiring age is a measure of the value the University of Sheffield attached to his services.

Few men in the academic world are able to achieve major distinction in the three branches of their work—research, teaching, and administration—and most are satisfied with fame in one of these. Leathes not only achieved the highest distinction in all three branches, but in addition he was always a humane and civilizing influence in the community which he served.

His researches were chiefly concerned with the metabolism of fats. At that time biochemistry had not yet split off from physiology, and Leathes was one of the first who recognized the great importance of bringing accurate chemical knowledge and chemical techniques to biological problems. He was an early member of the Biochemical Society, and did much to develop the biochemical outlook both in Sheffield and elsewhere. His many researches culminated in the publication of a monograph on fats in 1913, and this was enlarged in collaboration with the late Professor H. S. Raper into a second edition which appeared in 1925. Leathes's contribution to physiology was recognized by his election to the Royal Society in 1911. He became a Fellow

of the Royal College of Physicians in 1921, and two years later he gave the Croonian Lectures. In 1930 he gave the Harveian Oration, and for the following two years he served on the council of the College.

When Leathes went to Sheffield he had already completed his best scientific work, and, while he remained keenly aware of the importance of research and gave every encouragement and stimulus to his colleagues, his main effort in Sheffield was in teaching and in administration. His tenure of office included the period of the return to the university of the ex-soldiers of the first world war, and his patience and sympathy with this group was widely known. The problem of interesting medical students in chemistry is still not entirely solved, but Leathes by the force of his personality and his great scientific distinction was able to interest his students in his own field of work, and was universally loved and respected by those who went through his department. The medical school at Sheffield was undergoing considerable development at the time of his appointment, owing to the activities of the late Sir Arthur Hall, and Leathes threw himself enthusiastically into the problem of trying to evolve a medical course which would bring modern scientific methods into clinical medicine, and which would also keep the laboratory scientist in closer touch with what was happening in the hospital wards. He served as dean of the faculty of medicine from 1916 to 1922 and again from 1931 to 1933, and he was largely responsible for the initiation of the medical course in Sheffield which constituted an important experiment in medical education. Leathes's idea was that the clinical and preclinical sciences should be closely integrated and the teaching of anatomy and physiology continue throughout the clinical periods. His work for medical education was recognized by his election as chairman of the Education Committee of the General Medical Council. With the appointment of full-time clinical professors, the course introduced by Leathes seemed to be less necessary, and in 1947 Sheffield reverted to the more orthodox course similar to that in other universities. Leathes's work was, however, not wasted, and it is not impossible that his curriculum in a modified form will yet be found to have an important place in medical education. He received the honorary degrees of D.Sc. from the University of Sheffield in 1933 and from the University of Manchester in 1936, and he was an Honorary Fellow of New College.

In spite of his numerous activities, Leathes found time for those other things which add so much to a university. He was a classical scholar by education, and always retained a broad humanitarian outlook and a wide interest in education. His wife was a talented musician, and with her assistance Leathes did much to stimulate interest in music in the university. The following words written by Sir Arthur Hall, who knew him well and worked with him for many years, convey something of the magnitude of his contribution to the University of Sheffield. "The deep influence for good which during all those years he exercised, not only on the faculty of medicine but throughout the whole university, cannot be measured in words. He was a tower of strength and has left a stamp on us as no other man did before. . . . His strength to our school lay in his deep and far-seeing wisdom in all that pertained to university life and education, particularly as regards the relation of science to medicine. A classical scholar, a profound thinker, and a physiologist of the highest distinction, it was the conscientious and unselfish

personality of the man himself which created an atmosphere in the place we can only hope we may never lose."

M. SILVERSTONE, Ch.M., M.B., F.R.C.S.

Mr. Maurice Silverstone, consulting surgeon to the Liverpool Royal Infirmary, died on September 22, aged 50. Though he had been ill for some years, he had never wavered in his determination to continue his surgical career to the end.

Maurice Silverstone was born on January 30, 1906, and educated at Liverpool. As a final-year medical student he won a B.M.A. prize in 1928, and in the same year he graduated M.B., Ch.B., with honours, at the University of Liverpool. After holding a number of resident appointments at the Royal Infirmary he was awarded the Samuels Memorial Scholarship in Surgery in 1931. In the following year he took the F.R.C.S. and in 1933 he proceeded to the degree of Ch.M. Before being elected to the staff of the Royal Infirmary he had been senior surgical registrar there and tutor and radium curator. Mr. Silverstone avoided the spectacular and was the reverse of thrusting, but he soon built up a reputation on Merseyside as a first-class surgeon and was a tower of strength to several of the local hospitals, including the Birkenhead General Hospital, the Birkenhead and Wirral Children's Hospital, and the Clatterbridge Hospital. For the last ten years he had been assistant to Professor C. A. Wells on the professorial unit at the Liverpool Royal Infirmary. At the university he held the position of assistant lecturer in clinical surgery: the students liked him and appreciated the qualities that helped him to overcome the handicap of serious ill-health during the past few years. From his wife he received great support, and to her and his three young children the sympathy of his many friends will be extended.

We are indebted to Professor CHARLES WELLS for the following appreciation:

It is with a deep sense of personal loss, which all who knew him and all those who in recent years admired his fortitude will understand, that I write of the untimely death of Maurice Silverstone. He did a full day's operating on Friday; on Saturday morning, though far from well, he attended hospital for his duties in the out-patients' department; at sunset he died. Thus his death, when it came, was mercifully swift, but he had known for some years that his days were numbered and he had set himself to do precisely what he did—work to the end. He will be remembered as a man of character and of courage.

In his work as a surgeon he always showed sound judgment and good sense; his operating was purposeful and quick, and he regularly achieved outstanding success with a minimum of fuss. His teaching of students and graduates was remarkable for its impersonal modesty and for constant reference to the writings and work of others. Instant counsel he was outspoken but utterly free from either malice or self-interest. As a colleague he was an infallible and good-humoured ally who could be critical but not disloyal. A fervent devotion to his family rounded off a life of unstinted service for which there can be no regret except that it ended too soon.

W. CLEMENT, M.B., F.R.C.O.G., F.R.F.P.S.

Dr. William Clement, consultant gynaecologist to the Royal Samaritan Hospital and honorary lecturer in clinical gynaecology to Glasgow University, died on September 10 after a long illness. He was 53 years of age.

Born at Dunlop in Ayrshire on September 13, 1902, William Clement was educated at Glasgow Academy

and Glasgow University, where he graduated M.B., Ch.B. in 1926. After holding several resident appointments in the Royal Infirmary, the Royal Samaritan Hospital, and Glasgow Royal Maternity Hospital, and spending a period of postgraduate study in America, he was appointed to the consultant staff of the Royal Samaritan Hospital, and later to the Royal Maternity Hospital in Glasgow. He also acted as consultant obstetrician and gynaecologist to the Southern General Hospital, Glasgow, being in charge of wards there for a period before the inception of the Health Service. During the early part of the war Dr. Clement took charge of the maternity service in Ayrshire, returning to Glasgow in 1941 to become chief of a unit in the Royal Samaritan Hospital and resuming his work at the Royal Maternity and Southern General Hospitals. In 1937 he had obtained the Membership of the Royal College of Obstetricians and Gynaecologists and was elected to the Fellowship in 1948. He had already been elected to the Fellowship of the Royal Faculty of Physicians and Surgeons of Glasgow in 1940.

In the last fourteen years of his life Dr. Clement worked under the serious disability of poor health, and in 1948 and 1953 had illnesses which kept him from work for long periods. In spite of his disability, when he was able to attend to his duties he wholeheartedly carried out both his clinical and teaching work with a devotion and attention to detail which inspired his staff with enthusiasm and made him one of the favourite clinical teachers of Glasgow University. He was a neat and dexterous surgeon who always considered the needs and circumstances of his patients.

Dr. Clement was well known as a breeder of King Charles spaniels and Pekinese. Probably his happiest hours were spent at dog shows, at which he was a popular figure. He had a great love for his native village and for his home in Glasgow, in the history of both of which he was well versed. He had the good fortune to be born and brought up in a lovely part of Ayrshire, whose natural beauties and interest he appreciated to the full, and into a happy and devoted family. Dr. Clement was unmarried.

E. B. JAMIESON, M.D.

R. M. H. writes:

The passing of Dr. E. B. Jamieson marks the loss of a great Edinburgh figure revered by several generations. I had the privilege of living in his company for many years and also of being one of successive groups of students who visited his home at Twagios, Lerwick, and of seeing shades of his character less evident to others. The tribute in the *Journal* (September 8, p. 607) from T. B. J. contained a reference to a photograph of "Old Jimmie" fishing from the stern of his boat. This photograph, more than any which I took during a visit 31 years ago, so pleased him that he used reproductions on which to convey his Christmas greetings. The reference recalls, as it will to many others who enjoyed the hospitality of their kindly and courteous hosts, the undimmed memory of the long walks across the island, the bathing in the cold clear water, the games of golf, the offshore fishing amid the wonderful bird life, and all the features of Shetland to which he returned each summer vacation with almost boyish enthusiasm. On behalf of those who knew Dr. Jamieson under these circumstances and of those with whom he lived for so long in St. Giles House, University Hall, I presume humbly to add a personal appreciation.

A legendary character at an early age, he is best remembered for his clarity of judgment and expression, his disdain of humbug, and the frank advice he gave to any of us callow

young men who sought his help. He had a delight in simple things which only the truly great mentality can reveal. Outwardly stern and at times awe-inspiring mien, he had a puckish sense of humour and a kindly smile which was quite disarming. He exerted on us an influence far greater than we realized. My last meeting with him only a year or two ago is perhaps a most characteristic remembrance. I had not seen him for twenty years, but on meeting at the door of the anatomy department he looked quizzically for a minute as first my surname and then my Christian name came to his lips with that kindly smile of recognition which is a cherished memory. A great anatomist, an erudite teacher, but especially a man of fine character, steadfast faith, and simple kindness, he will live long in the thoughts of all who were privileged to know him.

One of Dr. Jamieson's students writes: Dr. E. B. Jamieson entertained many students and gave them large and interesting meals which were cooked by himself. He once said to me: "When I die and something is written about me in the *B.M.J.* you will be able to say, 'He was also able to cook.'" I said that I would write and tell you.

Miss M. E. GREGG, L.D.S. R.C.S.

It is with deep regret that we have to announce the death on September 23 of Minnie Elizabeth Gregg at the age of 45, after a short and painful illness bravely borne. Miss Gregg was a dental surgeon, and daughter of Dr. E. A. Gregg, who has recently retired from the position of Chairman of the Council of the British Medical Association. Miss Gregg carved out a career for herself and took the L.D.S. of the Royal College of Surgeons in 1938 after studying at University College Hospital Dental School. For some years she worked for the London County Council in their school clinics and hospitals, eventually giving up this appointment to nurse her mother in her final illness. In recent years she was dental officer to Carreras Limited at their factory in Hampstead Road. Here she cared for the dental health of a large number of employees, and they will greatly miss her, not only because of her skilled attention, but more especially because of her cheerful and radiant personality and human sympathy. Members of the B.M.A. will have a different but equally vivid memory of someone whom so many came to know simply as Min Gregg. When Dr. Gregg became Chairman of Council in 1949 he was a widower, and so in the seven years of his chairmanship Miss Gregg assumed the by no means light duties of the Chairman's lady on the many official occasions that are part of the life of a Chairman of Council. To those who knew her it was indeed remarkable that Miss Gregg could carry on an active professional life, supervise the house of a busy general practitioner, and yet with all this could appear fresh and charming at so many receptions and other occasions as the Chairman of Council's lady. Miss Gregg accompanied her father on official visits abroad, and at the Annual Meeting of the World Medical Association made many warm friends with doctors and their wives from other countries. She was a valued ambassadress for the B.M.A. Miss Gregg was such a happy, friendly, and warm-hearted person, with so much vitality and courage, that it is difficult to believe she is no longer with us. Her many friends mourn her loss, and extend their heartfelt sympathy to her father and her family.

Dr. R. A. G. SMITH, medical officer to Carreras Ltd., writes:

The untimely death of Miss M. E. Gregg has come as a great shock to her colleagues, friends, and patients at

Carreras'. Nine years ago she organized a dental service for the factory and quickly dispelled any doubts that existed as to whether so slight a young woman could do a man-sized job. Her reputation as a "good dentist" soon became so firmly established that her waiting-list grew to several months. Miss Gregg always said that she tried not to be a "bluestocking." Those of us who knew her could never have imagined such a thing. She combined charm and dignity with efficiency and sympathetic understanding which endeared her to many in the factory community. This was expressed in the concern shown by large numbers of employees and managers alike when it became known that she was seriously ill. She will long be remembered at Carreras' with gratitude and affection.

Dr. V. F. SOOTHILL, who was medical officer of health for the city and county of Norwich for over a quarter of a century, died suddenly at Bramerton, Norwich, on September 10. He was 68 years of age. Victor Farrar Soothill was born on October 21, 1887. From Emmanuel College, Cambridge, he went on to Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1912. He took the M.B., B.Chir. degrees in the following year, proceeded to the M.D. in 1918, and obtained the D.P.H. in 1920. His work as assistant medical officer at the Poplar and Stepney Sick Asylum was interrupted by the first world war, in which he served in the R.A.M.C., attaining the rank of major. Soothill began his career in the public health service in 1920 as assistant county medical officer of health for Dorset, and two years later he was appointed assistant (subsequently deputy) medical officer of health for the Ilford Urban District Council. In 1926 he succeeded Dr. H. Cooper Pattin as medical officer of health and school medical officer to the city of Norwich. He remained in that office for 26 years and was responsible for a great expansion in the public health services. At the time of his appointment there was only one infant welfare centre, but there were twelve when he retired, and during that time the infant death rate fell from 53 to 27. The slums in the centre of the city are no longer a serious problem, and new housing estates have been built on the outskirts of the city. It was a measure of his popularity that he was elected chairman of the Norwich Division of the B.M.A. within five years of his arrival in the city. Since his retirement in 1952 he had continued to live in Norwich. He leaves a widow, one daughter, and two sons.

Dr. A. A. FITCH died at Ambleside on September 2 at the age of 69. Arthur Alfred Fitch was born on March 29, 1887, and received his medical training at Liverpool University and St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1917. After serving in the R.A.M.C., he returned to Liverpool, where he was in general practice for a time, besides holding the appointments of medical officer in charge of the venereal diseases clinic at the David Lewis Northern Hospital and honorary dermatologist and physician in charge of the actinotherapy and venereal diseases departments at the Royal Southern Hospital. He left Liverpool shortly before the outbreak of the second world war, and for the last three years his home had been in Bath.

J. T. M. writes: Arthur Fitch was an unusual and complex personality. He was educated partly in France and spoke French fluently and German well, but not with the same ease. He served for a few years on the staff of the Hearst papers in America and used to declare he was the only Englishman ever employed by that by no means Anglophile agency. They sent him to the Middle East, where he learnt Arabic and claimed to have sat as a member at one time on the Young Turk Committee. Some time before the first world war he came home and began the study of medicine. When war broke out in 1914 the military authorities in their wisdom thought that his special gifts and experiences would fit him best for service in India, and there he stayed during

most of the hostilities. On demobilization he returned to the Liverpool and for a time was on the staff of the Royal Southern Hospital as a dermatologist. There was, however, to Arthur Fitch a wholly different side. He had a fine questing mind which led him to forsake the orthodox in his search for spiritual truth. For a time he linked himself with the Unitarian fellowship and indeed at one time was invited to accept the pulpit of one of the best-known of their churches in Liverpool. He loved his fellow men, and everything that concerned their welfare touched his heart. It was this emotional appeal that drew him at one time to join the ranks of the Labour Party. Particularly, however, it was children that most deeply stirred his feelings. He turned to the study of psychology and the problems of child delinquency. So to his friends it was no great surprise—however they might question the worldly wisdom of the move—when he gave up everything and opened—as a private venture—a residential school in Yorkshire for the benefit of "difficult" children—he would never call them delinquents. This was his real vocation, and this was his life so long as health permitted him to carry on. The practical problems arising out of the handling of these children led to a gradual acceptance of the view that a simple religious faith was essential if they were to be weaned from their warped ways and kept thereafter on the straight road. He came to associate himself and his school more and more with the beliefs and practices of the Quakers, and it was in this spiritual home that he died.

Dr. SIMON WIGODER died in Batley Hospital on September 13 from injuries received when struck by a car while he was on his way to visit a patient. He was 53 years of age. Simon Wigoder was born in Dublin and studied medicine at Trinity College, where he graduated M.B., B.Ch., B.A.O. in 1924. He proceeded to the M.D. in 1935 and took the D.O.M.S. in 1938. After graduation he worked for a short time in Wales and then settled in practice in Morley in 1924. He specialized in ophthalmology and worked for a time as registrar and assistant in the ophthalmological department at Leeds General Infirmary. He was on the executive of the North of England Ophthalmological Council and served as representative of the B.M.A. on the West Riding Ophthalmic Service Committee. He is survived by his wife and three children.

L. K. writes: Dr. Simon Wigoder's untimely death will be felt by a very great many people in Morley, where he had practised since 1924, becoming one of the town's best-known patients but to the community in general, serving for 19 years the town council and as chairman of its health committee. He was corps surgeon of the St. John Ambulance Brigade, physician to the four Morley courts, and superintendent of the juvenile court. Dr. Wigoder will be especially missed by his aged patients, to whom he showed every kindness and consideration. Simon Wigoder died as he lived—serving his fellows.

Dr. W. R. MARTINE, who practised in Haddington, East Lothian, for many years, died in Edinburgh on September 16 aged 85. William Robert Martine was born on June 18, 1871, the son of Dr. William Martine, a general practitioner in Haddington. His ancestors had lived in the district for several centuries: records show Martines as farmers in the county as far back as 1600, and many of them took an active interest in the public affairs of the county and the burgh. There was a provost Martine of the burgh in 1781, and other members of the family held the same office in later years. W. R. Martine was educated at the Knox Memorial Institute in Haddington, entering it on its opening day in October, 1880. At the age of 17 he started his medical course at Edinburgh University. During his student days an attack of rheumatic fever caused a setback in his medical education, but he graduated M.B., C.M. in 1894, and then held two assistantships, first to Dr. Barclay, of Inver Granton-on-Spey, and then to Dr. Sutherland, of Inver-gordon. Returning to Edinburgh, he was appointed house-

surgeon to Mr. A. G. Miller at the Edinburgh Royal Infirmary in 1895, but he had to relinquish this post because of the illness of his father and assume the responsibility of a large urban and country practice. Like all country doctors of his kind, he used a horse and gig to take him on his rounds. When he did have a car he never liked driving it. In addition to his work as a family doctor he was medical officer of the County Fever Hospital and a number of parishes in the district. A member of the B.M.A. for 60 years, he was chairman of the Lothians Division on two occasions, from 1914 to 1917 and from 1936 to 1937. In the years between he was honorary secretary of the Division. He was an active opponent of the National Health Insurance Bill, though, like many others, he came to accept the Act as a beneficial provision for many of his patients. He was president of the Edinburgh Branch of the B.M.A. from 1923 to 1924, and a member of the Scottish Committee from 1931 to 1934. He also served as a member of the Insurance Acts Committee for ten years and of the Rural Practitioners Subcommittee. For several years he was chairman of the Scottish Rural Practitioners Subcommittee. In 1936, after he had retired from practice in Haddington, he went to live in Edinburgh, and during the second world war he assisted the late Dr. Robert Craig, with whom he had a long and enduring friendship, in the secretarial work of the Scottish House of the B.M.A. Dr. Martine's recreations were curling, fishing, shooting, and, if not active gardening, at least the joy of a large garden and the cultivation of flowers. He was a successful exhibitor at the Royal Caledonian Society's shows and was Grand Master of the Ancient Fraternity of Freegardeners at Haddington for over 20 years. He married in 1897 a daughter of Mr. Charles Taylor, a solicitor before the Supreme Court, and had a family of three sons and one daughter, to whom the sympathy of a wide circle of friends is extended.—A. F. W. M.

Medico-Legal

MEDICAL EVIDENCE IN DIVORCE ON GROUNDS OF INSANITY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In the recent case of *Usher v. Usher*,¹ Lord Merriman, President of the Probate, Divorce, and Admiralty Division of the High Court, called attention to a change in the medical evidence required to support petitions for divorce on the grounds of incurable insanity. It is a result of the sanction given by the Minister of Health to medical superintendents to delegate responsibility for the clinical treatment of patients to psychiatric consultants on their staffs.

The President pointed out that as a result the medical superintendent was sometimes unable to give first-hand evidence about the diagnosis of the respondent's mental illness and the nature of the treatment. In that event the superintendent's affidavit must include a statement that he has delegated responsibility for treatment to a consultant, and when, and give the full name of the consultant concerned. There should also be affidavits from any consultants to whom responsibility has been delegated bringing the picture of the diagnosis and treatment of the patient up to date as at the presentation of the petition, and stating it to be the fact that in the opinion of the consultant, and in the light of present-day medical knowledge, the mental illness is incurable, and giving the reasons for the opinion. The evidence should also include information on whether the patient is able to appreciate "extra comforts" and if so to what amount, and anything else which is relevant. The President stressed that the evidence must bring the picture properly up to date and that the date of the assumption of responsibility by each and every consultant, and its duration, must be specifically stated.

¹[1956] 1 W.L.R. 894.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 8 (No. 36) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases

The only large variation in the trends of infectious diseases in England and Wales during the week ending September 8 was a fall of 290 for measles, from 1,382 to 1,092; the largest rises were 33 for whooping-cough, from 2,282 to 2,315, and 26 for dysentery, from 304 to 330. A fall of 19 was reported for acute poliomyelitis, from 124 to 105.

The largest falls in the number of notifications of measles were 68 in London, from 172 to 104, and 49 in Yorkshire East Riding, from 98 to 49. Only small fluctuations occurred in the local returns of scarlet fever. The largest fall in the number of notifications of whooping-cough was 32 in Yorkshire West Riding, from 198 to 166. 4 cases of diphtheria were notified, being 1 fewer than in the preceding week; 2 of the cases were notified in Birmingham C.B.

The rise in the incidence of dysentery was mainly due to cases in Yorkshire West Riding, where the number of notifications were 33 more than in the preceding week. The largest returns were Lancashire 78 (Liverpool C.B. 17, Blackpool C.B. 10, Salford C.B. 9); Yorkshire West Riding 66 (Leeds C.B. 35); London 33 (Southwark 8).

In Scotland 10 cases of diphtheria were notified, being 8 more than in the preceding week. 8 of the cases were notified from Stirling county and 2 from Edinburgh.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending September 15

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 313, whooping-cough 2,271, diphtheria 7, measles 932, acute pneumonia 205, acute poliomyelitis 111, dysentery 321, paratyphoid fever 6, typhoid fever 4.

Medical News

Hospital Building Programme.—Capital allocations to regional hospital boards for the year 1958-9 are announced in a memorandum from the Ministry of Health (H.M. (56) 80), and those for 1957-8 confirmed. The "plant replacement" programme is to continue, and £11m. has been earmarked for it in 1958-9; £11m. is expected to be available for other capital work that year. These sums are additional to any central expenditure on major projects from the list to which plans should be completed so that they may be begun in 1958-9. Regional boards are reminded that these capital allocations remain contingent on Government and parliamentary approval of the Health Service Estimates. The boards are asked to submit revised capital estimates for 1956-7 and 1957-8, to forecast estimates for 1958-9, and, as a help to planning for 1959-60, to notify any changes affecting major projects on their lists of such schemes. Capital

Capital Allocations (in Thousands of Pounds) for 1958-9

Hospital Board	Plant Replacement	Basic Allocation	Balance of Centrally Financed Schemes	Modernization of Mental Hospitals
Newcastle ..	140	679.69	—	100
Leeds ..	200	613.14	—	50
Sheffield ..	175	929.9	—	50

Birmingham ..	220	922.46	31.262	40
Manchester ..	270	880.7	—	45
Liverpool ..	150	419.96	—	
Wales ..	150	617.08	—	

allocations to boards of governors for 1958-9 are to be notified to each board of governors separately.

Association of Industrial Medical Officers.—This week the Association of Industrial Medical Officers has been celebrating its coming of age. Its first official meeting was held on September 27 and 28, 1935, at the London School of Hygiene and Tropical Medicine, when a company of 18 assembled under the chairmanship of Dr. N. HOWARD MUMMERY, medical officer to J. Lyons & Co. Ltd. At this meeting Dr. DONALD STEWART (Imperial Chemical Industries Ltd.) was elected honorary secretary, and somewhat later Dr. MARGARET DOBBIE-BATEMAN (Harrods Ltd.) was appointed honorary treasurer. Since those days the association has expanded enormously: it has now a membership of over 820, and there are eleven local groups covering the whole of Britain. In 1944, in conjunction with the British Medical Association, the association launched the *British Journal of Industrial Medicine*, and in 1951 the first number of its *Transactions* appeared. The 21st birthday celebrations were held from Monday to Friday this week at the London School of Hygiene and Tropical Medicine, under the chairmanship of the president of the association, Dr. R. S. F. SCHILLING. The meeting was opened by the Minister of Labour and National Service, Mr. IAIN MACLEOD, on the second day, and this was followed by Dr. Schilling's presidential address. At the scientific sessions there were discussions on "The Elderly Worker," "Research in Occupational Health," "The Impact on Medicine and Industry of the Use of Atomic Energy," and "Mental Health in Industry." There was also a lecture-demonstration on "Weight Handling." Two lectures were given during the meeting: the Mackenzie industrial health lecture, which is summarized elsewhere in this issue (p. 764), and the John C. Bridge memorial lecture, given by Professor R. E. LANE, on "The Place of Occupational Medicine in a Teaching Hospital." Other notable events of the meeting were the anniversary dinner on September 27 at the Royal College of Surgeons, and the presentation of the presidential jewel, given by the members of the association, by Sir WILSON JAMESON.

NAPT Canadian Scholarship.—The National Association for the Prevention of Tuberculosis offers a scholarship to enable a British chest physician to visit Canada for three months next year. The object of the scholarship is to promote the exchange of ideas and experience between British and Canadian doctors. The tour in Canada, which will start in May, will be arranged in conjunction with the Canadian Tuberculosis Association. The amount of the award is £350. The scholar will reside free of cost in Canadian sanatoria. Further particulars can be obtained from the secretary-general, NAPT, Tavistock House North, Tavistock Square, London, W.C.1. The last date for applications is December 31.

Surgeons' Visit to South Africa.—Mr. ALEXANDER MILLER, visiting orthopaedic surgeon at the Victoria Infirmary, Glasgow, and Mr. E. A. NICOLL, orthopaedic surgeon to the Chesterfield Royal Hospital, are leaving on September 30 for a six weeks' tour in South Africa as the guests of the gold-mining industry. They will give lectures and demonstrations in traumatic and orthopaedic surgery in hospitals owned by the industry in the Transvaal and Orange Free State. They have also been invited to lecture in the university centres of Johannesburg, Pretoria, Durban, and Capetown.

William Hunter Memorial Lecture.—Professor J. M. MUNRO KERR, a past president of the Royal Faculty of Physicians and Surgeons of Glasgow, and formerly regius professor of midwifery at Glasgow, delivered the inaugural William Hunter memorial lecture in the hall of the Faculty on September 12. The lecture is sponsored by the Glasgow Obstetrical and Gynaecological Society.

A Teaching Film.—In the United States medical audiences have recently had several opportunities of seeing closed-circuit television programmes on medical subjects sponsored by the pharmaceutical industry. One such programme, entitled "The Grand Rounds—Acute Abdominal Problems,"

has been filmed, and the film was recently shown in London by Upjohn of England Ltd. It is an interesting venture in medical film-making, for it records the unrehearsed remarks of some distinguished American clinicians and teachers who were presented with cases to diagnose and discuss in front of an audience at the Tufts University School of Medicine and the New England Medical Centre, with the co-operation of the Boston City Hospital. The film takes one hour to run, and three cases are shown—acute cholecystitis, haemorrhage from the spleen, and a duodenal ulcer which first perforated and then bled. The discussions on these cases were instructive without being didactic.

Melanocyte-stimulating Hormone.—Last week we noted the publication in the *Journal of the American Chemical Association* of a letter from Professor C. H. Li and his colleagues at California University on the structural formula of intermedin (see *British Medical Journal*, September 22, p. 719). An earlier publication on the same subject in *Nature* (July 14, p. 90) appeared under the title "Amino-acid Sequence of a Melanophore-stimulating Peptide," in which Dr. J. I. HARRIS, a member of the scientific staff of the Medical Research Council, and Mr. P. ROOS, a biochemist from Upsala University, Sweden, working together at Cambridge, recorded not only the complete amino-acid sequence of the hormone but also their appreciation of the possible significance of its central group of amino-acids at positions 7-13.

Scottish Hospitals.—On September 20 Mr. J. NIXON BROWNE, M.P., Joint Parliamentary Under-Secretary at the Scottish Office, began a fortnight's tour of hospitals in Scotland by inspecting the Edinburgh Royal Mental Hospital, where he saw examples of overcrowding; in the afternoon he visited the Royal Infirmary.

Sir Sydney Smith, Rector of Edinburgh University, has been elected an honorary member of the Royal Society of New Zealand. This honour is limited to thirty of the world's outstanding men of science at any one time. Sir Sydney was born in New Zealand, and received his early education there.

Dr. Macdonald Critchley has been elected an honorary member of the Rumanian Society of Medical Sciences. He is the first foreigner to receive that distinction. He has just returned from a lecture tour in Rumania.

Dr. H. Gardiner-Hill, physician to St. Thomas's Hospital, London, played himself into office as captain of the Royal and Ancient Golf Club at St. Andrews last week. According to reports, the ball proved difficult to find, as it disappeared into a thick mist. However, it was eventually retrieved and the traditional golden sovereign claimed.

COMING EVENTS

Charing Cross Hospital Medical School.—Viscount KILMUR will give the inaugural address at 3 p.m. on September 28 in the Egyptian Hall of the Mansion House, London, E.C.4.

Institute for the Study and Treatment of Delinquency.—Six lectures on "The Problem Family" will be given from October, 1956, to March, 1957, at St. George's Institute, Bourdon Street, Davies Street, London, W.1. Details from the general secretary, I.S.T.D., 8, Bourdon Street, Davies Street, London, W.1.

Institute of Dermatology.—Semi-permanent exhibition on "Dyskeratosis," October 1-27.

Medical Protection Society.—Annual meeting at Victory House, Leicester Square, London, W.C.2, on October 3 at 3 p.m.

London Hospital Old Students Dinner.—Will be held at the Trocadero, 7 p.m. for 7.45 p.m. on October 11, with Sir HENRY TIDY in the chair. Tickets, 32s. 6d. (or 25s. for those qualified under five years), from Dr. R. R. BOMFORD, 22, Harley Street, London, W.1.

British Council for Rehabilitation.—One-day conference on "Injury, Compensation, and Employment," October 12, from 10 a.m. to 5 p.m., at B.M.A. House. Details from the general secretary, British Council for Rehabilitation, Tavistock House (South), Tavistock Square, London, W.C.1.

Royal Society of Tropical Medicine and Hygiene.—The opening meeting at Manson House, London, will be on October 10 at 7.30 p.m., instead of October 18 as previously arranged. Dr. H. A. REID will read a paper on "Sea Snake Research."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, October 2

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: Circulation and Vascular Reactions.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. L. Guttman: Modern Trends in the Treatment of Traumatic Paraplegia (with lantern slides).
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. J. N. Milnes: neurological demonstration.

Wednesday, October 3

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. J. Hare: Sweat Secretion and Abnormalities.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. N. R. Barrett: Acalasia.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. G. Sandrey: Urological Emergencies in General Practice.
MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Medical School, Manchester University, 4.30 p.m., Dr. R. M. Forrester: Cerebral Palsy.
MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Professor Walter Bauer (Harvard): Management of Gout.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor M. Meizels: Place of Chemical Pathology in Medicine.
SOCIETY FOR ANALYTICAL CHEMISTRY.—At Chemical Society, Burlington House, W., 7 p.m., subject: Chromatography. Mr. W. H. C. Shaw, F.P.S., F.R.I.C., Mr. J. P. Jefferies, B.Sc., A.R.I.C., and Mr. T. E. Holt, B.Sc., A.R.I.C.: Determination of Vitamin D and Related Compounds. Part I.—Introduction and Preparation of Compounds in the Irradiation Series. Part II.—Analysis of Irradiation Products. Dr. A. S. Curry, Ph.D.: Some Examples of the Use of Paper Chromatography in Toxicological Analysis.

Thursday, October 4

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: neurology demonstration.
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases.

Friday, October 5

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Midland Hotel, 8 p.m., annual dinner. Guest speaker, Dr. J. R. Rees.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. M. S. Thomson: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical meeting for general practitioners. Mr. S. E. Birdsall: Tonsillectomy in Children and Adults.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. F. R. Edwards: Atrial Septal Defects and their Treatment.
SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP AND MICROBIOLOGY GROUP.—At London School of Hygiene and Tropical Medicine, 7 p.m., Professor A. Neuberger, F.R.S.: Some Uses of Isotopes in Biochemistry.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. R. M. B. MacKenna: Common Problems of Dermatology.

Saturday, October 6

ASSOCIATION OF CLINICAL BIOCHEMISTS.—At Royal College of Surgeons of England, 9.30 a.m., joint meeting with Association of Clinical Pathologists. Lecture by Sir Rudolph Peters, F.R.S. Also symposium: Biochemical Lesions: Keto-acid Metabolism and the Citric Acid Cycle.
NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At Beckett Hospital, Barnsley, 2 p.m., 10th annual meeting.

Sunday, October 7

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—10.15 a.m., clinical demonstration for general practitioners—obstetrics and gynaecology.

BIRTHS, MARRIAGES, AND DEATHS

MARRIAGES

Fox-Akker.—On September 13, 1956, in Cochin, South India, Wallace Fox, M.D., M.R.C.P., of Tuberculosis Research Unit, Medical Research Council, London, and now at Tuberculosis Chemotherapy Centre, Government Tuberculosis Institute, Chetput, Madras, India, to Gaye Akker, of 3, Chesham Close, London, S.W.

DEATHS

Bindley.—On September 11, 1956, at his home, Ninfeld, Sussex, Robert Alfred Bindley, M.B., late of Harlesden, London, N.W., and Prestwood, Bucks, aged 96.
Butler.—On September 9, 1956, at Tunbridge Wells, James Alfred Butler, M.D., of The Shrubbery, Firs Road, West Mersea, Essex.
Clement.—On September 10, 1956, in a nursing-home, Glasgow, William Clement, M.B., F.R.C.O.G., late of Kirkland, Dunlop, Ayrshire.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Human Anthrax

Q.—A patient of mine, a veterinary surgeon, quite often encounters cases of anthrax. Can he be protected against the disease by a vaccine? What treatment is advised for a human case of anthrax?

A.—For reasons given in the second paragraph of this answer it is doubtful whether active immunization of the human subject against anthrax, even in specially exposed individuals, is worth while. Commercially available vaccines are intended for use in cattle. It seems likely that they may be superseded by the antigen recently isolated by workers at Porton.^{1,2} This is a protein of which only 25 µg. will produce solid immunity in the rabbit. The serum of horses immunized with it contains at least as much protective antibody as that obtained in the usual way by hyperimmunizing the horse with a living-spore vaccine.

B. anthracis is regularly and highly sensitive to penicillin, and this antibiotic has been used with uniform success in the treatment of anthrax, even in patients with bacteraemia or meningitis. Judging by the experience of LaBocchetta³ it is not even really necessary to use large doses: he gave only 100,000-200,000 units daily to 36 patients, all of whom recovered. The organism is also sensitive to all the other major antibiotics, the order of their activity after penicillin (most active) being chlortetracycline and oxytetracycline, streptomycin, chloramphenicol.⁴ There are records, reviewed in Garrod's paper,⁵ of the successful clinical use of each of these drugs. It is significant that 7 of the 8 cases of Gold and Boger⁶ were treated as out-patients. That it should be thought safe merely to give a patient capsules to take at home is a striking indication of the altered outlook in this disease.

"Mental Deficiency"

Q.—(1) What constitutes mental deficiency from the legal point of view? (2) How does the legal definition compare with the clinical connotation?

A.—(1) In England and Wales since 1913 the term mental deficiency has been used to describe arrested or incomplete development of mind existing from an early age. An early age has since been defined as "before the age of 18 years." From the legal standpoint a mental defective is a person certified by the legal authorities as such. Ascertainment is carried out by the medical officers of the local authority and is frequently done in conjunction with the education authority, so that children deemed to be ineducable, or, in certain cases, children leaving special school at 16, are ascertained as mentally defective. Certification implies the compiling of a medical certificate of mental deficiency; for most purposes two of these are required. This procedure is carried out prior to "dealing with" a mental defective by putting him into an institution or under guardianship. In the case of a child, that of Mental Deficiency Act a magistrate's approval is also required, and under Section 3, in the case of a child, that of the parents. Mental defectives are dealt with under Section 8 and 9 of the existing Acts by courts and prison authorities, respectively.

(2) The clinical connotation of mental defect may be wider or narrower, depending on the point of view of the clinician.

Some persons who are of very limited intelligence will make do in society, given favourable circumstances. From the clinical angle these people may be said to be handicapped by mental deficiency; a few of them may also suffer from physical handicaps as well as their mental defect. At the other end of the scale many young persons who are in social difficulties, suffering from mental disorder, or classifiable as psychopaths are dealt with under the Mental Deficiency Acts as a matter of convenience, though they could well be handled by the ordinary social agencies. From the clinical standpoint there is little to recommend the classification of such persons as mental defectives, though legally they may be such. The criteria of mental defect are primarily social. There is no advantage in designating a person as mentally defective if he is able to fit into the community. On the other hand, not all people who have social difficulties can be classed as mental defectives, and it seems most logical to reserve the term for those persons who have both difficulty in fitting into society and who at the same time show gross limitation of mental ability existing from an early age.

Severe Reactions from Midge Bites

Q.—What treatment would you recommend for midge bites which weal and blister?

A.—Wealing and blistering of midge bites occur only if the subject is hypersensitive. This is an acquired specific allergic hypersensitivity to the minute amount of material which the midge injects into the skin.

Prevention is better than cure, so people who are subject to troublesome reactions from insect bites should use a repellent whenever they are likely to be bitten. Dimethyl phthalate is an excellent repellent for midges, since it is effective, colourless, odourless, and without any irritant effect on the skin. It is effective for several hours.

Midge bites which proceed only to the stage of wealing can usually be satisfactorily treated by the local application of an antihistamine cream. Prompt inunction will usually relieve irritation and diminish the duration of the weal, even if it does not entirely prevent its development. In those cases where blisters arise, these may be prevented if the antihistamine is applied in the early stage before blistering begins. After the blister has developed no local treatment is likely to influence it very much. Sometimes these blisters are very tense and may rupture, leaving a troublesome raw area which may then become secondarily infected. If they are large enough to threaten spontaneous rupture, it is best to prick the blisters with a sterile needle so as to allow the fluid to escape. They are then best dusted with a plain zinc oxide and starch powder and kept dry.

Brachial Plexus Block in the Unconscious

Q.—In what conditions is a brachial plexus block indicated in an unconscious or anaesthetized patient? How is the block best done and how is its effectiveness judged?

A.—Brachial plexus block in an unconscious or anaesthetized patient is performed in order to block the sympathetic nerve supply to the arm. In the anaesthetized patient the procedure is indicated if an inadvertent intra-arterial injection of thiopentone has been made, or if during the operation the main blood supply to the limb has been interfered with. The plexus is also infiltrated by some operators during high amputations of the limb, in particular during a forequarter amputation. In these latter instances, however, the block is part of the operation and is performed under direct vision. In unconscious patients the plexus is blocked to help restore a poor circulation due, for example, to trauma. Thus an unconscious patient, concussed as a result of a road accident, may at the same time have suffered an injury of the arm leading to an interference with its blood supply.

The best method of blocking the brachial plexus is to deposit local analgesic solution on the upper surface of the first rib, where this is crossed by the plexus. The elicitation

of paraesthesiae is not possible when the patient is unconscious. However, this is not a disadvantage, and indeed in Patrick's method paraesthesiae are not deliberately sought. A barrage of local analgesic solution is laid down in the path of the plexus where it crosses the first rib. The effectiveness of a brachial block in a patient who is not conscious may be judged by the following signs: the hand on the blocked side becomes noticeably warmer than that of the other side; a stimulus—for example, a pinch by a towel clip on the skin of the hand—sufficient to cause the unblocked arm to move does not cause this reaction on the blocked arm; sweating ceases in the blocked limb and the subcutaneous veins become more prominent. A detailed and well-illustrated description of brachial plexus block by a modification of Patrick's method is described in *Local Analgesia; Brachial Plexus*, by R. R. Macintosh and W. W. Mushin (3rd ed., Livingstone, 1955).

Aluminium and Dental Amalgam

Q.—Amalgam used in filling teeth commonly consists of approximately 90% silver with some mercury and tin. If the unused surplus is left overnight on any aluminium surface, white fluffly flakes are given off. How is this explained?

A.—In air aluminium rapidly forms a coating of oxide which protects it from further corrosion and is strongly adherent. If the formation of the film is prevented by amalgamating the surface of the aluminium with mercury, as will occur if amalgam is placed upon it, oxidation in air occurs so fast that the temperature of the metal is raised and a feathery growth of oxide develops in the course of a few minutes.

Blood-clotting Time after Dicoumarol

Q.—Why cannot the effects of dicoumarol and similar anticoagulants be assessed by the whole-blood clotting time rather than the prothrombin time?

A.—Blood-clotting time is controlled, to a great extent, by the rapidity of thromboplastin generation. The formation of active thromboplastin under appropriate conditions is dependent upon the interaction of numerous substances, among which factors V and VII are of considerable importance. Following ingestion of dicoumarol, factor VII is the first component to be inhibited, while factor V is unaffected. In practice, whole-blood clotting time is little affected when small changes in factor VII only are involved, as all the other factors are present; only if factor VII is grossly depressed is the whole-blood clotting time prolonged. The single-stage prothrombin technique, which in fact does not measure "prothrombin concentration" but rather the efficiency of the factor V-factor VII complex, is sensitive to even small reductions of factor VII and is therefore satisfactory in controlling dicoumarol therapy.

Action of Heparin

Q.—How does heparin exert its anticoagulant effect? Why does it affect the one-stage but not the two-stage prothrombin time?

A.—Heparin is a polysulphuric acid ester of mucoitin. It carries an exceptionally high negative electric charge, by virtue of which it exerts its effect by altering the charges on other coagulation factors. It has two main points of action; in the presence of plasma proteins (co-factor) it inhibits the conversion of prothrombin to thrombin. Heparin also inhibits the thrombin-fibrinogen conversion when plasma albumin is present.

The one-stage prothrombin estimation is a "blunderbuss" reaction. It should be given some non-specific name, since it does not measure prothrombin concentration but is affected by alterations in the thrombin-fibrinogen reaction, the true prothrombin concentration, and the presence of factors V and VII. It will therefore reflect changes caused

by heparin at the prothrombin-thrombin and thrombin-fibrinogen levels. The two-stage method measures the amount of prothrombin present irrespective of the rate at which it becomes available. The administration of heparin, though retarding the conversion of prothrombin to thrombin, does not influence the absolute amount of prothrombin present, and thus the two-stage test is no help in controlling heparin therapy.

School Medical Inspection

Q.—Under Section 48 of the Education Act, 1944, the local education authority may require any pupil attending a school maintained by the authority to submit to medical inspection. Any person who fails, without reasonable excuse, to comply with any such requirement shall be liable to penalty. Is there any case law which clarifies whether the following constitute "a reasonable excuse": (1) conscientious objection to medical examination by a parent who belongs to a certain religious sect; (2) the production of a certificate of fitness from the child's family doctor?

A.—I know of no case in the Courts on the interpretation of "reasonable excuse" in Section 48(2) of the Education Act, 1944. Any such case would come before the local bench of magistrates, and it is impossible to predict their attitude. I can only say that, if I were a principal school medical officer and a parent told me that he wished his child exempted from school medical inspection for either of the two reasons given, I would try to persuade him to change his mind; but if he were adamant I would let him have his way and advise the local education authority to do the same.

Sore Tongue from Pipe-smoking

Q.—A man wishes to change from cigarette-smoking to a pipe, but he cannot smoke more than a couple of pipefuls a day without his tongue getting very sore. What is the reason for this, and how can it be prevented? Does the soreness indicate any predisposition to lingual cancer?

A.—The soreness of the tongue is due to direct irritation by the tobacco smoke, though it is not possible to specify which component. Some tobaccos are more likely to burn the tongue than others, and it may be possible to find one which gives a cool smoke. A filter in the pipe stem may also help. It is true also that the tolerance of the tongue is likely to improve with practice. It is not possible to say whether this symptom indicates an undue predisposition to lingual cancer; it might well be the other way round. Although pipes and cigars are now regarded as safer than cigarettes, it is probably true that the statistics about their effects are not so comprehensive as those for cigarettes.

Books of "Any Questions?" and Refresher Course Articles.

The following books are still available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?* Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volume 2 (26s. 6d. inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Attology, Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: *Britmedads, Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: *Medisecra, Westcent, London*.

INTRAVENOUS CHOLANGIO-CHOLECYSTOGRAPHY WITH "BILIGRAFIN"

ITS VALUE AS COMPARED WITH THE ORAL CONTRAST METHOD

BY

R. W. W. HARDIE, M.B., Ch.B., F.R.C.S.Ed., and M. ISRAELSKI, M.D., D.M.R.

North and South Warwickshire Hospital Groups

[WITH SPECIAL PLATE]

Intravenous cholecystography was first introduced by Graham and Cole in 1924, but, owing to the relatively high degree of toxicity of the phenolphthalein compounds employed, its clinical use was almost completely abandoned when a number of effective and less toxic oral contrast media became available. The intravenous method of visualization of the biliary tract has recently received a fresh impetus with the introduction of the new contrast medium "biligradin" by Messrs. Schering, available in this country since 1954. As this dye appears to offer an advance in the accurate diagnosis of diseases of the biliary tract, the benefits which may be derived clinically from its use, and the subject generally, would seem worthy of review.

Pharmacology and Toxicity

"Biligradin intravenous" is the disodium salt of N:N'-adipic-di(3-amino-2:4:6-triiodobenzoic acid), in a watery solution, which is practically isotonic to normal saline. The substance is of very low toxicity. Winzer *et al.* (1954) found in experiments on rats that the lethal dose of biligradin is 3.4 g. per kg. body weight; this compares very favourably with the lethal dose of most oral contrast media for cholecystography, which is in the region of 0.4 g. per kg. body weight. It is therefore not surprising that the drug is very well tolerated.

This dye has been in wide use in various countries and there are reports on large series of cases—for example, by Frommhold (1953), Hornykiewytch and Stender (1953, 1954), and Gaebel and Teschendorf (1953, 1954) from Germany; Caroli *et al.* (1954) from France; Huber and Stoessel (1954) from Switzerland; Glenn *et al.* (1954) and Orloff *et al.* (1954) from the United States, where the dye is marketed under the name of "cholografin"; Sethna (1954) from India; Sutton and Tillett (1954) and Aldridge (1955) from Great Britain. Only mild side-reactions were recorded by these authors. In our own series of 106 cases we have not seen any severe reactions, but there have occasionally been slight nausea, a feeling of heat or of flushing in the face, and one of our patients had a mild and transient erythematous rash. Though biligradin is an eminently stable compound and does not liberate iodine in the body, it is generally agreed that it should not be used in cases of known iodine idiosyncrasy. However, the slight allergic reactions which occasionally occur are thought to be due to sensitivity to the whole molecule rather than to free iodine.

Generally our impression is that biligradin is better tolerated than the dyes used for oral cholecystography. The frequent side-reactions of oral cholecystography, such as nausea or vomiting, are rare, and diarrhoea is unknown after biligradin.

Technique of Examination

We have used 40 ml. of biligradin as a routine, as this amount did not seem to produce any more side-effects than 20 ml. and gave pictures of better diagnostic quality. Examination has recently been simplified by the introduction of "biligradin forte." This is the methylglukamine salt of the compound in a more concentrated solution, 20 ml. of which is adequate for diagnostic purposes. The injection can be completed in three minutes. Side-reactions are also negligible. Intravenous examination can easily be fitted into the routine of the x-ray department. For the bile ducts films are taken 30 and 50 minutes, and for the gall-bladder up to 3 hours, after the injection. Upright spot films under screen control are taken if necessary. Between exposures the patient is allowed to move about freely. Small accidental paravenous injections cause a slight local burning sensation, but no necrosis or other after-effects.

It has been suggested that oral cholecystography and the intravenous examination can be carried out in one session. We had not originally the courage to do this, in view of the possible cumulative toxic effects of the two dyes, and preferred to leave an interval of at least two days between the two examinations, but recently, in order to come to a quick conclusion, we have examined several patients in this way without noticing any unfavourable effects. We have not used any of the drugs recommended to provoke spasm of the sphincter of Oddi, such as neostigmine, morphine, pethidine, or paregoric, the results usually being adequate without such complicating procedures.

When cholangiography only is to be performed the patient is kept fasting, but when visualization of the gall-bladder also is required a fatty meal is given 1½ hours before the injection, in order to empty the gall-bladder as completely as possible. In agreement with Aldridge we have the impression that this accelerates filling of the gall-bladder with dye and facilitates uniform mixing of dye and bile.

Concentration in the Bile

Soon after injection biligradin appears in a high concentration in the bile, the flow of which is increased by the strong choleric effect of the drug. Frommhold (1953) quotes from animal experiments and observations of patients with external biliary fistulae that the concentration of

biligradin in the bile reaches 30 to 100 times that in the blood within 10 to 15 minutes of the injection. By this time the hepatic and common bile ducts are already clearly outlined. The filling of the gall-bladder follows later by gradual infiltration of the dye by way of the cystic duct towards the fundus. Full filling of the gall-bladder takes from one to three hours. Visualization of the biliary system by biligradin thus operates in the reverse order to that which occurs in oral cholecystography. In oral cholecystography the original concentration of the dye is not enough to visualize the ducts or gall-bladder, and further concentration in the gall-bladder is required to render that organ opaque.

Shehadi (1954) has shown that in a high percentage of cases the common bile duct can also be demonstrated by oral cholecystography while the gall-bladder is emptying after a fatty meal. Twiss *et al.* (1954) have even demonstrated that it is possible to visualize the common duct by oral cholangiography in cholecystomized patients. Their rather elaborate techniques appear, however, to be unnecessary in view of the more reliable results obtainable by the new intravenous method. With biligradin visualization of the common duct occurs with great regularity, the duct becoming visible whether the gall-bladder has filled with the dye or not, and in patients whose gall-bladders have been removed. As the filling of the gall-bladder with biligradin is a passive process dependent only on the cystic duct being patent and its lumen adequate, and as it does not require the concentrating power of the gall-bladder wall, it is sometimes possible with biligradin to visualize a gall-bladder which has failed to show with oral cholecystography. A fact to be remembered is that on occasions the thick bile in the gall-bladder mixes poorly with the dye. This leads to unequal densities, and may simulate a filling defect due to calculi, but the phenomenon disappears when time is allowed for adequate infiltration and mixing to take place.

It must be emphasized that in oral cholecystography the concentration of the dye or its failure to concentrate in the gall-bladder remains a valuable test of the function of that organ. A negative oral cholecystogram may be the only radiological sign of inflammatory or metabolic disease of the gall-bladder in cases where the findings with biligradin are normal. We therefore believe that for the time being these two methods are complementary and that neither can fully replace the other. The same point was stressed by Graham in a recent discussion on a paper by Glenn *et al.* (1954).

Jaundice

In obstructive jaundice results with biligradin are consistently poor, it being rarely possible to outline either bile ducts or gall-bladder, though the injection of the dye does not cause any harm. Such failure is probably due to the presence of inspissated bile in the tract, preventing the dye from infiltrating adequately. Useful results have, however, been obtained as soon as the jaundice begins to subside. We have demonstrated stones in the common duct in three of our patients under such circumstances (Special Plate, Figs. 1, 5, and 7). On the other hand, a case of haemolytic jaundice which was examined with biligradin produced a perfect filling. This patient had a splenectomy, during which stones were felt in the gall-bladder, which was left intact. As the jaundice showed little sign of improvement after the operation the question of an obstructive factor arose. Biligradin filled the stone-containing gall-bladder and demonstrated a slender common duct without stones, thus clearly eliminating an obstructive element.

Excretion of Biligradin

With normal liver function 90% of biligradin is excreted by the liver, about 10% by the kidneys. No reabsorption of the dye takes place in the bowels and its bulk is evacuated with the stools. Trebbin (1954) found that liver damage may lead to a rise in urinary excretion of up to 50% of the intake of the dye and to a protraction of its excretion time to several days. While traces of a transient intravenous pyelogram are not uncommonly present when liver function

is adequate (Special Plate, Fig. 4), in cases of liver insufficiency a prolonged pyelogram may be seen with greater regularity. The kidney takes over when the liver fails. Simple loss of portions of liver substance does not seem to affect the excretion of biligradin to a detectable extent. In three of our cases with extensive neoplastic infiltration of the liver, but without clinical jaundice, good excretion of the dye occurred.

Plan of Investigation

Altogether we examined 106 patients with biligradin—75 with an intact gall-bladder and 31 after cholecystectomy. The first group consisted of strictly selected cases, in all of which oral cholecystography was performed in the first instance. The examination with biligradin was undertaken only when oral cholecystography had failed to produce a satisfactory shadow of the gall-bladder or when it was considered that the questions raised by the clinical aspect of the case had not been adequately answered. It was thus attempted to assess the comparative values of oral cholecystography and intravenous cholangio-cholecystography. It may be mentioned that for oral cholecystography the double-dose method was employed, and that a series of upright spot films under screen control was taken in all cases with a clearly visible gall-bladder. A conclusive result regarding the condition of the gall-bladder itself can usually be obtained with this method alone, and in only a minority of cases did we find it desirable to continue the examination with biligradin.

Patients with Intact Gall-bladder

The results in the 75 cases with intact gall-bladders in which both tests were performed are given in Table I.

TABLE I.—Results of Intravenous Cholangio-cholecystography in Patients with Intact Gall-bladders

A. After Unsuccessful Results of Oral Cholecystography			
1. Ducts and gall-bladder filled:			
a. With stones—			
i. In the gall-bladder alone	16		
ii. In the common duct alone	1		
iii. In the gall-bladder and common duct	3

Total			75

A. Biligradin Examination After Unsuccessful Oral Cholecystography

In the 58 cases in this group the gall-bladder had either not filled with the oral method or had given such a faint shadow that no definite diagnosis as regards calculi could be made. Among these 58 cases the gall-bladder filled with biligradin in 27, thus indicating the patency of the cystic duct. Stones were shown in 20 of these cases—in 16 in the gall-bladder alone, in one in the common duct alone (Plate, Fig. 1), and in three in both gall-bladder and common duct. In all but one case the presence of stones had remained doubtful after oral cholecystography. The exception had a solitary giant stone in the gall-bladder, whose small opaque centre had been seen as a faint shadow in a plain film but whose actual size and position were demonstrated only by biligradin.

The case with the solitary stone in the common duct (Plate, Fig. 1) deserves special description. This patient had just recovered from an attack of obstructive jaundice. An oral cholecystogram showed a very faintly filled gall-bladder of normal size. With biligradin a large stone was demonstrated high up in the common duct approximately at its junction with the cystic duct, and only an incomplete filling of the gall-bladder was obtained. At operation to remove the stone the wide cystic duct and the gall-bladder

were found clear of stones. It appears that the stone in the common duct had intermittently occluded the cystic duct.

Two of the three patients with stones in the gall-bladder and common duct had never been jaundiced. Oral cholecystography had failed to outline the gall-bladder and had not shown any stones. The most spectacular of three cases showing gross lobulations of the gall-bladder as well as calculi is illustrated in Fig. 2 on the Special Plate. At operation the deformities were found to be due to the gall-bladder being partly embedded in the substance of the liver. An interesting feature in each of these cases was that stones were found in the distal compartment only of the gall-bladder, where stasis must have been most marked. None of this pathological picture was visible on oral cholecystography.

One of the six cases with a normal intravenous cholangio-cholecystogram following the failure of oral cholecystography turned out to have a benign pyloric stenosis. Oral cholecystography is naturally condemned to failure by any abnormality preventing the absorption of the contrast medium, and the risk of a mistaken diagnosis of biliary-tract disease in such cases is well known. With the intravenous method mistakes of this kind can now be avoided. No such cause for unsuccessful oral cholecystography was, however, found in the other five cases without calculi (Table I, A1b), and in our view these illustrate the persisting importance of oral cholecystography, demonstrating the failure of a pathological gall-bladder to concentrate the dye.

The unclassified case (Table I, A1c) showed features of particular interest. It was one in which two large gall-stones causing intestinal obstruction had been removed from the jejunum a short time previously. The common and cystic ducts showed normal outlines with biligradin, but the gall-bladder was only faintly demonstrated with its fundus pulled strongly across towards the duodenum, in which much dye could be seen. The very faint gall-bladder shadow and its distorted position suggested a cholecysto-duodenal fistula with leakage of the dye into the duodenum. There were no obvious residual calculi in the gall-bladder.

In the 28 cases where the hepatic and common ducts only were outlined (Table I, A2), obstruction of the cystic duct was presumed. This was confirmed in all cases at operation, and found to be due to calculus. We have not so far encountered any case of neoplastic obstruction of the cystic duct, but would expect the appearances to be similar. In two patients a non-opaque stone in the cystic duct became outlined by biligradin during the examination (Plate, Fig. 3). Another patient had had more prolonged jaundice than would normally be expected with temporary impaction of a stone at the lower end of the cystic duct. Biligradin showed pronounced dilatation of the hepatic ducts and of the common duct above the junction with the cystic duct, but the lower end of the common duct also appeared dilated to some extent (Plate, Fig. 4), suggesting that a calculus, after being impacted for a time in the first position, had been held up at the ampulla before being passed into the duodenum. At operation fine grit and inspissated bile only were found in the cystic duct, and the common duct was clear, so that this may well have been the case. In cases presenting the clinical picture of "acute cholecystitis" biligradin usually shows a blocked cystic duct, even if the examination is delayed until the acute stage has subsided.

Of the last three cases, in which neither ducts nor gall-bladder were demonstrable by biligradin (Table I, A3), one had advanced hepatic cirrhosis and one was a case of recent obstructive jaundice. The third had recently undergone transduodenal excision of a small tumour at the ampulla of Vater; this apparently resulted in incompetence of the sphincter of Oddi, with consequent entry of air into the biliary tract and rapid leakage of dye into the duodenum. Another similar post-operative case, included in Group A2 in Table I, showed alternate filling of the common duct with dye and air in a series of films after biligradin injection. In such cases only the presence of dye in the duodenum may indicate that it has been excreted by the liver.

B. Biligradin Examination After Successful Oral Cholecystography

The discovery of stones in the gall-bladder with oral cholecystography does not necessarily reveal the full pathological picture, particularly in view of the possibility of calculi in the common duct. The incidence of calculi occurring in the gall-bladder alone was stated by Walters and Snell (1940) to be 87%, in the gall-bladder and common duct 7%, and in the common duct alone 6%; but Bernhard (1935) found the incidence of common-duct stones as high as 20% of all cases of calculus. The occasional absence of obstructive jaundice with common-duct stones has been emphasized by various authors. Four such cases were seen in our series, two pre-operatively and two after cholecystectomy. As these common-duct stones can be readily demonstrated with biligradin, intravenous cholangiography should be performed in every case before cholecystectomy is undertaken. This will usually indicate whether the common duct needs to be explored or not.

Group B of Table I comprises 17 cases where oral cholecystography had been successful but where clearer anatomical detail of the gall-bladder was desirable or there was a suspicion of stones in the ducts. One patient in this group was found to have stones in the common duct in addition to those already diagnosed in the gall-bladder (Table I, B1). This patient had just recovered from a first attack of mild transient obstructive jaundice. It was the unusual degree of clinical shock during an attack of biliary colic on admission to hospital that prompted the biligradin investigation (Plate, Fig. 5). Another case examined early in our series (Table I, B3) showed no shadow of biligradin in gall-bladder or ducts, though a functioning gall-bladder full of stones had been demonstrated by oral cholecystography. The reason apparently was that the biligradin examination had been carried out too soon after an attack of obstructive jaundice, probably due to temporary impaction of a stone, which had intervened since the cholecystography. Had this negative result occurred later in the series the intravenous examination would have been repeated. No stone was, however, found in the common duct at operation.

The remaining 15 patients in this group had normal common bile ducts. Among them were a few with a normal oral cholecystogram without stones, examined because of recent attacks of jaundice believed to be possibly obstructive. In none of these did we encounter stones in the common duct, and the jaundice had probably been due to infective hepatitis. It appears that the presence of common-duct stones affects the quality of the oral cholecystogram, and that good concentration of the dye in a gall-bladder free of stones makes it unlikely that stones are present elsewhere in the biliary system. A normal oral cholecystogram thus seems to remain a reliable sign of a healthy biliary tract.

Intramural Diverticulosis of the Gall-bladder

In one case among the 15 referred to above the examination was carried out because oral cholecystography had demonstrated a bilocular deformity of the gall-bladder. The patient was a young man with several years' history of biliary dyspepsia. The intravenous examination with biligradin showed delicate protrusions of dye outside the main lumen

Operative specimen of gall-bladder shown in Fig. 6 of Special Plate.

of the gall-bladder, best seen at the waist between the two compartments (Plate, Fig. 6). A diagnosis of intramural diverticulosis of the gall-bladder (cholecystitis glandularis proliferans; Aschoff-Rokitansky sinuses) was made, and this was confirmed at operation. The operative specimen (see photograph) demonstrates the gross leathery thickening of the wall of the lower compartment and shows cuts through some of the sinuses. According to the histological report (Dr. E. N. Trounson) there were also extensive inflammatory changes. This condition is now generally considered as associated with chronic inflammation of the gall-bladder (March, 1948; Bean and Culver, 1950; Lawler, 1952; Sutton, 1955). The radiological demonstration of such sinuses thus appears to justify the diagnosis of chronic cholecystitis. It is likely that many cases of this kind have escaped detection by oral cholecystography, for, in spite of the frequency with which these sinuses are seen in pathological specimens, their radiological diagnosis has been rare. This may in future be altered owing to the increased anatomical detail which biligrafin can reveal even in a poorly functioning diseased gall-bladder.

Post-cholecystectomy Examinations

The second main group are patients who had undergone cholecystectomy. The results are given in Table II.

Normal Findings After Cholecystectomy

In the early stages of our investigation we examined 11 patients after cholecystectomy, without symptoms, in order to gain experience with regard to the range of normal findings. This subject has since been dealt with in greater detail by Don (1955). Visualization of the common duct was obtained in all cases. In most instances the duct was slender, measuring about 3 mm. in diameter, but in a few cases the duct measured up to 10 mm. It was noted that the time during which the common duct remained visible varied greatly; in some cases it was demonstrated up to several hours after injection. It seemed unlikely that these variations in the size of the duct or in the degree of spasm of the sphincter of Oddi, as indicated by the retention of dye, had any clinical significance. A grossly dilated common duct may be due to pre-operative obstruction which has been relieved.

Post-cholecystectomy Syndrome

Having excluded coincident peptic ulcer, hiatus hernia, chronic appendicular dyspepsia, and other possible causes of discomfort, there still remain a certain small number of patients in whom symptoms of a biliary-tract type continue or recur after cholecystectomy.

Stones in the Common Duct After Cholecystectomy

Moynihan, in his book *Abdominal Operations* (1926), claimed that the tiniest fragment of stone within the common duct could be detected by expert fingers. Most surgeons like to feel that this is the case, and in performing cholecystectomy do not open the common duct unless there has been jaundice or unless palpation raises the suspicion of stone or other obstruction. The fact remains, however, that occasionally a stone is missed during palpation of the common duct or has been lurking out of reach in one of the hepatic ducts and is allowed to remain, with consequent persistence of symptoms. It has been optimistically hoped in the past that these post-operative symptoms might be due to spasm of the sphincter of Oddi, but it now appears open to doubt whether such spasm in itself ever gives rise to symptoms.

Davidson *et al.* (1949) stated that in a series of patients with common-duct stone no less than 30% required operation because stones had been overlooked at previous cholecystectomy, and it is more disturbing still that Hughes *et al.* in 1948 and Thiessen in 1951 reported the discovery, at post-operative cholangiography, of retained stones in the common duct after choledochostomy in 24% and 15% of cases respectively. It is of interest also that Corff *et al.* in 1952 found that 41% of their patients with stones in the common duct had never been jaundiced. It is therefore of the greatest importance that intravenous cholangiography should be carried out as soon as possible when biliary symptoms recur after cholecystectomy, whether there has been jaundice or not. As recurring jaundice has always been an indication for laparotomy, the examination appears particularly important in the non-jaundiced patient. In the past, as there has been no non-surgical method of examining the common duct, there has been much speculation upon the cause of symptoms in these patients, with consequent delay and suffering. The advent of biligrafin, however, provides a reliable method of demonstrating the common and hepatic ducts without laparotomy.

Among 20 patients examined because of symptoms following cholecystectomy, five had stones in the common duct. The cholecystectomy had been performed at varying times up to ten years previously. In four of the five the stones were clearly demonstrated by biligrafin (Plate, Figs. 7 and 8) and corresponding numbers were removed subsequently at operation. Two of these (Plate, Fig. 8) had never been jaundiced. In one who had had recurring jaundice a rather wide and winding common duct was seen. At operation a small stone was found in the common duct which had not been diagnosed pre-operatively, but was seen on post-operative scrutiny of the films. It is to be hoped that with growing experience mistakes of this kind may be avoided.

A case with recurring jaundice after cholecystectomy and removal of stones from the common bile duct showed a rather complicated network of dilated branches of the hepatic ducts but no clear visualization of the common duct. The density of the hepatic-duct shadows was poor. This case proved at operation to have an extensively fibrosed common duct and early biliary cirrhosis (Table II, 2b). Although this is a solitary experience, we have the feeling that the picture may be characteristic of common-duct fibrosis with obstruction.

Small cystic-duct stumps were shown in four cases (Table II, 2c), but, although this condition has been held possibly responsible for symptoms in the past, the discomforts described by our patients passed off spontaneously.

Conclusions and Summary

Intravenous cholangio-cholecystography with biligrafin is a quick, safe, and reliable method of examination in biliary-tract disease. Unfortunately it is usually ineffective in the presence of obstructive jaundice or severe liver insufficiency, although its attempted use in such cases is not harmful. It may be used as a supplementary method to oral cholecystography: (1) in cases in which oral cholecystography has been successful; to show clearer and more comprehensive anatomical detail and to demonstrate the possible presence of stones in the hepatic and common bile ducts; and (2) in cases where oral cholecystography has been unsuccessful; to differentiate between calculous and non-calculous disease of the gall-bladder and to determine the detailed location of stones within the tract.

A series of cases in both the above groups is described and illustrated. In most of the cases which were subjected to both types of examination it was found that the intravenous examination provided greater diagnostic information than oral cholecystography. Moreover, the intravenous method makes cholecystography independent of absorption of the dye in the alimentary tract.

For these reasons intravenous cholangio-cholecystography might be substituted for oral cholecystography as the primary method of investigation. From a surgical point of view this can usually be expected to give all the information required. Where, however, it is desired to assess the concentrating power of the gall-bladder it can be supplemented by oral cholecystography. In abdominal emergencies the use of biligrafin intravenously may offer a means of quick differential diagnosis by confirming or excluding the biliary tract as the cause of symptoms.

The fact that the common bile duct becomes outlined with great regularity represents the main advantage of the intravenous method. After cholecystectomy the injection of biligrafin offers the only practical non-operative method of examining the bile ducts.

We are indebted to our colleagues for allowing us to use some of their case notes. We are also grateful to our radiographic staff for the help they have given us, and to Miss A. J. Wright particularly for the prints.

FUNGUS DISEASES OF BRITAIN*

BY

R. W. RIDDELL, M.D., F.R.C.P.Ed.

Bacteriologist, Brompton Hospital, London; Senior Lecturer in Medical Mycology, Institute of Dermatology (Post-graduate Medical Federation), University of London

During the past five years a number of different factions in British medicine and biology have shown increasing interest in fungous diseases. Fortunately, at this time, too, observations made in various parts of the world have become more reliably comparable now that the old confusion in nomenclature has disappeared. The most widely accepted present-day opinions in this subject have been summarized elsewhere (Riddell, 1951a, 1951b, 1952), but it is perhaps timely that recent trends in the study of these diseases in Britain should be reviewed.

*Read in the Section of Pathology at the Annual Meeting of the British Medical Association, Brighton, 1956.

Dermatophyte Infections

The recrudescence of epidemic ringworm of the scalp which occurred largely as a result of relaxation of preventive measures during the second world war has now abated, and *Microsporum* infections of the scalp now involve small groups of children only sporadically. Dr. H. G. Adamson, who died only last year, was responsible for the first fundamental observations upon the pathogenesis of this disease 60 years ago in Britain, but, surprisingly enough, the work was not adequately followed up until Kligman's studies on experimental infections, published in 1955 from Philadelphia.

TABLE I.—Susceptibilities of Different Keratin Structures to Infection by Dermatophyte Species

	Skin	Nail	Hair (Scalp)
<i>Microsporum</i> :			
<i>M. audouinii</i> ..	+	—	++ (SSE)*
<i>M. canis</i> ..	++	—	++ (SSE)*
<i>M. gypseum</i> ..	++	—	± (SSE)
<i>Trichophyton</i> :			
<i>T. mentagrophytes</i> ..	++	—	± (SSE)
<i>T. discoides</i> ..	++	—	± (LSE)
<i>T. interdigitale</i> ..	++	++	—
<i>T. rubrum</i> ..	++	++	++ (E)
<i>T. sulphureum</i> ..	+	+	++ (E)
<i>T. violaceum</i> ..	+	+	++ (E)†
<i>T. schoenleini</i> ..	+	+	++ (E)†
<i>Epidermophyton</i> :			
<i>E. floccosum</i> ..	++	±	—

(SSE)=Small-spored ectothrix hair infection. (LSE)=Large-spored ectothrix hair infection. (E)=Endothrix hair infection. *Bright yellow-green fluorescence produced in hair. †Dull green fluorescence produced in hair.

It is now possible to attribute the characteristic wide sheath of small spores indiscriminately arranged around a *Microsporum*-infected hair shaft to sporulation of much-branching fungous hyphae as they re-emerge into a follicle from the hair cortex. The sheath of spores is not derived from fungous hyphae growing down into a follicle and entwining the hair, as was previously supposed, and as is assumed to be the case in ectothrix infections caused by those *Trichophyton* fungi which infect lower animals as well as man. It would be difficult to repeat Kligman's experiments with *Trichophyton* species which produce only human infections, for these are of low pathogenicity. As to why fungous elements should completely disappear from the hair surface in this last type of infection and leave only an endothrix disposition of fungous hyphae and spores is an intriguing but unsolved problem.

An explanation for the differences which *Microsporum* and *Trichophyton* fungi exhibit in the production of fluorescing substances while growing as parasites in the hair-root keratin has been sought by Chattaway and Barlow (1954), using paper chromatography and electrophoresis. The production of three fluorescent fractions was demonstrated in *Microsporum* infections, and two additional fractions in infections due to the favus *Trichophyton*. Whether similar chemical substances are produced in hair by other *Trichophyton* species in quantities undetectable by ultra-violet light has not been investigated, nor whether they are produced in other keratin structures. Ringworm fungi virtually behave as saprophytes, for they invade only mature keratin and do not parasitize parakeratotic cells. An explanation for the rather specific way in which they attack different kinds of keratin has yet to be found (Table I). Some fungi have a predilection for certain body regions, and there are forms of tinea infection which differ greatly in their sex incidence. Chemical and/or physical differences in keratin structure, possibly occurring at different cutaneous sites, may in part determine this issue, and it has been suggested that the completeness of naturally occurring cross-linkages between radicals of the keratin molecule may be important in this respect.

Barlow and Chattaway (1955) have shown that measures which encourage the breakdown of disulphide linkages and hydrogen bonds of hair keratin facilitate fungal attack in

in vitro, while the reverse is the case where cross-linkages are increased between free amino- and carboxyl groups. The enzyme systems of dermatophytes which might explain their keratolytic properties have not so far been well characterized. Their amino-acid oxidase and asparaginase activities have been studied by Bentley (1953) and by Chattaway *et al.* (1954). An elucidation of the physico-chemical aspects of ringworm infections may lead on to much-needed advances in therapy, for the past decade has seen little improvement over the well-tried measures aimed at producing desquamation of infected keratinized cells and some fungicidal action.

Therapeutically, the fungicidal fatty acids have not given the results which might have been expected from the pertinent observations of Rothman and his colleagues in Chicago (1947), though these substances would appear to be important in providing the relative immunity of the adult scalp to fungous infection. Innumerable substances of very varied chemical structure are active fungicides, and the large number which come to be recommended for treatment of ringworm bears evidence of their inadequacy. This is explained by the failure of topical application to produce concentrations of fungicides sufficient to inhibit fungal growth in the deeper keratin of skin. Could this be achieved, the natural processes of keratin formation and desquamation would eliminate the fungus parasite. Prognosis in a ringworm infection appears to be determined chiefly by the toxigenic properties of the invading fungus and also by immunological factors, either natural or induced by fungous infection. A skin or follicular infection produced by a fungus which is naturally pathogenic for lower animals will be acute and short-lived in man, and be associated with the development of skin hypersensitivity. In contrast, obligate anthropophilic ringworm fungi produce long-standing infections in susceptible subjects usually associated with negative trichophylin skin reactions. In experimental infections, however, self-limitation of ringworm lesions weakens this distinction between anthropophilic and zoophilic dermatophytes (Sloper, 1955). While natural infection produces varying degrees of resistance to subsequent infection, active immunity acquired by inoculation with fungous antigens has not yet been achieved.

Regional changes in prevalence of fungous infections have been well recognized in various parts of the world. In Britain, as in many other European countries, our attention has been drawn to the increased incidence of infection due to one of the anthropophilic fungi, *Trichophyton rubrum*. Before the second world war this disease was recorded infrequently, but it has become the most prominent problem amongst ringworm infections in Britain. This increase is both real and apparent. Some of the real increase is to be found in patients who have resided overseas, but many new cases have occurred in persons who have never been abroad and have contracted the disease in their 'teens or earlier. On the other hand, the greater awareness of the problem by dermatologists and the improvement in laboratory facilities for clinical mycological work are undoubtedly responsible for an apparent increase in this type of ringworm infection.

Calnan (unpublished observation) has made careful clinical studies on 250 patients suffering from *T. rubrum* infection at St. John's Hospital in London, where between 100 and 200 new cases of this disease are recorded annually. The syndrome associated with this infection is typified by a low-grade inflammation of corium underlying infected keratin. Very occasionally inflammation is acute and vesicular, as is more usual in *Trichophyton mentagrophytes* infection, but is unassociated with hypersensitivity reactions. Follicular and hair invasion, little recognized until lately though reported 20 years ago by Lewis in New York, may produce lesions on the legs misdiagnosed as erythema induratum or nodular vasculitis; very occasionally kerion is produced. Unilateral hyperkeratotic infections of the palms and fingers are among the best-known manifestations of this condition; nail infections are practically always due to *T. rubrum*. In the United States, hyperkeratotic flexion

crease infections of the palms have been recorded less frequently than in this country (Silva *et al.*, 1955). Disease may present as patches of acute vesicular and crusted eczema, and fungous infection is thought of only belatedly. The feet are hardly ever spared, though classical ringworm of the toe-webs is not produced. Calnan has followed up contacts of these patients and has discovered that familial cases occur not infrequently, a fact not appreciated in the past; infection in children and babies is always associated with disease in parents. Other ringworm species may be associated with the primary pathogen in the *T. rubrum* syndrome (Partridge, 1955). There has been much speculation as to possible predisposing factors in this disease. In our experience a depressed glucose tolerance curve has not been found to be positively associated with these infections in the way suggested by Rothman (1953). That many of the patients suffer from acrocyanosis may prove to be significant. The main reason for the concern about *T. rubrum* infections is the permanent unequal disfigurement which may result and the failure of all available therapeutic agents to remove the causative organism. Customary measures for preventing infection or reinfection by ringworm fungi are largely unavailing, particularly in foot infections where frequent exposures are practically inescapable (Rosenthal *et al.*, 1956). Holmes and Gentles (in press), studying ringworm in a mining community, found that *T. rubrum* predominated in certain places of work. There was a much higher incidence of tinea pedis among men who had used communal baths than among those who had not.

Whereas the natural habitat for ringworm fungi has been assumed to be either man or the lower animals, the isolation of *Microsporum gypseum* from several soil samples has suggested a wider ecology for these fungi (Ajello, 1953) (Table II). Whittle (1954) has reported a small outbreak

TABLE II.—Natural Habitat of Ringworm Organisms

Human	Animal	Soil
Microsporum species: <i>M. audouinii</i>	<i>M. canis</i>	<i>M. gypseum</i>
Trichophyton species: <i>T. interdigitale</i> <i>T. rubrum</i> <i>T. sulphureum</i> <i>T. violaceum</i> <i>T. schoenleini</i>	<i>T. mentagrophytes</i> <i>T. discoides</i>	
Epidermophyton species: <i>E. floccosum</i>		

of *M. gypseum* infection among workers in a plant nursery in Hertfordshire, but was unable to isolate the fungus from soil. The first observation of the isolation of a dermatophyte from a non-living source was made by Muende and Webb (1937) in Britain; *Trichophyton mentagrophytes* was found to be growing on dry horse-dung in a shed where infected calves were kept. Whittle (1956) and Rook (1956) have made detailed observations upon the occurrence of animal ringworm due to *T. mentagrophytes* and *T. discoides* in Cambridgeshire; it is suggested that their relative incidences may differ in various parts of the country and may change significantly over quite short periods of time. Extensive measures are now being taken in this country to reduce the animal reservoir of infection responsible for a large part of human ringworm (Report by the Medical Mycology Committee of the Medical Research Council, 1956).

Superficial Infections

Though these common infections are unimportant in themselves from a clinical standpoint, they offer a challenge to our understanding of the skin flora. In their attempts to culture the causative organism of trichonocardiosis axillaris, Crissey *et al.* (1952) regularly isolated a lipophilic diphtheroid bacillus (*Corynebacterium tenuis*). A lipophilic yeast-like organism, *Pityrosporum obiculare*, was isolated

from a high percentage of cases of pityriasis versicolor by Gordon in 1951 and independently by Martin-Scott (1952), but it may also be found on skin unaffected by this disease. Insufficient attention has been paid to these infections, and to erythrasma, the pathological diagnosis of which continues to be made only by direct examination.

Aspergillosis

Apart from the allergic diseases, aspergillosis is the most important pulmonary condition due to fungi occurring in Britain. Primary aspergillosis of the kind well known in avian pathology is practically never seen in man. *Aspergillus fumigatus* is, nevertheless, a not infrequent secondary invader of lung tissues damaged in some way, for example by infection, mechanical trauma, or infarction. Necrosis and vascular thrombosis are the main histological features of tissues in proximity to growing fungous colonies. Haemoptysis is often a symptom of this disease, and signs of toxæmia may be pronounced if extensive invasion occurs. If a pulmonary cavity becomes infected with the fungus an increase in thickness of its walls is seen radiologically, and where drainage by the bronchi is established the sputum becomes profuse and purulent and may contain mycelium within fragments of necrotic material.

At the Brompton Hospital, our recent experiences with cavitary infections due to *A. fumigatus* have indicated that progression of fungous growth may lead in some cases to the development of a mycetoma. This consists of a mass of mycelium, usually spherical in shape, which lies more or less freely within the lumen. Partial or complete epithelization of the cavity from a communicating bronchus may or may not ensue, and the occurrence of haemoptysis will depend largely on whether this occurs. A most characteristic feature of the condition is to be found radiologically in the form of a crescentic area of translucency around the circumference of the mass (Monod *et al.*, 1952). The term "aspergilloma bronchiectasiant" is probably too limited a description for these lesions. Occasionally, movement of the fungous mass within the cavity may be demonstrated radiologically by changing the posture of the patient. Cultures of *A. fumigatus* from two cases of mycetoma have recently interested us in being white and non-sporing except for occasionally small areas of typical smoky-green sporing growth. These patients had been receiving isoniazid, but it is unlikely that the drug affects the growth of the fungus *in vivo*. It has, however, been observed that isoniazid in concentrations of 5 µg. per ml. or more inhibits sporulation of *A. fumigatus* under certain conditions *in vitro*, though not to any extent its mycelial growth (Clayton, unpublished observation). Hinson *et al.* (1952) have drawn attention to a manifestation of broncho-pulmonary aspergillosis not previously described. In this condition recurrent pyrexial attacks occur with radiographic evidence of pulmonary collapse and consolidation. Blood examination shows eosinophilia, and purulent sputum is expectorated containing "plugs" in which *A. fumigatus* is scantily present. Without treatment the prognosis is not good, for exacerbations continue indefinitely and may lead to a fatal termination in status asthmaticus. In our experience, termination in status asthmaticus. In our experience, inhalation of "nystatin" in suspension, or of solutions of brilliant green or hydroxystilbamidine, is effective in suppressing or removing *A. fumigatus* from the bronchial secretions.

Subcutaneous Mycoses

Mycotic infections of the subcutaneous tissues due to traumatic introduction of material contaminated by pathogenic fungi are virtually non-existent in Britain, though there is plenty of opportunity for these to occur—for example in agricultural workers—were these pathogenic fungi present in the soil. Climatic conditions and types of vegetation may determine the ecology of soil fungi. From his extensive experience of subcutaneous mycetomata in the Sudan, Abbott (1956) has pointed to the apparent importance of rainfall in the distribution of these infections; the habit

of going barefoot he believes to be of lesser importance. There is no explanation for the virtual disappearance of sporotrichosis from France, where it was observed with regularity in the early part of the century; to our knowledge, it has not occurred in Britain for a number of years.

These subcutaneous mycoses are only slowly progressive, so that it is to be expected that they may be met with from time to time in Britain among those who have lived abroad. One example was recently encountered in a West Indian male who had been resident in this country for two years prior to diagnosis. An infiltrated lesion with central scarring, thought at first to be tuberculous in nature, was present on one elbow and had apparently been increasing in size for 12 years. A diagnosis of chromoblastomycosis was made from histological and cultural findings (Crow and Riddell, 1954).

Infections by Yeast-like Fungi

While the conditions which predispose to moniliasis are well known, the intrinsic reasons for the occasional assumption of a pathogenic role by *Candida albicans* remain undiscovered. Henrici's hypothesis that this yeast may produce a toxin has received support from the experimental work of Winner (1956). The presence of agglutinins does not protect animals from the lethal effects of this organism. In man, humoral antibody titres are quite unreliable indicators of *C. albicans* infection. The predicted rise in incidence of moniliasis as a result of the increasing use of broad-spectrum antibiotics has not been experienced in Britain. Pulmonary moniliasis has not been seen as a true pathological entity, and there is little to add to Shrewsbury's studies in 1936 on secondary thrush of the bronchi. In vulvo-vaginitis a positive relationship between *C. albicans* in the secretions and certain features of the disease has been demonstrated (Dawkins *et al.*, 1953).

In contrast to *C. albicans*, *Cryptococcus neoformans* in exudates is practically pathognomonic of disease. One exception only has been brought to our notice where this yeast was present in bronchial secretions in the absence of evidence of bronchial or pulmonary disease. It is clear from residential histories that torulosis is endemic in Britain, where, though still rare, it is being reported with increasing frequency. Meningo-encephalitic infections occurring sporadically are sufficiently well recognized to go largely unreported. Torulosis of the lungs is best known to present as a pulmonary tumour of the kind described by Cruickshank and Harrison (1952), but in two recent instances of this infection in which the disease was unsuspected prior to operation, there were poorly circumscribed areas of pneumonic infiltration with cavitation (Beck *et al.*, 1955; Nightingale, unpublished observation). *Cr. neoformans* has been associated with a condition resembling Hodgkin's disease often enough to have raised doubts whether or not it was an aetiological agent (Symmers, 1953; Levene and Michaels, 1955; Misch, 1955).

Histoplasmosis and Other Systemic Mycoses

There are no reasons for supposing that the fungi responsible for these generalized mycotic diseases occur naturally in Britain. Restricted geographical distribution is a prominent feature of these infections, the extent of which has been supported by skin-testing surveys and soil studies. Those rare instances of blastomycosis, coccidioidomycosis, and histoplasmosis met with in this country occur in those who have resided in areas endemic for these diseases, particularly in the United States and Africa. Very exceptionally they may be contracted through inhalation of dust from imported materials by persons who have not been overseas. Healed histoplasmosis is the most frequent systemic mycosis encountered in Britain, and is discovered incidentally by its radiological appearances. Small spherical calcifying lesions are typically situated mainly in the middle and lower lung zones (Crofton, 1950). These patients are positive to the histoplasmin skin test, which is rendered the more significant

when the Mantoux reaction proves negative. Disseminated histoplasmosis has been seen in Britain, and three recent examples have been notable for the long interval recorded between the patients' last visit abroad and the onset of symptoms. This period was 14 years in the case reported by Hutchison (1952), and 7 years in each of those reported by Locket *et al.* (1953) and Poles and Lavertine (1954). With the increase of world travel the systemic mycoses, which almost without exception are acquired by the respiratory route, require consideration more frequently in differential diagnosis. Although they produce widely varying x-ray appearances, most of which are identical with those of tuberculosis, they each have their own individuality. At some stage during the course of infection they may present radiological features which should suggest the diagnosis (Pierce, 1953).

Summary

An increasing interest in mycotic diseases has been clearly evident in Britain during the past five years. A change of emphasis is occurring towards investigative studies of the kind which have long been established in the study of bacterial infections. The taxonomy of the pathogenic fungi is now sufficiently well adapted for accurate comparative studies, and pathologists are therefore no longer discouraged by a subject confused by synonymy. Critical laboratory opinion is now forthcoming for the support of clinicians in their widening appreciation of the diseases due to fungi.

Trichophyton rubrum infections of the skin and *Aspergillus fumigatus* infections of the lungs present difficult problems and are being recognized with greater frequency than in the past. The more unusual forms of torulosis have received study, and the subcutaneous and systemic mycotic diseases require consideration more often now that world travel is easier.

HISTOPLASMOSIS CONTRACTED IN BRITAIN

A CASE OF HISTOPLASMIC LYMPHADENITIS FOLLOWING CLINICAL RECOVERY FROM SARCOIDOSIS

BY

W. St. C. SYMMERS, M.D., M.R.C.P.

Charing Cross Hospital and Medical School, London

[WITH SPECIAL PLATE]

The case described in this paper is believed to be the first mycologically proved case of histoplasmosis in which the infection was undoubtedly acquired in Britain. The characteristic causative organism, *Histoplasma capsulatum*, was isolated from a biopsy specimen. The patient had never been out of the British Isles before the infection developed. Four years earlier he had developed sarcoidosis; this appeared to have subsided completely a year before the mycotic infection presented as a localized lymphadenitis.

Histoplasmosis has seldom been recognized in this country (see below), where it is looked upon as an exotic disease and consequently has attracted little attention. A brief account of it may therefore be helpful as an introduction to the case report which follows. Fuller descriptions are accessible in the periodical literature (cf. Monroe and Kurung, 1953; Poles and Lavertine, 1954; Schwartz, 1954; Leigh and Thomas, 1955; Silverman *et al.*, 1955); the disease is dealt with scantily, when at all, in current general textbooks.

Clinical Features of Histoplasmosis

Histoplasmosis was discovered in 1905 by Darling (1906) in the Panama Canal Zone. No cases were found elsewhere until some 20 years later, when a case in Minnesota was reported by Riley and Watson (1926) and one from Honduras by Phelps and Mallory (1926); since then the disease has been recognized in many parts of the world.

For many years histoplasmosis was thought to be both rare and mortal; since the introduction of a specific skin test for sensitivity to histoplasmin (cf. Palmer, 1945) it has been realized that fatal infections are in fact exceptional. The histoplasmin test has helped to define large areas, particularly in the United States of America, where histoplasmosis is endemic; a high proportion of the population of these areas has passed through a clinically silent infection, as judged by the demonstration of sensitivity to histoplasmin—a circumstance which has its parallel in the comparable response to infection by the tubercle bacillus. A very large majority of subclinical histoplasmic infections occur in the lungs, where the calcified healed foci may present a striking radiological picture. When histoplasmosis does cause symptoms the clinical picture can be remarkably diverse—overt histoplasmosis has been appropriately described as a disease of protean clinical manifestations (Schwartz, 1954), for no organ is immune from colonization by the fungus.

Pulmonary involvement is among the commonest causes of clinical illness in histoplasmosis, just as it is the commonest form of subclinical infection. Many varieties of acute and chronic pulmonary lesions occur (Monroe and Kurung, 1953; Schwartz, 1954). Radiologically these lesions can mimic any form of pulmonary tuberculosis; diagnosis between pulmonary histoplasmosis and tuberculosis depends upon the bacteriological findings, supported by the results of skin tests with histoplasmin and tuberculin, and possibly by serological investigations. Occasional cases of combined tuberculous and histoplasmic infections have been reported. Some cases of pulmonary histoplasmosis present

as tuberculoma-like lesions which may simulate peripheral neoplasms (Zimmerman, 1954). The lesions in the lungs may heal or may remain active for many years; the infection may remain localized to the lungs or it may become disseminated in the lymphatic and blood streams, setting up fresh lesions anywhere in the body.

Both the self-limiting and the progressive forms of histoplasmosis may present as single or multiple granulomatous or ulcerative lesions of the upper respiratory tract, throat, mouth, or skin. The cutaneous lesions, like those of cryptococcal infection, may simulate rodent ulcers (Symmers, 1953, 1956). The clinical picture may be dominated by adrenocortical deficiency due to destruction of the adrenals occur unexpectedly in any patient with active histoplasmosis—for example, after surgical operations—unless the possibility of adrenal involvement is remembered (Crispell *et al.*, 1956). In other cases lymphadenopathy and hepatosplenomegaly, alone or in combination, may be the only findings. Bone-marrow involvement is usual in cases of disseminated infection and may lead to anaemia, leucopenia, or purpura. Localized destructive lesions of bones and joints are rare (Key and Large, 1942). Histoplasmic meningo-encephalitis (Sproffkin *et al.*, 1955) and endocarditis (Beamer *et al.*, 1945) have been recorded.

Cytology

An interesting feature of some cases of the serious disseminated form of histoplasmosis is the predilection of the fungus for the cells of the so-called reticulo-endothelial system. In these cases the macrophages throughout the body may be filled with such great numbers of organisms, in the virtual absence of extracellular organisms, that it was even proposed that the disease should be described as "cytomycosis" (DeMonbreun, 1934). It is still uncertain whether this phenomenon is the result of active parasitic invasion of these cells or of brisk phagocytosis. The intracellular parasites are finely illustrated by photographs, reproduced by Payling Wright (1953), of preparations from a Southern Rhodesian case which came to necropsy in England (Cunningham and Garrod, 1950; Murray and Brandt, 1951—Case 3). However, histoplasmosis is by no means always associated with this type of systematized intracellular parasitization; a tuberculoid granulomatous reaction is characteristic of some cases, and in such lesions the parasites are usually found in foreign-body giant cells and may be scanty.

Mycology

Darling (1906) discovered histoplasmosis when he was actually looking for the organism which Leishman (1903) and Donovan (1903) had then just recently described independently as the cause of Dum-Dum fever, or kala-azar. Darling examined every enlarged spleen which he found at necropsy in Panama, and, although he found no leishmaniae at this time,* he collected three cases in which an encapsulated intracellular organism was present. He believed that this organism was a protozoon, and he gave it the name by which it is now generally known. Da Rocha-Lima (1913) drew attention to the morphological resemblance between Darling's *Histoplasma capsulatum* and *Cryptococcus farciminosus* (now commonly known as *Histoplasma farciminosum*), the causative organism of one form of epizootic equine lymphangitis; he suggested that *H. capsulatum* might belong to the fungal group of *Blastomyces*. The fungal nature of this organism was proved when DeMonbreun (1934) succeeded in cultivating it. *H. capsulatum* grows in two forms on culture media, a yeast-like growth developing at 37° C. and a mycelial growth at room temperature (cf. Conant, 1948; Conant *et al.*, 1954). Although the yeast-like phase seems to be the more patho-

*In view of Darling's (1906) discovery of histoplasmosis while looking for cases of leishmaniasis in Panama, it is interesting to note that, later, he was in fact the first to recognize and prove the occurrence of leishmaniasis ("oriental sore") in that country (Darling, 1911).

genic, both forms cause the disease when inoculated into animals. In each case it is the yeast-like form which develops in the tissues; the mycelial form has been found in naturally or experimentally infected tissues only as an extraordinarily rare phenomenon (Moore, 1955).

It is not certain whether all cases of human histoplasmosis are caused by a single type of histoplasma. Dubois *et al.* (1952) have suggested that at least some cases of the disease occurring in Africa are caused by an organism which they have named *Histoplasma duboisii*, and which differs from the usual strains of *H. capsulatum* in the presence of uncommonly large yeast-like forms in infected tissues. These large forms measure about 13 by 10 μ , while the yeast-like form of *H. capsulatum* measures about 3–4 by 2 μ . Such a large-cell strain was present in the skin lesions of Robb-Smith's (1943) case (mentioned by Duncan, 1945, 1946–7), in which the infection was probably contracted in West Africa, and also in my two cases in Nigerians (Symmers, 1956). Duncan (1946–7) also suggested that the large-cell strain might be a species or variety different from *H. capsulatum*. It should be noted that large yeast-like forms have been observed in exceptional American cases (Moore, 1955), although usually only in necrotic lesions (Binford, 1955; Silverman *et al.*, 1955). Similar large forms developed in tissue explants from organs infected with *H. capsulatum* which had been isolated from an American case (Schwarz, 1953). The significance of these atypical American observations is not clear, but Moore (1955) cited them in his rejection of the existence of *H. duboisii* as a distinct species. Drouhet and Schwarz (1956) also felt that there is not enough evidence to establish the African strains as a species different from *H. capsulatum*.

Some Epidemiological Factors

Histoplasmosis occurs as a natural infection in many species of domesticated and wild animals, including rats and house-mice (for references see Schwartz, 1954). Although there is no evidence of case-to-case transfer of infection in man, there is experimental evidence that infections can be transmitted naturally from dog to dog (Prior and Cole, 1951). It is possible that human infection has resulted from contact with infected animals in cases where the disease in man has occurred in households where pets or house-mice are also infected (Pará, 1946; Olson *et al.*, 1947); however, it may well be that in such cases man and beast have been infected from a common source, such as dust. Spread of the infection by vectors has not been observed. Ticks can be infected experimentally by feeding on blood from infected dogs, but there is still no evidence that they can then transmit the fungi to other animals (Olson *et al.*, 1947).

H. capsulatum has been isolated repeatedly from soil and dust (for references see Grayston and Furcolow, 1953). In some instances small local epidemics of acute pulmonary histoplasmosis, usually non-fatal, have been traced to exposure to infected dust, such as in cleaning out or demolishing derelict buildings, particularly on farms. Exploring caves and playing in hollow trees have been linked to other outbreaks. Sawdust, decaying wood, and excreta of animals and birds have been incriminated as the source of infection in some outbreaks; they possibly provide the moist environment necessary for growth of the fungus, while yet allowing the infective material to dry out enough to be carried on air currents, when disturbed, and so to enter the lungs of those exposed.

Incidence

Although only about 300 cases of histoplasmosis in which the diagnosis was confirmed by cultivation of the organism or by its histological demonstration have been published, the incidence of the infection is enormously higher than this figure suggests, if one judges it by the high proportion of individuals with positive histoplasmin reactions in endemic areas. Histoplasmosis is known to occur in many parts of

the world; its geographical distribution is far from completely worked out, and may prove to be world-wide. Its incidence varies greatly in those areas where it has been recognized. In some areas only sporadic cases have been found, and histoplasmin-sensitivity surveys show a low incidence of positive reactors. Elsewhere, as in parts of the great endemic areas of the Mississippi, Missouri, and Ohio valleys, as many as 80 or more persons in every hundred show evidence of past subclinical infection in the form of a positive histoplasmin skin reaction (cf. Schwartz, 1954), and according to Silverman *et al.* (1955) it has been estimated that 20 to 30 million people in the U.S.A. have histoplasmic infection. Outside the United States the infection is said to be most prevalent in Mexico and Central America; an increasing number of cases is being recognized in Canada, South America, Africa, the East Indies, the Pacific islands, and Australasia. Sporadic cases have been found in countries bordering the Mediterranean, and the few European cases appear to have been confined to that area.

Histoplasmosis Recognized in Britain

In an earlier paper (Symmers, 1953) reference was made to eleven occasions on which the diagnosis of histoplasmosis was suggested by various workers in Britain; this series included two then unpublished cases of my own which have now been reported (Symmers, 1956). Three more case reports have been published in this country, making, with the case recorded in the present paper, a total of 15 cases diagnosed here as histoplasmosis. This diagnosis appears to have been adequately substantiated in 13 of the cases, in six of which the causative organism was isolated by culture. These 13 cases are listed in the Table.

In Limerick's (1951) two cases the evidence is insufficient to warrant the diagnosis of histoplasmosis. The only evidence in his first case was that *H. capsulatum* was said to have been found on microscopical examination of pus obtained on incision of an abscess which developed in the

right iliac fossa following interval appendicectomy; his second case was given only passing mention as a case of "histoplasmosis of lungs following a visit to Ireland, where this infection is known to occur—possibly spread from the U.S.A." Limerick's first patient had never been outside England; he did not say whether his second patient had been farther afield than Ireland. Apart from Limerick's case and the one described below, in all cases in which histoplasmosis has been diagnosed in Britain the patient is known to have spent some time abroad in a country where histoplasmosis occurs. In view of Limerick's (1951) statement that histoplasmosis occurs in Ireland, it may be noted that there does not appear to be any published record that such is the case; the only histoplasmin-sensitivity survey which has been reported gave negative results (McWeeney *et al.*, 1946). I am obliged to Dr. J. A. D. Deeny, Chief Medical Adviser to the Department of Health of the Republic of Ireland, and to Dr. F. F. Main, Chief Medical Officer of the Ministry of Health and Local Government of Northern Ireland, for the information that they know of no cases of histoplasmosis occurring in Ireland.

The case of Poles and Lavertine (1954) is of particular interest because of their suggestion that their patient, a post-office clerk, acquired the infection in England about eight months before his death in 1951. Their diagnosis was based on the presence of morphologically typical histoplasmas in sections of tissues obtained at biopsy and necropsy; histoplasmin tests were negative and attempts to cultivate the organism failed. The patient had been in France in 1939, in Nigeria (where histoplasmosis is known to occur: Clarke *et al.*, 1953) in 1942, and in Burma in 1944; while overseas he had no illness except "jungle sores." Not enough is known about the natural history of histoplasmosis to exclude the possibility that the infection could have remained dormant for several years. Poles and Lavertine (1954) mentioned a personal communication from Furcolow, in which he stated his belief that relapses of histoplasmosis do not occur, but commented that the

* The case demonstrated in London by Cunningham and Garrod (1950), and reported by Murray and Brandt (1951—Case 3), is not included. The patient, a boy, contracted histoplasmosis while living in Southern Rhodesia; the diagnosis was made in South Africa; he died soon after arriving in England. This is the case mentioned by Locket *et al.* (1953) at the end of their paper (Atkinson, 1953).

† Unless otherwise stated, the available data suggest that the patients were born in Britain and lived there except during the times mentioned.

‡ This case was shown before the Section of Dermatology, Royal Society of Medicine, London, on January 21, 1943 (Carleton, 1942-3).

evidence for this is not yet conclusive. Observations such as have been made by Monroe and Kurung (1953) and others suggest, in fact, that the infection may sometimes lie dormant for years and then break out again. If it is eventually shown that histoplasmic infection does not exist in a dormant state, the case of Locket *et al.* (1953), and possibly that of Derry *et al.* (1942), as well as that of Poles and Lavertine (1954), will have to be accepted as indigenous British infections. The case which is reported here shows that the causative organism can be acquired in this country.

CASE REPORT:

Traumatic Siliceous Granuloma of Skin; Sarcoidosis; Histoplasmic Lymphadenitis

A man, born in 1909, fell and cut his forehead on a path of splintered flint near the Gobbins, County Antrim, when on holiday in 1936. The wound, about 2 cm. long, healed rapidly without suturing. In April, 1950, the scar became livid, and indurated, forming a slowly growing, smooth linear swelling (about 2×0.5 cm.). It was excised in August, 1950; sections showed a typical siliceous granuloma formed of tubercle-like structures of sarcoid type around irregular fragments of birefringent yellow or blackish material which withstood micro-incineration at 660° C. for ninety minutes.

In August, 1951, the patient consulted his doctor because of increasing enlargement of the lymph nodes in his neck, armpits, and groins. He had first noticed these nodes about six months earlier. He had no other symptoms. Examination showed generalized symmetrical enlargement of the superficial lymph nodes; none was larger than 1.5 cm. in longest dimension. The nodes were discrete, firm, and mobile. There was no other clinical abnormality. His skin, the scar following excision of the siliceous granuloma, and the scars of old superficial wounds on the knees and hands were healthy.

Investigations.—Radiograph of chest: sparse "woolly" miliary shadows in both lungs, mainly in the middle zones; pronounced enlargement of hilar shadows. Mantoux reaction negative with 0.2 ml. of 1 in 1,000 old tuberculin, weakly positive with 1 in 100. Wassermann and Kahn tests negative. Serum albumin 4.4 g., globulin 4.0 g. per 100 ml. Haematological findings normal. Biopsy of an epitrochlear lymph node (August 12) showed a picture consistent with sarcoidosis (Special Plate, Fig. 1). The node was uniformly and closely studded with rounded aggregates of epithelioid and histiocytes. In places the aggregates merged together, maintaining their rounded contour so that the constituent aggregates remained identifiable. No giant cells were seen; there was no necrosis.

Progress.—No treatment was given. The patient continued his administrative occupation without interruption. The lymphadenopathy subsided completely within the following year and the radiological changes in the lungs slowly resolved. In April, 1954, he felt perfectly well; chest radiographs were completely normal; Mantoux reaction positive (1 in 1,000); serum albumin 4.8 g., globulin 2.6 g.; erythrocyte sedimentation rate 3 mm. in one hour (Westergren). In May, 1955, he noticed two small, mobile lymph nodes above the medial end of the left clavicle. Clinical examination showed no other abnormality. At the patient's request, as he was about to go overseas, one of the nodes was excised (May 6).

Histology and Mycology.—Section of the lymph node excised in May, 1955, showed a granulomatous lymphadenitis quite different from that in the biopsy of August, 1951. There was patchy replacement of the lymphoid tissue by epithelioid histiocytes, without formation of rounded aggregates; moreover, in striking contrast to the earlier biopsy, every field contained many large multinucleated giant cells (Plate, Fig. 2), in which many organisms resembling *H. capsulatum* were present (Plate, Fig. 3). The organisms were exclusively intracellular, mostly in giant cells, although occasionally a single organism was seen in a simple histiocyte. Many of the organisms stained faintly

and appeared to be fragmentary or undergoing lysis. The siliceous granuloma of 1950 and the lymph node excised in 1951 were now re-examined; serial sections were cut at different levels in the paraffin blocks and stained by a variety of methods, including Gram, Gridley, and periodic-acid-Schiff stains; no organisms were found in either of these specimens.

The second supraclavicular node was excised (May 25, 1955) and cultures were prepared on blood-agar and on Sabouraud's medium at room temperature and at 37° C.; the pathologist did not keep the specimen for histological examination, a mistake which is the more regrettable as the paraffin block of the specimen of May 6 was lost while in transit to London. The cultures yielded an abundant pure growth of *H. capsulatum*. The yeast-like phase grew up well, within 48 hours at 37° C., as cream-coloured, smooth colonies of oval, budding cells 1 to 4 μ in diameter. Growth was slower at room temperature, but on the sixth day small, whitish, cottony colonies of fine, branching, septate mycelium were present; the mycelium carried smooth, rounded conidia, about 3 μ in diameter, on short lateral branches. After 16 days at room temperature the colonies had become ochre-coloured, and numerous characteristic thick-walled tuberculate chlamydospores, about 10 μ in diameter, had developed.

The laboratory where the case was being investigated was taken over by another pathologist at this time. He at once destroyed all the cultures and the animals which had been inoculated by his colleague, under the impression that *H. capsulatum* is particularly dangerous to laboratory workers. It is true that laboratory infections with *H. capsulatum* have occurred (Furcolow *et al.*, 1952; Nilzén and Paldrok, 1953; Spicknall *et al.*, 1956); the risk seems to be slight, however, and the opinion of Raphael and Schwarz (1953) that "reasonable precautions will protect the laboratory worker against Histoplasma infections" is generally accepted; moreover, laboratory infections usually result in the localized pulmonary form of the disease, which has a good prognosis, in contrast to the lethal but comparatively uncommon disseminated form.

The patient took up a post abroad before detailed investigations could be completed; at that time (May, 1955) there were no symptoms or abnormal physical signs. The chest radiograph was normal. A skin test (intradermal injection of 0.1 ml. of 1 in 1,000 histoplasmin) gave a strongly positive reaction, producing a 3-cm. circle of erythema with a central zone of induration, 1.5 cm. across, in 48 hours. When last heard from (September, 1956) he reported excellent health, with no symptoms.

Until leaving England in 1955 this patient had never been out of the British Isles. None of his household had ever been abroad, none reacted to intradermal histoplasmin, and there was no family history relevant to his illness. His work brought him into frequent contact with American visitors; this is probably without significance, as there is no evidence that the infection is transmitted from person to person. He did not handle stores or packings from abroad. His hobbies and recreations did not expose him to any environment which has been incriminated as a source of infection. He lived in the country, but had no interest in gardening or farming; he kept no pets and he had no contact with live-stock. Attempts to isolate *Histoplasma* from the soil of his garden and from various outhouses and wood-piles were fruitless.

Comment

This patient's initial illness (sarcoidosis) ran a benign course over about three years. All its manifestations had disappeared by April, 1954, a year before the histoplasmic lymphadenitis developed. The growth of a siliceous granuloma in a 14-year-old scar about six months before he noticed the generalized lymphadenopathy is interesting; this lesion was a typical example of Shattock's (1916-17) "pseudotuberculoma silicoticum." It is only recently that the occasional relationship between the appearance of this delayed and typically sarcoid tissue reaction around some

foreign bodies and the development of the manifestations of systemic sarcoidosis has been recognized (Reffvem, 1954; Löfgren *et al.*, 1955). There is no reason to presume any relationship between the old injury in this case and the eventual development of the fungal infection.

It is unlikely that the original illness, believed to be sarcoidosis, was in fact a manifestation of histoplasmosis. The absence of symptoms, the apparently complete recovery, the character of the radiological changes in the lungs and their disappearance without calcification, the clear-cut histological picture of sarcoidosis, and the failure to find parasites in the original biopsy and in the siliceous granuloma are all features which favour the diagnosis of sarcoidosis. However, none of these observations is incompatible with the diagnosis of histoplasmosis, and therefore the latter cannot be altogether excluded in considering this earlier phase in the patient's history.

There does not appear to be any record of histoplasmosis occurring in a patient who at that or any other time showed evidence of any illness which could reasonably be interpreted as sarcoidosis. There have been a few cases in which histoplasmosis mimicked sarcoidosis histologically, but none of these showed anything like the apparently clear picture of sarcoidosis in the case described here (Reimann and Price, 1949; Pinkerton and Iverson, 1952; Israel *et al.*, 1952; Binford, 1955; Crispell *et al.*, 1956).

The association of sarcoidosis with other fungal infections, particularly torulosis, is discussed briefly elsewhere (Plummer *et al.*).

Summary

A case of histoplasmosis is described. The only manifestations of the infection have been enlargement of two cervical lymph nodes and a positive histoplasmin skin reaction. Fungi were found in sections of one of the lymph nodes. The diagnosis was proved by the isolation of *H. capsulatum* in cultures from the second node. The patient is without symptoms 16 months after the mycotic lymphadenitis appeared.

The patient had never been out of the British Isles before he developed histoplasmosis. His case is believed to be the first unequivocal instance of mycologically proved histoplasmosis in which the infection was contracted in Britain.

He had previously had sarcoidosis, the course of which was benign. The first manifestation of sarcoidosis was probably the development of a siliceous granuloma at the site of an old injury.

I am much obliged to Mr. R. J. Lunnon, A.I.B.P., A.R.P.S., Department of Medical Photography, St. John's Hospital for Diseases of the Skin, London, for his kindness in preparing the photomicrographs.

LOCALIZED CUTANEOUS HIPOPLASMOSIS

BY

W. ST. C. SYMMERS, M.D., M.R.C.P.

Charing Cross Hospital and Medical School, London

Two cases of localized cutaneous histoplasmosis, confirmed by isolating *Histoplasma capsulatum*, are described in this communication. Both patients are Nigerians. The diagnosis was made while they were living in England; it is clear that the infection was acquired before they came here. Their cases were referred to as "unpublished observations" in an earlier paper (Symmers, 1953), and were listed in a more recent paper (Symmers, 1956) in a table of 13 acceptable cases of histoplasmosis which have been recognized in this country. A mycologically proved histoplasmic infection has only once been reported in a patient who had never been out of Britain (Symmers, 1956).

Case 1

A Nigerian man, aged about 28, came to England at the end of 1951. He had not been away from Nigeria before. His health had always been good. He travelled to England by sea from Lagos, where he lived, calling ashore at Accra on the Gold Coast, Freetown in Sierra Leone, and Bathurst in Gambia. Two days after sailing from Bathurst he developed a pustule on one cheek: thinking that this might be due to a bite by a tumbu-fly (*Condylobia anthropophaga*) he incised it carefully with a sterile scalpel and evacuated its purulent contents—no larva was present. The lesion healed over quickly, but a little painless nodule remained at its

site. Eighteen months later the nodule became slightly itchy and began to enlarge, and within a few weeks a small ulcer appeared at its centre.

Examination showed a shallow ulcer, 0.5 cm. in diameter, with a thin dry crust and a firm, slightly raised, rolled, pearly marginal zone about 0.2 cm. wide. The lesion was indistinguishable from a rodent ulcer. Films of fluid expressed from it contained a few leucocytes and some Gram-positive cocci; culture of the fluid yielded *Staphylococcus albus* and a diphtheroid bacillus.

The lesion was excised along with a 0.5 cm. rim of healthy skin. An immediate frozen section showed a giant-cell granuloma containing large yeast-like intracellular organisms; cultures were at once set up from the fresh specimens. After eight days' incubation at 37° C., on blood-agar and on Sabouraud's medium, a sparse growth of a yeast-like organism was present. This was subcultured at room temperature and at 37° C.: at room temperature a mycelial growth gradually appeared, with eventual formation of tuberculate chlamydo-spores. The cells of the yeast-like form, which grew only at 37° C., were of practically uniform size, not exceeding about 4 by 2 μ . The cultural characteristics were typical of *H. capsulatum*. Animal inoculation was not carried out.

Paraffin sections of the skin lesion confirmed that it was a tuberculoid giant-cell granuloma, with central ulceration and no caseation; histologically it resembled any other simple foreign-body reaction, except that the foreign bodies were clearly yeast-like fungi. The organisms were present only within the giant cells (see Fig.): most of the organisms were

Facial lesion in Case 1. Multinucleated giant cell containing many large histoplasmas. The organisms appear as round or oval double-contoured bodies, sometimes with a broad pale giant cell's nuclei, which they resemble in size. (Haematoxylin-eosin. $\times 435$.)

large (about 10–12 by 8–10 μ), although many giant cells also contained some small forms (about 4 by 2 μ). The organisms had a double-contoured "capsule"; many were birefringent. Periodic-acid/Schiff was the most satisfactory stain for demonstrating them, although they were clearly visible in haematoxylin-eosin preparations. Some organisms stained poorly, and some appeared to be disintegrating.

Investigations and Progress.—The operation wound healed quickly and cleanly. The patient had no other symptoms. The investigations showed no sign of disease clinically. There was rest of his skin and the mucosae were healthy. There was no lymphadenopathy; the liver and spleen were not palpable. Chest radiographs were normal. Haematological examination, including sternal marrow, showed nothing abnormal; no parasites were found in films of marrow, and marrow cultures were sterile. Wassermann reaction was negative. Serum albumin was 4.3 g. per 100 ml., globulin 2.1 g. Histoplasmin skin tests were repeatedly negative with concentrations up to 1:10.

The patient returned to Nigeria in 1954; he has remained perfectly fit. No treatment was given. When last heard from (December, 1955) he had no symptoms.

Case 2

A Nigerian woman, aged 23, left her home for the first time in September, 1952, and came direct to England. She had a routine medical examination soon after arrival here and was found to have an annular skin lesion, 2 by 1 cm., over the lower end of the sternum. This lesion consisted of an irregularly ovoid ring of induration, about 0.4 cm. wide, slightly raised, sharply outlined at its periphery, and less clearly demarcated at its inner margin. The normal skin markings were smoothed out over the indurated area, but elsewhere were unaffected. The skin within the ring was healthy, but very slightly less pigmented than that around the ring. The appearances were reminiscent of Majocchi's erythema annulare centrifugum (illustrated by Andrews, 1954). The patient said that this skin lesion had been present for two years, slowly enlarging for the first 18 months and then remaining stationary. No other abnormality was found; her health had always been good. The chest radiograph was normal.

Six months later, when a fellow-student (Case 1) was found to have a histoplasmic lesion, she raised the possibility of this diagnosis in her own case. A histoplasmin test was positive (induration 2 cm. in diameter 48 hours after intradermal injection of 0.1 ml. of 1:100 histoplasmin). She asked for a biopsy of the skin lesion, which remained unchanged: this request was agreed to, as it was remembered that the multiple skin lesions in an earlier case of histoplasmosis* seen in this country resembled her lesion.

Part of the indurated ring was excised; the wound healed uneventfully. The biopsy showed a histological picture identical with that in Case 1, except that there was no ulceration. As in Case 1, a typical strain of *H. capsulatum* was cultivated from the biopsy specimen: no large yeast-like cells were formed in the cultures, although they predominated in the lesion.

No other abnormality has been found in this patient. Marrow examination was not undertaken. She has remained in this country and her health is excellent: the skin lesion gradually disappeared completely during the year following the biopsy. No treatment was given.

Comment

The infection in each of these patients appears to have been confined to the single skin lesion. The source of their infection is unknown. The first patient had no knowledge of having been bitten by any insect: he merely mentioned his awareness of the possibility of early dermal myiasis as the cause of the pustule, particularly as he was not liable to boils; he had seen several tumbu-flies in the neighbourhood of Freetown. There is as yet no evidence that histoplasmosis can be transmitted by insects or other vectors.

Cutaneous lesions in histoplasmosis are not uncommon; when they occur they are usually multiple and are part of a disseminated infection, with visceral involvement (Miller, Keddie, Johnstone, and Bostick, 1947). Occasionally the infection is seemingly confined to the skin, and recovery takes place (Curtis and Grekin, 1947), as in the cases described above. Poles and Lavertine (1954) stated that signs of dissemination of the infection have been noticed on several occasions to follow a biopsy; it is not apparent, from what I have read, that this is a substantial risk, but it is obviously prudent to keep the possibility in mind until enough observations are available for the risk to be assessed, particularly as no dependable treatment is known yet. In many cases biopsy is likely to be essential for diagnosis.

*The case of Robb-Smith (1943). This is the case mentioned by Duncan (1945, 1946-7); it was previously described briefly by Carleton (1942-3).

It should be noted that the earlier conception of histoplasmosis as a rare and inevitably mortal disease is erroneous. Large-scale surveys of the incidence of histoplasmin-sensitivity, especially in parts of the United States of America, have shown that subclinical infections are infinitely commoner than clinically evident disease: most of these benign subclinical infections occur in the lungs. Greater knowledge of the disease has also shown that even severe clinical illness may be followed by recovery. Recent accounts of histoplasmosis to which reference may be made include those by Schwartz (1954), Poles and Lavertine (1954), and Leigh and Thomas (1955).

An unusual feature of the two cases described here was the uncommonly large size of the organisms in the tissues. Organisms of comparable size were characteristic of the lesions in the case studied by Robb-Smith (1943) and Duncan (1946-7): their patient likewise probably contracted the infection in West Africa. Duncan (1946-7) suggested that this large-cell type of histoplasma might be a species distinct from *H. capsulatum*, or a variant of *H. capsulatum*. Dubois, Janssens, Brutsaert, and Vanbreuseghem (1952) found a similar large-cell strain in a patient in the Belgian Congo and cited eight other African infections, including Duncan's (1946-7) case, which were probably caused by this type of organism; they too suggested that the large-cell histoplasma is a distinct species, and they proposed that it should be named *Histoplasma duboisii*.

Clarke, Walker, and Winston (1953) described an extraordinary case of widespread cutaneous histoplasmosis in a Nigerian: their histological findings appear to have been similar to those in the cases reported in this paper; the intracellular organisms were of the large-cell type. They isolated a histoplasma which they described as *H. duboisii*.

The status of the large-cell type of histoplasma as a distinct species has not been finally decided: if not identical with *H. capsulatum* it is at least closely related to it. It is noteworthy that naturally occurring large-cell strains have been recorded so far mainly in the case of infections originating in West Africa; Schwarz (1953), however, observed the development of comparable large forms in tissue explants from organs of mice which had been infected with *H. capsulatum* isolated from patients in the United States of America, and Moore (1955) cited some American cases in which the large forms were present in the tissues.

Summary

Two cases of solitary localized histoplasmic granuloma of the skin are reported. The patients are Nigerians, and were living in England at the time of diagnosis. The infection was contracted in West Africa in each case. The organisms in the granulomas were of the large-cell type which has been described as *Histoplasma duboisii*: their cultural characteristics were typical of *Histoplasma capsulatum*.

My thanks are due to Mr. K. W. Iles, F.I.M.L.T., A.R.P.S., Photographic Department, Charing Cross Hospital Medical School, for preparing the photomicrograph.

A CASE OF TRUE HERMAPHRODITISM

BY

J. D. ARNEAUD, M.B., B.S., D.C.P.

H. ANNAMUNTHODO, F.R.C.S.

J. H. M. PINKERTON, M.D., M.R.C.O.G.

AND

W. R. COLE, M.B., B.Chir., D.M.R.D.

(From the Departments of Pathology, Surgery, Gynaecology, and Radiology of the University College of the West Indies, Jamaica)

[WITH SPECIAL PLATE]

The literature on true hermaphroditism has recently been adequately reviewed by Bromwich (1955) and by Greene *et al.* (1952). From these surveys it appears that at most 60 proved cases have been recorded. The case described here is presented because the diagnosis was made after puberty and because the sex-chromatin findings have a bearing on sex differentiation.

Case Report

The patient, aged 18 years, lived in a remote Jamaican village. Both parents died during his infancy. He has always dressed and behaved as a boy; and, although he had noticed that his breasts were enlarging and his penis was small, he became concerned about his condition only at the age of 15 when he began to bleed from a small orifice in the perineum (Fig. A). The bleeding occurred every month, lasted about five days, and was occasionally accompanied by hypogastric pain.

When first seen he was dressed as a male. On physical examination he appeared to be a well-developed coloured (mixed African and European) youth. His voice was of average male pitch. The scalp and axillary hair were normal, there was little facial and no chest hair, and the abdominal hair was female in distribution. The breasts were well developed and pendulous (Fig. B). The body contours were not strikingly female and the body measurements were as follows: weight, 122 lb. (55 kg.); height, 5 ft. 6½ in. (166 cm.); span, 5 ft. 9 in. (173 cm.); vertex to pubis, 31½ in. (79 cm.); pubis to ground, 35 in. (88 cm.).

The genitalia are shown in Fig. A. There was no pronounced mons pubis. The phallus was more like a penis than clitoris and measured 3.5 by 1.5 cm.; there was a moderate hypospadias. No labial or scrotal swelling was present and no testes could be palpated. There was a small left indirect inguinal hernia. The perineal region was perforated 3 cm. in front of the anus by a small orifice 2 mm. in diameter through which the monthly bleeding occurred and urine occasionally escaped. The anatomy of the vagina and urethra is shown in Fig. C. On abdomino-rectal examination a small uterus could be palpated, but no prostate could be felt.

Contrast radiography with viscous diodone demonstrated a vagina, a long cervical canal, a small, normally shaped uterine cavity, a left Fallopian tube for a distance of about 2.5 cm., and a right Fallopian tube of normal length. There was no peritoneal spill on either side (Fig. D). Radiologically the pelvis was gynaecoid in type. The femoral-head epiphyses were fusing and the flake epiphyses of the pelvis were well advanced for the patient's age. The bone age was thus within the early limits of normal, which is more characteristic of the female than of the male. Urinary oestrogen and 17-ketosteroid excretion was not estimated.

Repeated interviews with the patient confirmed our first impression that he was definitely male in outlook. He was very anxious to be rid of his enlarged breasts and monthly

Fig. 1.—Large solitary stone in upper part of dilated common duct, opposite junction with cystic duct, causing partial block of cystic duct and incomplete filling of gall-bladder (arrowed). At operation no stones found in gall-bladder or cystic duct. Biligrafin examination soon after attack of obstructive jaundice. Large calcified primary focus in base of right lung.
 Fig. 2.—Gross deformity owing to tunnelling of portions of gall-bladder through liver tissue. Portions bulging out of liver simulate diverticula. Stones in distal compartment. No filling at oral cholecystography.

Fig. 3.—Cystic duct blocked by non-opaque stone (arrowed) becoming outlined with biligrafin (one hour after injection). Suggests recent impact of calculus at junction, with further hold-up at ampulla before passage into duodenum. Cystic duct still obstructed. Also an accidental pyelogram (arrowed). No filling at oral cholecystography.
 Fig. 4.—Dilated hepatic and common ducts. Dilatation most marked above junction of cystic with common duct. Suggests recent impact of calculus at junction, with further hold-up at ampulla before passage into duodenum. Cystic duct still obstructed. Also an accidental pyelogram (arrowed). No filling at oral cholecystography.

FIG. 1.—Internal genital organs at operation.

FIG. 2.—Ovarian component of left gonad. ($\times 480$.)

FIG. 3.—Testicular component of left gonad. ($\times 480$.)

FIG. 4.—Epidermis showing sex-chromatin body on nuclear membrane. ($\times 5,350$.)

FIG. 5.—Interstitial tissue of testis showing sex chromatin. ($\times 5,350$.)

A. D. DIXON AND J. B. D. TORR: SEX CHROMATIN IN ORAL SMEARS

FIG. 1.—Male nucleus typical of those included. ($\times 1,125$.)

FIG. 2.—Female nucleus typical of those included. ($\times 1,125$.)

FIG. 3.—Nuclei excluded because of bacterial contamination. ($\times 1,125$.)

FIG. 4.—Nuclei excluded because of folding of cell body. ($\times 1,125$.)

FIG. 1.—Section of spleen of control male guinea-pig given one subcutaneous injection of trypan blue daily for six days and killed the following day. Shows a moderate number of dye-bearing cells in sinuses of red pulp and in reticulum. Dye appears black in photomicrograph. (Stained weak eosin. $\times 200$.)

FIG. 2.—Section of spleen of male guinea-pig given 10 mg. cortisone acetate intramuscularly daily for seven days plus one subcutaneous injection of trypan blue daily during last six days before being killed. Compared with control animal (Fig. 1) the number of dye-bearing cells in sinuses and reticulum has become reduced, indicating reduced phagocytic activity. Dye appears black in photomicrograph. (Stained weak eosin. $\times 200$.)

FIG. 3.—Section of spleen of male guinea-pig given 10 mg. cortisone acetate intramuscularly daily for 14 days plus one subcutaneous injection of trypan blue daily during last six days before being killed. Shows complete absence of dye granules, indicating gross depression of phagocytic activity of reticulo-endothelial cells. (Stained weak eosin. $\times 200$.)

FIG. 4.—Section of medulla of lymph node of control male guinea-pig given one subcutaneous injection of trypan blue daily for six days and killed the following day. Shows numerous phagocytic cells in sinuses of medulla. Large amount of dye present in cells, indicating normal phagocytic activity. Dye appears black in photomicrograph. (Stained weak eosin. $\times 200$.)

FIG. 5.—Section of medulla of lymph node of male guinea-pig given 10 mg. cortisone acetate intramuscularly daily for 14 days plus one subcutaneous injection of trypan blue daily during last six days before being killed. Shows complete absence of dye granules, indicating gross depression of phagocytic activity of reticulo-endothelial cells. Lymphoid tissue shows marked degree of atrophy. (Stained weak eosin. $\times 200$.)

FIG. 6.—Section of medulla of lymph node of male guinea-pig given 10 mg. cortisone acetate intramuscularly daily for 21 days plus one subcutaneous injection of trypan blue daily during last six days before being killed. Shows moderate number of dye-bearing cells, especially on walls of lymph sinuses, indicating that phagocytic activity of reticulo-endothelial cells has started to recover. Dye appears black in photomicrograph. (Stained weak eosin. $\times 200$.)

R. S. CROW: PERIPHERAL NEURITIS IN MYELOMATOSIS

FIG. 1.—Case 1: The hands, showing pigmentation, "white nails," and clubbing. Left-hand nails are tobacco-stained.

FIG. 2.—Case 1: Myeloma of scapula with pathological fracture.

bleeding. A psychiatrist reported that there was strong evidence that he was psychologically masculine.

Cystoscopy under general anaesthesia showed the bladder and ureteric orifices to be normal. At laparotomy the internal genitalia were found to be predominantly female. The uterus was 90 mm. in length, with a long, narrow hypoplastic supravaginal cervix measuring 55 mm. The

right tube was long and hypoplastic and measured 90 mm. The left tube was thickened and its fimbrial end was buried amongst peritoneal folds near the brim of the pelvis. The right gonad looked like normal ovary and contained a corpus luteum; biopsy and frozen section confirmed this. The left gonad lay close to the left internal inguinal ring, covered by peritoneal folds. Dissection disclosed that it was made up partly of a testis and partly of an ovary also containing a corpus luteum (Special Plate, Fig. 1). Subsequent histological examination confirmed that the right gonad was an ovary and the left a combined ovary and testis. Total hysterectomy was performed with removal of the upper third of the vagina, both tubes, the right gonad, and the ovarian portion of the left gonad. Convalescence was uneventful.

Fifteen days later bilateral mastectomy was performed through semicircular incisions in the upper circumference of the areolae, with removal of semilunar pieces of skin and preservation of the nipples and areolae. Eleven days after that operation the hypospadias was repaired, and six days later the perineal orifice was closed in two layers.

Social adjustment of the patient was facilitated by securing him congenial employment as a manservant. He is much happier since his operations and is to all appearances a cheerful, normal young man.

Pathology

The uterus, cervix, right gonad and tube, left gonad and tube, both breasts, and portions of thoracic skin were all examined histologically. The endometrium was in the proliferative phase. The right ovary showed a well-developed corpus luteum with a haemorrhagic centre, the remainder of the section being composed of normal ovarian

tissue. The ovarian portion of the left gonad showed normal ovarian tissue and contained a corpus luteum of later date than the right (Plate, Fig. 2). The small portion of testis removed contained seminiferous tubules and relatively prominent interstitial tissue. The tubules had a thickened basement membrane and the majority of cells appeared to be of Sertoli type. There was no evidence of spermatogenic activity and no definite spermatogenic cells were seen (Plate, Fig. 3). Sections from the isthmic and infundibular portions of the left Fallopian tube were normal. The histo-

Discussion

Success in the management of the hermaphrodite depends on early diagnosis, accurate clinical, psychological, and histological evaluation, and the adoption of appropriate surgical, endocrine, and psychotherapeutic measures to adjust the patient as a normal member of society.

Diagnosis

It is extremely difficult to differentiate clinically true hermaphroditism from other types of intersex. The external

genitalia and physical development are variable. By cystoscopy and urography it may be possible to demonstrate accessory structures and communications between the urinary and genital tracts. The presence of a female genital tract and the extent of its development may be demonstrated radiologically, as in this case.

Blood and urine levels of oestrogens, androgens, and ketosteroids are generally unaltered except in the female pseudohermaphrodite. The possibility that the gonad of the intersex may be abnormal with regard to hormone production has been suggested by Morris (1953). Descent of the gonad is no indication of its nature. Helpert (1939) and Laycock and Davies (1953) have reported cases of ovotestes in the scrotum. Macroscopic appearances of gonadal tissue have been misleading. Fischer *et al.* (1952) stated that there was an associated inguinal hernia in 21 of 49 cases, and stressed its importance in diagnosis. Diagnosis was made at operation for hernia in 6 of 20 cases studied by Young (1937). The hernial sac often contained a gonad, and in some cases part or whole of the uterus. Giacobine (1946) found 36 male cases of hernia uteri inguinalis in the literature. Accurate diagnosis can be established only by gonadal biopsy, which in most cases involves laparotomy.

Management

As our patient was past puberty, it was assumed that no reversal of psychic sex was likely to occur, and his strongly marked maleness was taken as the guide in our surgical endeavours to render him a more normal person. This procedure has the approval of most modern workers in this field (Creadick, 1953; Greaves, 1954; Wilkins *et al.*, 1955; Barr, 1956). Any attempt to make these individuals behave contrary to their psychological sexual bias, whatever their clinical sex, often gives rise to serious mental conflict and doubtless accounts for many of the suicides common amongst these patients.

Attention has been drawn to the association of malignancy and the cryptorchid testis of the hermaphrodite (Taub, 1954; Gilbert, 1942). Orchidopexy did not significantly lower the incidence in one series of cases (Gilbert and Hamilton, 1940). In our case there was a clear demarcation between the components of the left gonad, and we were able to remove the female component and leave the remainder, since the advantages of preserving the gonad for endocrine function were considered to outweigh the risk of malignancy (Howard, 1951).

Hormone therapy was considered, but it was decided to withhold this until the function of the testis could be evaluated, since substitution therapy may depress gonadal function (Marshall, 1954).

Sex-chromatin Studies

The work of Barr and his associates (1949, 1950) has established that intermitotic nuclei of human tissues bear evidence of the true nature of their sex chromosomes. Sex-chromatin studies were made in this material from three aspects: (1) the type of nuclei present in the tissues; (2) the presence or absence of gynandromorphism; and (3) the nuclear structure of the male components of the reproductive system. All the material except the skin was fixed in 10% neutral buffered formal saline. The skin was preserved in a modified Davidson's solution as recommended by Moore *et al.* (1953). For the sex-chromatin studies sections 5 μ thick were stained with haematoxylin and eosin and Feulgen stains, and the counts made on 100 suitable nuclei in each section (Plate, Figs. 4 and 5). The heavy deposit of melanin in the deeper cells of the negro epidermis increased the difficulty of the counts in this area, but this was overcome by the use of the Feulgen stains. Also the squamous cells around the skin appendages in the dermis were found to be relatively free of melanin, so that the nuclear type could be satisfactorily evaluated.

1. Nuclear Types.—Studies on the nuclear types of true hermaphrodites have previously been completed on nine cases (Barr, 1955a); six of these showed female-type nuclei

and three male-type nuclei. Our case had a nuclear pattern of the female type (see Table).

2. Gynandromorphism.—The phenomenon of gynandromorphism has been shown to occur in insects. In the three cases reported to date (Barr, 1955b; Greene *et al.*, 1952), and in the present case, there was no evidence of gynandromorphism.

3. Nuclear Structure of Male Components.—The presence of female-type nuclei in the interstitial tissue of the testis is an interesting finding. As the small piece of testicular tissue removed at operation was fixed immediately, examination by the squash technique (Greene *et al.*, 1952) was not possible. In the sections the cells within the seminiferous tubules did not show any structure that could be regarded as sex chromatin. However, these cells are unsuitable for cytological study in sections (Barr, 1956).

Of 57 cases of true hermaphroditism the social sex was male in 41, or 72% (Bromwich, 1955). Among 10 similar cases in which the sex chromatin has been studied only three were male in type. This suggests that in the majority of instances of true hermaphroditism the genetic sex, which is usually female, has been suppressed by the social and psychic sex, which is usually male. In our case the hormonal influences must have been strongly female, since the patient had nearly normal female secondary sex characteristics and apparently normal ovarian function. Despite this the psychic sex was male.

Graham (1954a, b) has demonstrated in the cat embryo that the nuclear configuration antedates the sexual differentiation of the reproductive system. Bromwich (1955) has suggested that the apparent sex among intersexes may not be absolutely determined by the sex chromosomes and that the genetic direction of development may be overridden by other factors. In our case, however, the genetic sex and the hormonal sex are female, but the psychic sex is strongly male. It would therefore seem that environmental and psychic influences have successfully suppressed the other factors. This is in agreement with the views of Howard (1951), Creadick (1953), and Greaves (1954), who have all stressed the part played by environment in psychic development.

Summary

A case of true hermaphroditism and its treatment are described. Although in this case the genetic sex and hormonal sex were female, the psychic sex was strongly male, and evidence is put forward to suggest that extrauterine environmental factors were responsible for this.

We are indebted to Professor Murray Barr for his comments on our sex-chromatin studies, to Dr. William Davidson for assistance with the polymorphonuclear sexing, and to Dr. K. D. Royes for the psychiatric evaluation of the patient.

of Science, Rehovoth, Israel

DAVID M. SERR, M.B., Ch.B.

Department of Obstetrics and Gynaecology, Rothschild-
Hadassah University Hospital, Jerusalem, Israel

AND

MATHILDE DANON, Ph.D.

Department of Experimental Biology, Weizmann Institute
of Science, Rehovoth, Israel

For many years attempts have been made, by different approaches, to develop a method that would give a reliable prenatal diagnosis of foetal sex. We have previously shown (Serr, Sachs, and Danon, 1955; Sachs, Serr, and Danon, 1956) that a reliable prenatal diagnosis can be made by a study of chromocentres in amniotic fluid cells.

This method of diagnosing sex is based on a well-established theoretical and practical foundation, since it is known that in humans, as in most other mammals, there is a difference in the sex chromosome constitution of normal males and females—males having the sex chromosome constitution XY, and females the sex chromosome constitution XX (reference in Sachs, 1954, 1955)—and since identification of normal males and females by a study of chromocentres has invariably given correct results when applied to human cells from other sources (Moore, Graham, and Barr, 1953; Moore and Barr, 1954, 1955; Emery and McMillan, 1954; Marberger and Nelson, 1955; Marberger, Boccabella, and Nelson, 1955; *Lancet*, 1955; Sachs and Danon, 1956).

The present paper deals with our detailed findings in an analysis of amniotic fluid cells in 40 cases in the ninth month, and in 8 cases in the third, sixth, and seventh months of pregnancy.

Material and Methods

Amniotic fluid was obtained prior to delivery by puncture of the membranes, and in the earlier months of pregnancy, excepting the case in the third month, by abdominal puncture (Dieckmann and Davis, 1953; Alvarez and Caldeyro, 1950). The case in the third month was obtained during hysterectomy performed by Professor B. Zondek.

The fluid was centrifuged at 2,500 rotations a minute for five minutes. The sediment, which contained the cells, was smeared on slides that had previously been coated with Mayer's albumin, and then fixed for at least one hour in a fixative consisting of equal parts of absolute alcohol and ether. We also tested 3:1 alcohol-acetic acid, and although these modified Kahle's fixative (see below), and although these were both satisfactory they were not superior to the alcohol-ether, which was therefore routinely used. If the slides had to be kept for any length of time after fixation, or if they had to be transported, they were rinsed in 70% alcohol, 50% alcohol, water, and then kept after rinsing in glycerin-water.

For the study of chromocentres we routinely used Feulgen staining, with fast green as a counterstain for the cytoplasm. The Feulgen method of staining is specific for desoxyribose

nucleic acid, a chemical constituent that is found only in the chromosomes, and it therefore gives a clear staining of the chromocentres.

For the Feulgen staining, the slides, after rinsing in water, were transferred for eight minutes to normal hydrochloric acid at 60° C., stained with leucobasic fuchsin for one hour, and this was followed by three rinses, totalling 10 minutes, in SO₂ water, and three rinses in distilled water. The slides were then rinsed in 70% alcohol, 95% alcohol, counterstained in a dilute fast green solution in 95% alcohol, followed by two rinses in 95% alcohol, and a rinse in absolute alcohol, equal parts of absolute alcohol and xylol, xylol, and mounting in canada balsam.

For the analysis of the different types of cells the slides were stained, after alcohol-ether fixation, with Papanicolaou EA-36 and OG-6.

When sections of embryonic and foetal membranes were examined, pieces were fixed in a modified Kahle's fixative consisting of 100 parts absolute alcohol, 7 parts glacial acetic acid, and 40 parts 40% formaldehyde. After fixation for at least 12 hours, the pieces were transferred to 70% alcohol if they had to be stored. For embedding they were passed through 95% alcohol, absolute alcohol, equal parts

of absolute alcohol and xylol, two changes of xylol, and embedded in wax. Sections were cut at 10 μ , and the sections, like the smears, were stained with Feulgen and fast green for the study of chromocentres, and with Papanicolaou for the cell types.

Results

Types of Cells in the Amniotic Fluid

An analysis of the types of cells in the amniotic fluid was made on Papanicolaou smears of fluid taken prior to delivery. Three main types of epithelial cells were found, which could be classified (Vincent Memorial Hospital, 1950) as basal cells with vesicular nuclei and green-staining cytoplasm; precornified and cornified cells with vesicular to pyknotic nuclei and square or folded and wrinkled cytoplasm which stains green in the precornified and pink in the cornified cells; and keratinized cells with advanced nuclear degeneration or no nucleus at all and an orange-staining wrinkled cytoplasm. In many anucleate cells the cytoplasm was not stainable.

The basal and precornified cells, with green-staining cytoplasm, are the most suitable for the sex diagnosis. Most of the cells with pink-staining cytoplasm and the cells with orange-staining cytoplasm are unsuitable since they have nuclei with different kinds of degeneration such as pyknosis, loss of stainability, and karyorrhexis.

In order to determine the origin of the cells suitable for the diagnosis of sex we examined Papanicolaou-stained sections of skin from a 6-months-old foetus, and Papanicolaou-stained sections of skin and smears of the oral mucosa and vagina from a newborn infant. The skin of the 6-months-old foetus was found to have a surface sheet of cornified cells without nuclei and pink- or orange-staining cytoplasm. In some places this sheet of dead cells had peeled off, so that small patches of cells suitable for diagnosis could then be in contact with the amniotic fluid. In the skin of the newborn infant there was a continuous surface sheet of dead cells in the pieces that were examined, whereas both the oral mucosa and the vaginal smears showed that nearly all the cells of the surface layers were suitable for diagnosis. The cornified and keratinized cells found in the amniotic fluid thus seem to come from the skin, and it can be assumed that the cells suitable for diagnosis come to a large extent from the mucosae of the foetus. The epithelium of the amniotic membrane as a possible source of suitable cells is also not excluded.

A small proportion of polymorphonuclear leucocytes were found in the amniotic fluid. But these were all degenerate or badly spread, so that it was not possible to make a sex diagnosis such as that which can be made on these cells in blood smears taken after birth (Davidson and Robertson Smith, 1954; Sachs and Danon, 1956).

Percentage of Cells Suitable for the Diagnosis of Sex

Since the amniotic fluid contains many cells that are not suitable for sex diagnosis, we determined the percentage of

diagnosable cells in cases prior to delivery and in earlier stages of pregnancy. The results of five separate determinations on 100 cells each in 15 males and 15 females are given in Table I. In both males and females, Cases 1 and 12 are prior to delivery. In the males, Cases 13 and 14 are from a 5½-months-old foetus and Case 15 from a 6-months-old foetus; and in the females, Case 13 is from a 5½-months-old foetus and Cases 14 and 15 from a 6-months-old foetus.

It can be seen from Table I that the percentages of diagnosable cells in the five- and six-months cases are similar to those found in some of the later cases. One case of hydramnios with a male foetus that was examined in the middle of the ninth month gave, on a count of 500 cells, an average of $15.2 \pm 1.2\%$ diagnosable cells, and this is equivalent to Case 12 among the normal cases of pregnancy. In one of the sixth-months cases there was a piece of tissue in the amniotic fluid with 70 diagnosable cells (Fig. 1, No. 9). A comparison of the totals of the 15 cases in males and females gives an average of 12.1 ± 0.2 for males and 12.4 ± 0.9 for females, so that there is no significant difference between the two sexes.

In the one case that was at the end of the third month there was a total of 36 cells (in 4 ml. of amniotic fluid), of which 22 (61%) were suitable for diagnosis.

Study of Chromocentres for Diagnosis of Sex

The diagnosis of sex on the amniotic fluid cells is based on determinations of the percentage of cells with a chromocentre that may or may not be at the nuclear membrane. The results of five separate counts of 100 cells each in five males and five females prior to delivery are shown in Tables II and III.

The data on 40 cases in the ninth month (Table IV, Figs. 2 and 3), which consist of 39 cases prior to delivery and 1 case of hydramnios in the middle of the ninth month, show that there is a clear difference both in the percentages of cells with a chromocentre and in the percentage of cells with a chromocentre at the nuclear membrane, in the cases diagnosed as males and females. In each of these cases the diagnosis of sex on the amniotic fluid cells was confirmed at delivery.

In the seven cases in the sixth and seventh months (Table V), there is also a clear difference between males and females. One of these was a pathological pregnancy in a woman who had been bleeding intermittently for two months before she was examined, and the diagnosis of sex on the amniotic fluid cells was confirmed both from the appearance of the foetus and from an analysis of a skin biopsy. The other six cases have not yet been delivered, but since there were a sufficient number of diagnosable cells there is no reason to doubt that, as in all the other cases, the diagnosis will be confirmed at delivery.*

*The sex of these foetuses has now been confirmed at delivery.

SEX CHROMATIN IN ORAL SMEARS

BY

[WITH SPECIAL PLATE]

A sex difference in the morphology of intermitotic nuclei was first described as a feature of nerve cells in the female cat by Barr and Bertram (1949). This difference is characterized by a mass of chromatin which, from its intimate relationship to the nucleolar membrane in nerve cells, was first called the nucleolar satellite, but as its position varies with the condition of the cell and the type of tissue examined it was renamed the sex chromatin. Further studies have shown that sex chromatin may be demonstrated, not only in many tissues of the cat, but also in the cells of other species, including man (Moore and Barr, 1954). These findings have been of value in the study and elucidation of cases of abnormal sex development by the examination of nuclei in biopsy specimens of skin.

Moore and Barr (1955) in Canada and Marberger *et al.* (1955) in the United States, in order to simplify still further the diagnosis of chromosomal sex, examined smears of epithelial cells taken from the mucous membrane of the oral cavity, and found that in the nuclei of these cells also the sex chromatin could be identified.

Recently it has been pointed out (Barr, 1956) that, as the precise relationship of the female mass of sex chromatin to the XX chromosome complex has not yet been established, the use of such terms as male or female chromosomal sex should be replaced, in clinical use, by "chromatin negative" (male) or "chromatin positive" (female).

The purpose of the present investigation is twofold: first, to examine smears from a large number of individuals with a view to testing the validity of the oral smear method, as it has not yet been extensively used in this country; and, secondly, to establish a number of criteria by which the method may be standardized and the diagnosis of chromosomal sex made more or even quite certain.

Materials and Methods

Oral smears were taken from 260 individuals, of whom 98 were female and 162 male. Ages ranged from 16 months to 60 years and there was some racial variation. The smears were obtained by gently scraping the inner surface of the cheek with a wood orange-stick and transferring the material thus removed to a slide previously coated with a thin layer of albumen. Fixation in equal parts of 95% ethyl alcohol and ether was begun immediately, and continued for 24 hours. Following careful hydration, staining was carried out in 1% cresyl violet at 57° C. for 20 minutes. Excess stain was removed by brief rinsing in 95% alcohol (two changes), dehydration was completed in absolute alcohol, and the specimens were then cleared in xylol and mounted in Canada balsam. Other staining techniques, such as the Feulgen reaction, which demonstrates the sex chromatin because of its high content of deoxyribose nucleic acid, were tried, but preference was given to the cresyl-violet method as it was found to give adequate differential staining of the nucleus and has the advantage of greater simplicity.

The slides were numbered serially and examined independently by each investigator, without reference to the records

In the one case that was obtained during hysterectomy at the end of the third month, out of the 22 cells suitable for diagnosis in 4 ml. of fluid there were 21 with a chromocentre, in 12 of which the chromocentre was at the nuclear membrane. The diagnosis of female sex on the amniotic fluid cells was confirmed by a study of embryonic membranes. We also found it possible to make a diagnosis on the cells in the fluid of an 8-weeks-old aborted embryo, and this was again confirmed by a study of embryonic membranes.

In some cases prior to delivery, but never in any of the earlier cases, the fluid was obviously contaminated with cells from the mother, and if there was a male foetus it was possible to distinguish both male and female patches of cells. In these contaminated cases, which have of course been excluded from the data, the membranes had

presumably broken before the fluid was collected, so that maternal cells were mixed with those of the foetus. Papanicolaou smears, which showed the presence of bacteria, confirmed that there had in fact been maternal contamination in these cases.

The present results show that a diagnosis based on the percentage of cells with a chromocentre at the nuclear membrane gives no less a sex difference than a diagnosis based on the percentage of cells with a chromocentre at any position in the nucleus. The former analysis, which is easier to carry out, is therefore to be recommended as a routine procedure. It should also be noted that the chromocentre of the older epithelial cells found in the amniotic fluid, which may really be a double structure (Sachs and Danon, 1956), is larger when found in a female than when found in a male.

The term "sex chromatin" (Moore, Graham, and Barr 1953) has been used for the chromocentres which are presumably formed by the sex chromosomes. But the term "chromatin" refers to chromosome material in general, so that the sex chromatin of the sex chromosomes is present in all the cells both in males and in females. Since the diagnosis of sex is based not on the presence or absence of sex chromatin but on the different abilities of the sex chromosomes to form chromocentres in the non-dividing nuclei of males and females, the use of the term "chromocentre," or possibly the term "sex chromocentre," seems to be more appropriate than the use of the term "sex chromatin."

Discussion

It can be seen from the present data that an accurate prenatal diagnosis of foetal sex can be made by a study of chromocentres in amniotic fluid cells. In all normal cases there have been a sufficient number of diagnosable cells, and it has been shown that a diagnosis can be made in normal cases from the third month, and possibly even earlier.

Since our original report was published (Serr, Sachs, and Danon, 1955; see also Sachs, Serr, and Danon, 1956) we have

been informed by Dr. Landrum B. Shettles (1956) in New York and Drs. Fritz Fuchs and Povl Riis (1956) in Copenhagen, that they have independently found that a diagnosis of foetal sex can be made by an examination of amniotic fluid cells. A report has also appeared from Minneapolis (Makowski, Prem, and Kaiser, 1956), Amsterdam (James, 1956), and Sheffield (Dewhurst, 1956). The diagnosis is therefore well established, and the only possible source of error would seem to be in the rare case of an intersex whose appearance does not correspond to that expected from his or her sex chromosome constitution. Even in cases of twins with different sexes in the same amnion, it should be possible to make a correct diagnosis, since one would expect to find both male and female patches of cells in the amniotic fluid. Regarding the clinical value of a correct prenatal diagnosis of sex, the most obvious application would be in cases of certain sex-linked abnormalities.

Summary

It has been shown in 40 cases in the ninth month, and in 8 cases in the third, sixth, and seventh months of pregnancy, that it is possible to diagnose the sex of the foetus by a study of chromocentres in amniotic fluid cells. It was also possible to make a diagnosis on an 8-weeks-old aborted foetus.

A clear sex difference has been found both when the diagnosis is based on the percentage of cells with a chromocentre and when it is based on the percentage of cells with a chromocentre at the nuclear membrane. The latter determination is to be recommended as a routine procedure, since it is easier to carry out.

In the 47 cases in the sixth, seventh, and ninth months there was a mean of 4% of cells with a chromocentre at the nuclear membrane in males, and a mean of 35% of such cells in females. The chromocentre was also larger when found in cells of a female than when found in cells of a male.

Three main types of epithelial cells—basal, precornified or cornified, and keratinized—were found in the amniotic fluid. Of these, the basal and precornified cells are the most suitable for the sex diagnosis.

Determinations of the percentage of cells in the amniotic fluid that are suitable for the sex diagnosis gave, for the cases in the sixth, seventh, and ninth months, a mean of 12% suitable cells both for males and for females. In the one case in the third month 61% of the cells were suitable for the diagnosis.

of the sex of the subjects. A 1/12-inch oil-immersion objective was used, as lower magnifications were not satisfactory. Twenty-five suitable cells were counted in each smear, and the incidence of sex chromatin, the first cell in which it was seen, and the degree of bacterial contamination were noted. Only cells which fulfilled the following criteria were included in the counts: (1) they must have large, circular, lightly stained nuclei; (2) there must be absence of crenation of the nuclear membrane and no undue folding of the cell body; (3) there must be no obscuring of the nucleus due to overlapping by adjacent cells; (4) freedom from bacterial contamination in the vicinity of the nucleus is essential; (5) only plano-convex, darkly stained bodies in actual continuity with the nuclear membrane were considered to be sex-chromatin masses. Figs. 1 and 2 on the Special Plate show male and female nuclei typical of those included in the counts, while Figs. 3 and 4 show nuclei of the type which were excluded because of bacterial contamination and folding of the cell body respectively.

Observations

Three of the 260 smears were unsuitable for examination. In the 162 male smears examined no sex chromatin was seen, whereas, by contrast, in the majority of the 95 female smears between 30% and 50% of the cells counted contained a sex-chromatin mass. The average incidence is shown in the

the investigation. As experience in the examination of the smears was gained the accuracy of our estimations improved, in great part owing to the application of the criteria for suitable cells which have been enumerated above. The smears in which errors had been made were re-examined at the end of the investigation, and no difficulty was then experienced in providing a correct diagnosis.

Discussion

It has already been established that there is a well-recognized difference between the nuclei of male and female epithelial cells, and our results fully confirm this finding. Other investigators have given different values for the percentage

of female cells possessing sex chromatin, but this variation in values would appear to be due to differences in the type of cells counted and also to the fact that some estimations have included cells in which the mass of chromatin was not in an absolutely peripheral position in the nucleus. Unless it is in such a position it is partially obscured by the substance of the nucleus and cannot be positively identified. This probably explains why, in a proportion of cells in any smear from females, the sex chromatin is not visible. The limiting criteria we have used tend to give a low percentage incidence, but in our opinion greater accuracy of forecast.

In female smears the sex chromatin was usually first seen in one of the first five cells counted. As this finding occurred with such regularity we decided that a count of 25 cells was quite adequate for sex determination. This fact at first sight may not seem significant, but in the case of children, and more particularly of young infants, we have found great difficulty in obtaining smears in which more than 25 cells fulfilling the above essential criteria can be seen.

Summary

The examination of oral smears from 260 individuals, representative of a wide age and racial variation, has enabled their chromosomal sex to be determined with considerable accuracy. With increasing experience in assessment the diagnosis becomes progressively more accurate. The procedure is simple in its application and if necessary may be readily repeated.

The findings of previous workers have been confirmed, and a number of criteria established the use of which may help to standardize the method and ensure correct diagnosis.

We are indebted to Professor G. A. G. Mitchell, who permitted this investigation to be undertaken in the Department of Anatomy, and to the members of staff, students, and others who so willingly gave their co-operation. Our thanks are also due to Mr. P. Howarth, A.R.P.S., for the photomicrography.

EFFECT OF CORTISONE ON THE DEFENCE MECHANISMS OF THE BODY

BY

King's College

[WITH SPECIAL PLATE]

Many records have been published showing that cortisone depresses the reaction of the body to all common bacterial infections in both animals and man (Thomas, 1953). In the mouse it was found that cortisone increased the severity of a tuberculous infection (Hart and Rees, 1950), and in the human subject there is evidence that it may cause a quiescent tuberculous lesion to become active. Furthermore, cases of sudden death from acute fulminating pneumonia in patients with rheumatoid arthritis undergoing cortisone therapy have been reported. In a number of animal experiments the doses, weight for weight, exceeded those given

to patients, and it was thought that overdosage might account for some of the unfavourable results. Further clinical trials largely substantiated this view, and it is now accepted that severe intercurrent infection tends to occur only when very large doses are given. Wayne (1955) is of the opinion that the critical dose of cortisone in the human subject is in the region of 75 mg. per day, since nearly all patients receiving more than 100 mg. of the hormone daily develop some adverse side-effect.

Present Investigations

The research now described was designed to investigate the mechanism by which cortisone depresses the defences of the body, and also that by which it brings about improvement in certain diseases. Studies were therefore made of the effect of cortisone on (1) the phagocytic activity of the reticulo-endothelial system; (2) the total and differential leucocyte counts of the blood; and (3) the gamma-globulin level in the serum, which may be taken as the measure of the antibody level present, since most antibodies are found in association with the gamma-globulin fraction of the serum protein. All three are known to be important in defence against infection.

To study the effect of cortisone on the phagocytic activity of the reticulo-endothelial system 79 mature male guinea-pigs were used. Each received one daily subcutaneous injection of trypan blue for the last six days before being killed by chloroform, the dosage of the dye being calculated on the basis of 0.8 ml. of a 1% solution in distilled water for each 100 g. body weight. Seven of the animals were given dye only and used as controls. The remaining 72 were divided into three groups of 24 and given cortisone acetate (Roussel) once daily intramuscularly in addition to the dye. The animals in the first group each received 5 mg. of the hormone daily, those in the second 10 mg. daily, and those in the third 25 mg. daily, and all were killed in batches of six at the end of the first, second, third, and fourth weeks. These doses were planned to be proportionately much higher than those given therapeutically to the human subject. Specimens were taken from the spleen, liver, and lymph nodes and fixed in Heidenhain's "Susa." Sections were cut 10 μ thick and stained with weak eosin, dilute carbol fuchsin, or alum carmine. The degree of phagocytic activity was assessed by studying the intensity of the vital staining as judged by the number of dye granules seen within the cells. Only cells containing dye granules were regarded as belonging to the reticulo-endothelial system.

Twelve male guinea-pigs were used to investigate the effect of cortisone on the total and differential leucocyte counts and the gamma-globulin level in the serum. Each received 10 mg. of cortisone intramuscularly once daily for a period of five weeks. Blood samples were taken from each animal by heart puncture before treatment started and thereafter at weekly intervals, the blood films being stained with Giemsa's stain. The gamma-globulin level in the serum was estimated by first separating the gamma-globulin fraction by electrophoresis, then treating the electrophoretic paper with dye and estimating the optical density of the protein dye complex by means of a photoelectric cell. In this manner the percentage of the gamma globulin in relation to the total protein in the serum could be assessed.

Results

The phagocytic activity of the reticulo-endothelial system was greatly depressed in the animals which received cortisone treatment for one or two weeks, as indicated by reduced concentration of the dye in the macrophages of the spleen, liver, and lymph nodes compared with the appearances in the controls (Special Plate, Figs. 1-5). Moreover, the lymph nodes were atrophied and the mortality rate was high. Post-mortem examination of animals which died showed gross reduction in size of the lymph nodes and a slight reduction

in size of the spleen. No evidence of infection was found and the cause of death could not be determined. In contrast, the intensity of the vital staining in the animals given cortisone for three or four weeks was practically similar to that in the controls, indicating a recovery of the phagocytic activity of the reticulo-endothelial system (Plate, Fig. 6). In addition the lymph nodes showed signs of hypertrophy and the mortality was low.

The total and differential white cell counts were also found to be affected by cortisone. During the first two weeks of cortisone treatment the total leucocyte count fell from 8,700 to 4,200 per c.mm., owing to reduction in number of both lymphocytes and polymorphs. When the cortisone was continued for a further two weeks the total leucocyte count returned to normal, the number of polymorphs having increased, but the lymphocyte count remained at about one-quarter the normal.

The concentration of gamma globulin in the serum was reduced to about half the normal level during the first two weeks of cortisone injections, and remained at this low level during the succeeding three weeks of treatment. These results were obtained by the electrophoresis and scanning of 40 samples of guinea-pig serum.

Discussion

Our investigation has shown that large doses of cortisone greatly depress the phagocytic function of the reticulo-endothelial system during the first two weeks of treatment and that phagocytic activity returns to normal during the third and fourth weeks. The high mortality during the first two weeks of the hormone injections, together with the failure to find a definite cause for death at necropsy, suggest that the animals died of an acute fulminating infection with the minimal inflammatory signs, or more probably from the toxicity of the trypan blue, since the reticulo-endothelial system was depressed and its cells were unable to remove the toxic dye from the circulation. This initial depressive action of cortisone is in accord with the findings of White and Marshall (1951), who reported that cortisone inhibits the clearance of pneumococci from the blood of the rabbit. These findings suggest that it is during the early stages of treatment with cortisone in large daily doses that intercurrent infection is most likely to develop, and that during this time the patient should specially avoid exposure to infection and perhaps also be given antibiotics.

The atrophy of the lymph nodes which occurred during the first two weeks of cortisone treatment in the present animals coincided with the marked reduction in the number of circulating lymphocytes. Dougherty and White (1945) also reported rapid atrophy of lymphoid tissue after cortisone treatment, and believed it to be due to increased destruction and also reduced production of lymphocytes. The return of the lymph nodes to normal or above normal size when cortisone was continued for four weeks indicates that the initial atrophy is followed by rapid recovery. The persistence of the low lymphocyte count may be due to delay in the appearance of new lymphocytes in the general circulation.

The depression of the serum gamma globulin in the present experiments is in agreement with the results of Bjørneboe *et al.* (1951), who showed that in the rabbit cortisone inhibits the production of antibodies during active immunization and also after immunization is well established. Further, the persistence of a low gamma-globulin level in the serum and a low lymphocyte count in the circulating blood during the third and fourth weeks of cortisone treatment in the present researches suggest that in the guinea-pig the lymphocytes are probably important in relation to antibody formation. This is in agreement with Dougherty *et al.* (1944) and Harris *et al.* (1945), who reported that lymphocytes contain antibody protein. On the other hand, in the human subject Larson and Tomlinson (1951) and Havens *et al.* (1952) have shown by immunization experiments that cortisone in therapeutic doses does not inhibit

antibody production. The lowered antibody level in animal experiments is probably due to the very high doses of cortisone administered. The effect of cortisone and corticotrophin on the leucocytes of the blood in animals, healthy human subjects, and patients with diseases not primarily of the haematopoietic system has been described by many workers (Quittner *et al.*, 1951; Hills *et al.*, 1948; Kellgren and Janus, 1951; Rebuck and Mellinger, 1953). It would appear that these hormones are capable of producing a decrease in the number of circulating eosinophils and lymphocytes and an increase in the number of neutrophils. The present results in the guinea-pig show that during the first two weeks of cortisone treatment both lymphocytes and polymorphs become markedly reduced in number, but when the hormone is continued for a further two weeks the lymphocytopenia persists while the polymorph count rises steadily until it exceeds the normal level. The increased number of polymorphs in the blood during the third and fourth weeks of treatment does not, however, necessarily ensure that their defence function is normal, for Crepea *et al.* (1951) found that neutrophils in the blood obtained from patients under cortisone therapy exhibited decreased phagocytic activity for Type I pneumococci. Furthermore, Robinson and Smith (1953) showed in the rabbit that cortisone inhibits the accumulation of polymorphonuclear leucocytes at the site of infection. Cortisone therefore appears to be capable of reducing the defence functions of the polymorphs, not only in the blood stream, but also at the site of inflammation.

Summary and Conclusions

Animal experiments were carried out to investigate the mechanism by which cortisone depresses the defences of the body, and also that by which it brings about improvement in certain diseases. The conclusions drawn indicate that cortisone lowers the body defences by depressing the phagocytic activity of the reticulo-endothelial system, the total and differential white cell counts in the blood, and the gamma-globulin level in the serum. Its beneficial use in certain diseases is probably due to a similar mechanism whereby it depresses the inflammatory reaction of the patient and thus holds in check the cycle of pathological changes. This is well illustrated in cases of tenosynovitis and iridocyclitis, in which the use of cortisone reduces the inflammatory response and prevents the formation of adhesions while the infecting organisms can be attacked therapeutically with antibiotics. It would seem desirable, whenever possible, to give cortisone locally rather than systemically, in order to limit the depression of the defence mechanisms.

PERIPHERAL NEURITIS IN
MYELOMATOSIS

BY

R. S. CROW, M.B., Ch.B., M.R.C.P.

Senior Medical Registrar, Bristol Royal Infirmary*

[WITH SPECIAL PLATE]

In myelomatosis there is a high incidence of neurological lesions. Neurological abnormalities were reported by Geschickter and Copeland (1928) in 40% of 425 cases, by Batts (1939) in 35% of 40 cases, by Adams *et al.* (1949) in 35% of 61 cases, and by Snapper *et al.* (1953) in 40% of 97 cases. The commonest type of lesion is direct compression of nervous tissue or its blood supply by a pathological fracture or tumour mass (Davison and Balser, 1937; Clarke, 1954). Occasionally vascular thromboses or haemorrhages due to gross abnormality of serum globulin occur (Wintrobe and Buell, 1953; Marshall and Malone, 1954). Rarely the meninges, and with them cranial or peripheral nerves, are infiltrated by direct spread from tumour tissue (Sparling *et al.*, 1947). Extramedullary deposits of myeloma, which have been found in most organs, have not been reported in nervous tissue.

Peripheral neuritis, distinct from these mechanical or vascular lesions, also occurs in myelomatosis. Senator (1899) reported a case with bulbar palsy for which no anatomical cause was found. Scheinker (1938) described the case of a man of 39 with a solitary myeloma of the sternum who had a painful progressive peripheral neuritis. This patient also developed two large patches of thickened, deeply pigmented skin on the anterior chest wall. Scheinker postulated a specific "toxic" metabolite of myelomatous tissue which affected skin and peripheral nerves, and he suggested that in many cases the pain of myelomatosis is due to a "toxic disease" of the nerves. Davison and Balser (1937) reported a case of multiple myelomatosis in a woman of 49 who had a painful peripheral neuritis mainly affecting the arms. There was an iron-deficiency anaemia (haemoglobin 50%), and they attributed the neuropathy to the "severe secondary anaemia" or to "unknown toxic factors." Kurnick and Yohalem (1948) described extensive painful peripheral neuritis in two cases of multiple myelomatosis, and regarded the neuropathy as comparable with that which occurs in "some metabolic diseases such as diabetes and pernicious anaemia." Snapper *et al.* (1953) mention four cases with "glove and stocking" type of peripheral neuritis, and also several cases showing "striking atrophy of the interosseous muscles and the musculature of the arms without other evidence of neurological involvement." One of Brewer's (1948) cases had "some loss of feeling in the hands and feet."

The purpose of this paper is to report two further cases of myelomatosis with peripheral neuritis and other striking features.

Case 1

In May, 1953, a married man aged 54, who worked as a lorry driver, developed sudden pain and limitation of movement in the right shoulder without preceding trauma. These symptoms subsided in a few weeks, but mild intermittent pain persisted. About the end of 1953 a painless swelling

*Now Senior Medical Registrar, Royal Devon and Exeter Hospital, Exeter.

appeared in the region of the right acromion process and slowly increased in size. During that year his wife was concerned about a darkening of his skin and noted a "shininess" of his finger-nails.

In February, 1955, he first experienced a sensation of coldness and prickling in both feet with pain on walking. Thereafter weakness of the ankles and increasing numbness of the lower legs developed. Pain in the feet occurred even at rest, and there was oedema of the ankles in the evening. During the first half of 1955 he lost 17 lb. (7.7 kg.) in weight. On July 28 he was admitted to the Bristol Royal Infirmary. He complained of rapid increase in weakness, numbness, pain, and hyperaesthesia of the legs, now extending to the knees, and also the recent development of paraesthesiae and weakness of the hands. He had a good appetite and took a normal mixed diet with very little alcohol. There were no gastro-intestinal symptoms. The only previous complaints of note were a carpal tunnel syndrome of the left hand, which was completely relieved in May, 1948, by division of the flexor retinaculum, and an identical syndrome of the right hand early in 1953, which was only partially relieved by operation in March of that year.

The salient findings were as follows. General wasting; diffuse skin pigmentation of a dark grey-brown colour, most marked distally on the limbs, on the neck, and in the axillae; moderate clubbing of fingers and toes; increased opacity and pallor of the proximal three-quarters of all the finger-nails with loss of normal lunulae (Special Plate, Fig. 1); hyperhidrosis of palms and soles; soft oedema of legs. There was a painless, soft, fluctuant swelling over the right acromion process, over which the skin was hot, red, and shiny. In the right supraclavicular fossa were several enlarged, rubbery, discrete lymph nodes, and there was one smaller similar node in the left supraclavicular fossa. There was a severe peripheral neuritis with marked wasting and weakness of all the small muscles in both hands and of the finger flexors and anterior tibial muscles. Foot-drop was complete. In the upper limbs the only sensory change was loss of vibration sense in the hands, but in the lower limbs there was impairment of all sensation below the ankle-joints with extreme hyperaesthesia of the soles and calves. Deep reflexes could just be elicited in the arms, but were absent in the legs. The gait was "stepping" with sensory ataxia.

After his admission the peripheral neuritis progressed rapidly. Spontaneous pain and hyperaesthesiae were severe. Both sensory loss and weakness increased in severity, and extended proximally so that after three weeks he was unable to stand unsupported and had difficulty in shaving. Radiographs of the right shoulder were reported on as follows: "There is a multiloculated lesion involving the outer two-thirds of the spine of the right scapula and extending into the acromion process. It shows expansion of the bone and sclerosis at the margins of the translucent areas. There is a pathological fracture in the region of the base of the acromion process." (Plate, Fig. 2.) Radiographs of the rest of the skeleton revealed small, well-defined translucencies with sclerotic margins in the right ischium and left ilium. The chest was normal. There was no abnormality of the blood count, serum calcium or phosphorus, blood urea, fractional test meal, or five-day fat balance, and there was no proteinuria at any time. The E.S.R. was 11 mm. in one hour (Wintrobe). The serum proteins were 6.3 g. per 100 ml. (albumin 4.2 g., globulin 2.1 g.) with a normal electrophoretic pattern. In the cerebrospinal fluid there was increased protein, 264 mg. per 100 ml. on July 9 and 400 mg. per 100 ml. on September 10. The sternal marrow was normal, but that from the iliac crest contained 7% plasma cells.

A lymph node from the right supraclavicular fossa and a solid soft-tissue tumour arising from the right scapular spine were removed for histological examination. The tumour was a plasma cell myeloma, and in the node there was complete replacement of normal lymphatic tissue by myeloma cells.

Intensive parenteral vitamin therapy had no effect. At the end of September, 5 millicuries of radioactive phosphorus was given followed by radiotherapy, 500 r $\times$ 2 to each supraclavicular fossa and 300 r $\times$ 5 to the right scapula. During radiotherapy the neuropathy continued to extend, but the pain and hyperaesthesiae of the extremities were a little improved. Within a few weeks of his discharge from hospital on October 5, however, spontaneous pain recurred.

On December 14, 1955, he was readmitted. Pain in the limbs was now very severe, consisting of a constant painful tingling, with frequent exacerbations which occurred spontaneously or in response to minor external stimuli. There was no change in the physical signs apart from slight progression of the neuropathy. Blood count, E.S.R., and levels of serum calcium and phosphorus, plasma proteins, and blood urea were unchanged and there was no Bence Jones proteinuria. Hepatic function tests showed no abnormality. The C.S.F. protein was 150 mg. per 100 ml. with only slight increase in globulin. Radiographs showed the scapular fracture to be united and consolidated with some new bone formation. There were two small osteolytic lesions in the ribs and an increase in size of the pelvic lesions. Biopsy of skin, muscle, and sensory cutaneous (sural) nerve from the calf showed no significant abnormality.

The patient was given a course of injections, by slow intravenous drip, of 2-hydroxystilbamidine di-esethionate, totalling 2.8 g., in three weeks. The pain in the limbs was dramatically and completely relieved, improvement beginning within 48 hours of the first dose. Coincident with the relief of pain there was a considerable improvement in his general well-being but no significant change in the neurological signs. At the time of writing he is still free from pain and claims to be much better, but there is no objective improvement.

Case 2

A widow of 67 lost over 2 stones (12.7 kg.) in weight in the early months of 1954, but she felt well until May, when she began to have a sensation of coldness and tingling in both hands. Shortly afterwards painful paraesthesiae, hyperaesthesiae, and numbness of the feet with sensory ataxia developed. Towards the end of 1954 she became aware of dusky discoloration of the hands and feet and had paraesthesiae of the lips, while her hands and feet became weak and more painful and her gait more ataxic. Oedema of the ankles also developed. Her diet was normal, she had no gastro-intestinal symptoms, and never took alcohol. When first seen in December, 1954, there was pigmentation of the limbs. All modalities of sensation were impaired peripherally in the limbs and all the deep reflexes were absent, but there was no demonstrable weakness. Radiography of the chest revealed a well-circumscribed soft tissue shadow anteriorly in the upper mediastinum, and bone destruction of the lower two-thirds of the sternum with new bone formation on the anterior surface. The appearances were thought to indicate an osteogenic sarcoma of the sternum with a secondary lesion in the mediastinum.

She was admitted to the Bristol Royal Infirmary on February 24, 1955. She had been given intensive therapy with aneurin hydrochloride during the previous eight weeks, but there was no change in her neurological state apart from the development of weakness of the small muscles of the hands. The pigmentation of the skin, a dusky greyish-brown, was more marked and was most prominent distally on the limbs. There was oedema of the ankles. Apart from a slight prominence of the sternum at the level of the third costal cartilage there was no clinical evidence of the sternal or mediastinal tumour. The sternum was not tender. The relevant investigations were as follows. Blood count normal; E.S.R. (Wintrobe) 6 mm.; blood Wassermann negative; fractional test meal normal; serum proteins 7.4 g. per 100 ml. (albumin 3.9 g., globulin 3.5 g.). There was a trace of protein in the urine but no Bence Jones proteinuria. The C.S.F. protein was 80 mg. per 100 ml. Radiographs showed no change in the mediastinal or sternal lesions and no abnormality in the rest of the skeleton. A

pyruvate tolerance test gave normal results. Biopsy specimens from the sternal tumour showed it to be a highly cellular plasma-cell myeloma.

In April, 1955, the patient was treated with radiotherapy, 2,500 r $\times$ 10 to the sternum, and vitamin therapy was continued. There was no change in her symptoms or signs until six months after radiotherapy, when her symptoms began to improve, although no change in the objective signs took place. At the same time enlarged discrete rubbery glands became palpable in the axillae and the lateral chest wall, the serum proteins were abnormal (albumin 3.5 g., globulin 4.0 g. per 100 ml.), and there was increasing albuminuria with casts in the urine. From this time she refused further treatment and all investigations except blood examination.

In February, 1956, she was almost symptom-free and her general condition was maintained, but there was no objective change in the neuropathy or the pigmentation.

Review of Earlier Cases

Prompted by the unusual features of these cases, the records of 14 other consecutive cases of myelomatosis admitted to the Bristol Royal Infirmary between 1950 and 1955 were reviewed. Two of these had features suggesting peripheral neuritis. One patient, a woman of 62, had complained of tingling of the fingers, numbness below the knees, and painful feet for one year before admission. The other, a man of 58, was found to have "particularly noticeable" wasting of the small muscles of both hands, although no reflex or sensory abnormality was noted. There is a close resemblance between the latter case and those mentioned by Snapper *et al.* (1953). Skin pigmentation and clubbing were not found in any of these patients.

Comment

The initial radiological appearances were not characteristic of myelomatosis in either Case 1 or Case 2, and a diagnosis was reached only after biopsy. The high incidence of atypical radiological findings has been stressed in recent reviews of this disease (Bayrd and Heck, 1947, and others), and the diagnostic difficulties encountered have been well reviewed by Heiser and Schwartzman (1952).

In both cases there was lymph-node involvement. This occurrence in myelomatosis, though infrequently mentioned in the literature, is not rare. Churg and Gordon (1950) found such involvement in 18 of 28 consecutive necropsies, and in five of these cases superficial lymph nodes were affected.

Pigmentation was striking in both cases. It was a uniform greyish-brown most marked on the extremities and neck and in the axillae. It is interesting that in Scheinker's case with peripheral neuritis there were localized patches of thickened, deeply pigmented skin. The only other writers to comment on pigmentation in myelomatosis are Adams *et al.* (1949), who describe a "peculiar dusky sallow" coloration associated with the pallor of anaemic cases, but pigmentation is noted without comment in a number of case reports (Geschickter and Copeland, 1928: Case 3; Stewart and Parkes Weber, 1938: Case 3). This pigmentation is probably akin to that seen in malignant disease, which in spite of advances in our understanding of abnormal pigmentation is still unexplained (Lerner, 1955).

Mendlowitz (1942) in his exhaustive review of finger-clubbing did not mention myelomatosis as a cause, but Snapper *et al.* (1953) noted the presence of clubbing of the fingers in a few cases in their large series. In Case 1 clubbing developed before the onset of symptoms. There was no accompanying pulmonary, mediastinal, hepatic, or intestinal disease. The curious "white nails" seen in this case were also reported in myelomatosis by Snapper *et al.*, and have been described by Terry (1954) as occurring in hepatic and other diseases, including malignant states.

Discussion

From the scanty references in the literature and the present two cases there can be no doubt that peripheral neuritis occurs in association with myelomatosis. The finding of two

suggestive cases in a retrospective survey of 14 others may indicate that the occurrence is not very uncommon. There is nothing distinctive about the nature of the neuropathy. In the present cases, as in most of those previously reported, spontaneous painful paraesthesiae and cutaneous and muscular hyperaesthesiae were prominent features. But in Case 1 the condition was predominantly motor, while in Case 2 it was almost entirely sensory. In Case 1 it advanced steadily, whereas Case 2 improved spontaneously even though the myelomatosis was progressing. In neither case was there any response to treatment with vitamins or radiotherapy, nor in Case 1 with radioactive phosphorus.

The pain of the peripheral neuritis in Case 1 was dramatically relieved by stilbamidine. A similar effect is recorded in two cases by Kurnick and Yohalem (1948). This lends some support to Scheinker's suggestion that the pain of myelomatosis may be neurogenic, for stilbamidine frequently relieves the pain, which is the commonest symptom of this disease.

Both cases showed an increase of protein in the C.S.F. In the cases with peripheral neuritis reported by others the C.S.F. protein has been recorded as normal in two (Davison and Balser, 1937; Kurnick and Yohalem, 1948) and raised (200 mg. per 100 ml.) in one (Scheinker, 1938). In myelomatosis, however, an elevated C.S.F. protein, unrelated to neurological or vertebral involvement, is not an uncommon finding (Degenhardt and Sheehan, 1949) and is probably often a general manifestation of the disease (Madonick and Solomon, 1953).

Little is known of the pathological changes. Scheinker (1938) described an unusual proliferation of connective tissue in the peripheral nerves of his case, and a similar proliferation in the affected areas of skin. Davison and Balser (1937) found degeneration of anterior horn cells and patchy demyelination and axon degeneration in peripheral nerves. The biopsy specimen in Case 1 revealed no abnormality of skin or sensory nerve.

Abnormal protein metabolism was considered as a possible cause of this neuropathy, since amyloidosis of the "primary" type is a not uncommon complication of myelomatosis (Lichtenstein and Jaffe, 1947; Kolff and Dhont, 1948) and "primary" amyloidosis can cause peripheral neuritis (Navasquez and Treble, 1938; Kernohan and Woltman, 1942). In neither case, however, was there any clinical evidence of amyloidosis, and in Case 1 biopsy revealed no amyloid in skin, muscle, peripheral nerve, or their blood vessels. The Congo-red absorption test was not carried out, as it is not applicable to this pathological type of amyloidosis (Snapper *et al.*, 1953).

It is tempting to relate this neuropathy to that occurring in bronchogenic carcinoma (Lennox and Prichard, 1950; Henson *et al.*, 1954). Such "carcinomatous neuropathies" have shown very similar features and they often run a course unrelated to the course of the underlying disease, a peculiarity observed in Case 2. But the only apparent common factor in the two diseases is that both are neoplastic. It is true that both Bence Jones proteinuria and plasmocytosis have been reported in bronchogenic carcinoma (Hughes, 1954), but such occurrences are very rare and appear to bear no relation to carcinomatous neuropathy.

Although no explanation can be offered to account for the neuropathy nor for the pigmentation and clubbing in these patients, it is hoped that this account of such an unusual association may lead to the recognition and study of further cases.

Summary

The types of neurological involvement in myelomatosis are briefly surveyed and the literature concerning peripheral neuritis in myelomatosis is reviewed. Two cases are described in which myelomatosis (proved by biopsy) was associated with peripheral neuritis and diffuse pigmentation of the skin. One case had in addition clubbing of the fingers and toes and increased opacity of the finger-nails.

A retrospective survey of 14 other cases of myelomatosis revealed two cases with features of peripheral neuritis. It is suggested that this complication of myelomatosis may not be rare.

The clinical and pathological features of this type of peripheral neuritis are considered, but no distinctive characteristics can be ascribed to it. Similarities to reported cases of peripheral neuropathy complicating bronchial carcinoma are pointed out.

The pigmentation and "white nails" are regarded as being features of the underlying malignant disease, although the mechanism of their production is unknown.

The dramatic relief of neuritic pain by treatment with stilbamidine in one case supports the theory that the pain of myelomatosis is neurogenic.

I am indebted to Dr. J. A. Cosh for permission to follow up and to publish Case 2; to Dr. R. M. Norman for special studies of the nerve biopsy in Case 1; to Dr. F. G. M. Ross for radiological reports on Case 1; and to the Medical Photographic Department, University of Bristol, for the photographs. My thanks are especially due to Dr. A. M. G. Campbell for permission to publish Case 1 and for much help and advice.

"Francis Galton once showed that, in the British peerage, wealth in women was correlated with infertility. An heiress by definition comes of an infertile family, for otherwise there would be many to share her wealth, and many noble families have become extinct through the love of heiresses whose riches were matched by their infertility. We may now put forward another rule, that not only wealth but also nobility in women is likely to be associated with infecundity. Attractive girls will usually marry, and the fecund will have large families while the less fecund will do their best and will certainly leave some descendants in future generations. Unattractive but highly fecund girls will be less likely to marry; but those that do will have plenty of children so that, as a group, the unattractive but fecund will also leave descendants. However, the group that is both unattractive and infecund will be at a double disadvantage and so will tend to be under-represented in future generations. Consequently, in each generation, owing to the elimination of this last group, we would expect to find that the mean fertility of nubile and attractive mothers should be below that of the less attractive."—C. B. GOODHART, *Nature*, September 15, 1956.

RENAL TUBULAR OSTEOMALACIA TREATMENT OF A CASE WITH DIHYDROTACHY- STEROL AND MANAGEMENT OF A SUBSEQUENT PREGNANCY

BY

G. ALAN ROSE, M.A., D.M.

Medical Unit, University College Hospital, London

[WITH SPECIAL PLATE]

In the first careful metabolic study of so-called resistant rickets Albright *et al.* (1937) described the case of a 16-year-old boy who was known to have had rickets for 14 years despite repeated therapy with what had been considered adequate doses of vitamin D. The metabolic abnormalities—inability to absorb normal quantities of calcium and phosphorus from the diet, hypophosphataemia, and a high plasma alkaline phosphatase content—as well as the radiological signs were characteristic of long-standing classical rickets. However, the abnormalities could be reversed only by increasing the daily dose of vitamin D to 450,000 i.u. (11.25 mg.). Since then sensitivity to vitamin D has also been reported in increasing numbers of cases of a somewhat different syndrome in which renal damage was accompanied by an osteodystrophy. Thus Liu and Chu (1943) reported five cases of renal failure with uraemia in which osteodystrophy ("osteomalacia") was accompanied by lack of response to calciferol in a daily dosage of up to 60,000 i.u. (1.5 mg.), whereas "A.T.10" (dihydrotachysterol), 3 ml. a day (containing presumably 3.75 mg.), was markedly effective in promoting a positive calcium balance in both of the patients given this therapy.

Albright and Reifenstein (1948) recognized another renal osteodystrophy in which the renal tubules were damaged more than the glomeruli ("renal tubular insufficiency without glomerular insufficiency"). Failure of renal tubular action in such cases is shown by impaired ability to produce an acid urine or ammonia. This leads to acidosis and hypercalciuria, which in turn causes subsequent development of osteomalacia, without, however, conspicuous signs of nitrogen retention or other signs of chronic renal failure. Dent (1952) presented a new classification of the various types of renal rickets (or osteomalacia) (see also Jackson and Linder, 1953), according to which the renal damage is either mainly glomerular or else mainly or purely tubular. The tubular conditions are then subdivided into six types, which are similar to each other in showing a high renal clearance for phosphate, but differ in the extent of further renal tubular damage. Thus Type 2 shows glycosuria and Type 3 glycosuria and aminoaciduria, and Types 4-6 show an inability to acidify urine.

Recently an opportunity occurred of studying in detail a case which could be described as one of Dent's Type 1 renal tubular osteomalacia. The case was of particular interest in several respects. The patient presented at the age of 19 in an early stage of the disease, and the diagnosis was made elsewhere before any marked bony deformities had occurred. Within a year after treatment was instituted at University College Hospital her symptoms and signs had been completely relieved, she had married, carried a pregnancy to full term, and been delivered normally of a healthy son.

A search of the literature reveals few other cases of this disease. McCance (1947) described a girl with a

similar condition, which he attributed to raised resistance to vitamin D acquired at about the age of 15 years. He considered that cases described by Leedham-Green and Golding (1937-8), Michaelis (1932), and Monier-Vinard (1940) were probably similar, although proof by calcium-balance studies or cure with massive doses of vitamin D was never demonstrated.

Dent and Harris (1956) have extended and reconsidered the classification of the various hereditary forms of rickets and osteomalacia. The patient whose case is now reported has the disease which they briefly describe under the heading "Severe osteomalacia presenting in early adolescence or adult life and very closely mimicking deficiency of vitamin D," and is included among the four cases they quote as having studied personally. They note that this clinical variety is conspicuous for the severity of the signs and symptoms and for its usual intractability to treatment.

Case History

A 19-year-old girl clerk was referred to Dr. Dent at the Metabolic Ward of University College Hospital by Dr. T. D. Kellock, of the Connaught Hospital, Walthamstow. During her school life she had been healthy, she had been athletically inclined, played tennis and swam, and competed well with others in her class. She left school at 16. Three months later she began to experience dull aching pains in both hips. At first this was no more than a "stiffness" which would wear off with exercise, and she was able to carry on with her work for another two years, during which, however, the pains became much more severe. At 18 she fell down the stairs, but suffered no ill effects other than mild concussion. Two months later her lower ribs began to ache and were tender on palpation, this being especially noticeable on turning over in bed. She also developed a low backache which was worse after walking or stooping; it did not radiate. She sought advice for these symptoms and was seen at the Connaught Hospital at 18½, when she was found to have osteomalacia with "typical Looser's zones in several ribs and in the pelvis." She was treated with calciferol, 10,000 units (0.25 mg.) intramuscularly per day and calcium lactate, 30 g. orally per day, and after six weeks on this regimen she was a little better, but her symptoms recurred when treatment was stopped.

At the age of 19, in December, 1954, she was admitted to the Metabolic Ward at University College Hospital. She then had all the symptoms described above. Her activities were severely restricted by the pains in her hips and she had developed a waddling gait. On rising to walk she was obliged to wait a few minutes before setting off, as she felt unsteady on her feet. She had not actually been subject to falls, however. Her description suggested that some muscular weakness was present, but it was difficult to decide whether the waddling gait was due to this or to the associated pain on walking. Her appetite had been a little diminished in the previous year and her weight had fallen from 9 st. 10 lb. (61.688 kg.) to 8 st. 6 lb. (53.524 kg.). She had no particular food fads. There were no abnormalities of urinary, bowel, or menstrual function. She had noticed no loss of height. Her other past history was non-contributory. She had four older siblings; all were healthy, and there was no family history of bone disease.

Clinical Examination

She was a healthy-looking young woman with no abnormalities in the cardiovascular, respiratory, or alimentary system. Her height was 63½ in. (1.613 m.); crown to pubis, 30½ in. (0.744 m.); pubis to heel, 32½ in. (0.825 m.); span, 65½ in. (1.663 m.). These body proportions suggest some recent loss of trunk length. There were no stigmata of old rickets and no bone deformities. The sternum, lower ribs, and vertebrae were tender to palpation. External rotation

and abduction of the right hip were slightly limited by pain, but there was no limitation of movement of other joints. A sustained ankle clonus could always be elicited on each side, but no other abnormalities were found in the central nervous system. Muscular power was good and there was no wasting.

Investigations

Plasma sodium 140, potassium 5.4, chloride 102, and bicarbonate 22.8 mEq per litre; calcium 10.4 and phosphorus 2.1 mg. per 100 ml.; alkaline phosphatase 22.5 King-Armstrong units.

On routine urine examination no abnormalities and no reducing substances were found. A standard amino-acid chromatogram revealed a marked excess of glycine but no generalized aminoaciduria. The pH of an early morning urine sample was 5.16. Blood urea, 33 mg. per 100 ml.; standard urea clearance, 91% and 70%. Urine concentration and dilution tests gave specific gravities of 1024 and 1002 respectively. Maximum urea concentration, 3.8%. The phosphate clearance was persistently high for the plasma level, and the phosphate T_m (maximal tubular excretory rate) low. The measurements of phosphate excretion before and after dihydrotachysterol treatment will be reported elsewhere (Anderson, Dent, and Senior: in preparation).

A six-day fat-balance study showed 97% absorption on a diet containing 68 g. of fat per day.

Radiological examination showed well-formed bones with a very slight degree of decalcification of the central bones. Looser's zones were present in the ischial rami and in ribs R 2, 10, and 11 and L 11 (Special Plate, Figs. 1 and 2). The renal outlines were normal and there was no nephrocalcinosis. There were no signs of hyperparathyroidism.

Course and Treatment

A diagnosis of renal tubular osteomalacia (Dent, Type 1) of recent acute onset was decided upon and confirmation of this was sought by calcium-balance studies. Full details of the results will be published later, when it is hoped to review this particular syndrome more fully, but may conveniently be summarized here. During two six-day control periods the faecal calcium was high and urine calcium low, and there was a very slightly positive balance. Treatment with pure dihydrotachysterol, 5 mg. a day for 13 days, then 2.5 mg. a day for 10 days, was given, followed by a maintenance dose of 1.5 mg. a day. The faecal calcium rapidly fell to very low levels, the urine calcium rose to high-normal levels, and the positive calcium balance increased to about 600 mg. a day. The plasma phosphorus level rose from 2 to over 3 mg. per 100 ml. There were no marked changes in levels of plasma urea, bicarbonate, or calcium.

During the first two weeks of treatment she experienced some curious feelings of stiffness in various parts of the body. These then disappeared, and on February 8, 1955, after 31 days of treatment, she was discharged on a daily maintenance dose equivalent to 1.25 mg. of dihydrotachysterol taken in the form of two capsules of crude A.T.10. She was then in much better clinical condition; the waddle in her gait had greatly diminished and her aches and pains almost completely gone. Radiographs showed the formation of callus around the pseudo-fractures (Special Plate, Figs. 3 and 4). She married the following month, having been told there was now no clear contraindication to such a step. She has remained to date (January, 1956) on the same maintenance dose of A.T.10, and has been virtually symptom-free since her discharge. Her gait has become normal and x-ray examination has shown progressive healing of the pseudo-fractures.

Pregnancy and Puerperium

In April, 1955, she became pregnant; the pregnancy was uneventful, and no symptoms developed other than occasional "heartburn" in the last month. It was decided

that she should be allowed to have a natural labour in the Obstetric Hospital under the care of Professor Nixon. On December 28, two weeks before the expected date of delivery, she gave birth per vaginam to a 7½-lb. (3.4 kg.) boy, after an uneventful labour. At the time of delivery blood was obtained from the mother and from the umbilical cord of the infant. Plasma values were as follows:

	Calcium (mg. per 100 ml.)	Phosphorus (mg. per 100 ml.)	Alkaline Phosphatase (King-Armstrong Units)
Mother	10.0	3.2	22.5
Infant	11.7	4.9	11.9

The puerperium was uneventful. On January 5 the infant's plasma was found to contain 10.0 mg. of calcium and 7.3 mg. of phosphorus per 100 ml., and 12 K.-A. units of alkaline phosphatase. Mother and infant were discharged on January 7, the former still continuing on the same maintenance dose (1.25 mg. per day) of A.T.10. Lactation was suppressed by stilboestrol, starting with a dose of 18 mg. a day on the day of delivery and being steadily reduced to nil during the next 16 days.

Discussion

This case presents several features of particular interest. It fits in very well with Type I renal tubular osteomalacia of Dent (1952) in that it had clinical, biochemical, and radiological evidence of osteomalacia with a renal-tubular loss of phosphate ion. The production of an acid urine was possible, but there was no glycosuria or general aminoaciduria apart from an excessive excretion of glycine. The amino-acid excretion is considered by Dent and Harris (1956) to be characteristic of the condition. The patient's athletic record, as well as her build and radiological appearances, leave little doubt that she was a normal, healthy adolescent until the age of 16, when her calcium and phosphorus metabolism must have undergone a sudden change. The onset of symptoms was gradual but characteristic. Vague pains in the thighs, hips, and back were first attributed to "rheumatism." Later the lower ribs became tender and she developed a waddling gait. The latter symptom is frequently seen in any form of osteomalacia; it was also described by McCance (1947) and by Leedham-Green and Golding (1937-8) when reporting cases clinically resembling the present one. The latter authors also referred to hesitation before walking, as was present in this case. The cause of these two symptoms remains obscure, but they may be the earliest signs of the muscular weakness which is usually a more marked feature of the condition.

That the patient fell down the stairs was fortunate in leading to x-ray examination of her bones; pseudo-fractures were found in otherwise comparatively normal bones, enabling an early diagnosis to be made. These pseudo-fractures are the zones of reconstruction (Umbauzonen) described by Looser (1920), and considered by Dent and Hodson (1954) to be signs of any relatively acute form of osteomalacia. There is as yet no accepted explanation of why and where the zones appear, although recently Le May and Blunt (1949) and Steinbach *et al.* (1954) claim to have shown that they are caused by the pulsations of arteries which they have demonstrated to be overlying them.

The nature of the disease was confirmed by the calcium-balance and other biochemical investigations. A plasma alkaline phosphatase definitely higher than normal was found on admission and taken to suggest biochemical disease of bone. No renal glomerular damage could be detected, and a mild metabolic acidosis was accompanied by a low plasma phosphate level, presumed to be due to a low renal threshold for phosphate ion, a low urine calcium, and a high faecal calcium. These findings are also characteristic of the other forms of rickets and osteomalacia which mimic vitamin-D deficiency without being caused by it, and are

therefore often called "resistant rickets or osteomalacia." Treatment, first in the form of pure dihydrotachysterol and then of A.T.10, cured the symptoms, raised the plasma phosphorus level (and presumably the renal threshold for phosphate ion), established a large positive calcium balance, and led to calcification of the Looser zones. With treatment the plasma alkaline phosphatase value also fell to normal, to rise again only during pregnancy; even then it did not rise above the level considered normal for pregnancy by Beck and Clark (1950). It had returned almost to normal a week after delivery. The excellent clinical response occurred in spite of the customary statement on the bottle of A.T.10 that "this substance has no antirachitic action." The current view in this laboratory is that dihydrotachysterol has excellent antirachitic action in the human subject and can be considered in every way as a form of vitamin D. No alkali was given and the degree of acidosis remained unchanged throughout, indicating that the acidosis is not the cause of the bone changes.

The diagnosis was made by Dr. Kellock and the patient subsequently treated by us before any significant deformities had occurred, so that after treatment she had no residual disability. Her pelvis was obstetrically satisfactory and her labour uneventful.

Early diagnosis and treatment can hardly be more rewarding, and their advantages need no further stressing. Failure to diagnose and treat this condition, however, results in rapid progression with development of deformities which are crippling (Dent and Harris, 1956) and irreversible.

It is not yet clear whether this type of adolescent osteomalacia is inherited. There was certainly no family history in this case. Even if the infant of an affected mother should develop the same disease in adolescent life, it would still probably be normal at birth and for the first few years of life. In the present case there was the further danger, however, that the treatment of the mother with dihydrotachysterol might affect the infant by causing a hypercalcaemia. The first analyses of the plasma of the infant were therefore awaited with some anxiety, and the cord blood, when obtained, showed a high calcium and low alkaline phosphatase content, suggesting a degree of vitamin-D intoxication. Hallman and Salmi (1953) have, however, shown that blood plasma travelling from the placenta to the foetus has a calcium content of 11-13 mg. per 100 ml. Clinically the infant thrived, and a week later its plasma values were normal. Its progress will now be followed with great interest and less anxiety.

It was considered highly undesirable that the mother should breast-feed the infant, since this would presumably greatly alter the calcium metabolism and consequently affect the requirement of A.T.10. Lactation was therefore suppressed by the method in routine use at the Obstetric Hospital.

The basic aetiology of this condition remains obscure, and no new suggestions are put forward here. The object of this paper is to describe the condition and to indicate how beneficial are the results of early diagnosis and therapy, even when there is the added strain of pregnancy.

Summary

A case is described in which a healthy adolescent girl suddenly developed renal tubular osteomalacia. She also showed some of the metabolic features of vitamin-D deficiency. These were reversed by oral administration of pure dihydrotachysterol and later A.T.10, resulting in rapid clinical and radiological improvement. Early therapy, before the development of deformities, resulted in complete functional cure, and she was able to sustain a normal pregnancy, labour, and delivery within 12 months of her first admission to hospital.

I wish to thank Dr. C. E. Dent for permission to publish this case and for his encouragement in the preparation of this paper.

My thanks are also due to Professor W. C. W. Nixon for supervising the patient's pregnancy and delivery, and to Messrs. Merck (Darmstadt) for a gift of pure crystalline dihydrotachysterol.

Medical Memoranda

Acute Haemorrhagic Leuco-encephalitis

Few cases of this condition have been reported since Weston Hurst (1941) described two cases of fatal encephalitis with specific macroscopic and microscopical appearances of the brain, which he named "acute haemorrhagic leuco-encephalitis." The disease consists of an encephalitis of acute onset, which is usually but not necessarily preceded by a prodromal upper respiratory infection. This is followed in some cases by a period of apparent recovery, before the onset of neurological symptoms leading to coma. In the cases reported the prodromal period had varied from 0 to 15 days, the intervening period from 0 to 11 days, and the neurological stage from 2 to 6 days, terminating fatally.

Post-mortem examination of the brain shows lesions confined almost entirely to the white matter of one or both cerebral hemispheres, but these may extend to the white matter of other parts of the brain. Some parts show only microscopical involvement. Macroscopically there are haemorrhages varying in size from pin-point up to a few millimetres in diameter. They are confined almost solely to the white matter and are associated with oedematous swelling of the adjacent tissues. Microscopically there are characteristic lesions: (1) perivascular ring and ball haemorrhages; (2) serous exudates; (3) perivascular polymorphonuclear exudates; (4) focal and perivascular demyelination; and (5) vascular degeneration with replacement of the wall by fibrinoid material, fibrinoid material in the lumen, and perivascular tissues.

Detailed descriptions of both macroscopic and microscopical lesions are given by Hurst (1941), and by Crawford (1954) in a paper reviewing the cases published to date. The aetiology is unknown.

CASE REPORT

A shop assistant aged 19 was admitted unconscious into hospital on February 9, 1955. The clinical history was taken from the parents and the general practitioner's letter. This girl developed acute glomerulonephritis at the age of 16. She was investigated and treated at the London Hospital. The nephritis became chronic. At the follow-up attendances albumin in the urine, moderate oedema of the ankles and legs, and a normal blood pressure were found.

About the middle of January, 1955, she developed a simple cold and a loose cough with moderate amounts of white sputum. Her condition improved, but nine days before admission she developed a temperature and left-sided

pleuritic pain, which subsided in two days with chlortetracycline (1 g. daily for four days). Three days before admission she felt less well and in the evening developed intense headache, nausea, and vomiting, which persisted until the onset of coma. The doctor examined her the following morning. Her temperature was 103° F. (39.4° C.) and pulse 100. She had mild photophobia, but no neck stiffness was present. Chlortetracycline was recommenced. On the morning of admission she was semiconscious and very restless and had been incontinent of urine.

On admission the patient, a well-built girl, was unconscious and extremely restless. She was picking at her lips and nose. Her temperature was 98.4° F. (36.9° C.), pulse 80, and respirations 20. She was incontinent of urine. There was no skin rash. She had conjugate deviation of the eyes to the left. The pupils were dilated and did not react to light. Nothing abnormal was seen in the optic fundi. There was trismus. The teeth appeared to be normal. The

Photograph of section taken from white matter of right occipital lobe. Stained with haematoxylin and eosin.

tongue, so far as could be seen, was coated and moist. There were sordes on her lips. Both eardrums appeared normal. The lungs were clinically normal. The pulse was regular and the blood pressure 160/90. A soft mitral systolic murmur was heard. There was no sacral or ankle oedema and the jugular venous pressure was not raised. A corneal reflex was present on both sides. The reflexes and tone in both arms were normal. The abdominal reflexes were absent. The reflexes and tone in both legs were increased. There was ankle clonus. The left plantar response was extensor. Neck rigidity, mild opisthotonos, and a positive Kernig's sign were present. The patient failed to respond to nociceptive stimuli on the left side of the body. A provisional diagnosis of pneumococcal meningitis was made.

Lumbar puncture showed a pressure of over 300 mm. and 5 ml. of slightly yellow opalescent fluid was removed, crystalline penicillin (20,000 units) was injected into the theca and 2 g. of sulphadiazine was given intravenously, followed by 2 g. intramuscularly every four hours.

Despite treatment she lapsed into deeper coma. The corneal reflexes were unobtainable and the arms and legs became flaccid. A gallop rhythm was heard over the praecordium. The patient died 17 hours after admission.

Investigations.—C.S.F.: pressure, 300+ mm.; cells, 2,000 (polymorphs 90%); protein, 620 mg./100 ml.; chlorides, 720 mg./100 ml.; sugar, 80 mg./100 ml.; no organisms seen on direct examination. The 24-hour culture was sterile. Post-mortem blood urea, 124 mg./100 ml. The urine contained albumin.

Post-mortem Examination.—Apart from the kidneys and brain, nothing abnormal was found. The kidneys were enlarged one and a half times by thickening of the cortex,

which was a pale yellow colour with some red streaking. There was a thin layer of subarachnoid haemorrhage round the mid-brain, especially in the cerebro-pontine angles. The vessels of the circle of Willis and its branches were not obstructed. There was a large area of ischaemic softening involving almost the whole of the right occipital lobe. Finger-like processes of a similar nature extended along the wall of the lateral ventricle on both sides, especially at the junction of the lateral, posterior, and inferior horns, and the hippocampus. The right basal ganglia were similarly softened and there were isolated zones in the right parietal white matter and in the mid-brain.

Histological examination of the white matter of the right occipital lobe beyond the edge of an area of softening showed lesions of a patchy nature separated by brain tissue which was apparently normal. The affected parts were centred on blood vessels, particularly the small venules. These showed a curious loss of structure of the vessel wall which was converted into the structureless eosinophilic material usually described as "fibrinoid," and, although the endothelium was absent and the fibrinoid material somewhat fragmented, there was no effusion of red corpuscles through the wall. Polymorphs, however, were present in large numbers in the lumen, in the wall, and in the tissue surrounding the vessels. Capillaries were hardly affected, but small flame-shaped and ring-shaped haemorrhages were seen (see Fig.), the latter surrounding small areas of necrotic brain tissue. Serous exudate was not found in the sections examined, but fibrinoid material appeared to have diffused out of most of the damaged vessels in the surrounding tissue.

I wish to thank Dr. G. R. Steed for advice and permission to publish this case, and Dr. M. R. Thomas for performing the necropsy and preparing the histological sections.

Case of Acute Haemorrhagic Leuco-encephalitis

Acute haemorrhagic leuco-encephalitis is a rapidly fatal disease of the central nervous system in which haemorrhagic lesions are found in the white matter of the brain. Crawford (1954) described three cases and found a further seven in the literature up to that time. Adams, Cammermeyer, and Denny-Brown (1949) described four similar cases under the name of acute necrotizing haemorrhagic encephalopathy.

Clinical Description.—The condition is commonest in young adults, but the youngest in Crawford's series was aged 2 years 10 months, and the oldest reported case was aged 51. It is commoner in males than in females. In most cases an acute upper respiratory infection precedes the neurological signs by a few days. The latter are acute in onset, with high fever, neck rigidity, sometimes convulsions, and paralyses with no characteristic distribution. The onset of coma is early and death follows in a few days. The cerebrospinal fluid usually shows an increase in cells, the maximum in Crawford's series being 220 per c.mm., but Adams *et al.* reported up to 5,000 per c.mm. Most of the cells are polymorphs. The protein is slightly increased in about half the cases; it was 140 mg. per 100 ml. in one of Crawford's. The sugar and chlorides were normal in three cases. Those cases in which the blood count was recorded showed a polymorphonuclear leucocytosis.

Pathology.—The meninges may appear normal or congested. The convolutions are flattened. The cut surface of the brain shows one or more pinkish oedematous areas, with numerous small haemorrhages of varying size, not more than a few millimetres in diameter, scattered through the white matter. The distribution is usually mainly in the cerebral white matter of either or both sides, often asym-

metrical, and may extend down into the cerebral peduncles, pons, and, less commonly, into the white matter of the cerebellum. The microscopical findings are described in detail by Crawford and are a combination of haemorrhage, vascular lesions, demyelination, and neurofibril degeneration. Fibrin impregnation of the walls of small vessels, and often the surrounding tissue, is characteristic. Perivascular collections of cells, especially polymorphs, are also seen. Adams *et al.* describe similar lesions.

CASE REPORT

A carpenter aged 50 was admitted to hospital on December 12, 1952, complaining of vomiting blood. He had had two episodes of gastro-intestinal haemorrhage, in 1945 and 1951, and pneumonia in 1951. He was treated by blood transfusion, and his condition on December 29 was satisfactory. On January 7, 1953, he had seven septic tooth stumps removed under penicillin cover. On January 10 he complained of headache and cough, his temperature rose to 101° F. (38.3° C.), and there were signs of bronchitis. Penicillin, 500,000 units twice daily, was prescribed. Next day the headache was worse; he complained of slight neck stiffness and was coughing up a little blood-stained sputum. A few rales were heard at the base of the right lung. Lumbar puncture gave a turbid cerebrospinal fluid at a pressure of 110 mm. with 1,400 cells (almost all polymorphs) per c.mm.; no organisms were seen or cultured. Penicillin, 500,000 units four-hourly, and sulphadiazine, 1 g. four-hourly, were prescribed.

On the 12th he was semiconscious, neck rigidity had increased, but there were no other neurological signs; he was incontinent of urine. Lumbar puncture gave a turbid C.S.F. at a pressure of 100 mm. The treatment was changed to intravenous chlortetracycline, 300 mg. twice daily, intrathecal streptomycin, 100 mg., and intramuscular streptomycin, 1 g. twice daily. Later in the day he was unable to swallow, and at 7 p.m. he suddenly became very pale, sweated profusely, and died within a few minutes. A tentative diagnosis of septicaemia and meningitis following the dental extractions was made.

Necropsy was carried out 16 hours after death; the body was that of a thin middle-aged man. The meninges over the brain and spinal cord were congested; no pus was found. The cut surface of the brain showed large numbers of small haemorrhages throughout the white matter of both cerebral hemispheres, extending down into the cerebral peduncles and in the white matter of the cerebellum. The spinal cord appeared normal. Thick mucus was present in the larynx, trachea, and bronchi; there was almost confluent bronchopneumonia at the base of the left lung, with patchy bronchopneumonia at the base of the right lung.

Section from the cerebral white matter, stained by phosphotungstic acid haematoxylin, showing exudate of fibrin and red cells in a perivascular space.

The stomach was congested, but no gastric or duodenal ulcer was found. There were no gross lesions in the other organs.

Microscopically the cerebral white matter showed extensive demyelination, haemorrhages round capillaries, and small arterioles, and marked perivascular infiltration, mainly with polymorphs. A few polymorphs were also scattered diffusely through the white matter. Fibrin impregnation was especially noticeable round capillaries, but also as fibrin plugs, and in the walls of some arterioles. Section of the left lung showed bronchopneumonia. The spinal cord was normal.

COMMENT

Diagnosis.—Clinically the present case resembled meningitis, and the failure to culture any organisms from the C.S.F. would not exclude it. In other cases an intracranial abscess or thrombophlebitis might be suspected, and middle-ear and other local infections would have to be excluded. The course of the disease is more rapid than in most cases of brain abscess. Adams *et al.* mention a similarity to epidemic equine encephalitis, which can be excluded in this country. Post-vaccinal and post-infective encephalitis usually run a milder course, polymorphs are not found in the cerebrospinal fluid, and there is a history of vaccination or an acute exanthem.

Necropsy.—Severe equine encephalitis and purpura can be excluded, as they are not confined to the white matter. Fat embolism may present a similar picture, but can be excluded histologically. Haemorrhages are not seen in other forms of encephalitis. There is no difficulty in excluding meningitis, brain abscess, or thrombophlebitis. In polyarteritis lesions will be found in other organs.

The aetiology has not been established; the following points, however, must be considered. (1) Bacterial: no organisms were isolated from the C.S.F. in the present case or any of Crawford's series. (2) Virus: Adams *et al.* were unable to transmit the disease to mice; Crawford could not transmit the disease from one case to a monkey. (3) Sensitivity to drugs is unlikely, as most of the cases occurred in previously healthy patients; the use of sulphonamides has been mentioned in only one case (Adams *et al.*); penicillin has been given only to the more recent cases. (4) The direct action of circulating toxins cannot be excluded. (5) Acquired hypersensitivity to an unknown antigen seems the most likely in view of the resemblance of the vascular lesions to those of polyarteritis and experimental hypersensitivity reactions (Crawford, 1954).

We wish to thank Dr. E. N. Davey and Dr. R. F. Jarrett for permission to publish the pathological and clinical details of this case, and Mr F. G. Warburton for the photomicrograph.

"Cruel Parents" is the title of a 25-page pamphlet written by two of the staff of the Institute of Psychiatry, London University—Dr. T. C. N. GIBBENS, senior lecturer in forensic medicine, and Mrs. A. WALKER, a psychiatric social worker. The pamphlet reviews the results of interviewing and examining clinically 32 men and 7 women sentenced to prison for cruelty to children which involved violence. As much information as possible about these offenders was also obtained from other sources such as the N.S.P.C.C. The pamphlet is published by the Institute for the Study and Treatment of Delinquency, 8, Bourdon Street, Davies Street, London, W.1, price 1s. 6d.

Reviews

BREAD THROUGH THE AGES

Breads White and Brown: Their Place in Thought and Social History. By R. A. McCance, C.B.E., F.R.S., M.A., Ph.D., M.D., F.R.C.P., and E. M. Widdowson, D.Sc., Ph.D. (Pp. 174+xi, 30s.) London: Pitman Medical Publishing Co. Ltd. 1956.

Since the beginning of this month the composition of the nation's flour, except for whole meal, has been left to the discretion of the millers, subject only to its containing stipulated quantities of vitamin B₁, nicotinic acid, iron, and chalk, and to an agreement that the improver agene will not be used. The appearance of this book by two eminent authorities on bread, therefore, has been nicely timed to attract widespread interest. If the nature of our daily bread is to be decided by a policy of *laissez-faire*, after a period of sixteen years of benevolent bureaucracy, it may be instructive to know what has happened in the past and to surmise what may happen in the future.

The period covered by McCance and Widdowson dates from 430 B.C. to A.D. 1955. A bibliography covers writers so diverse as Hippocrates, Plato, Virgil, Chaucer, Shakespeare, George III and V, Alphonse Daudet, Lloyd George, J. H. Plumb, and Mother Goose. Classical allusions abound, and for the full appreciation of the first chapter, on bread in early Mediterranean civilization, a knowledge of Greek and Latin will be helpful. The hours spent by the authors in libraries, and in consultations with colleagues well versed in the humanities, have borne fruit in a history of bread which is not only instructive but easy and fascinating to read. The eye is charmed by a richly coloured picture, supplied by the British Museum, which depicts the Duke of Lancaster entertaining the King of Portugal, together with several mitred bishops, to a fifteenth-century dinner, which seems to consist mainly of manchets of white bread.

After perusing chapters on mediaeval and modern England, the eighteenth century, peace and plenty (1820-1914), shortages and war (1914-21), return to plenty (1921-9), and the second war (1939-45), the thoughtful reader is left with the impression that the problems by which we are confronted to-day have been faced repeatedly before. Without going into ancient history we may note that brown or brownish bread was advocated in 1840 by Graham, in 1885 by Allinson, and in 1909 by a Bread and Food Reform League, which recommended a "standard bread" containing the wheat germ. The first two of these campaigns were prompted by a general assumption of the health-giving properties of whole meal, and by a religious belief that God had intended the wheat berry as the ideal food for man. During the third campaign, however, knowledge of the distribution of vitamins in the outer layers of the berry had begun to dawn. Advocates of fine flour countered the reports of higher contents of vitamins and minerals in the brown by claiming higher digestibility for the white. Throughout the years the weight of medical opinion has alternated between preference for brown or white, according to such new evidence as the protagonists of each colour have produced. During the first and second world wars, of course, shipping considerations favoured brownish flour, which enabled an increased yield to be obtained from each ton of wheat which was imported. Until recently, however, white flour has always been more popular with the public than brown flour. We are told by the millers that the same preference for the greatest possible whiteness is also shown between flour of 70% extraction and slightly off-white flour of 80% extraction, whenever these two types can be bought for the same price.

In their extensive experiments in German orphanages, which are briefly recapitulated in the present book, Widdowson and McCance were unable to demonstrate any differences between the nutritive values of various brown

and white flours, fortified or not with vitamins and minerals, as measured by their powers to promote growth and maintain health. Since children grew well on diets containing large amounts of bread, either white or brown, the conclusion was drawn that bread is a much more nutritious food than had previously been supposed. Except when the diet is otherwise lacking in B vitamins and iron, however, the importance of the superiority of brown bread in these nutrients is considered to have been overemphasized. The reader is left, therefore, with the impression that the star of white bread, made from 70% flour, is in the ascendant.

A semi-popular book obviously cannot deal with the statistical treatment of the complicated mass of scientific evidence which was obtained in the German experiments, nor would the review of such a book be a fitting place for a detailed discussion of this evidence. We may perhaps question the authors, however, on their stressing of all sorts of psychological and social motives for preferring white or brown bread, to the virtual exclusion of the simple question of taste. Thus we are told of doddering old men who have nostalgic memories of the kind of bread which they ate during their youth. Their recollected preference is apparently regarded by our authors as nothing more than "a psychological escape from the present to which a man has failed to adapt himself, or with which he cannot keep pace." If our bread follows the American pattern, we may well become familiar during the next few months with a material which has the consistency of sponge rubber and the insipidity of cotton-wool. It will be a poor consolation, if we dislike it, to be told that our objections are due not to the normal discriminating powers of our palate but merely to advancing senility.

T. MOORE.

FOOD

Hutchison's Food and the Principles of Dietetics. Revised by V. H. Mottram, M.A., and George Graham, M.A., M.D., F.R.C.P. Eleventh edition. (Pp. 630+xviii, 40s.) London: Edward Arnold (Publishers) Ltd. 1956.

Fresh air and adequate housing, proper rest and exercise, and good food are a great trinity of factors in the preservation of health; but the greatest of these is good food. Perhaps more than anything else the impact of two world wars has made us realize how far-reaching are the applications of the study of nutrition. They concern not only the sick but public health, agriculture, domestic politics, and world politics. While, therefore, the importance of nutritional science can hardly be overestimated, yet medical dietetics—a term which now tends to have the restricted connotation of the treatment of disease by specific diets—occupies a less important position than it used to do. Twenty years ago many of us were in the habit of prescribing the most complicated diets for a great variety of disorders. In these diets simple scientific principles were often forgotten and fashion and tradition made many impositions, but particularly restrictions, which were almost always inconvenient to the patient and often actually detrimental. Nowadays we recognize relatively few indications for the prescription of specific diets as opposed to simple nutritional advice. Diabetes, obesity, certain renal and hepatic diseases, the steatorrheas, oedematous states, and possibly gout probably complete the list.

Though the distinguished authors of the 11th edition of this well-known and excellent book continue to call it *The Principles of Dietetics*, yet they use the word "dietetics" in the sense given it by Sir Robert Hutchison when he published the first edition 56 years ago—namely, the study of food in relation to human need. Thus only about one-sixth of the work is devoted to the dietetic treatment of disease, and even this might be curtailed with advantage. It seems unnecessary, for instance, to describe a raw vegetable and fruit diet for the treatment of rheumatism. The scrupulous dietetic instructions for the treatment of peptic ulcer could be shortened, since few authorities now believe that the great problem of peptic ulceration is a dietetic one at all. The dietetic advice given for the treatment of achlorhydria

and flatulent dyspepsia is superfluous. With modern replacement therapy low-potassium diets in the management of Addison's disease are undesirable. And why on page 560 are mutton, venison, grouse, partridge, pheasant, whiting, sole, and turbot considered to be more "easily digested" than beef, snipe, woodcock, haddock, and plaice? Apart from these trivial criticisms, the book provides a store of useful and interesting information on food in which the practical aspects of nutrition take precedence over what is more severely scientific. The chapter on beverages has a peculiar charm.

HEART FAILURE

Advances in Cardiology. Edited by R. Heggin. With seven contributors. (Pp. 296+viii; illustrated. Sw. Fr. 39.50.) Basle and New York: S. Karger A.G. 1956.

This volume, which is partly in German and partly in English, forms the first of a series of monographs which will deal with various aspects of cardiological problems. Several authors contribute to it. The themes are most interesting and very important, for the disturbances of cardiac metabolism that underlie heart failure are particularly considered. First of all Szent-Györgyi writes on the chemistry of muscle contraction. The histological structures are beautifully illustrated and their interpretation is given in terms of function. This is all extremely interesting. The practical application or explanation of digitalis therapy is given, and the author concludes that one should not hesitate to administer digitalis even for mild degrees of weakness. The next article, by R. Bing, is on disturbances in myocardial metabolism—again most stimulating. Raab discusses adrenergic-cholinergic control; here there are nearly 600 references. Lenzi, of Siena, writes on electrolyte balance. In the German part of the book there is a chapter by Rothlin and Taeschles on the action of cardiac glycosides on the metabolism of the myocardium.

This book is an excellent survey of the latest views on how the heart-muscle fibre works, sickens, and dies, and how it may be revived to continue its work. Much has already been known darkly by the clinicians, but now it is getting clearer and we are coming face to face with reality.

TERENCE EAST.

ADVICE TO THE ORTHOPAEDIC SURGEON

Clinical Orthopaedics—No. 6. Editor-in-chief: Anthony F. DePalma. With the assistance of the Associate Editors, the Board of Advisory Editors, and the Board of Corresponding Editors. (Pp. 219+viii; illustrated. Subscription price 40s. Single copies 60s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

The publishers have announced the subject-matter for the subsequent six numbers of this series on clinical orthopaedics, which will become available during the next two and a half years. In this volume one section is devoted to endoprostheses and another contains a series of essays of general orthopaedic interest. Frederick Thompson writes a historical account of Barton and his work, and then makes his own observations on the indications and contraindications for a prosthesis. He considers that the outstanding indication is for salvage of a fractured femoral neck when treatment has failed, but he does consider there are other justifiable indications for the introduction of a prosthesis. Each chapter is written by a surgeon who has not lacked experience of arthroplasty, and there is no hesitation in revealing the difficulties and disasters that may have to be experienced by a patient. Thompson's criteria for operation are not accepted by other authors. Macfarland is enthusiastic and writes a helpful review of the use of prostheses in the joints of the upper limb. Robert O'Brien describes the operative details, the complications of operation, and the post-operative care when the Hueter approach is used. McKeever gives reasons why stainless steel and vitallium are suitable for a prosthesis, and suggests

that acrylic plastics and nylon are unsuitable; he describes how he lines the acetabulum with bone from the great trochanter when its base requires repair. Compere discusses the type of prosthesis suitable for the treatment of osteoarthritis of the hip-joint.

In the second section of the book is a variety of subject-matter all of interest to the orthopaedic surgeon, including essays on decubitus ulcers in a paraplegic and on the treatment of the foot of a diabetic patient. Charles Goff provides information on growth acceleration in Legg-Calvé-Perthes's syndrome from a study of 25 children treated by complementary feedings of aureomycin. He concludes that the growth acceleration was accompanied by an accelerated reossification of the femoral head, or of other growth centre which may have comparable pathological changes. Those studying the purely mechanical aspect of fracture treatment will be interested in articles by Hipps, Burke, and Bear and Johnson. Garrett Pipkin provides original illustrations to his article on infections subsequent to arthroplasty of the hip. To the last section of the book, headed "Items," John Charnley, with characteristic humour, has contributed an open letter written at a time when he was thinking of fibrositis, neurosis, and the shortcomings of other specialists. The concise nature of the articles and the good print and illustrations are helpful to readers, and the book deserves a wide circulation.

BRITISH PAEDIATRIC ASSOCIATION

The British Paediatric Association, 1928-1952. By H. C. Cameron. (Pp. 107; illustrated. 12s. 6d.) London: The British Paediatric Association. 1955.

This wholly delightful little book will bring back happy memories to all those who have been in any way linked with the British Paediatric Association during the last quarter of a century. It may well astound readers who have not followed and appreciated the rise of paediatrics in this country during this period, and it should certainly stimulate the younger paediatricians, who may learn what has been accomplished by a comparative handful of enthusiasts. There were not many people who could, from first-hand knowledge, set down the story of the association, and the choice of Dr. Hector Cameron, himself an original member, as archivist was singularly fortunate, for he has presented a concise and well-written "Part I" of the history of the association. There are eight excellent photographs of past and present worthies—more could have been included with advantage—and the book ends, rather sadly, with obituaries of the 21 members who died between 1940 and 1952. There is an appendix, contributed by Professor Moncrieff, which describes the history of the association's journal—*The Archives of Disease in Childhood*. It is inevitable that some highlights have been glossed over or omitted, but no one will cavil at the contents. The omissions may be remedied in the next instalment if, in perspective, it still appears in 1980 that they were in fact of outstanding significance either in the history of the association or in the advancement of paediatrics.

WILFRID GAISFORD.

In the eighth edition of *A Handbook of Ophthalmology*, by H. Neame and F. A. Williamson-Noble, three-colour plates have been replaced by improved versions, and the total of 13 such plates for a small book is very generous indeed. In the text, note has been taken of the newer developments in antibiotic treatment and on the use of cortisone, whilst on the surgical aspects descriptions of intracapsular extraction and the use of orbital implants have been amplified. Accounts of ocular toxoplasmosis and of retrolental fibroplasia appear for the first time. The book has retained its individuality and its character as a balanced exposition of the subject for the undergraduate. That no drastic revision was needed to keep this book up to date speaks for the soundness of the text; that some fifteen pages of extra text were incorporated is testimony to the thoroughness of the revision. The book is published by J. and A. Churchill Ltd., price 30s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 6 1956

METABOLIC UPSETS AND MIGRAINE

The signs and symptoms of migraine have become so familiar that even such bizarre features as sudden gains or losses in weight are accepted without comment. It is one of the complaints from which the patient always recovers, and in which there are interim periods of good health. Nevertheless, the life of the migrainous subject is spoilt by apprehension of an attack and by the uncertainty of being able to fulfil his engagements. He inevitably becomes nervous; his diet and sleep may become erratic, and by the time he seeks medical advice the prescription of remedies to be taken during an attack is usually insufficient to bring about a cure. His state of tension¹ is not always recognized, but long-term therapy has been advocated, for this will help him to understand "the basis of his tension, the factors which aggravate it and to aid him in resolving his conflicts."² While appreciating these psychological factors it is equally important to recognize that certain well-marked physiological changes occur in some of the sufferers. Not only does general oedema appear, which is responsible for the gain in body weight, but local oedema is found in the areas affected by headache. Further, the continuation of an irregular and inadequate diet may in some instances lead to a transient state of hypoglycaemia, which acts as the instigating factor for a migrainoid headache.³⁻⁵ Evidence has also been found in some cases of a deficiency of vitamin B₁, as shown by an abnormally high level of bisulphite-binding compounds in the blood.⁶

Of these phenomena the generalized oedema is the most interesting—and significant. It occurs in the prodromal phase of an attack of migraine and is associated with oliguria and salt retention.⁷⁻⁸ It disappears as the attack diminishes, usually with a coincident diuresis. Patients complain of being unable to fasten their skirts, to remove their rings, and even of an inability to wear their false teeth. Women are more often affected than men, and apparently accept these discomforts without complaint. These signs usually coincide with a premenstrual attack of migraine. Such cases may be a severe form of the premenstrual

syndrome,⁹ in which headache and tension regularly occur, especially in subjects who have a strong family history of migraine. Before menstruation there is a similar retention of water and sodium in the body,¹⁰ and a peak of oestradiol secretion.⁹ The same phenomena may occur in the middle of the menstrual cycle. Oliguria and water retention have also been observed as prodromal features of migraine in male patients. In a few cases of both sexes the reduction of salt in the diet and the prolonged administration of a mild diuretic such as urea¹¹⁻¹² have proved successful in preventing attacks. The part played by the sex hormones is still obscure. An attack of migraine can be induced by oestrin,¹³ and oestradiol will cause retention of sodium and chloride in dogs.¹⁰ Oestrogens, androgens, and progestogens¹⁴⁻¹⁵ can all cause retention of water, yet a high proportion of patients with premenstrual syndrome, and some of those suffering from migraine, respond favourably to treatment with a progestogen⁹ (in the form of ethisterone or progesterone). It is doubtful whether general retention of water plays any part in the production of headache, since this has been shown to be due primarily to vasodilatation² and to local oedema in the brain.¹⁶ Headache cannot in fact be promoted by inducing a state of overhydration,¹⁷ and recent experiments have shown that in migrainous subjects neither the imbibition of water alone or with an injection of pitressin, nor the administration of a large dose of salt together with an injection of D.C.A., will provoke an attack. Again, it has been reported from a limited series of experiments on individual subjects¹⁷ that the frequency and severity of a migrainous headache were unaffected by the removal of body fluid by a mercurial diuretic or by diamox, by the administration of a low-salt diet, or by the use of sodium-removing carbo-resins, although these measures reduced the fluctuation in weight to a minimum.

It is more probable that retention of sodium is the dominant factor which leads to retention of water.

OCT. 6, 1956

So far as the premenstrual syndrome is concerned it has been suggested that "the best working hypothesis is that which postulates a cyclical change in sodium⁹ (and therefore in water) metabolism, which occurs to a slight extent in sufferers from the premenstrual syndrome." Independent observations on migrainous patients of either sex have shown that a cyclical variation of sodium may actually take place.¹² Thus, in the successive phase of prodrome, attack, recovery, and interim, the level of serum sodium has been found to vary in an individual patient from 352 to 357 to 336 and to 332 mg. per 100 ml. respectively.¹² High levels of blood sodium are repeatedly found in association with headache, and are often accompanied by abnormally low levels of plasma proteins.⁶ Some interesting abnormalities have also been observed in headache-free migrainous subjects of either sex subjected to a water imbibition test.¹² Whereas in the control period preceding the test the excretion of sodium, chloride, and water was the same as in normal control subjects, after the imbibition of 1,500 ml. of water migrainous subjects showed a considerable increase in the amount of sodium and chloride excreted, although the water output was virtually the same as in normal subjects. But in the latter there was only a slight increase in the output of chlorides and an actual decrease in the excretion of sodium. These facts suggest that the imbibition of water provides the migraine subject with an opportunity of excreting an excess of sodium, but how the latter comes to be accumulated in the body is still unknown. These patients are characterized by a mental and physical hyperactivity which may well include an overaction of the adrenocortical and anti-diuretic hormones; these together are said to control the concentration of sodium and chloride in the extracellular fluid.¹⁸

The phenomenon of local oedema is of different origin. It occurs as a painful swelling in the area of the scalp or face affected by migrainous headache, and in the brain tissue. The local dilatation of the arterioles is said to be accompanied by a rise in intracapillary hydrostatic pressure, which favours the transudation of water and of certain chemical constituents of the plasma into the surrounding tissues.¹⁷ Vasodilatation has also been observed in the capillaries of the conjunctiva of the eye on the side affected by headache, and these vessels are found to be abnormally resistant to the application of vasoconstrictor agents. Vascular changes of a different character have also been observed in the nail-bed capillaries,¹⁹ which have been seen to dilate during an attack and to become blurred by a transudate. These phenomena

can be reproduced by inducing overhydration, and may be a visible symbol of the abnormal fluid exchanges which occur throughout the body during an attack of migraine. In conclusion it would appear that the knowledge of these physiological changes might be usefully applied in the diagnosis and treatment of migraine—particularly of the "classical" or premenstrual type.

SUICIDE AND ATTEMPTED SUICIDE

Since 1945 the suicide rate in England and Wales has fluctuated, with no clear upward or downward trend. Recent advances in psychiatric care and treatment, particularly the use of electric convulsion therapy in depressive states, has probably favourably affected it; but its expected wartime fall, coinciding with the development of these new methods of treatment, has made their impact difficult to gauge. Increased efficiency in the treatment of barbiturate poisoning has undoubtedly saved the lives of many potential suicides. But even so the present rate is still high enough to cause concern. In 1954 in England and Wales 5,043 people (11.3 per 100,000 of the population) took their own lives. In his annual report for 1954 the M.O.H. of Middlesex stated that in the economically important group of people aged 25-44 suicide was the second most frequent cause of death in Middlesex, the number exceeding that due to motor vehicles. Since in western civilization suicide is now relatively more common among older people, the suicide rate may also be expected to rise as the proportion of old people in our community becomes larger.

The methods of suicide adopted have altered over the years. Recently there has been a notable increase in suicides due to poisoning by drugs or gas; and, as E. M. Brooke¹ has shown, particularly since the end of the war, the taking of barbiturates has risen rapidly. Depressed patients are too often prescribed lethal doses of barbiturates, and these drugs are now

chosen agents in the great majority of cases of attempted suicide which are admitted to general hospitals.

Recent work in Britain, the U.S.A., and Scandinavia has added to our knowledge of suicidal acts, hitherto rather neglected by psychiatrists in their researches. P. Sainsbury² has made an important ecological study of suicide in London. He has shown that the London boroughs differ in their suicide rates, and that these differences correlate with the social characteristics of the localities; with their social isolation, mobility (whether of class, occupation, or neighbourhood), and disorganization (as evident in rates for divorce and illegitimacy). Sainsbury believes that social isolation provides a consistent explanation of the high incidence of suicide found in a wide variety of immigrants. This agrees with the experience recorded by Dr. E. B. Strauss at p. 818 of the *Journal* this week—"an appreciable proportion of the patients admitted into my observation wards after a serious suicidal attempt are old people who regard themselves as 'useless mouths' and who have lost all sense of honourable group-identity."

The relationship between attempted suicide and suicide is not straightforward. The former is much commoner. D. Swinscow³ has shown that under the age of 50 the majority of suicidal attempts are made by women, while after 50 the majority are made by men. But of those who commit suicide at any age the majority are men, and acts usually described as attempted suicides are not all suicides which have failed; some were never intended to succeed, in the sense of causing death. E. Stengel⁴ has drawn attention to the social element in the pattern of suicidal attempts, and has suggested that in most of these acts there is an appeal to others for help and intervention. He has further advanced the hypothesis that those who commit suicide and those who attempt it form two populations which overlap, but which differ in the representation of the sexes, in age, and in methods.

The later histories of those who attempt suicide lend some support to Stengel's hypothesis, which requires further detailed testing. From a one-year follow-up of 200 consecutive cases of attempted suicide I. R. C. Batchelor and M. B. Napier⁵ reported a subsequent suicide rate of 2%; R. W. Ettlinger and P. Flordh⁶ 3.6% in 500 cases. Similar or lower rates have been reported by E. H. Schmidt and his colleagues⁷ and Stengel⁴ in follow-ups over periods of eight months and five years. People who have

attempted suicide may of course continue to present social and medical problems, and further suicidal attempts, mental breakdown, delinquency, and disruption of the emotional lives of others may mark their subsequent careers. Furthermore, it certainly cannot be concluded in the individual case that someone who has attempted suicide is not very likely to commit it. American and Scottish studies report in old age completion of the suicidal act in 11-12% of cases^{8,9} within two years. In old age those who attempt suicide and those who commit it seem to come from very closely allied, if not identical, clinical groups.

Detailed clinical studies of some hundreds of consecutive cases of attempted suicide admitted to general hospitals have recently been made by Batchelor and Napier in Edinburgh, by Ettlinger and Flordh in Stockholm, and by Schmidt, O'Neal, and Robins in St. Louis, U.S.A. It is clear that suicidal acts form a continuous series, running from the superficial gesture intended to manipulate the environment to the determinedly fatal injury. Among younger people a heterogeneous collection of reaction types is found. Many of these patients are temperamentally unstable individuals, unable to solve conflicts in their personal relationships. Batchelor¹⁰ has studied those suffering from psychopathic states, who constitute probably at least one-fifth of those who attempt suicide, and has drawn attention to the repetitiveness and explosiveness of these acts, describing them as suicidal fits. Few of these acts can be forestalled, but more attention should be given, he suggests, to such traumatic factors as a broken home in childhood¹¹ and alcoholism.¹² H. Pozner¹³ has given an interesting description of the influence of the military environment on suicidal incidents. Detailed studies of cases of attempted suicide after the age of 60 have been made,^{9,14} which, though from different countries, give results that are strikingly in agreement. The attempts were usually serious, all the patients had a clinically diagnosable illness, the large majority were psychotic, and most were suffering from depressions. Once again the truth of the maxim is seen that in every depressive illness, at every age, there is a risk of suicide.

The assessment and immediate management of suicidal attempts has been the subject of a recent article in this *Journal*.¹⁵ Their prophylaxis now requires much more emphasis. We could make a beginning with an attack on the causes of social isolation in our cities, with its attendant loneliness.

But further research is required. Sainsbury² has suggested that comparative studies of attempted suicides should be made from selected districts with high and low suicide rates. Clinical, psychological, and social data should be sought together, and wherever possible control groups should be investigated.

SEX OF HUMAN NUCLEI

Until a few years ago observation of the sex chromosomes in man had been confined almost entirely to cells in mitosis, but the techniques were so specialized that they could rarely be applied to clinical problems. Nevertheless an immense amount of valuable knowledge accumulated, and the presence of the XX chromosomes in the female and the XY in the male was well established.¹ This enabled M. L. Barr to consider, with some certainty, that a mass of chromatin found in a high proportion of resting (intermitotic) nuclei of the neurons of female cats represented chromatin associated with the XX chromosome pair.² He later showed that a nuclear sex difference was present in almost all tissues of many species of mammal including man,^{3,4} and this work has been amply confirmed.⁵⁻⁷ W. M. Davidson and D. R. Smith^{8,9} showed a comparable morphological sex difference in the polymorphonuclear leucocytes in stained blood films. This has now been confirmed by many haematologists.¹⁰⁻¹⁴ Barr's method is usually applied to skin biopsy, but it has also been shown that smears of buccal or vaginal mucosal cells¹⁵⁻¹⁷ show the characteristic sex difference found in the tissues and like blood films can be obtained easily without inconvenience to the patient.

Mr. A. D. Dixon and Dr. J. B. D. Torr report in the *Journal* this week (p. 799) a study of oral smears; they found the procedure simple, but that accuracy of diagnosis increased with experience. There is no doubt that sex can be determined accurately by any of these methods, but the microscopist must have considerable special experience, and the preparations used must be of the highest quality technically or errors will occur. As there are no reports of discrepancies between the techniques, the particular one adopted will depend on the circumstances and personal preference.

The method of nuclear sexing has been fairly widely applied to the study of hermaphrodites; B. Lennox¹⁸ has recently reviewed the literature and examined the evidence in favour of the belief that the nuclear sex represents the genetic sex. As there is not always agreement between the genetic sex and the development of the external genitals and psychological outlook, it is often unwise to make known the genetic sex to the patient. For this reason Barr¹⁹ has recommended that female nuclei should be reported as "chromatin positive" and male nuclei as "chromatin negative." The male pseudo-hermaphrodite has testicular tissue and chromatin-negative nuclei, the female pseudo-hermaphrodite has ovarian tissue and chromatin-positive nuclei, while the true hermaphrodites have both testicular and ovarian tissues and may be either chromatin positive or negative. A case of true hermaphroditism is reported by Dr. J. D. Arneaud and colleagues at p. 792 of the *Journal* this week. Although the genetic sex was female, and female secondary sex characters developed, the patient was psychically male; surgical removal of the female components of the patient's body converted him into "a cheerful, normal young man." The independent observations of L. Décourt *et al.*²⁰ and P. E. Polani *et al.*²¹ have demonstrated the interesting fact that many apparently female cases of Turner's syndrome are genetically male, confirming the prediction of A. Jost made from experimental destruction of the gonads in the foetal animal.²² The determination of the genetic sex is therefore an important investigation in the classification of hermaphrodites. This applies particularly to the recognition of congenital adrenal virilism in infancy, when estimation of the 17-ketosteroid excretion may give equivocal results and early treatment with cortisone must be considered. In the management of cases of hermaphroditism seen in older children and adults L. Wilkins and colleagues have emphasized rightly the overriding importance of psychological, social, and anatomical factors.²³ Among other anomalies is the recently reported finding of chromatin-positive nuclei in association with testicular hypoplasia, which is of great theoretical interest.²⁴ Again, a discrepancy between the nuclear sex of the host and teratomata has been noticed and has stimulated discussion on the origin of these tumours.²⁵

L. Sachs and colleagues,^{26,27} as well as other workers,²⁸⁻³⁰ have shown that it is possible to predict the sex of the unborn child by examination of the desquamated epithelial cells in a specimen of amniotic fluid, and a further paper from Sachs's team appears this week in the *Journal* at p. 795. They now report the accurate pre-

natal diagnosis of the sex in 40 cases in the ninth month of pregnancy, and 8 cases in the third, sixth, and seventh months, as well as on an 8-weeks-old aborted foetus. There seems no doubt about the technical accuracy of this test, but the advisability of carrying it out has been questioned.³⁰

HEALTH SERVICE PRIORITIES

With its usual striking array of statistics the Ministry of Health has reported on the Health Service in England and Wales for the year 1955,¹ and in the preface Mr. R. H. Turton, the Minister, sets out his view of the three main priorities to-day. These are: "First, to bring existing hospitals to a satisfactory standard and to provide, as far as possible, new accommodation as and where it is needed; second, to ensure that the mental health services, with their high proportion of out-of-date buildings, receive a proper share of the new construction and the resources available; finally, to tackle the problem of making adequate provision for the care of old people." All three of these objectives will be achieved the more quickly in consequence of the revolution in the treatment of tuberculosis brought about by the newest methods. The long waiting-lists for beds of only a few years ago have so dramatically shortened that nearly everywhere they have disappeared, and in some areas beds are redundant.

The total number of consultants increased by 140 during the year to 6,650, while the number of senior registrars declined by 26 to 1,094. At December 31, 1955, 266 consultants were receiving "A" distinction awards (£2,500 p.a.), 665 "B" awards (£1,500 p.a.), and 1,330 "C" awards (£500 p.a.).

The number of principals in general practice at the end of the year was 19,756, of whom 18,978 were providing unrestricted services; 6,715 of these were single-handed, a decrease of 184 from the previous year's figure. "A gradual movement away from single-handed practice" is reported. Last year's report, as this one recalls, drew attention to the Minister's advice that the young doctor wishing to start in general practice should consider the north in preference to other parts of the country because the opportunities were better there. Whatever the opportunities may be, it seems that doctors on the average still prefer the south, though not so strikingly as to make the north an easy place to start in, if we may judge by the numbers of applicants for advertised vacancies. In the north in 1955 the average number of applicants for each of the 34 vacancies was 36; in the midlands for 16 vacancies it was 38; in the south for 28 vacancies it was 58; and in Wales for 6 vacancies it was 20. Comparing these averages with those for 1954 (north 31, midlands 35, south 46, Wales 20), the report comments that "so far it cannot be said that there has been a response to the Minister's advice." Possibly the advice did not appeal to young doctors because competition in the north, though less than in the south, is yet notably keen.

The drive for economy in prescribing goes on in odd contrast to the spate of political promises with which the Service was presented to voters a few years ago. During the year, says the report, the Pricing Offices supplied statistics to executive councils for transmission to general practitioners showing the average cost of a doctor's prescribing compared with the average for the area in which he practised. These statistics, the report adds, "were welcomed in most areas." As a result of the investigations into prescribing costs visits were paid by regional medical officers to 543 doctors and letters were sent to 1,225. The recipients of these attentions fell into line, for this was the first year in which no case of excessive prescribing had been referred to a local medical committee for investigation. In spite of all, however, the average cost of a prescription continued to rise—from 4s. 2½d. in 1954 to 4s. 4d. in 1955. But the Ministry does not compare these figures with the costs of many other articles which conspired to increase the general cost of living, so that their significance is more problematical than a casual reader of the report might suppose.

The Ministry has carried out much useful propaganda to diminish the number of accidents in the home, especially accidents to young children. A leaflet "to make parents more aware of their responsibility and stimulate action" is reported to have been favourably received, and the press and the B.B.C. were helpful in publicizing some of the quite simple ways in which these tragedies can be averted by a little foresight. As a corollary the Ministry might well encourage wage-earning children to look after their aged parents, and issue a leaflet "to make children more aware of their responsibility," for it is too often set aside.

HISTOPLASMOSIS IN BRITAIN

Since 1940 about a dozen cases of histoplasmosis have been recognized in Britain, all but two in the last five years. The causative fungus, *Histoplasma capsulatum*, was claimed to have been cultured from only half of these; diagnosis of the remainder was presumptive and based either on the association between radiological changes and results of histoplasmin skin tests, or on histopathological studies.

Infection by *H. capsulatum* may manifest itself in several ways. The initial infection after inhalation of spores may be inapparent clinically or radiologically. When pneumonitis is produced complete resolution often follows, but fibrosis or calcification, sometimes of typical distribution, may result. In such patients a positive skin reaction to histoplasmin, or possibly an anamnestic serological response, suggests the possible aetiological agent.¹ The cause of pulmonary calcification in patients who fail to react to either tuberculin or histoplasmin nevertheless frequently remains undetermined. In a

⁷ Mochi, A., and Edwards, P. Q., *Bull. Wld Hlth Org.*, 1952, 5, 259.

very small minority of cases infection may become generalized. All organs can be attacked, particularly lymph nodes, spleen, suprarenal glands, and the lungs; indolent ulcers of the upper respiratory and gastro-intestinal tracts commonly occur. Generalized disease is often rapidly fatal, and three such cases have been reported in Britain. Systemic histoplasmosis may also run a chronic course, sometimes with apparent arrest of the disease,² the larynx, lungs, lymph nodes, and oral structures being most commonly affected. It is possible that isolated lesions are sequelae to these chronic infections, possibly exemplified by the laryngeal lesion reported by H. E. Hutchison³ and various cases of cutaneous histoplasmosis, such as the two reported by Professor W. St. Symmers at p. 790 of the *Journal* this week. Yet another example may be the case of "histoplasmic lymphadenitis" reported by Symmers at p. 786, but the case history described is a complicated one. It recalls the successful isolation of *H. capsulatum* by J. E. Johnson and J. M. MacCurdy⁴ from a scalene lymph node of a patient with benign pulmonary histoplasmosis.

Symmers reports the first apparently unequivocal instance of histoplasmosis contracted in Britain; F. C. Poles and J. D. O'D. Lavertine,⁵ too, have suggested that a case of disseminated disease was acquired in this country, but their patient had travelled abroad. Dr. R. W. Riddell states in an article at p. 783 of this issue that there is no reason for supposing that the fungi responsible for histoplasmosis and similar systemic mycoses occur naturally in Britain. But these concepts are not necessarily incompatible. While it is tempting to postulate that further British cases will now come to light, it is sobering to recall that no further case of North American blastomycosis acquired in Britain has been recorded since G. B. Dowling and R. R. Elworthy's report in 1925.⁶

Histoplasmosis is contracted from infected soil or dust and not by contagion. The occurrence of *H. capsulatum* in the soil seems to be patchy in the United States, and, though this disease occurs throughout the world,⁷ prevalent skin sensitivity to histoplasmin has an irregular and limited geographical distribution. Many problems therefore require elucidation in the future, and critical laboratory standards are needed for this. The fallibility of histopathological diagnosis, except possibly in typical disseminated histoplasmosis, requires emphasis. The histoplasmin skin test, though non-specific, is informative in Britain, where the population is predominantly histoplasmin-negative, though its limitations are obvious for patients who have travelled overseas. Above all, critical identification and full description of fungi grown from pathological material are the only certain diagnostic criteria of infection.

NUFFIELD FOUNDATION

Many medical men have reason to be thankful to Lord Nuffield for financial assistance in some way or other, and the latest report of the Nuffield Foundation¹ shows how exceedingly varied are the researches being carried

¹ Nuffield Foundation Eleventh Report for the Year Ended March 31, 1956, 1956, Oxford.

out under its patronage. Started by Lord Nuffield with £10m., the Foundation has since 1949 devoted much attention to research in biology, and in view of the present interest in the possibility of genetic damage from radiation it is appropriate that grants should have been made towards the study of population genetics. In Northern Ireland, in a community of about half a million people, an attempt has been made to obtain reliable data on the frequency and distribution of specific genes, on consanguinity, and on inherited anomalies such as deaf mutism, dystrophia myotonica, arachnodactyly, and achondroplastic dwarfism. This work on human beings has been supplemented by studies at the University of Cambridge on plant mutation, with special emphasis on the modification of the effects of radiation by means of chemical agents, and on micro-organisms with a view to finding a chemical basis for genetical phenomena.

At the Anthropological Blood Group Centre information on the frequency of abnormalities of haemoglobin is being assembled, and at the Lister Institute of Preventive Medicine a long-term investigation into the relations between certain mucopolysaccharides and the serological specificity of human blood groups will also have a bearing on the problem of the so-called collagen diseases. Special attention has been paid to research on chronic rheumatic diseases, "which have till recently been somewhat neglected."

In the department of neuropathology at the Radcliffe Infirmary, Oxford, a new method of studying the after-effects of tuberculous meningitis has been developed with a view to explaining the nature of the mental changes and spasticity resulting from this disease. This investigation will probably add greatly to medical knowledge of degenerative processes in the nervous system as a whole. The use of plastics for splinting and prosthesis generally has been extended to the more intricate problems of bone replacement, and a biomechanical unit has been established at the Institute of Orthopaedics and King's College in order to apply the methods of mechanics to the study of forces and actions in the living body, with a prospect of future work on the flow of fluids and gases in the whole living organism.

Among social investigations being financed is a plan of research drawn up by the London School of Economics into the use of prison sentences by magistrates' courts; in view of the overcrowding in local prisons and the high average annual cost for each prison inmate, possible alternatives to short prison sentences are to be specially studied. The problem of the West Indian and other immigrants in the Brixton area forms one of a series of surveys being undertaken by the department of social anthropology in the University of Edinburgh. Among the projects for which grants have been made to countries of the British Commonwealth are studies of the enzymes of the endocrine glands, cosmic ray particles, and the chemistry of inositols in Australia; mediaeval manuscripts in Canada; the Christian Medical College and Hospital at Vellore, India; geochemical and cardiosurgical research in Africa; and family life studies in Jamaica.

SUICIDE*

BY

E. B. STRAUSS, D.M., D.Sc., F.R.C.P.

Physician, Department of Psychological Medicine,
St. Bartholomew's Hospital, London

A surgeon, I suppose, is more upset by a death on the table than by anything else. Most psychiatrists feel the loss of a patient by suicide as the most distressing professional accident, although in so many instances, even if a suicidal attempt ("successful" or otherwise) is predictable, we know it to be unavoidable.

Suicide can be studied from a great number of aspects: clinical, statistical, historical, psycho-analytical, social-psychological, forensic, ecological, moral, and anthropological.

I would like briefly to discuss suicide as an anthropological problem, using the word anthropology in a very wide sense, so as to include ecology, social psychology, religion, and ethics.

Although a great deal has been written on the subject of suicide, two works stand out as being of special importance: (1) *Le Suicide* by the late Professor Durkheim, published as long ago as 1897, and (2) *Suicide in London, An Ecological Study*, by Peter Sainsbury, published in 1955. The interesting feature, to my mind, about Dr. Sainsbury's valuable Maudsley monograph is that it so amply confirms the views of the well-known professor of sociology at the Sorbonne.

Before getting down to my main thesis, it would be as well, perhaps, to get the clinical aspects of suicide out of the way in as few words as possible by briefly considering suicide and attempted suicide from the strictly psychiatric point of view.

I shall precede these clinical remarks by trying to dispel a false impression which is almost superstitiously held by so many doctors and laymen alike: if a patient "talks" suicide, he is unlikely to attempt it. Nothing could be further from the truth.

Associated Mental Disorders

The mental disorders which stand out as being especially associated with a suicidal risk are: (1) cyclophrenia, as I prefer to call manic-depressive psychosis; (2) involutional depression, particularly the agitated form; (3) schizophrenia; (4) paraphrenia; (5) inadequate psychopathy; and (6) reactive and post-infective depressive states.

Anorexia nervosa, about which condition I have very individual views, is, of course, a slow attempt at suicide, but it is outside the scope of this paper.

Patients exhibiting the depressive syndrome of whatever origin are such obvious suicidal risks that if properly diagnosed they are for all practical purposes less of a risk than might be supposed. The trouble is that the diagnosis is so often missed, not only by general physicians but also by many (especially, perhaps, psycho-analytically trained) psychiatrists. Even in correctly diagnosed cases the suicidal risk is nowadays somewhat raised, in view of the fact that so many depressives—to my mind, rightly and properly—are given electroplexy under out-patient conditions. Every psychiatrist knows that the danger-point is reached when the treatment is beginning to abolish the inhibition and retardation which are so frequently cardinal features of the depressive syndrome; in other words, when the patient is starting

to show signs of satisfactory recovery. If I may be excused for stating the obvious: general practitioners should never provide such patients with large supplies of barbiturate or other possibly lethal drugs, and should in all cases make a relative responsible for doling them out at the correct times. Further, a general practitioner should make a point of seeing a depressed patient, even if he is receiving treatment from a psychiatrist, at least once a week. This alone renders suicide much more unlikely in depressive cases.

Schizophrenia and paraphrenia again offer such an obvious warning that the risk of suicide is thereby reduced, although such patients are often a source of anxiety to mental hospital doctors and nurses.

The suicidal methods of straightforward depressives are usually clear-cut and practical—precipitation from a height, shooting, poison, stepping on to a railway line under an in-coming train, and the like. Those of schizophrenic and paraphrenic patients are apt to be more bizarre, dictated, as they so often are, by hallucinated voices. The following suicidal attempt by a young male schizophrenic stands out in my mind as being by no means atypical: he procured a couple of pounds of meat, which he allowed to decay for a fortnight. He extracted the juice in a press and injected it from a large syringe with a rusty needle directly into his liver. Strangely enough, he survived.

Professor Stengel (1955) sets great store in differentiating between "successful" suicide (if the somewhat cynical use of the word successful be excused) and attempted suicide. To quote Professor Stengel, "... often the experience of the suicidal attempt signifies to the patient death, survival, and a new beginning." This interesting and important point of view is dealt with more fully under "anthropology of suicide."

Psycho-analysts' Explanation

At this stage it would be as well, I think, to consider the psycho-analytical contribution to the psychology and psychopathology of suicide: the psycho-analysts explain suicide in accordance with two main theories, which are not mutually exclusive. At one point in his quasi-philosophical speculations Freud posited the existence of a death instinct in man. It might happen, for one reason or another, that the death instinct would overpower the various ego instincts, in which case death might be sought for its own sake. There has never seemed much point to me in translating the Second Law of Thermodynamics into psychological terms and making use of the analogy to explain something like suicide in pseudo-causal terms.

However, the psycho-analysts themselves have never been very happy about the death instinct, and often prefer to explain suicide in terms of aggression: suicide is the final act of aggression directed against the self rather than against elements in the outside world. This act of self-aggression covers three main wish-derived impulses—the wish to die (this is the link with Freud's death instinct), the wish to be killed, and finally the wish to kill. The psychopathology of suicide in these terms is carefully elaborated by Karl Menninger in his book, *Man Against Himself*.

In general terms, however, I would say that, as is the case with so much psycho-analytical teaching, what purports to be an explanation in causal terms is really an account of a phenomenon in descriptive terms, based on analogy. According to Freudian natural history, we all have a death instinct; and all of us harbour aggressive impulses, consciously or unconsciously. Why is it, then, that so few of us, numerically speaking, commit suicide, in spite of the fact that so many of us suffer severe reverses of fortune in the course of our lives and are called upon at various times to put up with almost intolerable pain? A simple interpretation in such psycho-analytical terms does not seem to cover all the facts. Nor does it altogether account for the type of suicide which is sanctioned, or even demanded, by the prevailing pattern of culture, although the three

components of the suicidal impulse mentioned above can often be seen to enter into socially conditioned suicides and killings of that nature.

"Biological Suicide"

Ellenberger (1953), in a most interesting article entitled "Suicide in the Light of Ethnological Psychiatry," gives examples of the three types of suicide occurring in various parts of the world.

As an example of what he calls "biological suicide," suicide determined by the "wish to die," he instances both African and Melanesian cultures, in which death appears to follow automatically the violation of religious taboos or as the result of magical practices. In the same way, primitive folk seem to die naturally enough from simple home-sickness.

As examples of suicide as the wish to be killed, Ellenberger mentions the Tschuktschi tribes in North Siberia, amongst whom two kinds of socially accepted suicide were found: (a) suicide proper, occurring only amongst boys, who were not permitted to meet death at the hands of others after the manner of (b) "allowing oneself to be killed." Death sought and found in either of these two ways was regarded as very honourable and assured one of special privileges in the after-life. The grounds for death of that sort were various—for example, painful or chronic illness occurring in old men, or following a fit of temper arising out of a domestic quarrel, or grief over the death of a friend.

The candidates for death enjoyed every honour and consideration. Three methods were available for the loving executioners: strangling, stabbing, or—much more rarely—shooting.

Ceremonial Suicide

As examples of suicide as a wish to kill traditionally forming part of the culture-pattern we have, according to Clark Wissler, the Blackfoot Indians of North America and amok in Malaya. It used to be the case among the Blackfoot Indians that if a man believed himself to be suffering from an incurable illness he would take up his arms and try to kill as many people as possible in his environment before he himself was killed by one of them. It would also seem that amok is not so much to be regarded as an acute homicidal mental illness as a ceremonial rite connected with wounded honour, loss of face, and a desire for revenge. This would bring amok much more into line with other well-recognized forms of ceremonial suicide, such as harakiri in Japan and the self-sacrificing types of suicide, such as suttee, in India.

It is interesting to note that a case of amok was recently reported in the newspapers as occurring at an American Air Force Camp in this country, when an American airman shot as many of his fellows as he could before committing suicide; but I do not remember the full details.

There is a form of ceremonial suicide in Melanesia which is the exact opposite of harakiri and suttee, in that the suicide is directed by the individual against the community. This is described by the late Professor Seligman in his book, *The Melanesians of British New Guinea*.

Space does not allow of further consideration of ceremonial suicide of all kinds or even from mentioning the kind of suicide permitted at various times and in various cultures to members of the upper classes as an alternative to trial and execution: the bowstring in Persia and the old Turkish Empire, the severing of a vein in a hot bath in Imperial Rome, the high-ranking officer in Germany being left alone for a moment in a room with a loaded revolver, and the like.

Nevertheless, all these considerations lead up, naturally enough, to my main "anthropological" thesis, if it can be called a thesis.

Anthropology of Suicide

The late Alfred Adler established at least one very important psychological principle, although he did not, to my mind, always express himself very clearly: man, being a herd-animal, in addition to existing in time and space, requires, as it were, another dimension, the social dimension, which may be called "community," in which to live.

It is my belief that Durkheim's sociological study and Sainsbury's "ecological" survey, already mentioned, clearly point to the following broad generalization: *the most important stimulus for suicide is the loss of the inner feeling of identity with any of the social groupings implicitly or explicitly recognized by the culture-pattern and society in which a person lives*—if you like, the subjective experience of "excommunication." I believe that most attempted suicides even can fit into that formula; but I will deal later with attempted suicide, in the light of Stengel's research.

"Subjective Excommunication"

Let us consider some of the more usual motives for and circumstances connected with suicide.

1. Before the very recent advent in this country of the modern Welfare State, it was a proud working-class sentiment that one should go through one's life without ever being a burden to other people. When one was unable to support and care for oneself the signal for suicide might be sounded. It is for that reason, I think, that until quite recently the Fifth Commandment given on Sinai was burned into the collective unconscious in these islands. The grown-up children therefore automatically and lovingly looked after their ageing parents to the best of their ability; and old folk with near relatives to look after them formed an acceptable, recognized, and honourable social group. When this device broke down, the workhouse ward—with all its horrors, real and alleged—provided a social setting, where the inmates, although *déclassés*, were not pariahs.

Nowadays, an appreciable portion of the patients admitted into my observation wards after a serious suicidal attempt are old people who regard themselves as "useless mouths" and who have lost all sense of honourable group-identity.

2. Other examples of "subjective excommunication" are obvious enough.

(a) A man who has, let us suppose, devoted all his efforts to the identification of himself at all levels with the wealthy, privileged classes suddenly finds his position jeopardized by threatened bankruptcy proceedings, imprisonment, an ugly divorce, or what have you, and converts social death into the real thing.

(b) Sensitive, civilized homosexuals who are "found out" after many years of successful identification with "respectable" social groupings find themselves in a very similar position: they see themselves from now onwards forced to live in a social vacuum, which spells death. That is the reason, I think, why blackmail in this context is so frequently a cause of suicide.

In a sense, I suppose, I am merely giving the idea of loneliness a special kind of connotation. Anyhow, group (c) would include culturally isolated people such as refugees who have not yet had time to put down new roots. I have been told that in large camps for displaced persons suicide is a comparatively rare occurrence: for the inmates very soon form a cohesive group and evolve a group *ethos*. When individuals, however, leave camp and migrate to strange lands, the experience of loneliness, not "belonging" and not even being allowed to "belong" can become almost intolerable. This, of course, links up with the idea of spontaneous death from nostalgia mentioned earlier.

(d) Cultural isolation can work in other ways too: in Esther Warner's (1955) remarkable book, *Trial by Sasswood*, which deals with life in tribal Liberia, there is only one mention of attempted suicide. It was that of a young man who, instead of being properly initiated into his tribe, had been to a mission school and wished to become a doctor. He was the son of the head of the local Poro cult and had been rejected by his father. After he had failed to kill himself by drowning, he gave up the unequal struggle to be identified with two different culture-patterns at one time and returned to his tribe.

*Paper read to the Medical Society of London on March 12, 1956.

It would seem, then, that a simple homogeneous culture, involving community of belief, customs, and *mores*, with which a man identifies himself, at the deepest levels of his being, is the best safeguard against that dreadful isolation which may lead to self-destruction.

The Catholic Culture Pattern

When as a boy I used to travel on the Continent I remember being very impressed by the half-starved, often deformed, repulsive-looking beggars whom one used to see congregated outside churches in Latin countries; and I recollect expressing surprise that they did not commit suicide. What had they got to live for? I think that I found the answer many years later when I read Durkheim's book. Durkheim compared the suicide rate in Catholic and non-Catholic communities and found that the suicide rate amongst Protestants and non-Catholics in general was six, seven, or eight times higher than amongst Catholics.

It is true that a Catholic is brought up to regard despair as one of the most heinous of mortal sins and hence looks on suicide with abhorrence; but I think that one must interpret this differential suicide rate in sociological rather than theological terms: the Catholic culture-pattern is much more compact, communal, and cohesive than the more individualistic Protestant pattern. A Catholic in a predominantly Catholic country like Ireland, Southern Italy, or Spain is always "doing something," which gives him a sense of belonging to the 430-million-strong Catholic family in this world and all the others who are dead—making the sign of the cross, dressing up and walking in processions, taking holy water, saying his rosary, and the like. The Protestant has none of these aids and traditions to come to his support. Fromm (1942), commenting on the burden that freedom of thought and action imposes on the individual, says that the price that has to be paid for these liberties is "isolation and moral aloneness."

One would expect that the suicide rate would for the same reason be low in Communist Russia, but I have not been able to get hold of any statistics.

The trouble about Western (non-Catholic) patterns of culture is, of course, the ever-increasing loosening of all the factors that go to make up natural social and cultural units.

Modern Western man for the most part has few beliefs and practically no convictions; nor has he got a mythology to add meaning to and sustain his psychic life. There are no birth and initiation ceremonies or really stable marriage customs to prepare the way for death occurring at its allotted time. Truly, as Fromm says, the price of "freedom" is high indeed when it is the kind of freedom that leads to nihilism.

American sociologists have shown that the suicide rate was highest in those cities and in those districts where the population was most shifting and the social organization least cohesive.

Economic Factors

The way that economic factors affect the suicide rate is interesting and somewhat unexpected. According to Durkheim, during a period of economic disturbance—unusual prosperity or the reverse—an individual's material ambitions, owing to the consequent relaxation of social control, are apt to become so exaggerated as to be unrealizable, with the result that feelings of frustration lead to an enormous increase in suicide. The period of inflation through which we are passing now is particularly dangerous from that point of view. I well remember the staggering suicide rate in Austria and Germany during the inflationary period in the early nineteen-twenties. Conversely, the feeling of social solidarity and group-identity associated with war and clear-cut national disaster leads to a fall in the suicide rate.

Dr. Sainsbury was well aware of all the factors responsible for suicide that I have mentioned and decided to study the problem from the point of view of locality, taking as his

field five London boroughs representing a total population of some 825,000. His book is, I think, wholly admirable, and his study methodologically as sound as any statistical survey can be.

His work confirms the point of view that I have been trying to put before you—namely, that although suicide is, of course, a psychiatric problem, it is perhaps even more a sociological, cultural, or anthropological (if you prefer the term, as I do) phenomenon.

Suicidal Attempts—A Hysterical Reaction

Let me conclude with a few observations on suicidal attempts, as opposed to suicide proper. If we regard the presence of secondary gain—that is, the advantages accruing from symptom-formation in relation to the external world—as one of the important factors differentiating the hysterics from other psychoneurotic reaction-types, we find that attempted suicide is in many cases almost a pure hysterical reaction. It is as though the patient were saying in so many words: "I am lonely; I am ill; I am ill-treated; my married life is impossible; you must do something about it." The suicidal attempt sounds the alarm bell; and somebody is bound to take note of it, for it always occurs in a place from which help is almost certain to come.

Even the inadequate psychopath who makes repeated attempts at suicide is behaving hysterically, for he is in effect saying: "I am only a poor, helpless creature: please look after and cherish me." In Stengel's (1955) words: "The most important difference between suicide and attempted suicide seems to have been overlooked—that is, that the person who has attempted suicide lives on, and that the attempt becomes a meaningful event in the course of his life and is bound to call forth reactions from the group he belongs to."

With regard to the psychological and social sequelae of the suicidal attempt for the individual and his group, Stengel quotes from a recent article by Seigal and Friedman: "The threat of suicide forces persons to marry, prevents marriage dissolutions, coerces companionship between persons despite their mutual infidelity, prevents marriages, forces parents to acquiesce in their offspring's vicious habits, precludes institutionalization, is rewarded by escape from military duty, is used to obtain favoured treatment over siblings, is employed as a device to avoid military induction, etc."

In my view, however, this rather crude summing-up of the kind of secondary gain attaching to suicidal attempts is a little too harsh and over-simple; for the sequelae of attempted suicide, short-lived though they may be, are as often as not much more "moral" and socially constructive.

I am only too aware that these remarks on suicide and attempted suicide are scrappy, ill-coordinated, and inconclusive. In my defence, I may be allowed to say that it would be quite impossible in so short a space to do anything more than just touch the fringes of so vast a problem.

The Medical Section of the Library Association held a week-end conference in Manchester on September 21-24. Members were the guests at dinner of the University, when they were welcomed by Sir GEOFFREY JEFFERSON and Dr. WILLIAM BROCKBANK. The programme included visits to the John Rylands Library, Manchester City Library, the University Library (including the library of the Manchester Medical Society), Chetham's Library, and the libraries of I.C.I. (Pharmaceuticals) Ltd.

NEW ACADEMIC YEAR

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL

Lord Justice Denning's Address

Lord Justice DENNING analysed the Hippocratic Oath and discussed moral problems facing doctors when he delivered the inaugural address at King's College Hospital Medical School. Referring to recent court decisions, he said that he thought that the balance had now been restored, and medicine and the law could have mutual confidence.

The Hippocratic Oath would not solve all the problems which a doctor had to face in his everyday practice. It was easy to enunciate that a doctor must be upright and honourable in the practice of his art, but problems arose from it. Was a doctor ever permitted to tell a lie to his patient? If a person was suffering from cancer, it was expected that he should not be told about it. Was that right? Was it permissible to tell a lie for the good of the patient? His lordship suggested that it was never permissible to seek a good end by bad means, to do a little wrong to get a great right. Indeed, if it were generally known that doctors did not tell the whole truth to their patients, the confidence which should exist between doctor and patient would be seriously undermined.

The Oath stated that the doctor should, to the utmost of his power, seek to cure. It might be argued that in the case of a long illness with great pain an overdose of a drug might be justified. Plato and Æsculapius said that the interests of the community at large were paramount. So a good case could be made by the Devil's advocate—but an entirely wrong case. The basis was the Christian ethic. A doctor must keep his patient alive as long as ever he might, for every fraction of a second that nature would permit.

Lawyers had the same problem. Strachen murdered a child and was found insane. He escaped and killed another child. He was sentenced to death. No doubt the jury thought that he would be better out of the way. Was not the Home Secretary right in reprieving him? The son of an under-sheriff of one of the western counties murdered his parents, put their bodies in a wheelbarrow, and threw them over the cliff. Although there was insanity in the family he was hanged, and it was said that he went to death in peace with his Maker. Whether in law or medicine the principle was right which placed the sanctity of human life above all else.

Law and medicine went hand in hand when the Oath stipulated that the doctor should in no way misuse his art or skill. The law in regard to abortion would, his lordship was sure, permit the practice in regard to German measles. The law in England, he hoped, was in complete accord with common sense in this matter.

Lord Justice Denning suggested that it was not right for a doctor to lend himself to any operation for sterilization unless there was just cause, such as a transmissible heritable disease, and it was not just for that individual's own gratification. It might well be that artificial insemination with the husband's seed was well and good. Outside that the medical profession would be justified in denouncing it. A doctor must do everything to cure a patient but do nothing contrary to the public interest of the community at large.

The Oath stated that the doctor must respect the confidence of his patients. It might happen that justice required disclosure, but as his lordship understood the Oath it did not say that a doctor must never divulge information; he must be a judge of the land said so.

Some people suggested that the freedom of the doctor had been impaired under the National Health Service. His lordship suggested that it was not. It was true that by decisions of the courts hospitals had been made responsible for the way they had been inexcusable conduct on the part of the staff. But that was the extent of the matter. He thought that the decision in St. Bartholomew's Hospital's case in 1911

was influenced by the fact that St. Bartholomew's was a charitable institution. It was an illogical decision which rendered the hospital not liable when a professional person made a mistake, but liable when a non-professional one did so.

The medical profession had been disturbed, but he thought that the balance had been restored as a result of the indulgent decision of the court in a recent case. His lordship concluded by stressing that moral problems could not be solved on material lines alone.

In his annual report the dean, Dr. VERNON F. HALL, said that the first stage of the extension to the buildings would be completed by next year. He announced that the University of London had included the full cost of the second stage in their building programme for 1957. The first stage includes student accommodation, a new practical pathology classroom, and a floor to accommodate the new medical professorial unit. The second stage will contain research accommodation for the department of chemical pathology, a clinical lecture theatre, a clinico-pathological demonstration room, and a suite of rooms for the student health service, as well as teaching and research accommodation for the department of surgery comparable with that of the medical unit. The whole of the available site will then be occupied and the accommodation of the school will be increased by 60%. For the next quinquennium (1957-62) a proposal has been made for the building of an entirely new dental school to accommodate nearly twice as many students as at present.

Dr. TERENCE EAST, director of studies of the medical school, presided at the opening of session ceremony which was held on September 28.

The annual dinner was held at the Savoy Hotel on September 29, with Dr. R. D. LAWRENCE in the chair. Dr. C. RICKWORD LANE, proposing the toast to the medical school, spoke of Dr. V. F. Hall as a very popular and successful dean. In reply Dr. HALL described the school as a friendly corporate institution and an excellent training-ground for the young. Quoting J. S. Mill's aphorism, "Genius can only breathe freely in an atmosphere of freedom," Dr. Hall said that what was taught at King's was a system of medicine designed for the treatment of the individual by the individual. The health of the chairman was proposed by Mr. J. H. PEEL, who said that when the subject of diabetes was discussed in any part of the world the name of R. D. Lawrence was bound to be mentioned with admiration and affection. Dr. Lawrence had had the unique opportunity of showing diabetics how to live full and complete lives by his own example. Replying to the toast, Dr. LAWRENCE first welcomed the guests, and then, having spoken feelingly of his impending retirement, gave some fascinating glimpses of his own early career as a young doctor in London and in Italy.

CHARING CROSS HOSPITAL

Future Site of Medical School

The presentation of prizes and certificates to the students of Charing Cross Hospital Medical School took place at the Mansion House on September 28, with the Lord Mayor of London, Alderman Sir CUTHBERT ACKROYD, presiding. This was said to be the first occasion on which any medical school has had the privilege of using the Mansion House for this ceremony. The presentations were made by Viscountess KILMUIR, and were followed by a brief address by Viscount KILMUIR, the Lord Chancellor.

The new dean of the school (Professor W. J. HAMILTON) began with a tribute to his predecessor, Dr. E. C. WARNER, who recently retired from the deanship after serving for six years. He said that the school council and the academic staff desired to place on record their appreciation of the work done under Dr. Warner's tenure. Many major projects designed to improve the facilities and accommodation of the several departments and to meet the ever-increasing demands upon the school buildings as a whole had been successfully

carried through, and it was entirely due to Dr. Warner's efforts that they were one of the first medical schools in the country to introduce the general-practitioner firm—the "G.P. firm," as it had come to be known—which afforded each senior student a short period of tuition and experience in general practice.

Professor Hamilton went on to say that since 1944 it had been the intention to move the medical school, with the hospital, to Northwick Park. In his report last year Dr. Warner had informed them that the Minister of Health, in February, 1955, had notified Parliament that Charing Cross Hospital was designated as one of the first hospitals to be rebuilt and had subsequently announced that funds would be available for rebuilding at Northwick Park in the financial year 1957-8. While these developments were taking place, however, it had become increasingly apparent to the medical school that neither the University nor the University Grants Committee were in favour of any proposal for the removal and rebuilding of the school at Northwick Park, and that the University did not consider that there was any possibility of their meeting the cost of such a scheme. This was very disappointing news to many of them who had hoped to see a new school erected on a fine site adjacent to the hospital. A joint consultative committee with representatives of the Ministry of Health, the University Grants Committee, and the committee of vice-chancellors and principals had been set up to discuss general problems affecting both Charing Cross and other hospitals and schools in a similar predicament, and he was confident that a solution to the problem would be found. They felt that the closest association between the school and the hospital must be maintained, not only in regard to their respective policies and staff but also to their function as a teaching unit. Therefore the school and hospital must remain in close proximity, and any plans for the development of the school must be integrated in all respects with those of the hospital. It would be fatal to the present efficient and harmonious relationship existing between both institutions if the hospital were to be rebuilt at Northwick Park and the school remained at Charing Cross.

School Successes

Speaking of school successes during the year, the dean said that at the first M.B. examination in July all but one student passed; only two students failed to complete the preclinical course successfully. In the final examination the pass lists varied between 79 and 100% in the different subjects, and 72% of the students passed in every subject. Further, the students of the school claimed half the places in the honours list of the combined 12 medical schools of the University.

Viscountess KILMUIR then presented the prizes. The outstanding prizewinner was Dr. JOHN ROBERT CURTIS, who carried off an exceptionally large number of awards, including the Llewellyn Prize, the Governors' Clinical Gold Medal, and eight other prizes and two certificates of merit. The trophy for the athlete of the year was presented to J. D. WRIGHTON, who recently ran for Great Britain in the 4 x 400 metres relay against the German Olympic team at the White City and won his lap.

The LORD CHANCELLOR said that it was a very great pleasure to hear of the vitality and progress of the school now approaching the end of the first quarter of its second century. When the school was founded in 1834 the hospital had already been in existence for 15 years, and it must have been a great joy to the founder of both institutions, Dr. Benjamin Golding, to have seen them established. It was good also to know that Golding lived for 20 years longer to see the two institutions flourish and complement each other. The audience did not need to be reminded that among the early students (1842-5) was Thomas Henry Huxley.

This was an occasion, however, for looking forward to what remained to be achieved. He himself, although his

life's work had been in another direction, could not be ignorant of the great advances of scientific medicine which institutions like Charing Cross had made possible. He was for some years senior counsel to the Royal College of Physicians of London. He knew that scientific achievement never stood still, and he had every hope and expectation that the great wave of research to which Charing Cross itself had notably contributed would continue. The scholarships, exhibitions, and prizes presented that day were a sign of the awareness of the coming generation of the great opportunities which spread before them. But a hospital was more than a home of science. The hospital movement in this country had been started by a sense of voluntary service, and despite many changes that feeling of voluntary service still remained. He wished Charing Cross godspeed for another year of achievement.

Mr. JOHN ADAMSON, a member of the school council, said that the present occasion coincided with the 35th year of Lord INMAN's devoted service to the hospital and to the medical school. In gratitude and commemoration the governors and staff and his many friends in connexion with Charing Cross were presenting him with his portrait, to be painted by an artist of his choice. He spoke of Lord Inman as the ideal chairman who had shown that the wellbeing of the hospital and school were, of all his interests, the nearest to his heart.

Lord INMAN, in accepting the gift, said that in the boardroom of the hospital there was a bust of Benjamin Golding, the founder, and many visitors asked who he was. If in time a portrait of himself also found a place there and any should ask the same question he would be well content if it were answered, "He was one of many who loved and tried to serve Charing Cross Hospital."

Sir NORMAN BIRKETT supported a vote of thanks to Lord and Lady Kilmuir at the close of the proceedings.

MIDDLESEX HOSPITAL MEDICAL SCHOOL

At the annual dinner of the Middlesex Hospital Medical School held at the Savoy Hotel on September 28, under the chairmanship of Mr. F. W. ROQUES, it was announced that it was hoped that the building of the new medical school would start early in the new year. This had become possible as a result of the great generosity of the chairman of the hospital, Lord ASTOR OF HEVER, who last year had opened the building fund with a gift of £400,000; the grant of £124,000 from the University Grants Committee for the purchase of the site; and a new covenanted benefaction, amounting to £122,000, from Mr. EDWARD LEWIS, a director of the Decca Company, a "friend of the school and hospital for many years." To Mr. ROQUES fell the task of proposing the toast of "The Hospital and the Medical School," and he was the first gynaecologist to do so since Victor Bonney 30 years before. Overshadowing the dinner, he said, was the tragic loss the previous night of Sir WILLIAM GILLIATT, one of the school's most distinguished sons. Two honours during the year had particularly delighted Middlesex men, continued Mr. Roques: the barony conferred on Colonel J. J. Astor, their chairman since 1938, whose personal interest in the hospital matched his generosity towards it; and the award of the gold medal of the Royal Society of Medicine to Sir Gordon Gordon-Taylor. The dean, Professor B. W. WINDEYER, and the senior Broderip scholar, Dr. L. G. WHITBY, a son of Sir Lionel Whitby, replied. After referring to the successful experiment of exchange visits of clinical, and now preclinical, staff with Toronto, Professor WINDEYER described the building programme. The first phase, due to begin in the new year, would comprise the preclinical school and a residential hostel for 150 students, on a site bounded by Howland Street, Cleveland Street, and Charlotte Street. The cost was estimated at one and a quarter million pounds. At this point Professor Windeyer announced Mr. Lewis's benefaction. Later the clinical departments would be added.

Dr. WHITBY, as tradition demanded, reported on the student affairs. The final speaker was Mr. E. W. RICHES, who had the rewarding task of exposing the life history of the evening's chairman. Over 350 past and present members of the school attended the dinner.

MEDICAL STATISTICS

[FROM A SPECIAL CORRESPONDENT]

"Facts, not opinions" was one of the watchwords of the Royal Statistical Society when it was founded in 1834. Professor A. BRADFORD HILL showed how this austere aim proved hard to live up to when he reviewed the history of the Society's interest in medicine from its foundation, with three medical men on the council, until to-day, when it had an active section devoted to the study of the statistical aspects of medicine. Professor Hill was opening the first conference of the Society's medical section, which was held at County Hall, London, on September 28.

Reproductive Efficiency

Professor DUGALD BAIRD's paper, on the use of statistics in clinical obstetrics, was indeed an admirable illustration of the virtue of facts in a field where unsupported opinions have held sway for too long. His department in Aberdeen had been studying the influence of social and environmental factors on child-bearing for the past eight years, he said, and had built up a picture which not only provided a background for further clinical and laboratory research but also revealed many new facts. It was not generally realized that a woman's reproductive efficiency began to deteriorate even from the age of 20. A convenient yardstick was the proportion of all deliveries which were spontaneous and which followed a labour of 24 hours or less. In his series this figure ranged from 80% among primigravidae of less than 20 years to 30% in those of 35 or more. As well as age the most important factors were height, shape of pelvis, and general health; these were closely related to one another and also to social grade. In the study of lactation facts were particularly hard to come by. Hytten, working in the same department, had broken fresh ground in his surveys. His finding that as many as one-third of women may be physically incapable of maintaining adequate breast-feeding for more than a few weeks should be given more attention by those who hold, as an article of faith, that "it is all a matter of will-power."

The most interesting demonstration of the use of statistics in Professor Baird's department was his description of the effects of his policy of inducing labour, and, if necessary, performing caesarean section, in women over the age of 25 if pregnancy reached the 42nd week. The figures suggested that the policy had brought about a considerable reduction in the perinatal mortality rate due to "unexplained" causes, but they also suggested to Professor Baird that the pendulum had swung too far, that too many caesarean sections were being done. To at least one listener the analogy between his methods and the industrial use of statistical "quality control" was most striking.

Mutation Rates

Professor L. S. PENROSE spoke about the genetical effects of radiation on human populations, a subject in which, as the speaker would be the first to admit, the ratio of opinions to facts is regrettably high. He considered the first problem here was to determine the rate at which genetical mutations occurred in the presence of normal background radiation. There were two ways in which the problem might be tackled: one might study the family trees of people suffering from certain clearly defined conditions (often skeletal deformities); or one might, assuming the population to have reached a state of genetical equilibrium, equate the mutation rate with the rate at which bearers of unfavourable genes, such as haemophiliacs, were bred out as a result

of their unfitness as reproducers. When the base-line had been fixed there remained the problem of determining the sensitivity of various genes to increases in the level of radiation. At present, in order to make any progress at all, it was necessary to adopt the working hypothesis that the doubling dose was the same for all genes. This might be very far from the truth. All this was difficult enough; but these methods applied only to the very rare, and therefore not vitally important, single-gene conditions. What happened when we turned to the multiple-gene effects—stature, intelligence, and the like? Here the chief problem was that the effect of doubling the mutation rate was likely to be slight, because only a very small part of the total variation could usually be attributed to fresh mutation.

Professor Penrose described some of the ways in which more exact information could be obtained on the effects of radiation on human genes. Studies making use of the ages of parents should prove fruitful; it would be a useful start if the national vital statistics included information of the ages of fathers as well as of mothers.

Cancer and Leukaemia

After an entertaining film, in which Dr. A. L. COCHRANE showed how the Medical Research Council's Pneumoconiosis Research Unit carries out its well-known x-ray surveys in South Wales, Dr. PERCY STOCKS read a paper on statistical studies in relation to environment. Much of this paper was taken up with a discussion of the reliability of answers given by patients and their relatives to specific questions. Is the wife of a man who dies from stomach cancer likely to over- or under-estimate her husband's average weekly consumption of tea? Dr. Stocks gave the preliminary answers to such questions as this in describing his investigation into the environmental histories of people with and without cancer, which he has been directing for the British Empire Cancer Campaign. Discussing the investigation of soil samples taken from gardens of houses where people with and without cancer had lived for long and short periods, he showed how the statistics suggested that some, at least, of the regional variation in the incidence of stomach cancer might be attributable to differences in soil composition.

In the final paper Dr. W. M. COURT BROWN described one particular investigation—that into the association between leukaemia and therapeutic x rays. This was a good example of the value of a statistical inquiry based on existing records. The survey was concerned with the fate of some 13,000 patients treated for spondylitis at 79 radiotherapy centres during a 20-year period, and showed that in these patients the mortality from leukaemia was at least nine times the normal expectancy. Subsequent work had shown no such association with patients with spondylitis not treated with x rays. It is therefore reasonable to conclude that the increased mortality from leukaemia was the direct result of exposure to therapeutic x rays.

Professor BAIRD expressed the opinion that the practice of obstetrics would suffer no immeasurable loss if the use of x-ray pelvimetry was drastically curtailed.

The need for more rapid progress in the regrouping of water undertakings into units adequate to meet modern demands was stressed by Mr. J. ENOCH POWELL, Parliamentary Secretary to the Ministry of Housing and Local Government, when he opened Friar's Wash pumping-station, between St. Albans and Luton, on September 27. In the next 12 months, Mr. Powell said, the Government hoped to see substantial progress in various parts of the country, and the Minister's decision on schemes submitted to him would be influenced by this consideration. The small water undertaker had in the past done pioneer and excellent work, but without large financial resources, full-time qualified supervision, and adequate staff it was difficult for water undertakers to-day either to maintain the highest standards or to secure the economic and timely utilization of water resources.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Christmas Gifts Fund Appeal

SIR,—I shall be very grateful if you will spare room for me to remind your readers that Christmas will be coming round again soon, and to ask them to give a kind thought and a generous gift to the beneficiaries of the Royal Medical Benevolent Fund.

To those of our colleagues who have fallen by the way-side, and to the widows and children of those who have passed away, a little cheer at Christmas-time means much more than the gift itself. It is especially heart-warming for them to be remembered by members of the profession who are in a position to help them. I earnestly beg all your readers to send contributions marked "Christmas Gifts" to the Secretary, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15.—I am, etc.,

WEBB-JOHNSON,
President,
Royal Medical Benevolent Fund.
London, S.W.15.

Purpose of Medical Education

SIR,—The *B.M.J.* has published many searching papers on this topic, but none has revealed the sense of desperation implicit in the excellent address of Professor G. W. Pickering (*Journal*, July 21, p. 113). After many years devoted to the aim which he underlines—i.e., that of training the mind of the medical student—I must say that I approach the end of my teaching life with a sense of despair.

The answers to Professor Pickering's questions which deal with the "three great obstacles"—namely, the enormous body of "so-called facts," the rigidity of the curriculum, and its disorder—are in their simplest form the domination of examinations, the oppressive influence of the General Medical Council, and the vested interests of the teachers.

For more years than I care to enumerate I have sat on a committee the object of which is to achieve some degree of evolution in the curriculum. Inevitably any real reform is frustrated by these three Norns. As Professor Pickering rightly says, "Readiness by teachers and taught to admit and remedy ignorance . . . will not be easy, since most teachers mould themselves on those who taught them." So it emerges that the examination is the aim, and to such an extent has this become the dominating factor in the school in which I teach that no supplementary examinations are now permitted, with the avowed object of "weeding out" the less intelligent—this in face of the fact that past experience provides many examples of final-year prizemen who stumbled more than once. So long as this attitude is dominant, no education in the university sense is possible. It is to be noted that the examination is greatly overrated because of the manner in which postgraduate students prepare for and are sorted out by the two Royal Colleges.

As for the influence of rigidity, one has merely to raise the question of reduction of courses or the incidence of examinations to be faced by a colleague with a *non possumus* resulting from his interpretation of the General Medical Council's recommendations. It is idle to emphasize the fact that the Council does not, in so many words, define hard limits. It does not indicate clearly enough that it is for a university faculty of medicine to act in an enlightened manner to achieve educational objectives as it sees fit. The disorder arises from failure of the educational aim. Obviously there can be little discrimination as to the importance of this or that subject or part of a subject if there is a technological aim only. What saddens me most is the fact that the study of medicine, from the basic sciences up, should provide one of the most exciting educational

adventures open to a university student, whereas, as countless graduates have come and told me, they have all their enthusiasm and even their interest reduced to the point where they long for the final examination as a release.

Professor Pickering's most trenchant question is: "Will the medical course be arranged primarily in the interests of educating the student, or primarily in the interests of the prestige of the teachers?" My answer is that, unless some august body like the General Medical Council actually states in words that education does not mean training, and that examinations are not to be made the aim or the simple test of intelligent capacity, and that there is no need to include certain specialties in the undergraduate course, we can expect the situation to remain as at present.—I am, etc.,

Adelaide.

C. STANTON HICKS.

The Discipline of Learning

SIR,—It is more than 25 years since I learned anatomy in detail, and admittedly at that time "without understanding its place and purpose in the knowledge of the modern doctor" as Dr. A. Morgan Jones writes in your issue of September 1 (p. 494). Now—after a number of years in a coal-mining practice where the amount of work to be done has to be experienced to be believed—I am of the opinion that the discipline of learning anatomy is the most important single factor in preparation for the rigours of general practice. When doing anatomy most students feel that the detail is such that they can never hope to learn it all, but they do. In general practice on most days one feels the work cannot possibly be done, but it is done, and this largely I am sure because one is conditioned to hard work by the severe training in anatomy imposed upon us in our pre-clinical days.—I am, etc.,

Cymmer, Glam.

E. W. KINSEY.

Adrenal Cortical Function

SIR,—In his extremely able review of "Chemical and Clinical Problems of the Adrenal Cortex" (*Journal*, September 22, p. 673) Professor F. T. G. Prunty kindly refers to my studies of adipose children (adipose gynandrm and gynism) under the heading "Adiposity Resembling Cushing's Syndrome," and concludes, "We are inclined to agree with Simpson that there is an underlying abnormality of adrenal cortical function in these individuals which by present methods fails to be demonstrated." In this connexion may I mention a very recent and overlapping publication,¹ in which, using chromatographic methods of hormone assay, it was concluded from the data that "in adipose gynism and in adipose gynandrm the excretion of compound F was significantly increased above that of normal children. In children with adipose gynandrm the excretion of an unknown Δ^4 -3-ketosteroid, X_4 , was also significantly increased"?

Professor Prunty also has a very interesting paragraph on the "Time of Adrenarche," in which he states, in relation to a child who developed hirsutism at 8 and puberty at 13, "It is suggested that she had an early adrenarche as mentioned by Talbot, Sobel, McArthur, and Crawford (1952), but which is poorly documented." Professor Prunty further gives an interesting example of delayed adrenarche in a male of 18.

My studies of groups of fat children (given the name of adipose gynandrm for males and adipose gynism for females) over the last decade led me to a similar conclusion, which I recorded in 1951 in a lecture² to the Endocrine Section of the New York Academy of Medicine as follows:

"In speaking of puberty, we think of chronological puberty—for example, 13+ or —, with sex maturation. Fuller Albright has reminded us that the adrenals as well as the gonads come into play at that time, a thought propounded by Bulloch and Sequeira in 1905—'The adrenal cortex is connected with the growth of the body and the development of puberty.' Albright has coined the term adrenarche as supplementary to menarche. He appears to have limited this conception to androgens and to chronological

puberty. I would extend the conception to the adrenal glucocorticoids and recognize that there may be, and often is, a pre-adrenarche at the age of 7+ or —; and that the adrenarche, like the climacteric, may precede chronological puberty by several years and persist after it by an equally long period. My views are based on clinical considerations, but are supported by some hormone assays."

I am, etc.,

London, W.1.

Intracranial Aneurysm

SIR,—Mr. I. R. H. Kramer (*Journal*, September 22, p. 711) raises certain queries in relation to the material described in my preliminary note (September 8, p. 585), in which detail was omitted for the sake of brevity.

The material used is a self-curing acrylic (a self-explanatory name) for the repair of dentures, curing being achieved by tertiary amine in the monomer and benzoyl peroxide in the polymer. The manufacturers' stated time for "completion" of polymerization is twenty minutes. Smith and Bains¹ state that incomplete polymerization is the rule with cold-curing materials, that the residual free monomer is 1%, and that 0.5% is relatively stable and inextractable except with great difficulty.

Shrinkage is proportional to the amount of monomer used. In a three-to-one mix, and allowing for partial evaporation of the monomer, shrinkage is about 6%. These statements refer to the use of acrylic compounds in dental conservation. Initial work, discovering the properties of the material used, was done on glass rods, and collars were run around these. Cracking of the polymerized collar was never observed, and it was always possible to slide the collar off the rod, even after several weeks. Thus it was in its use around a vessel that the phrase "no shrinkage" was intended.

All the cases treated by this method were under hypothermia, with the blood pressure lower than normal, so that the sac was not tense when invested. Arterial spasm of the parent artery in the cases so far dealt with has not been noted, but it would seem an obvious step to apply papaverine sulphate solution to the artery bearing the sac, so that it would be at maximal calibre when encased.

The phrase "neither clinical nor experimental evidence" was intended by me only to refer to personal findings. The use of the material in experimental cavities has revealed its tendency to result in odontoblast damage, or necrosis, and the toxicity of free monomer has been stated to be approximately that of acetone.—I am, etc.,

JOHN DUTTON.

Bristol.

Adrenalectomy for Intracranial Metastases

SIR,—I was very interested to read the article by Mr. Allan Clain and Mr. Alan H. Hunt on "Adrenalectomy for Intracranial Metastases from Carcinoma of the Breast" (*Journal*, September 15, p. 627), as I have under my care a patient with an intracranial metastasis who has had a good remission following adrenalectomy.

A single woman, then aged 43, had a radical mastectomy performed for carcinoma of the right breast in 1953. In August, 1954, x-ray therapy was given to the right cerebral hemisphere for a presumed metastasis. The headache re-emerged with increasing intensity until she was admitted to St. Leonard's Hospital on March 5, 1955, in semicomatose with gross papilloedema and a left hemiparesis. She responded to dehydration therapy and was given testosterone propionate, 100 mg. thrice weekly, pending her decision regarding operation. She was readmitted on April 24, again in semicomatose, and once more responded to dehydration. On May 5, 1955, bilateral oophorectomy and left adrenalectomy were performed, with removal of the right adrenal a fortnight later. She responded very well: her headache

went, she became alert, the fundi returned to normal, and the hemiparesis improved. She returned to full duties as a clerk and remained well until two months ago, when morning headache recurred. Although the patient is still at work there is now early papilloedema to be seen.—I am, etc.,

London, W.1.

G. M. LUNN.

Statistics of Therapeutic Trials

SIR,—My attention has been drawn to Dr. I. Sutherland's review of my book *Statistics of Therapeutic Trials* (*Journal*, December 10, 1955, p. 1433). It is not for the author to question the reviewer's opinion, but if the review contains misstatements or distortions of facts the author is entitled to a correction. After careful consideration of Dr. Sutherland's statements, I must ask you to oblige me by publishing this letter in your *Journal*.

The reviewer blames the author for "a tendency to oversimplify medical situations, exemplified by the dichotomy of diseases into acute and chronic. . . ." He does not mention that it is repeatedly emphasized in the book that the dichotomy of diseases into acute and chronic is only a first approximation. The first time this is stressed is on page 9 of the book with these words: "Considering that the dichotomy of diseases into acute and chronic is only a first approximation to nosological classification . . . it follows that the allocation of statistical methods given above is also to be regarded as a first approximation and will have to undergo modifications as the nosological description becomes more detailed."

The reviewer is opposed to "the author's advocacy [sic] of alternate allocation of cases to treated and control groups to the virtual exclusion of other methods. . . ." The reviewer cannot have overlooked the fact that throughout the book the reader's attention is always drawn to the need for modifying the simple alternate allocation of cases in such a way as to ensure due consideration of possibly concurring causes. Contrary to the reviewer's statement, I have hardly anywhere recommended the method of simple alternates. Moreover, it is inconceivable how the reviewer could make a statement of this sort in view of the fact that the sampling methods advocated in the whole of Part 3, and most of Part 4, and thus in little less than 200 pages, have *nothing whatsoever* to do with sampling by alternates.

The reviewer states: "There are careless statements like 'the coefficient of contingency . . . is a correlation coefficient.' " If the reviewer has never heard of the Bernoullian correlation coefficient or the tetrachoric correlation coefficient, this is his fault, and it is, therefore, the reviewer's statement which is "careless," not mine.

The reviewer blames the author for conveying "the impression that the statistician and the clinician are each to be encouraged to plan trials without reference to each other," and that "close co-operation between clinician and statistician appears to be nowhere stressed in the book." How, in the face of the second paragraph, page viii, the reviewer could make this statement is difficult to understand, since what I say there is the precise opposite of what the reviewer imputes to be my intention. The passage runs: "But there is yet another aspect of therapeutic trials on which the medical statistician should be able to comment and advise, and that is the suitability of a criterion for the therapeutic trial in question. As a rule, there are a number of criteria available, and, perhaps, equally important ones from the clinician's point of view, and it is now for the statistician to say which of them is most suitable from the statistical angle."

What I have said in the preface seems to have made the reviewer apprehensive of the consequences for statisticians, as a professional class, should physicians ever master the rudiments of their craft. But it is just this tendency of pretending that this would be a hopeless undertaking which I wanted to counteract and disprove. This does not mean, as the reviewer fears, that physicians might cease to consult statisticians altogether, but only that they could acquire such knowledge of statistics as is required for carrying out simple significance tests, and forming their own conclusions instead of following blindly the statistician's conclusions. I cannot help Dr. Sutherland: statistics as applied in medical significance testing is not so difficult that a physician could never hope to master the craft.—I am, etc.,

G. HERDAN.

Shoe-fitting

SIR,—I have read the letter from Mr. C. A. Pratt (*Journal*, September 22, p. 714), and I think that most people would agree with this. With many others, of course, I deplore the use of shoe-fitting fluoroscopes, since they are undoubtedly dangerous and are of little value. In 1949 I had a conversation with a leading Swedish shoe importer and retailer, and we discussed the question of shoe-fitting fluoroscopes. These are illegal in Sweden, and he much regretted his inability to use these machines—he recognized the fluoroscope as being of little value, but he appreciated it as a publicity agent. He informed me that he overcame this difficulty, at least in the case of children, by having transparent plastic shoes made in the various sizes on the lasts of the different makes and types. This enabled the fitter, the parent, and the child to see clearly just how closely fitting the shoe might be, even in the more rigid types. He considered this method to be good publicity and to obviate difficulties in some cases. I have often thought that this method might be used in this country in preference to the use of x-ray machines.—I am, etc.,

Oxford.

G. M. ARDRAN.

Painless Cardiac Infarction

SIR,—I was very interested to read the annotation on "Painless Cardiac Infarction" (*Journal*, September 22, p. 705), and particularly the theories which have been put forward to explain their occurrence. I am in full agreement with the view expressed by Evans and Sutton that this might be explained on the basis of the efficiency or otherwise of the collateral circulation. Threshold to pain no doubt plays a part in the symptomatology which may result from such infarction, but I would suggest that a high threshold would be the operating mechanism in symptomless cardiac infarction, rather than a low one.—I am, etc.,

Leeds.

T. KRAFT.

SIR,—In your annotation (September 22, p. 705) you write: "However, undoubtedly some cases of cardiac infarction are symptomless. A low threshold to pain . . . have all been suggested as explanations." An obvious error—"low" should be "high." The analgesic effect of morphine and other drugs results from a raising of the pain threshold so that the stimulus which was previously adequate no longer evokes pain. Similarly certain states (e.g., inflammatory) lower the threshold: thus tenderness is elicited by a strength of stimulus which in normal conditions would be ineffective.—I am, etc.,

Dundee.

F. R. BROWN.

Clinical Psychologist in the Mental Hospital

SIR,—In his paper on the work of the clinical psychologist in the mental hospital, Dr. R. Hetherington (*Journal*, September 22, p. 708) states that "the tests he [the clinical psychologist] uses are based on scientific research and depend as little as possible on personal subjective impressions and as much as possible on objective measurement." He then proceeds to state that "the various so-called 'projective techniques,' such as the Rorschach ink-blot test and Murray's thematic apperception test, give valuable information about a patient's personality. The former gives indications of how the patient operates: anxiously, depressively, obsessively, and so on; the latter yields information about his attitude and opinions with regard to his parents, death, violence, sex, and the like."

With respect to the use of the Rorschach, at least, it would be interesting to know how Dr. Hetherington reconciles the first sentence quoted above with the second. It would be a pity if the general practitioner were to conclude from Dr. Hetherington's paper that the Rorschach is "based on scientific research" and depends "as little as possible on subjective measurement." Most of the published work on the Rorschach fails lamentably to reach acceptable

standards of scientific rigour. In recent years, it is true, a fairly large number of carefully controlled studies have tested the various claims embodied in the second quotation from the paper. After a careful review of this evidence carried out in the Institute of Psychiatry's department of psychology it was concluded that these objective studies failed to support any of the claims made on behalf of the Rorschach. The evidence was considered sufficiently conclusive to lead to the abandonment of the use of the Rorschach in clinical work.—I am, etc.,

London, S.E.5.

AUBREY J. YATES.

SIR,—With reference to Dr. R. Hetherington's article (*Journal*, September 22, p. 708) I would like to draw attention to the fact that there exists an official instrument dealing with the functions, status, training, etc., of clinical psychologists on a national basis (within the National Health Service). Dr. Hetherington's account of the working of clinical psychologists, as he himself states, refers to one hospital only—namely, Crichton Royal, Dumfries—and thus represents rather a personal view.

The instrument I am referring to is the agreement reached between a working party, set up in February, 1952, of the Committee of Professional Psychologists (Mental Health), English Division, of the British Psychological Society and the Ministry of Health. This agreement was published by the Whitley Councils for the Health Services in the Circular No. 27 (Professional and Technical A), 1954. This circular, however, does not represent the views of the Scottish Division of the Committee of Professional Psychologists.¹ The Scottish Division of the Committee of Professional Psychologists (Mental Health) expresses a somewhat different view on the question of functions, status, and training of clinical psychologists. Their policy is embodied in a memorandum published in the *Bulletin of the British Psychological Society*.² Since the publication of P.T.A. Circular No. 27 in 1954, two further P.T.A. Circulars have superseded it (No. 30 in 1955 and No. 39 in July, 1956). These latter two deal mostly with training and remuneration of clinical psychologists. The basic functions and status of clinical psychologists, however, have not been altered.

It is therefore of importance that hospital boards, management committees, medical officers, especially in mental hospitals, and clinical psychologists themselves, in case of doubt, or for reference, should consult the Whitley Councils for the Health Services P.T.A. Circular No. 27, 1954.—I am, etc.,

Chester.

B.C.G. and Vole Bacillus Vaccines

SIR,—The report of the Medical Research Council on vaccination against tuberculosis (*Journal*, February 25, p. 413) has been accepted as evidence in favour of B.C.G. vaccination with such an astonishing lack of critical examination that it seems most important to draw attention to those parts of the report which are in need, at least, of clarification. The first is the method of dealing with the complications of vaccination. The report states (p. 417): "Leaflets describing the normal course of the vaccination reaction were given to the vaccinated children, and they were instructed to report any abnormality to the school medical officer. By these measures a few cases of regional adenitis . . . were brought to the notice of the teams, but there was no evidence that such complications were common." Just how uncommon they were is not mentioned, but, of the complications of which a record was kept, there were two cases of erythema nodosum after B.C.G. vaccination and three cases of tuberculous adenitis caused by vaccination with the vole bacillus. In addition, vole bacillus vaccination resulted in an unspecified number of lesions indistinguishable from lupus vulgaris, of which 22 were severe enough to need treatment.

All these complications were excluded from the calculations from which the incidence of tuberculosis in the vaccinated children was assessed. Only those lesions which appeared to have been caused by the human tubercle bacillus were regarded as "cases of tuberculosis," even if vaccination had caused similar lesions or perhaps worse—and before the days of chemotherapy lupus vulgaris was a very terrible form of tuberculosis. It is scarcely surprising, therefore, that the vaccinated children seemed to have less tuberculosis than the unvaccinated. It does not seem unreasonable to say that the true tuberculosis morbidity in this group consisted of all the patients who had tuberculous lesions whether they were caused by infection with the human tubercle bacillus or by vaccination. If the 27 known cases of complications of vaccination are added to the 20 "cases of tuberculosis" which were found in this group the incidence is little different from that in the unvaccinated children.

The second criticism is of the efficiency of the follow-up. To keep in touch with 56,700 children must have been extremely difficult, and contact was maintained by personal letter, by a visit from a health visitor, and, within each 18-month period, by x-ray examination of the chest. More than 90% of the participants were investigated by one or other of these methods. But, although this would seem to have been an impressive achievement, only the x-ray examination can be regarded as having been of any scientific significance in diagnosing tuberculosis, and here the achievement is not nearly so impressive. From the random sample on which these results are based, 77% of the unvaccinated controls, 74% of the B.C.G. vaccinated, and 70% of the vole bacillus vaccinated had a chest radiograph during the period of the follow-up, and it would seem that 3,036 of the controls and 5,586 of the vaccinated were not x-rayed after admission to the survey.

Finally, it should be remembered that the survey was carried out in three separate centres—London, Birmingham, and Manchester—but the report does not state whether or not the cases of tuberculosis were distributed evenly between the different groups in the different areas. If, for instance, most of the cases amongst the vaccinated occurred in London and most of those amongst the unvaccinated in Birmingham or Manchester, accidental environmental factors or the application of different diagnostic criteria might easily account for an apparent protective effect of vaccination.

There is little in the report, therefore, to suggest that vaccination against tuberculosis is any more effective now than it was in 1927, when the Editor of the *British Medical Journal* exposed Calmette's fallacious claims for B.C.G.¹—I am, etc.,

Dungannon, Co. Tyrone.

Is Tonsillectomy Necessary?

SIR,—May I trespass once more on your valuable space in order to comment on the letters of Drs. J. C. Ryle (*Journal*, September 8, p. 603) and J. Burkinshaw (*Journal*, September 22, p. 713)? Much as I support their commendable statements on tonsillectomy, yet I cannot let the contention in the M.R.C. Report No. 227¹ go unanswered. This implies that tonsillectomy may render the patient at least as resistant as non-tonsillectomized persons and that the case against operation is statistically unanswerable. Those of us working in infectious diseases hospitals have ample proof (if this be needed) that tonsillectomy *per se* does not influence resistance to infections to any considerable degree. I can provide many instances, including my own personal experience, where the patient has contracted nearly every common infection since operation. Not that this is related in any way to the operation or even to the absence of tonsils themselves.

Immunity is gained by the body's capacity to produce antibody. This, in turn, may be achieved by a single

massive infection or by repeated subclinical exposures. The presence or absence of the tonsils *per se* is immaterial, except in so far as they provide a ready and available source of antibody production, though it has been shown that bulbar poliomyelitis is more likely in tonsillectomized persons, because presumably the virus missed the tonsillar barrier. In other words, unnecessary tonsillectomy removes a valuable link in the immune chain. The operation is only likely to influence subsequent events beneficially when the tonsils themselves are diseased.—I am, etc.,

Romford, Essex.

The Brown Dog of University College

SIR,—On returning from my summer holiday I was interested to read Dr. Baron's paper (*Journal*, September 1, p. 547) on "The Brown Dog," given before the Osler Club of London on June 16, 1955.

On November 19, 1907, when I was house-surgeon to the late Sir John Bland-Sutton at the Middlesex Hospital, I received a telephone message from the police station at Battersea to say that a medical student who had been taken in charge for damaging the Brown Dog statue wished to speak to me. It was a request that I should stand bail for a notorious character, then a student at Middlesex. He told me on the telephone that he had no time to give me full details of the incident because he was playing an exciting game of snooker with the police. The protest meeting in Trafalgar Square on the night of December 12 was a terrifying affair. Eventually the crowd was dispersed by mounted police, and many were lucky to escape without injury.—I am, etc.,

London, N.W.11.

CLIFFORD MORSON.

Enzyme Tests for Glycosuria

SIR,—The evaluation of the new enzyme test for the detection of glycosuria is of importance not only to the hospital physician but also to the general practitioner. It is important to remember that in using any of the copper-reduction tests (Fehling's, Benedict's, or "clinitest") two distinct tests should be made: (1) Is there a reducing substance in the urine? (2) If there is, is it glucose? The accurate identification of the reducing substance has never been easy, and so in practice we rarely ask ourselves the question. Because the new tests are specific for glucose they resolve this difficulty.

The results published by Dr. J. A. Hunt, Professor C. A. Gray, and Mr. D. E. Thorogood (*Journal*, September 8, p. 586) and Professor R. E. Tunbridge, Dr. R. G. Paley, and Mr. D. Coulson (p. 588), as well as my own tests, have shown that both "test-tape" and "clinitix" are, if anything, over-sensitive, a positive result being obtained when the smallest quantity of glucose is present. False negatives do not occur. Quantitatively they do not fare as well, as the articles have shown. In addition to the difficulties already published, others must be pointed out. The manufacturers of test-tape say that the darkest area on the tape is the one to be compared with the colour scale, and the colour scale varies from batch to batch. The difference in shade (note shade, not colour) between 0.5 g. and 2 g. or more of glucose per 100 ml. is not in my opinion sufficiently great for the average layman to detect without considerable practice—those diabetic patients I have asked to use the test-tape were unable to record such a difference with any degree of accuracy, whereas all have been able to recognize the bright orange that clinitest gives when there is 2 g. or more of glucose per 100 ml. Furthermore, some patients (I have two who do it) after dipping the test-tape into the urine tend to wipe it dry between their thumb and index finger. The galaxy of shades they produce makes any quantitative reading wellnigh impossible, though I stress that this does not affect the qualitative reading—a positive or a negative result is as easy to see as ever. This problem does not arise with clinitix; only one end of the stick is impregnated with the enzyme. All in all, the reticence of the manufacturers of the clinitix—who do not make any claims for the quantitative capabilities of their product—is fully justified.

Another difficulty with the enzyme test is that it takes one minute before the reading can be made—during which time the tape or stick must not come into contact with paper and should therefore be held in the hand. (Actually clinistix with their firm handle will balance nicely on the top of the test-tube or bottle.) Testing large numbers of urines—for example, antenatal clinics or Services recruits—by this method is not as convenient as the clintest “screening” test in which a tablet is dropped into a clintest dropperful of urine (not more than 1 ml.), and if after bubbling has stopped any other colour than blue is observed the test is regarded as positive. On the other hand, at an antenatal clinic, the enzyme test being specific for glucose has the advantage in not responding to lactose. More experience of the two tests under these conditions is undoubtedly called for, and they warrant a full trial.

Translating these findings into daily practice, I suggest that these enzyme tests have a very definite place in the G.P.’s diagnostic kit. Without the use of a test-tube or water—let alone heat—by merely dipping the tape or stick into the urine, we can see if glucose is present or not. If the result is negative a great deal of effort (and perhaps mess) has been saved. If, however, the result is positive, then, because of its excessive sensitivity and its lack of quantitative value, the result should be checked with a copper-sulphate test—preferably clintest, which is easier than Benedict’s (it needs no spirit lamp) and more accurate (what is an inch of urine?). In dealing with the urine of a known diabetic it is perhaps easier to do a clintest estimation straight away. For the patient in his home clintest is the safest and most accurate, unless we are anxious to be told every time there is any glucose present.

Incidentally, I have also been testing a new tablet test for the quantitative estimation of sugar in the blood (albeit within a limited range). I have tried the test on a newly suspect diabetic (found in enzyme test screening), and found his blood sugar two hours after a meal to be over 200 mg.%. If the test proves, after fuller investigation, to be accurate, then G.P.s will be able to diagnose diabetes in the surgery with ease and confidence.

I wish to thank Messrs. Ames Company (London) Limited for supplies of clinistix and the blood-sugar tablet test, and Messrs. Eli Lilly and Co. for supplies of tes-tape.—I am, etc.,

London, N.W.2.

STUART CARNE.

Early Management of Poliomyelitis

SIR,—Dr. E. G. Brewis in his letter (*Journal*, September 15, p. 657) has retreated considerably from the position he took up in his article in your issue of June 30 (p. 1539). There, let us recall, he told us that “hospital admission has nothing to offer the patient [suffering from poliomyelitis] which cannot be done in the ordinary decent home.” Indeed, it might do harm, and the ambulance journey might “be a deciding factor in initiating paralysis.” It should therefore “be firmly resisted.” He now writes, “In advocating the domiciliary management of suspected and early cases in the meningitic phase—and after all only a small proportion ever pass beyond this stage—I did not mention the paralytic patients at all.”

Let us look at his article again. There he conceded that in some circumstances resistance to hospital admission might be abandoned, and he gave a list of cases that might with propriety be allowed to undergo the “risks” involved. Of these, number four reads: “Extensive paralysis of the limbs or back which make home-nursing too difficult under ordinary circumstances.” Surely this unequivocally implies that cases with moderate paralysis, or even with extensive paralysis, might be kept at home provided that the family were able to cope with them?

Dr. Brewis assures us that there are many consultant paediatricians, physicians, and orthopaedic surgeons who have considerable experience in poliomyelitis, and no doubt there are, but when he gives as early signs of spinal and diaphragmatic paralysis without bulbar involvement “restlessness, rapid shallow respirations, increasing cyanosis and

distress” one is bound to question the extent of his own experience. These signs in purely “spinal” cases are not early but terminal. When cyanosis appears the patient has lost some 90% of his vital capacity, and is within measurable distance of his last gasp. When cyanosis appears early in a patient whose respiratory muscles still possess a reasonable reserve of power it is a sign of an obstructed airway with or without collapse, almost invariably due to secretions which he can no longer swallow. In other words the medulla is already involved, and the case is a dreaded “bulbo-spinal.”

Quite clearly Dr. Brewis has recognized (as who has not?) that many cases of poliomyelitis are sent to hospital that could have been nursed at home. Unfortunately we are only wise after the event, and retrospective wisdom is of little use. There is no means whatsoever of telling in the meningitic phase which patient is going to be able to walk out of hospital unscathed a few weeks later, and which is going to die or spend the rest of his life in a respirator. “Only a small proportion,” writes Dr. Brewis, ever progress to paralysis. I invite his attention to the following statistics of admissions to the Blegdams Hospital, Copenhagen, during 1952–3:

Number certified as poliomyelitis	2,830
Number diagnosed poliomyelitis	2,241
Number progressing to paralysis	1,235
Number requiring artificial respiration	345
Number of deaths	144

Dr. Brewis assures us that his policy has not been a factor in the fatality rate which he quoted, but I believe that most of us will accept that assurance with considerable reserve. Everyone is agreed that in cases of life-threatening polio the first essential is to bring the patient under skilled observation and within reach of help at the earliest possible moment—hence the organization of specially equipped teams to go (by air in Denmark and by ambulance in this country) to bring the patient to a special centre. Dr. Brewis’s policy of “wait and see” is clearly incompatible with this principle, and, unless he possesses special divinatory powers, cannot fail to influence the results.—I am, etc.,

Isleworth, Middlesex.

G. E. BREEN.

Congenital Hypoplastic Thrombocytopenia

SIR,—The article by Drs. A. D. Bell, J. W. Mold, R. A. M. Oliver, and S. Shaw (*Journal*, September 22, p. 692) emphasizes both the rarity of this condition and the temporary effect of therapeutic measures. Two identical cases have been observed in the Sheffield hospitals.¹ In one of them the same therapeutic measures were tried as in the quoted article, with an equally unsatisfactory result. Transfusion of platelets direct from donor to patient through silicone syringes in the form of fresh blood seemed to give the best survival. Splenectomy would not appear to hold out any promise unless at least some megakaryocytes are present in the bone-marrow.² This again underlines the importance of obtaining satisfactory marrow samples even at the cost of repeated punctures.

The nosological position of this condition is not absolutely clear yet. While, on the one hand, one might feel justified in seeing in it the infantile equivalent of the Fanconi syndrome, on the other hand, one has to take into consideration at least a relationship to congenital (granulocytic) leukaemia. The peripheral blood count is “leukaemoid,” there is a hyperplasia of the leucon in the bone-marrow, and often some degree of haemopoiesis in lymph glands and liver, too. The association with the described skeletal and other deformities can occur in both conditions.—I am, etc.,

Sheffield.

Obituary

Sir WILLIAM GILLIATT, K.C.V.O., M.D., M.S.
F.R.C.P., F.R.C.S., F.R.C.O.G.

The death of Sir William Gilliatt in a road accident at Chertsey on September 27 deprives obstetrics and gynaecology in this country of one of its outstanding figures. He was 72 years of age. His appointment as surgeon-gynaecologist to H.M. the Queen naturally attracted public attention to him. It was he who acted as obstetrician when Prince Charles was born at Buckingham Palace in 1948 and again at the birth of Princess Anne at Clarence House in 1950. Previously he had attended the Duchess of Kent in all her three confinements. But, apart from the public notice which such a position inevitably attracts, Sir William Gilliatt gained the highest distinction in his profession. He was President of the Royal College of Obstetricians and Gynaecologists in 1946, and in 1954 he became President of the Royal Society of Medicine. At the time of his death he was consulting surgeon to King's College Hospital and to the Samaritan Free Hospital for Women, two hospitals with which he had been associated during most of his professional life.

William Gilliatt was born at Boston, Lincolnshire, in 1884. There, under the shadow of the famous “Stump,” he spent his childhood. He came of Lincolnshire farming stock. His paternal grandparents lived at a village a few miles from Boston, and, although his grandfather died at an early age leaving a large family, his widow carried on the farm, and all but one of their sons also became farmers. The exception was Sir William's father, who opened a chemist's shop in Wide Bargate, Boston. He, too, died while still a young man, but his widow carried on the business and sent her son William to Boston Grammar School and later to Wellingborough College, where he is still remembered as a prefect and a useful half-back. From there he went for his medical studies to Middlesex Hospital, where he seems to have captured all the prizes. He was Hetley Clinical Scholar, Junior Broderip Scholar, and Leopold Hudson Scholar in 1908, and Lyell Gold Medallist and Scholar in 1909. After graduating M.B., B.S. in 1912 he occupied posts of obstetrical surgeon at Queen Charlotte's and gynaecological registrar and tutor at the Middlesex.

Having proceeded M.D., London, with gold medal, in 1910, he gained his M.S. and F.R.C.S. in 1912, established his consulting practice in Wimpole Street, and quickly became known as a brilliant gynaecological surgeon. In 1916 he was appointed assistant obstetric and gynaecological surgeon at King's College Hospital and also lecturer in gynaecology in the medical school. During the first world war he served as a captain in the R.A.M.C. For many years he was on the staff of the Samaritan Free Hospital for Women, and among other hospitals with which he was associated were St. Saviour's Hospital, the Bromley Cottage Hospital,

[Central Press Photos, Ltd.]

and the Maudsley Hospital. In 1925 he succeeded Hugh Playfair as senior obstetric and gynaecological surgeon at King's, a post he held for 21 years. Since 1932 he had been a member of the committee of management of the hospital, being appointed vice-chairman in 1945.

It was in 1946, the year he retired from the active staff of King's, that Gilliatt became President of the Royal College of Obstetricians and Gynaecologists. He had taken a leading part in the affairs of the College, of which he was a Foundation Fellow, having served as a member of its council and as honorary treasurer. During his tenure of the presidential chair the Royal Charter was granted to the College, and in 1949, just before the induction of Professor Hilda Lloyd as the new president, Sir William had the honour of admitting Queen Elizabeth (now the Queen Mother) an Honorary Fellow of the College. Two years later he presented Princess Elizabeth, when she visited the College to be made an honorary Fellow. He was appointed C.V.O. in 1936, knighted in 1948, and promoted K.C.V.O. in 1949.

In 1953 the Honorary Mastery of Midwifery was bestowed upon him by the Society of Apothecaries of London in recognition of his eminence in his chosen field. From 1954 to 1956 he was president of the Royal Society of Medicine, and he filled this office with distinction during a somewhat difficult period of the Society's history.

From time to time Sir William Gilliatt served on special committees of the British Medical Association. He was a member of the Negotiating Committee which preceded the introduction of the National Health Service in 1947 and of the Evidence Committee which was sitting at the same time. In 1949 he was appointed chairman of the Standing Maternity and Midwifery Advisory Committee under the National Health Service.

A busy life did not leave much time for authorship, but he will be remembered as joint author of *Ten Teachers of Midwifery and Diseases of Women*.

Sir William was a commanding figure, and to some who came into only fleeting contact with him he may have appeared dour. That is the last word which those who enjoyed his confidence would apply to him. He was the most approachable of men, with kindness for all who sought his help, and his quiet confidence must often have proved as efficacious as his expert skill in the cases he had under his care. Nurses and midwives will have particular occasion to remember his kindness and help, especially as president of their annual conferences.

Sir William Gilliatt married Anne Louise Kann, herself a member of the medical profession. They had one son and one daughter. The son, Dr. R. W. Gilliatt, follows his father's calling, and is an assistant physician at the National Hospital for Nervous Diseases.

We are indebted to Sir WILLIAM FLETCHER SHAW for the following appreciation:

The tragic death of Sir William Gilliatt, in full vigour of mind and body, when we might anticipate his leadership and friendship for many years to come, is a sad blow to the profession and especially to our special branch of obstetrics and gynaecology. I first met Gilliatt in the early days of

the formation of what is now the Royal College of Obstetricians and Gynaecologists. He was a young man in those days, but sufficiently advanced to be made a Foundation Fellow, though not as yet playing an active part in its administration. It was only when I became President and he a member of council that we were brought into close contact. It was soon obvious that here was a potential leader, clear-headed, reliable, knowledgeable, not given to expressions of opinion until the facts had been studied, but, once that opinion was formed, of inflexible purpose, clear in exposition, and endowed above all with shrewd common sense.

During the first four years of my presidency we were drawn together more and more closely, and at the end of this time the post of honorary secretary unexpectedly became vacant and the council, recognizing the necessity for close integration of these two executive offices, unofficially allowed me to nominate a successor. Without any hesitation I chose Gilliatt, and during my last years we worked in even closer harmony.

In those war years many problems suddenly arose which had to be dealt with by the executive officers without time to place them before the council or executive committee, or at least to be put in train before those bodies could meet. I unhesitatingly chose Gilliatt to work with me, partly for the great qualities I have enumerated, but even more because his independence of mind could be relied upon to express his opinion clearly and forcibly, even if it did not accord with mine, though I knew I could rely upon his loyalty to carry out the ultimate decision, whichever this might be. For a year we worked in the closest co-operation, and I more and more came to appreciate and rely upon his outstanding qualities of mind and spirit and formed a close friendship which was broken only by his untimely death.

It was during his own presidency, three years later, that Gilliatt was chosen to attend the Queen, then Princess Elizabeth, at the birth of Prince Charles, and well-deserved honours now fell to his lot—first a knight bachelor as President of the Royal College of Obstetricians and Gynaecologists, and the following year a K.C.V.O. for his services to the Princess.

Many men would be content to reap personal advantages and others might be too deficient in personality to carry out their own wishes, but Gilliatt saw that his College, whose aims and objects would naturally appeal to the Queen and the Princess, was brought to their notice and shared in his honours. Queen Elizabeth, now the Queen Mother, became an Honorary Fellow of the College and later the first Patron, while the Princess, now Queen Elizabeth, became an Honorary Fellow and, with the Duke of Edinburgh, honoured the President by attending the annual dinner of the College.

After laying down the presidency Gilliatt still laboured hard for the College and could always be counted upon to give of his best. In 1937, at considerable sacrifice, he visited both New Zealand and Australia on behalf of the College. For many years Gilliatt was a member of the honorary staff of King's College Hospital, where his clinical work and teaching in both obstetrics and gynaecology were of the highest order, and to the end one could be sure that his patients, hospital or private, royal or common, received of his best. There was no second best in his work; it was all or nothing, and in this he set a shining example. A Court appointment in the eyes of the general public means leadership in a particular branch of medicine, but it by no means follows that this opinion is endorsed by the profession. In Gilliatt's case there could be no other opinion, and if the choice had been left to those of his profession best fitted to give an opinion he undoubtedly would have been elected.

To those of us privileged to see him in his own home circle comes the full realization of what this tragedy means to his wife, son, and daughter. Our sympathy, which is all we can give, seems very inadequate in the circumstances. He will be greatly missed.

Mr. J. H. PEEL writes:

The sudden death of Sir William Gilliatt has robbed the medical profession of one of its most illustrious contemporary personalities. With a brilliant record behind him as student, resident, and registrar, Gilliatt was appointed to the staff of King's. He soon identified himself with his new hospital, which he was to serve so loyally and faithfully for the rest of his life. King's has never had a more devoted servant, even from its own alumni, and it was here that he showed the first signs of his especial gift as a committee man. In 1932 he was elected to the committee of management, and in 1945 he became vice-chairman of the hospital. When, with the coming of the National Health Service, the new board of governors was formed he was an automatic choice as one of its members, and he was appointed vice-chairman and chairman of the nursing committee. The fact that the King's medical staff has had the happiest possible relationship with its committee of management and later its board of governors has in no small measure been due to Sir William's influence. He continued to exert this influence for good just as much after his retirement from the active consulting staff and medical committee of King's in 1949. The medical committee was also fortunate when after his retirement he agreed to serve as chairman of the medical school council for five years. Equally valuable have been his services to the nursing staff since he became chairman of the nursing committee.

Outside King's his statesmanship has received equal recognition. A foundation member of the Royal College of Obstetricians and Gynaecologists in 1929, he was soon elected to the council and subsequently served on practically every College committee, and was in turn acting secretary, treasurer, and finally President during 1946-9. He filled each office in turn with the highest distinction, and after he retired from the presidential chair his wise counsel and mature judgment were as freely available to the College as they were before. His outstanding gifts and wise statesmanship were recognized by succeeding Ministers of Health, and he served on many ministerial committees which helped to guide the affairs of the profession and the health of the people of this country. The last distinguished office to which he was elected was the presidency of the Royal Society of Medicine in 1954, and he had only very recently completed his term of office.

With such very onerous administrative duties I often wondered how he was able to achieve also such a high degree of eminence in his purely professional work. But it was always his principle to undertake only that which he could do properly according to his own very high standards. He undoubtedly had a great gift for organizing his own life and professional activities so that they never got out of control. He resigned from the staff of Queen Charlotte's after only five years because he felt that he could not devote enough time to the maternity department at King's if he endeavoured to hold both offices. He built up rapidly a very successful obstetric practice, and his patients were utterly devoted to him, for he served them without reservation of any kind.

It is given to few in our profession to receive such a glittering series of distinctions and honours, and so richly to deserve them. That he did richly deserve them those of us who knew all that had gone before were in a position to appreciate. The foundation stone of his success was character. He set himself the highest possible standards of professional conduct, and he lived by them. His patients were his life, and fundamentally it mattered not whether they were from the aristocracy or from the humblest homes—they were all patients requiring whatever service he could render. And, because he gave them so much, they in turn revered him to a degree that was at times remarkable. He inspired in them a confidence that was never false. He was incredibly kind to them. It was as a clinician that he excelled. His diagnostic acumen and sound clinical judgment were the basis of his pre-eminence. No detail in the manage-

ment of his patients in the ward was too trivial to escape his attention. He expected the highest possible standard from his assistants and could, if he thought they had been negligent in the care of a patient, chastise them with a biting phrase which cut to the quick. Praise from him was praise indeed, but it had to be won by diligence and good work. However, having won his trust, he gave his help and encouragement without reservation. No one knows this better than I, and to him I owe a debt that can never be repaid.

As a surgeon Sir William's success was based upon sound principles rather than brilliant and spectacular performance. His judgment of the need for surgery and his choice of operation were usually right, and his patients did extremely well. He was scrupulously careful in technique, especially haemostasis. He was at times perhaps overcautious, particularly in later years, but I think he realized his limitations as a surgical technician. He would never learn to do a vaginal hysterectomy. Having made up his mind early in life that it was a bad operation, he never changed his opinion, and I could never convince him to the contrary.

As a teacher he was didactic, dogmatic, clear, and concise. His logical brain enabled him to reduce the complex to the simple for the sake of the student, who came away from his lectures and ward rounds with clear and concrete ideas. He never wrote a lot. He had very firm views about a good deal of medical literature and he only wrote when he felt that he had something really worth while to contribute.

Sir William had an innate shyness and reserve which was difficult to penetrate, and which some of his friends and admirers found difficult to understand. His stern self-discipline and single-minded determination gave at times the impression of austerity, even ruthlessness. It always seemed a little strange that someone who was at heart so essentially kind should be on occasions aloof. Though his death came as a great shock to all who knew him, there is some consolation to be found in its very suddenness. None of us could ever have imagined him in complete retirement. The gradual deterioration of mental and physical powers which must inevitably come with advancing years would have tried him sorely. This, happily, he has been spared, and for his sake we must be glad. It was fitting that a man who was truly great and who had achieved such eminence in his profession should pass on while still enjoying life to the full.

A happy private life is the only sure foundation for a successful professional one, and in this Sir William was fortunate. Lady Gilliatt, herself a doctor, was throughout the years a great companion and support to him, contributing in no small measure to her husband's success. She and a son, also a member of the medical profession, and a daughter made up his utterly devoted family, and to them we send our heartfelt sympathy.

Dr. DAVID BRAHAM died at his home in Bournemouth on September 20, after a long illness patiently borne. He was born in Leeds on July 18, 1900, and was the second son in a family of four boys, three of whom became doctors. From the Central High School at Leeds he went on to study medicine at Leeds University, graduating M.B., Ch.B. in 1923. After a year spent as house-surgeon in the Hospital for Women and Children in Leeds he started in general practice in Darwen. Here he took a prominent part in local government, becoming a town councillor and serving on the health committee. Ill-health eventually forced him to give up his practice in Darwen, and in 1931 he moved to Bournemouth, where his health soon improved and he built up a thriving practice and made many friendships which lasted for the rest of his life. In 1940 he went to Leicester, where he soon won the affection and esteem of his patients and colleagues. He was a keen bridge player and golfer, and in 1954 he was joint winner of the annual trophy of the Leicester Medical Society. Always interested in the improvement of general practice, he was a founder member of the College of General Practitioners.

Unfortunately in 1955 the state of his health necessitated his retirement, and he went back to live in Bournemouth and await the end which he well knew was inevitable. He bore his illness bravely, and his untimely death will be widely mourned by his colleagues and patients in Leicester and Bournemouth. He was the ideal general practitioner, accurate in diagnosis, skilled in treatment, and always a personal friend of his patients. The sympathy of his friends will be extended to his wife and two married daughters, and particularly to his mother, who in the same week suffered a double bereavement by the sudden death of another son, Dr. Harvey Braham, of Huddersfield.—R. J. D.

Dr. C. F. X. O'SULLIVAN died at his home at Navan, Co. Meath, on August 20 at the age of 70. Born in the city of Galway, Christopher Francis Xavier O'Sullivan was educated at the Jesuit College, Galway, and at Rockwell College, Tipperary. He graduated M.B., B.Ch., B.A.O. at the Royal University of Ireland at the age of 21, and for two years thereafter he took temporary posts in several districts in the west of Ireland. In 1909 he was appointed to the dispensary district of Williamstown, Co. Galway, where he practised for over 40 years. His health began to fail in 1950, and he retired to live in Navan. He is survived by his widow.

We record with regret the death at the age of 29 of Surgeon Captain G. C. E. WILSON, regimental medical officer to the Household Cavalry Regiment. He was murdered in his car in a suburb of Nicosia by E.O.K.A. gunmen on September 26. Gordon Charles Edwyn Wilson was born on November 6, 1926, the son of the late Captain Ian Wilson and of Mrs. Wilson, of St. Andrews, Fife. From Cambridge, where he won a blue for running, he went on to complete his clinical training at St. George's Hospital, graduating M.B., B.Ch. in 1953. After holding resident posts at St. Martin's Hospital, Bath, and the Eastern General Hospital, Edinburgh, he joined the Royal Horse Guards as a surgeon captain—an old-fashioned title held only by those who are directly commissioned in the Household Cavalry without serving in the R.A.M.C. He leaves a widow and two young children, and we sympathize with them and with his mother in the tragic and deplorable loss of this young doctor.

Dr. E. A. GREGG wishes to thank people for their kind letters of sympathy, and regrets that he is unable to answer them all.

The Services

Major-General P. F. Palmer, O.B.E., late R.A.M.C., has been appointed Honorary Surgeon to the Queen, in succession to Major-General R. Murphy, C.B., C.B.E., retired. Lieutenant-Colonel Sir Arthur E. Porritt, K.C.M.G., C.B.E., R.A.M.C., T.A., has relinquished the appointment of Honorary Colonel 57 (Mx) General Hospital, retaining the rank of Honorary Colonel.

A Supplement to the London Gazette has announced the following awards:

Second Clasp to the Territorial Efficiency Decoration.—Major (Lieutenant-Colonel) H. H. Kenshole, D.S.O., T.D. (seconded to University of London, O.T.C.); Majors D. S. Austen, T.D., and H. Dickie, T.D., R.A.M.C.

First Clasp to the Territorial Efficiency Decoration.—Colonel A. McK. Reid, M.C., T.D. (retired), Lieutenant-Colonel (Honorary Colonel) E. M. Elmhirst, T.D. (retired), Major (Lieutenant-Colonel) H. H. Kenshole, D.S.O., T.D. (seconded to University of London, O.T.C.), R.A.M.C.

Territorial Efficiency Decoration.—Majors W. J. Atkinson, G. V. Cole, M.C., J. S. B. Mackay, and D. K. W. Picken, R.A.M.C.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 15 (No. 37) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in August was 86, compared with 127 (revised figure) in the previous month and 111 (revised figure) in August, 1955.

The numbers of cases of industrial disease in the United Kingdom reported during August, 1956, were as follows: lead poisoning 1, aniline poisoning 2, toxic jaundice 2, toxic anaemia 1, epitheliomatous ulceration 17, chrome ulceration 8; total 31. There was one death from toxic anaemia.—*Ministry of Labour Gazette*, September, 1956.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending September 15 were falls of 160 for measles, from 1,092 to 932, and 44 for whooping-cough, from 2,315 to 2,271, and rises of 65 for food-poisoning, from 189 to 254, and 60 for scarlet fever, from 253 to 313.

Small falls in the incidence of measles were recorded throughout the country, but no large local fluctuations were reported. The largest variation in the trends of whooping-cough was a rise of 50 in Yorkshire West Riding, from 166 to 216, and in most of the other areas a small decline in incidence was reported. 7 cases of diphtheria were notified, being 3 more than in the preceding week. Only small changes occurred in the local returns of scarlet fever.

111 cases of acute poliomyelitis were notified during the week. These cases were 9 more for paralytic and 3 fewer for non-paralytic cases than in the preceding week. The largest centres of infection were Lancashire 29 (Manchester C.B. 14, Heywood M.B. 4, Liverpool C.B. 3), Cheshire 9 (Stockport C.B. 5), and Surrey 9 (Banstead U.D. 2, Reigate M.B. 2).

321 cases of dysentery were notified, being 9 fewer than in the preceding week. The largest returns were Yorkshire West Riding 73 (Leeds C.B. 49), London 40 (Southwark 12), Lancashire 30, and Warwickshire 27 (Coventry C.B. 19).

In Scotland the number of notifications of dysentery rose from 146 to 202. The largest returns were Glasgow 85, Edinburgh 44, Midlothian county 24, and Dundee 11.

Week Ending September 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 376, whooping-cough 1,848, diphtheria 6, measles 1,082, acute pneumonia 195, acute poliomyelitis 111, dysentery 390, paratyphoid fever 7, typhoid fever 9.

Medical News

Calling the Resident.—St. Thomas's Hospital has now had three months' experience of a new magnetic system for quickly summoning residents from anywhere in the hospital. It replaces the bells, supplemented by the leg-work of two porters, which was the former method. Because the system has proved a success at St. Thomas's, the Governors have arranged a demonstration of it on September 26 to an invited audience of doctors and hospital administrators from all over the country. The object, said the Treasurer, Sir ARTHUR HOWARD, was simply to let others decide whether the St. Thomas's system would be useful in their own hospitals, where conditions might be different. The capital cost and maintenance of the system were less, he added, than those of any comparable system he knew of. The system, which is based on that used at the Palais de Chaillot in Paris for transmitting simultaneous translations of speeches at international congresses, has been developed as a result of research by Mr. STYLES at St. Thomas's in conjunc-

tion with Multitone Electric Company, Ltd., the producers. The hospital buildings are enclosed in a loop of magnetized wire about 2,500 yards (2,286 m.) in length. Each member of the staff on call is provided with a receiver, looking rather like the handle of a small ophthalmoscope, 13.7 cm. long and 2.9 cm. in diameter, which is clipped into a pocket. Each receiver—up to 56 can be run on one circuit—responds only to a signal from the controlling transmitter given at its own frequency. The response is a low-tone "peep peep." With slight modification, the receiver can be adapted to transmit the human voice, but at St. Thomas's they prefer a non-verbal signal, as this means that the resident has to ring up the main porter's lodge (where the controller is housed) to find out his message. In this way it can be known for certain that he has received it. The system is described in detail by Mr. W. PEARSON, deputy clerk to the governors, in the October issue of *Hospital*.

Association of Industrial Medical Officers.—The association ended its anniversary celebrations with a dinner at the Royal College of Surgeons on Thursday, September 27. Sir HARRY PLATT proposed the health of the association and the reply was made by Dr. R. S. F. SCHILLING, president of the association. The toast of "Medicine in Industry" was proposed by the EARL OF VERULAM and of the guests by Dr. L. G. NORMAN, past president of the association. Dame FLORENCE HANCOCK replied on behalf of the guests.

Royal College of Obstetricians and Gynaecologists.—The PRESIDENT and Mrs. CHARLES READ received a large number of guests at the annual dinner of the College at the Dorchester Hotel on September 28. In proposing the health of the College the MINISTER OF HEALTH said that infant mortality had been remarkably reduced in the last 50 years, but the mortality of infants in the first week of life and the stillbirth rate were far from satisfactory. Mr. Turton also suggested that members of the College should give their advice and consider what was best in providing the best maternity services. He had set up a committee and hoped to get its report very soon. In reply Mr. READ said that the College was determined to see the country had a first-class maternity service. Professor T. N. A. JEFFCOATE, with elegance of phrase, provided a series of neat biographies which caused no discomfort to the guests whose health he proposed, and in response Mr. DICKSON WRIGHT made even the most austere relax at intervals into unseemly mirth.

Occupational Health Institute Advocated.—Professor R. E. LANE, Nuffield professor of occupational health at Manchester, in his John C. Bridge memorial lecture on September 27 to the Association of Industrial Medical Officers, advocated the establishment of an occupational health institute. Such an institute, he said, should be prepared to undertake operational research, and it might also carry out routine biological and environmental examinations. He suggested that, to begin with, the institute might be jointly financed by employers and trade unions, though later it might become in part self-supporting, or, having demonstrated its usefulness, receive Government aid.

R.C.O.G. Honorary Fellows.—At a meeting of the Council held in the College House on September 28, with the President, Mr. CHARLES D. READ, in the chair, Lord NUFFIELD and Lieutenant-General Lord WEEKS were admitted to the Honorary Fellowship of the College.

World Medical Journal Editor.—Dr. S. S. B. GILDER has been appointed associate editor of the *World Medical Journal*, which is published by the World Medical Association. Dr. Gilder is editor of the *Canadian Medical Association Journal* and was formerly assistant editor of *Abstracts of World Medicine*, published by the B.M.A.

Dr. W. F. Widdas, senior lecturer in physiology at King's College, London, has been appointed to the university readership in physiology tenable at that College.

Dr. Victor A. Sutter, aged 53, Assistant Director-General in charge of Advisory Services in the World Health Organization, has resigned his position in order to accept an

appointment as Minister of Public Health and Social Assistance in his own country, the Republic of El Salvador.

Professor W. J. Hamilton, professor of anatomy in the University of London, has succeeded Dr. E. C. Warner as Dean of the Charing Cross Hospital Medical School as from August 1.

COMING EVENTS

A service for doctors and nurses will be held in the Old Meeting House Congregational Church, Colegate, Norwich, at 3 p.m. on Sunday, October 14. The address will be given by Mr. A. S. ALDIS, F.R.C.S.

British Institute of Radiology.—Annual congress and exhibition, December 6 and 7. Final date for registration, October 15. Details from the general secretary, British Institute of Radiology, 32, Welbeck Street, London, W.1.

British Association of Allergists.—Autumn meeting on October 19, 5.30 p.m., at Brompton Hospital, Fulham Road, London, S.W.3. Full details from Dr. A. W. FRANKLAND, St. Mary's Hospital, London, W.2.

Society of Apothecaries.—The Master's Day Service of the Society of Apothecaries is to be held on Sunday, October 21, at 11.15 a.m. at the Church of St. Mary Aldermary (opposite Mansion House Station).

Westminster Medical School.—Viscount CHANDOS will give the inaugural address at 3 p.m. on October 22 at Church House, Westminster.

Wessex Rahere Club.—The autumn dinner will take place at the Grand Spa Hotel, Bristol, on October 27. Details from Mr. A. DAUNT BATEMAN, 11, The Circus, Bath.

Abortion Law Reform Association.—Immediately following the annual meeting, a public meeting will be held at 7 p.m. on October 31 at Conway Hall, Red Lion Square, London, W.C.1. The subject will be "Immediate Prospects for our Private Member's Bill." Details from the honorary secretary, 53, Gloucester Terrace, London, W.2.

Leeds Medical School.—Annual dinner for past and present male students will be held at the Griffin Hotel, Leeds, on November 2, at 7.30 p.m. Tickets (25s.) from the dinner secretary, Medical School, Leeds, 2.

St. Thomas's Hospital Medical School.—The old students' dinner will take place in the New Hall, The Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on November 8, at 7 p.m. for 7.30 p.m. Professor A. D. GARDNER will be in the chair. Tickets £1 11s. 6d. (exclusive of drinks).

Gastro-enterology Conference.—A specialist conference on gastro-enterology will be held in Glasgow at the Royal Faculty of Physicians and Surgeons, November 26-30. Details will be found in our advertisement columns (p. 54).

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, October 8

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. D. McAlpine: Multiple Sclerosis—Clinical Aspects of the Problem.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. E. G. L. Bywaters: Henoch-Schönlein Purpura.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. D. H. Patey: Some Points in the Surgery of the Parotid Gland; 6.30 p.m., Mr. D. Trevor: Surgery of the Patella.

Tuesday, October 9

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Sir Albert Richardson: Development of the Nineteenth Century (Illustrated by slides).
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. M. B. Mackenna: Sebaceous Glandular System.
MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Clinical Sciences Building, York Place, 8 p.m., Presidential Address by Mr. S. M. Milner: Business as Usual.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Imperial Cancer Research Fund Lecture by Dr. C. P. Rhoads: Soluble Puzzle of Cancer Control.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. T. Holmes Sellers: Carcinoma of the Lung; 6.30 p.m., Mr. F. R. Kilpatrick: Prostatectomy.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. G. C. Knight: Spinal Compression.

Wednesday, October 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynihan: Connective Tissue.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. Lloyd Rusby: Collagen Disorders with particular reference to Respiratory Manifestations.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. R. C. Higham: Enuresis.
MANCHESTER MEDICAL SOCIETY.—At Medical School, Manchester University, 4.15 p.m., ordinary meeting of Fellows. Presidential Address by Dr. J. F. Wilkinson: What's Bred in the Bone.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. F. W. G. Wolff: Biochemistry of Diabetes (1).
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. R. Sampson Handley: The Spread of Breast Carcinoma and its Relation to Treatment; 6.30 p.m., Mr. J. B. Pennybacker: Chronic Subdural Haematoma.

Saturday, October 13

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Grove Park Hospital, 10.30 for 11 a.m., Dr. J. E. Stokes: Some Cases of Pulmonary Pneumatocele; Mr. I. M. Hill: Some Cases of Miral Disease and Surgery; Dr. C. W. L. Jeanes: A Chest Physician Visits the New World—The Lighter Side.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Hayman.—On September 22, 1956, to Eva (formerly Diamant), S.R.N., S.C.M., and Michael Hayman, M.B., B.S., of 13, Church Street, Bridgwater, Somerset, a daughter—Joanna Louise.
Oakenfull.—On September 19, 1956, at the Maternity Home, Scunthorpe, Lincs, to Isabel (formerly Heath), M.B., Ch.B., wife of Basil G. P. Oakenfull, F.F.A.R.C.S., a son—Michael George.
Roe.—On September 1, 1956, at University College Hospital, London, W.C., to Kathleen (formerly Dempsey), wife of Dr. Peter W. Roe, of 43, Belmont Road, Bushey, Herts, a daughter—Jane Martha.
Taylor.—On April 3, 1956, at the Lady Chancellor Maternity Home, Salisbury, Southern Rhodesia, to Edna (formerly Parish), M.C.S.P., wife of Dr. P. A. Taylor, D.C.H., a sister for Susan, Michael, and Philip—Hilary Margaret.

MARRIAGES

Douglas-Foster.—On September 22, 1956, at Christ Church, Guildford, Surrey, Dr. Eric Murray Douglas, of Beaconsfield, Bucks, to Jean Foster, S.R.N., S.C.M., of Guildford.

DEATHS

Braham.—On September 20, 1956, at Hurlingham Cottage, 14, Manor Road, Bournemouth, Hants, David Braham, M.B., Ch.B., aged 56.
Cuthbertson.—On September 19, 1956, at 157, Essex Road, Leyton, London, E., William Cuthbertson, M.B., Ch.B.
Mackay.—On September 8, 1956, Ernest Charles Mackay, M.D., of West Dene, St. Leonards-on-Sea, Sussex.
Rohan.—On September 7, 1956, at Churchfields, Old Basford, Nottingham, Mary Teresa Rohan, M.B., Ch.B., D.P.H.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Fog Precautions

Q.—*What precautions are worth taking in any severe fogs this winter, either at home or out of doors? What classes of person need special protection, and what is advised for them?*

A.—The group of people who above all are liable to suffer serious effects in fogs are the chronic bronchitic and emphysematous. Asthmatics without organic lung damage may or may not be affected; usually they are not in such danger of severe exacerbations of symptoms as patients with permanently diminished respiratory capacity from chronic bronchitis and emphysema. To a less extent, patients with certain types of heart disease may be adversely affected by fog, especially those who have suffered congestive heart failure. For any patient who has in the past suffered severely during a fog the best policy, beyond doubt, is to move out of towns where heavily polluted fogs are apt to develop during the winter. For those who must remain in town the simplest advice is to remain indoors in a well-warmed room during the persistence of fog. It seems clear that the coldness of the air has some effect in increasing the liability to serious effects from exposure to fog. On the hypothesis that the acid sulphur dioxide and its derivative sulphur trioxide, which are known to be present in urban fogs, are an important factor in causing irritation of the respiratory tract, the use of ammonia to neutralize the acid has been suggested. Although the results of a formal investigation of its value are not available, some suggestive evidence has been obtained. Strong ammonia solution is put into a bottle with a wick which is raised sufficiently to provide the required concentration of ammonia. The only objective way of judging this is by means of special test papers, but it is possible that the patient's subjective sensations might be a satisfactory guide. Obviously this method could be tried only with an intelligent patient to whom the principles involved could be explained. In the management of acute exacerbations of bronchitis caused by fog, if the patient must remain in the foggy atmosphere, oxygen is invaluable, providing, as it were, local air-conditioning. They must be used, however, with due regard to the dangers of too high a concentration of oxygen giving rise to carbon dioxide narcosis.

Platelet Production and Treatment of Thrombocytopenia

Q.—(1) *What is the physiological mechanism concerned in the regulation of platelet production?* (2) *Have there been any recent advances in the treatment of thrombocytopenic purpura? Is adrenochrome monosemicarbazone of value in this condition?*

A.—(1) The physiology of platelet production has not been so completely elucidated as that of the red or white cells. There is no morphological equivalent of the reticulocyte, the "band" cell, or the early lymphocyte, therefore assessment of activity has had to be made on the number of circulating platelets. Even the origin of platelets has been disputed, but it is now generally accepted that Wright's¹ original hypothesis of origin in the megakaryocytes is correct. Some idea of platelet activity may occasionally be obtained by a study of marrow smears, but this is a very inaccurate method and often misleading. Platelet production appears to be stimulated by thrombocytopenia, widespread tissue damage, haemorrhage, cortisone, and corticotrophic hormone. The spleen controls the platelet count by destroying aged platelets or by a direct hormonal influence on the marrow. Splenectomy in both the normal and the thrombocytopenic

subject is in many instances followed by marked thrombocytosis, whereas increase in splenic size for any reason is often accompanied by thrombocytopenia. Modern techniques with radioactive markers may perhaps throw new light on thrombopoiesis.

(2) The most recent and practical advance in the therapy of the thrombocytopenic haemorrhagic state has been the use of corticotrophic hormone and cortisone.^{2,3} One or other or both of these hormones may produce a rise in the platelet count, and even thrombocythaemia, with considerable improvement in the bleeding tendency. Even if the platelet count fails to rise, the tendency to bleed is usually lessened, presumably owing to the direct action of the hormones on the blood vessels. Thus they provide a means of controlling the haemorrhagic episode before an elective splenectomy or until a spontaneous remission occurs. The technique of platelet transfusion has also been perfected, but the indications for this procedure are few. Failure of hormones or splenectomy to control haemorrhage is probably the only certain indication for selective platelet transfusion.

Adrenochrome monosemicarbazone will reduce the bleeding time and decrease capillary fragility in experimental animals.⁴ In the reports of the sporadic clinical studies so far available there is lack of adequate evidence to prove that cessation of capillary bleeding can be attributed to the action of this drug. Its clinical use in the thrombocytopenic state is as yet unestablished.

Subception

Q.—*There was a report in the national press some weeks ago that experiments in the U.S.A. with sub-liminal visual stimuli had been apparently successful in boosting the sales of a particular brand of ice-cream advertised in this way. The advertisement was thrown on to a cinema screen during an ordinary film for a time so brief that the audience was not aware of having seen it, yet the sales of the product are said to have risen. If this result is to be accepted at its face value, the implications seem thoroughly alarming. What experimental support is there for these claims?*

A.—The question divides itself into two parts. First, can physical signals or differences in these, the presence of which the observer cannot report, yet affect his behaviour in some way? Second, have these surreptitious means of stimulation a power of suggestion which is equal to, or greater than, modes of stimulation of which the person is aware? A great deal of work has been done on the first question by experimental psychologists, and the subject is still controversial. This work on "subception," as it has been called, has shown that subjects will block their awareness of obscene words when presented tachistoscopically, even though their psycho-galvanic reflex shows that the words have produced some reaction. A further experiment, designed to eliminate the possibility that the subjects may have been simply embarrassed and thus unwilling to report, was done by pairing an electric shock with some nonsense words, and the previous result was substantiated. Some other experimental possibilities remain to be checked, and the whole set of conclusions based on these and similar experiments has recently been challenged on statistical grounds. Work is at present being done on this subject at University College, London, and the television service has been used in the experiments.

So far as the second question is concerned, there is no good evidence. It is of course well substantiated that suggestion can by-pass consciousness, as in hypnosis. However, there is only the report on the ice-cream advertisement to show that stimuli below "threshold" can have the same effect. Mass experiments of this nature are not very convincing because of the large differences in threshold sensitivity existing in a population. It is very difficult to be certain, unless this is ascertained individually and indepen-

dently, whether or not a subject is aware that he is being stimulated, and, to make it even more difficult, there are large fluctuations in the threshold of an individual's sensitivity from moment to moment. We do not therefore know what proportion of the purchasers of the ice-cream were aware of actually seeing the advertisement. Further work by experimental psychologists is clearly necessary.

Hydrocortisone Snuff

Q.—In a recent annotation¹ you describe a trial of hydrocortisone snuff, in a dosage of 15 mg. hydrocortisone acetate per ampoule, for hay-fever. Is there any evidence that prolonged treatment with this snuff might have undesirable local effects on the nasal mucosa, or even adverse systemic effects?

A.—A dose of 15 mg. of hydrocortisone acetate daily is extremely unlikely to produce adverse systemic effects, especially in cases of hay-fever, whose season lasts from a week or so up to two months; nor would treatment with this dose be likely to cause ill-effects if used for more prolonged periods. Local applications of hydrocortisone in solution have been shown to produce histological changes in the skin, but only temporarily, and it has not been shown that these changes are harmful.

It is not known whether particles of hydrocortisone applied to mucous membranes cause undesirable local effects on the nasal mucosa. Clinically the beneficial effects in hay-fever are not accompanied by any obvious adverse local effects.

Repeated Blood Transfusion and Haemosiderosis

Q.—In conditions necessitating repeated blood transfusions, such as aplastic anaemia, is haemosiderosis an unavoidable sequel? How soon is it likely to develop, and what can be done to minimize its effects when it does?

A.—Whenever iron is introduced into the body without removal of a corresponding quantity—usually as blood—that iron will be deposited in the tissues; and, if present in large enough quantities, it will excite the production of fibrous tissue which sooner or later will strangle the liver lobules and the pancreatic islets and produce the pathological picture of haemochromatosis, and later still its clinical manifestations. Haemosiderosis is thus an inevitable result of repeated blood transfusion without bleeding: haemochromatosis will appear only if the patient lives long enough, and its clinical signs may be long delayed. The speed with which fibrosis develops around deposited iron depends on many factors, most of which are not clearly differentiated. Probably the most important is the quantity of iron deposited and the time it remains in the tissues: there is little chance of clinical haemochromatosis developing within two years from less than 15 g. iron, which is contained in 30 litres of blood. One patient received about 25 g. of iron over a period of five years without developing skin pigmentation, hepatomegaly, or diabetes, though her pancreas contained much fibrous tissue; of two others who received 15 g. of iron within a year, one became pigmented and developed hepatomegaly before the year was out, but the other has neither pigmentation nor hepatomegaly three years later. It is proposed to subject this last patient (who seems to be fully recovered) to repeated venesections until most of the excess iron has been removed.

Prevention of haemosiderosis is thus not an urgent matter, since most subjects with aplastic anaemia die within 10 years, but experiments with intramuscular dimercaprol (B.A.L.) or intravenous sodium calcium-edetate have been tried without much success; too little iron is removed to compensate for the prolonged immobilization of the patient. However, if a patient with aplastic anaemia has completely recovered, it is worth while subjecting him to repeated venesections.

NOTES AND COMMENTS

Exact Control in Diabetes.—Dr. WILLIAM BRAND (London) writes: The answer to this question ("Any Questions?" August 18, p. 430) prompts me to introduce a very important point that appeared to be taken at a tangent—namely, that there is no real statistical evidence in favour of hyperglycaemia *per se* being prejudicial to health or expectation of life. I feel that this is a consideration to be faced in the basic treatment of the malady. Every diabetic that I have encountered in hospital and private practice periodically tests his or her urine for sugar. When I endeavour to determine whether they have been testing for ketone bodies they almost invariably and incredulously answer in the negative. From my own small experience I am convinced that patients do not realize, as they should, that it is the presence of ketones in the urine which might herald the onset of diabetic coma (not hyperglycaemic coma), and not glycosuria alone. To counteract the production of ketone bodies, and by the usual methods of supervision, we can assess the minimum of carbohydrate required to balance the fat and protein, the amount of the latter depending on the individual's dietary propensity. Any amount of sugar or carbohydrate over and above this would do no harm but on the contrary would ensure safety under various grades of activity, always keeping in mind that the more active individual will tend to require more insulin than his sedentary counterpart. The resulting hyperglycaemia and associated glycosuria can be compared with cases of renal glycosuria which are classically benign. Do you not think, Sir, that the principles of treatment in diabetes should be established along these lines instead of along those of the complicated and erroneously exact dietary methods set out in every textbook which the student regards with bewilderment? He is thus more often than not completely at sea when confronted by a diabetic he has himself diagnosed.

OUR EXPERT replies: It is true that it is difficult to say for certain that hyperglycaemia *per se* is a bad thing: but there is not only a general impression among those with long experience of diabetes that it is so, but also not a little evidence to support this view. The detailed follow-up of a very large number of cases in Dr. Joslin's clinic in Boston and a similar study by Professor Dunlop in Edinburgh agree in showing that the incidence of complications of the disease is significantly greater in those patients who, by blood-sugar standards, are poorly controlled than in those whose blood sugars approximate more closely to physiological levels. Secondly, in early cases there is good reason to believe that prolonged hyperglycaemia tends to aggravate the diabetes and prevent any recovery of natural function. Further, patients who consistently run a high blood sugar not only more readily develop the symptoms of diabetes when, for any reason such as infection, their diabetes becomes worse, but also have a reduced margin of safety, with the result that they are particularly liable to develop ketosis in these circumstances. I am well aware that these arguments are not conclusive, but taken together I think they constitute a valid reason for continuing the generally accepted practice of trying within reason to keep the blood-sugar level in diabetes as near as possible within physiological limits, although I am equally aware of the fact that this is rarely possible.

Books of "Any Questions?" and Refresher Course Articles.

The following books are still available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volume 2 (26s. 6d. inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Aitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. SUMMARY

... a guide to the use of
*Cortisone in the treatment
of asthma*

Because of its powerful anti-allergic and anti-inflammatory effects cortisone is of great value in the treatment of asthma. The best methods of using it are fully discussed in this new Glaxo publication. Comprehensive, but to the point, the book is a very useful ready-reference guide for the busy practitioner.

Just send us a signed card marked "Asthma Book" and we shall be pleased to post you a copy free of charge.

THE PROBLEM OF STAPHYLOCOCCAL INFECTION*

BY

WALSH McDERMOTT, M.D.

Livingston Farrand Professor of Public Health and Preventive Medicine, Cornell University Medical College, New York

The control of the great plagues and certain of the acute bacterial infections has not delivered mankind from infectious disease, but it has very decidedly changed the nature of that disease in certain countries of the world, including the United States of America.

The principal change in these countries has had the effect of throwing into prominence those bacterial diseases which characteristically require a relatively greater reduction of bodily defence before infection can become disease. To be sure, the initiation of any disease involving a particular microbe presumably requires some breakdown, however temporary, of the defence mechanisms of the host. Nevertheless, certain microbes seem to require more such help than others.

As we all know, the three principal diseases involving bacteria which are most prominent in the U.S.A. are those produced by the bowel flora, by tubercle bacilli, and by staphylococci. These three groups of diseases have a number of features in common; above all, they share together in the fact that harbouring of the parasite is commonplace but disease is rare. This means that the spread of these diseases among a group of persons is not to be regarded as a visitation from without but rather as an indication that something is going wrong with the crude equilibrium which had previously existed in that community.

If this is so, it follows that we should not be exclusively preoccupied with attempts to drive invaders out, for we are not really dealing with invaders but with original settlers. If they were not actually here first, they were certainly a close second. Indeed, in the specific case of staphylococci most babies acquire them during the first week of life. No, our preoccupation should be instead with attempts to discover what it is that goes wrong which permits these hangers-on to gain control; or, more specifically, with study of what there is to go wrong. And the fact that this indeed is a subject of widespread experimental preoccupation may be seen from the topics listed in our Conference.

Some Generalizations

Before concentrating exclusively on staphylococci, however, it might be helpful to recall to our minds certain of the other properties held in common by staphylococcal disease and its two sister diseases—those caused by tubercle bacilli and those caused by individual members of the bowel flora. There is, first of all, with

* This article was one of a series of papers presented at the conference on "Staphylococcal Infections" held by the New York Academy of Sciences on February 16 and 17, 1956, and is included in the monograph published under the same title in the *Annals of the New York Academy of Sciences*, volume 65, article 3, pp. 55-246.

all three groups of diseases the fact mentioned previously that the presence of the microbe is commonplace, but disease and illness are rare. And this leads to that obvious inference that either the microbe or the host must undergo some significant alteration before infection can become disease. In addition, and with certain individual exceptions, there runs through the microbes of all three groups of disease the common tendencies: to produce localized lesions with destruction of tissue; to produce endotoxins or tuberculin; to survive intracellularly (only in the case of tubercle bacilli and staphylococci); to produce illness which may range from the exceedingly acute all the way to the barely perceptible chronic forms; and, finally, there is the common tendency to exist or to emerge in a form resistant to one or more antimicrobial drugs.

For these reasons, and even without respect to the matter of drug-resistance, the antimicrobial therapy of these forms of localized bacterial diseases has always represented a less important portion of the total therapy than is the case with certain of the acute relatively non-destructive microbial diseases.

Generalizations such as these are quite helpful when we are trying to outline and define a problem, but, as we all know, these generalizations soon reach their limits. And if there is one thing characteristic about staphylococci it is the complete lack of generality which they display with respect to many of the attributes related to disease-production in which we are most interested.

Thus, although we are gathered here to discuss something called staphylococcal infection we all know that this is not always quite the same thing as staphylococcal disease. We know, too, that even if we limit ourselves to the staphylococci which regularly produce the aureus pigment and coagulase, or even to the members of the same bacteriophage type, we are not necessarily on firm ground with respect to their homogeneity in terms of ability to initiate disease in man or some laboratory animal. At times it almost seems as if every staphylococcus is different.

The Microbe and the Lesion

In addition to the strong individualistic tradition among staphylococci, consideration of the subject of staphylococcal infections or disease is further complicated by the very real difficulties in establishing a diagnosis. We have here the same general problem that we face with any ubiquitous microbe, but with the added obstacle that we know that staphylococci are capable of producing lesions virtually anywhere on the body surface and that human carriers of staphylococci are commonplace. As a consequence, we cannot accept the mere

presence of staphylococci in an open lesion such as a wound—even an operative wound—with any degree of confidence that the microbe and the lesion are necessarily related. In short, open wounds in open wards, no matter how carefully the wound may be protected by surgical dressing, are seldom suitable objects for the study of staphylococcal infection and disease, yet we know that some of these lesions could be related to the staphylococci.

Accordingly, in considering staphylococcal infection and disease, one must limit the discussion to lesions which had never shown external drainage at the time of first culture—that is, the so-called “closed lesions” and the infections accompanied by bacteraemia. Even with the so-called “closed lesions” the chance of contaminating the lesion by an irrelevant staphylococcus is present, but can be minimized with proper care.

These points are quite well known to all of us. Nevertheless, I am convinced that we who are familiar with them have almost completely failed to communicate them to our scientific colleagues not directly connected with the staphylococcal field. We have sinned further, in my opinion, by not clearly pointing out that most of the large-scale clinical investigations on drug-resistant staphylococci were not concerned with staphylococcal disease at all but had to do with something quite different—namely, the healthy carriers of staphylococci. Finally, while I am on the subject of our sins, until recently we quite failed to emphasize something we all knew—namely, that a penicillin-susceptible staphylococcal infection in a patient virtually never becomes drug-resistant during therapy. As a result of this failure in ordinary communication I am quite confident that physicians and others interested but not directly engaged in the field have the misconception that the number of patients with actual drug-resistant staphylococcal infections and disease seen each year on a general hospital service can be numbered in the hundreds. They have the further misconception that if one treats a penicillin-susceptible instance of serious staphylococcal disease with penicillin the drug will soon prove valueless because of the emergence to predominance of drug-resistant staphylococci.

Exposure in Hospitals

With full appreciation of the problems presented by this individualistic tradition of staphylococci and the difficulties in diagnosis, let us turn now to the question of the staphylococcal problem as we face it to-day. Let us also try to see whether the problem is significantly different from that presented a decade or so ago.

First, let us ask whether our population at large or the special population in our hospitals are experiencing any greater exposure to staphylococci than was the case ten or twelve years ago. Fortunately, we have careful studies bearing on this point available, and it appears that the answer is “No.”

We have, for example, the detailed studies of A. A. Miles and his associates in England which were published in 1944, and we have many studies with the phage-typing method conducted in widely separated portions of the world during recent years. All of these studies show substantially the same thing.

Approximately one-half of any group of adults not in hospital are nasal carriers of staphylococci when studied at a single point in time. When members of the group are followed individually for periods of several weeks or longer, the percentage harbouring staphylococci at one time or another goes up and may reach 70 or 80%. Likewise, when patients are studied on first admission to a hospital and then throughout a hospital stay, the percentage harbouring

staphylococci goes up appreciably from the 50% level on admission and then tends to fall back again after discharge.

One of the many interesting observations brought out in this type of study has been the indication noted by Miles *et al.* (1944), who stated: “The nasal carrier state varies, not with the environment of the person, but with the person himself. There is a marked tendency for persons to be either persistent carriers* or persistently free from nasal *Staph. aureus*.”

Thus, in answer to this first question it can be said that there is no indication that our degree of exposure to staphylococci either in or out of our hospitals is any greater to-day than it was twelve years ago. This is not particularly surprising, and is perhaps just another way of saying that staphylococci were plentiful then and are plentiful now.

The Problem of Pathogenicity

The next question which arises is whether there is any reason to believe that strains of staphylococci of enhanced pathogenicity for man are more prevalent to-day than ten or fifteen years ago. This question is less readily answered than the previous question, because of the nature of the problem. However, if such an increased prevalence of more pathogenic staphylococci was occurring it would be most readily apparent in the number and the clinical forms of the staphylococcal disease seen in patients on admission to the hospital.

Infections which occurred in the hospital environment itself would not provide much information on this subject unless the infections were truly overwhelming. The reason for this is that in a hospital population the presence of so many people ill with other diseases, or ill as a consequence of treatment, would make it difficult to distinguish in any individual situation between increased pathogenicity of the staphylococci and decreased resistance of the host.

So far as concerns patients newly admitted to hospitals, there appears to have been surprisingly little attention directed to this point in recent years. Everyone seems to agree that one of the commonest forms of serious staphylococcal disease, the primary haematogenous osteomyelitis of childhood and adolescence, has virtually disappeared from our admitting-rooms. I also suspect, but cannot substantiate, that patients with carbuncles and recurrent boils are seen less frequently requesting admission to the hospital than was the case ten or fifteen years ago. In several of the recent reports—for example, one by Barber and Burston (1955) from London a few months ago—the number and the form of staphylococcal disease seen in patients on admission to the hospital are listed, but no comment is made concerning how the material compares with the experience in years past.

Fisher *et al.* (1955) reported that in the twenty-year period, 1933–53, at the Johns Hopkins Medical Center, slightly over one hundred patients with staphylococcaemia were seen. This number presumably also includes patients who developed bacteraemia while in the hospital. Nevertheless, the crude figure of 5 to 10 patients admitted annually with staphylococcal bacteraemia would be about what has been seen at New York Hospital–Cornell Medical Center. It should be mentioned, however, that admission rates of patients with staphylococcal bacteraemia to the large university centres may give a falsely high value because of the tendency to transfer such patients from a smaller hospital after therapeutic failure.

Another serious form of staphylococcal disease, the primary pneumonia of adults, tends to occur in sporadic outbreaks in association with viral influenza. Hence it is difficult to form an estimate of its general annual incidence. By the same token, it seems safe to say that there has been no recent steady increase in primary staphylococcal pneumonia in non-hospitalized patients. Such an increase, related or unrelated to influenza outbreaks, might be expected if strains of appreciably enhanced pathogenicity for man were becoming more prevalent.

* Italics mine.

There is one entity, the staphylococcal empyema of infants, particularly those under the age of 6 months, which has been reported to be on the increase. This entity probably represents a situation which is closer to that of the development of infection in the hospitalized patient than to the adult coming to the hospital with established staphylococcal disease. Hence if there is an increase in this entity—and the fact that a real increase has occurred is by no means clear—it should be considered in relation to the problem of the development of staphylococcal disease by persons with hospital experience.

With this possible exception, however, there is remarkably little to suggest that there is any notable increase in the number of patients, particularly adult patients, appearing at our hospital admission rooms with staphylococcal disease. Moreover, there is nothing to suggest that the forms of the staphylococcal disease seen represent the dissemination of more malignant strains of the microbe or the concentration of more malignant strains in particular localities outside our hospital. Indeed, the one apparently definite change in the form of staphylococcal disease seen is for the better—namely, the virtual disappearance of the serious diseases of primary haematogenous osteomyelitis.

The type of evidence available on this question of the form and numbers of patients with staphylococcal disease requesting hospital admission is admittedly sketchy. Nevertheless, while much has been published on staphylococci in recent years, no one seems to be mentioning any remarkable increase in the number of patients with staphylococcal disease or any increase in unusually malignant forms among the patients who present themselves for admission to hospital.

Is there an Increased Virulence?

We have therefore a situation in which neither our patients in hospitals nor what might be loosely termed the public at large are apparently undergoing any greater exposure to staphylococci than was the case a decade or so ago. And we have no particular reason to believe that there has been a wide increase in the prevalence of unusually pathogenic staphylococci or even that there has been any substantial numerical increase in staphylococcal disease occurring outside our hospitals.

In brief, we have no convincing evidence, or indeed even any particularly well-founded suspicion, that the crude equilibrium between the public at large and the ubiquitous staphylococci is shifting for the worse. If any shifts have occurred they seem to have been on the side of a more favourable situation for the members of the public.

What, then, is the situation of our special communities of hospitalized patients with respect to their crude equilibrium with their staphylococci?

As mentioned before, their risk of exposure to staphylococci in general is presumably no different from what it ever was—or at least from what it has been in the past decade. But how about the possibility that there is a wider prevalence of particular strains of increased pathogenicity for man? Because of the localized and highly special circumstances involved, is it not possible that especially pathogenic strains of staphylococci might be lurking around our hospital environments, whereas the same strains would not be so readily detectable when spread through the community at large?

Let us set a measure of increased virulence in terms of epidemics of unusually serious staphylococcal disease involving a dozen or more patients at a time in a single hospital and occurring throughout our hospitals in general. Viewed in these terms I do not believe that we have a particularly good case for increased virulence of the so-called “hospital staphylococci.” But when one considers the highly individualistic nature of staphylococci it is by no means inconceivable that such strains are present here and there, though operating, thus far, only in terms of tiny localized epidemics. Indeed, there is some reason to believe, in the case of a few strains, notably the enterotoxin-

producing strains, that this sort of thing is actually happening even though its overall numerical expression is still quite small.

Even this occurrence of tiny but multiple epidemics involving enterotoxin-producing staphylococci, however, does not establish that these strains are necessarily newcomers to our hospitals or necessarily have assumed increased virulence for man. For we are obviously doing other things to our patients which we were not doing in years gone by, and it may be that it is the setting rather than any absolute increase in microbial virulence which determines this highly alarming phenomenon.

There is another phenomenon, re-emphasized by Barber and Burston (1955), which might indicate that the staphylococci prevalent in our hospitals to-day have an increased pathogenicity for man. In brief, they have presented evidence that strains of staphylococci from the lesions of active staphylococcal disease may be the chief offenders in terms of cross-infection and the ability to initiate staphylococcal disease in new hosts. It should be emphasized that these investigators do not present their findings as evidence that the lesion-producing staphylococci are necessarily more virulent than the more virulent of our present strains. They merely suggest that it is these lesion-producing staphylococci which have the capacity to initiate new disease, in relative contrast to the staphylococci of the nasal carriers.

These observations made by Barber and Burston with modern techniques are particularly timely and should form the basis for detailed epidemiological investigations. Hence it is no disparagement to point out that their findings recall to mind the well-respected item in the clinical lore of our fathers' generation to the effect that a hand infection in a surgeon or a pathologist was a far more dangerous thing than a hand infection in a housewife who had stuck herself with a pin. It was reasoned that the strain of microbe in the case of the surgeon or pathologist was more dangerous on the grounds that it had been so recently producing disease in a patient.

Although these last few remarks on hospital staphylococci are relevant to the central topic they represent a slight digression from the consideration of whether to-day's hospital staphylococci contain an impressively increased prevalence of unprecedentedly virulent strains. On this subject, I believe it can be said that when one considers the wide range among individual strains of staphylococci in terms of ability to initiate new human disease, there is no convincing evidence that—on the whole—our hospital staphylococci are any more virulent for man than they ever were.

Lowering of Defences

As I see it, therefore, we are not subjecting our patients in hospitals to a greater risk of exposure to staphylococci or to any more especially virulent strains of staphylococci than we ever were.

Does this mean that we are not seeing the development of more staphylococcal disease among our patients while they reside in our hospitals to-day than was the case a decade or so ago? Almost certainly not. Indeed, the only reason for qualifying the situation at all is the lack of precise comparative data for the two time periods. Despite the absence of precise data, I am confident that most of us are convinced that to-day we are seeing with greater frequency the actual development of staphylococcal disease in patients after they have come into our hospitals than was formerly the case. In short, we are beginning to detect signs that the hitherto satisfactory equilibrium between our hospital patients and staphylococci is becoming unbalanced.

It is not so much that our patients in hospitals are being subjected to any greater challenge by staphylococci as it is that they are less well equipped to meet the same old challenge. Because they are less well equipped, it is up to us to give them better protection. At the present time, however, we are doing considerably less than that. Indeed, in many cases we are actually lowering such defences as the patient brought with him to the hospital. We are doing

this by the bodily disturbances we create as an unsought-for accompaniment of many of our modern therapies. In effect, an unfortunate by-product of our life-saving and life-prolonging procedure is to create a favourable market for staphylococci.

This favourable market is being created in several ways. First, our modern therapies are permitting the survival of people who are less able, in various undefined ways, to cope with bacterial infections. Examples of this sort are the insulin-treated diabetics, the children who have had splenectomies for various haematological disorders, the adults who have had total gastrectomies, and perhaps even some who have had partial pulmonary resections. Second, certain of our commonly used treatments such as cortisone, hydrocortisone and corticotrophin, the more widely acting antimicrobials, and x-ray irradiation are known to create circumstances which at times facilitate the development of infection. It is conceivable that on certain occasions treatments such as the antihistamines or the anticoagulants might unfavourably influence infection. Finally, in order to manage many of these modern treatments properly, it is necessary to perform venepunctures and skin punctures with unusual frequency on these very patients who for one reason or another are more liable to the development of infection.

To be sure, this increased congregation of more susceptible hosts in our hospitals is not necessarily the only reason for the apparent increase in staphylococcal infections developing in the hospital. Nevertheless, it does seem to be the principal factor which is *different* in our situation to-day from that of a decade or so ago. Moreover, if it is happening in the hospitals to-day, it is reasonable to expect that it will happen outside the hospitals in the future as these various forces become active on a wider scale.

If we assume the validity of this analysis, how can the situation be improved? It would be pointless to think in terms of attempting to oppose many of the forces which are contributing to this situation, because so many of these forces are such notable scientific achievements for the common good. Moreover, as staphylococci are so ubiquitous, an approach based on attempts to eliminate them from the environment would not seem hopeful. In the same way, it does not appear that antimicrobial drugs *per se* would play an important part. Chemoprophylaxis is a two-edged sword at best. In the present situation, the necessity for protecting the patient for such very long periods against a number of microbial species in addition to staphylococci makes the use of drugs impracticable.

Two approaches exist which seem reasonable. The first is for us all to have a continuing awareness of the fact that our hospitalized patients to-day are on the whole less able to cope with staphylococci than was formerly the case. This means that we should review and probably intensify our aseptic practices not only in the operating-room but especially in connexion with the ordinary "puncture" procedures used in the wards.

The second approach is the major one—namely, to find means for increasing bodily defences against staphylococci and means to restore these defences when they have been reduced. The logic of this approach is evident if you agree with me that the crux of to-day's staphylococcal problem lies not so much in changes in our staphylococci as it does in changes in the status of our hosts. Our difficulties with this second type of approach arise immediately, however, and stem from the fact that we are almost wholly ignorant of the mechanics of staphylococcal infection and disease. Until we can discover more than we now know concerning what determines the pathogenicity of certain staphylococci and how the healthy host manages to live in peace with them, it is not likely that our situation will materially improve.

THE TRANSMISSION OF STAPHYLOCOCCUS AUREUS

BY

RONALD HARE, M.D.

Professor of Bacteriology and Honorary Consulting Bacteriologist

AND

C. G. A. THOMAS, B.M., M.R.C.P.

Lecturer in Bacteriology

From the Department of Bacteriology, St. Thomas's Hospital Medical School, London

There is now a great deal of evidence that a high proportion of the staff of many hospitals are nasal carriers of penicillin-resistant *Staph. aureus*, that they soon acquire them after coming into residence (Barber, Hayhoe, and Whitehead, 1949; Rountree and Barbour, 1951; Barber and Burston, 1955), and that similar strains are responsible for sporadic infections of clean operation wounds and for outbreaks of conjunctivitis, mastitis, and pemphigus neonatorum in hospital nurseries. Although this suggests that the nasal carrier is primarily responsible for such infections, it is possible that transfer of organisms from minor staphylococcal infections such as boils, styes, or acne pimples on the person of members of the staff who have remained on duty may be equally important.

Attempts to prevent transfer of infection from either of these two sources are, however, hampered by our lack of knowledge of the methods by which *Staph. aureus* is transmitted from person to person. Except for the work of Duguid and Wallace (1948), little attention has been paid to this. The experiments reported in this paper were designed to throw further light on this question.

Experimental Methods

The manner in which experiments were carried out is given in the appropriate place in the text. It is, however, necessary to give some general details of the methods employed.

Media and Identification of Colonies.—The medium consisted of 1% Lemco agar, and in some of the early experiments an attempt was made to pick out colonies of *Staph. aureus* by their colour, consistency, and behaviour in coagulase tests on slides. In most of the experiments, however, phenolphthalein diphosphate (0.01%) was incorporated in the medium at the time the plates were poured. The majority of strains of *Staph. aureus* (Barber and Kuper, 1951) produce arylphosphatase, with liberation of free phenolphthalein in and around the colonies, which can be detected by a red colour developing when the culture plate is held over the open neck of a bottle of strong ammonia. All plates were examined in this way after incubation for eighteen to twenty-four hours, and counts made of colonies which had a red coloration and which resembled those of *Staph. aureus*. When necessary, subcultures were made in broth, coagulase tests being carried out by the tube method (Fisk, 1940).

Total colony counts were made after incubation for a further 24 hours.

Expression of Results.—The time of exposure of the plates varied in different experiments, and in order to secure uniformity the results are expressed as the number of organisms (or *Staph. aureus*) falling on to 1 square foot (930 square cm.) of medium in one minute.

Transmission of *Staph. aureus* Originating in the Respiratory Tract of Carriers

Except in very exceptional circumstances, it is improbable that *Staph. aureus* in the respiratory tract of a carrier comes directly into contact with that of normal persons, the eyes of newborn babies, or open wounds. Transfer must therefore occur by a more indirect route involving (1) egress from the respiratory tract, (2) transportation to the recipient, and (3) entrance into his tissues.

1. Egress from the Respiratory Tract

Staph. aureus occurs so infrequently in the throat that egress from the mouth need not be considered as an important factor in the dissemination of this organism. Large numbers are, however, present in the anterior nares of about half the population, and such organisms may reach the outside world by (a) expulsion, (b) excretion in the faeces, or (c) outflow on to hands, etc.

Expulsion in Expired Air

In order to study the number of *Staph. aureus* emitted from the nose, and under what conditions they emerge, experiments were carried out with a thin plastic sheet, holding a culture plate horizontally in such a position that its outer zone was only a few millimetres below the nasal orifice of normal adults. The edge of the plastic was cut away into such a shape that it fitted against the upper lip, and prevented organisms from the mouth reaching the culture medium. Subjects sat upright in an armchair in a laboratory, with as few draughts as possible, and carried out certain standardized activities. At intervals during this process the culture plate was rotated a few degrees, to bring a new area of medium below the nose. After exposure the plates were incubated, and both the total number of colonies and those identified as *Staph. aureus* were counted.

These experiments were carried out with known carriers of *Staph. aureus*, and also with individuals from whom this organism had not been obtained on nasal swabs. The results are given in Table I. Contrary to what might have been supposed, *Staph. aureus*, even when present, was generally not expelled. Only as a result of "snorting" did large numbers of organisms emerge; if the individual was a carrier a high proportion were *Staph. aureus*. Snorting is an unusual type of activity which generally occurs into a handkerchief. These results are similar to those obtained by

TABLE I.—Number of Colonies Isolated on Culture Plates held below the Nose during Different Types of Activity

Duguid and Wallace (1948), and suggest that expulsion in droplets or "droplet nuclei" from the nose is not a very successful method for obtaining the egress of *Staph. aureus* into the outer world.

Excretion in Faeces

Brodie, Kerr, and Sommerville (1956) have suggested that nasal carriers of *Staph. aureus* swallow this organism, and have shown that it may reach the faeces, but it is im-

probable that this is the principal reason for the wide dissemination of staphylococci among hospital staffs.

Outflow in Nasal Discharges

The nasal secretions flow towards the nasal orifice, and eventually reach the skin of the upper lip or face in the liquid condition or as dried crusts. Thence they may be transported by the hands or handkerchief to other parts of the body or to objects in the vicinity. Observation of a group of nine students during a lecture of one hour showed that they touched their mouth or nose on 23, 19, 15, 15, 14, 11, 10, 7, and 6 separate occasions. Fluorescent patches (in the light of Wood's lamp) could also be detected on the fingers and many areas of the body, desk, etc., if small quantities of the zinc chelate of 8-hydroxyquinoline were previously placed in the nostrils.

To show that *Staph. aureus*, if present in the nose, may be carried in similar fashion, surveys (using sweep plates for clothing and saline-soaked swabs for skin) were made of healthy individuals working in the hospital. The results are given in Table II, showing that *Staph. aureus* was present

+ = *Staph. aureus* isolated. — = *Staph. aureus* not isolated.

on the majority of the sites on the skin and clothing of nasal carriers of this organism, but was found only infrequently on the same areas of individuals who were not carriers.

Swabs taken from the nose of one subject, Pri, on November 1, and on four subsequent occasions, failed to yield *Staph. aureus* until December 22, when a heavy growth was obtained. During the period he was known not to be a carrier—that is, on November 15—examination of his skin and clothing showed that only small numbers of *Staph. aureus* were isolated from a few of these areas. On December 22 this organism was present in large numbers on all areas examined, except one on the skin and one on the clothing. This change in the flora of his nose, skin, and clothing was not accompanied by clinical signs of any description on his part or in his family. This state has persisted. A similar, though less marked, change was also observed with subject Geo.

Sensitivity tests with antibiotics suggested that, in general, strains recovered from the skin and clothing of a carrier were similar to those in the nose. Phage-typing determinations were carried out in detail with strains isolated from the two carriers Ric and Pri. In the case of Ric, his left nostril contained type 52/52A/80, and this strain was found on his face, wrist, and fingers, the back and front of his coat, his pocket, handkerchief, trouser leg, shirt, and socks. His right nostril contained type 3A/3B/55/71+, but this strain was not detected on skin or clothing. The carrier Pri had type 29 in both nostrils, and this type was found on the fingers, abdomen, the front and back of his coat, his handkerchief, trouser leg, and socks. Type 53 was found on his

face, wrist, chest, shirt, and handkerchief. It would thus seem probable that the majority of the staphylococci found on skin and clothing of carriers have been derived from the individual's own nose.

Because of the wide dispersion of *Staph. aureus* on the skin and clothing, it is to be expected that other objects, such as bedding, with which the individual comes into close contact, will be similarly polluted. Five known carriers and five non-carriers took samples of their own bedding, using large woollen swabs moistened with saline. From Table III

TABLE III.—Presence of *Staph. aureus* on the Bedding of Carriers and Non-carriers

	No. Studied	No. of Individuals with <i>Staph. aureus</i> on:				
		Lower Sheet	Upper Sheet	Blanket	Counterpane	Pillow
Nasal carriers	5	3	2	1	2	2
Non-carriers	5	0	0	0	0	1

it is clear that the bedding of carriers was often contaminated by *Staph. aureus*, whereas that of non-carriers was generally free. It is also of considerable interest that the sheets, counterpane, or pillow were quite as likely to possess *Staph. aureus* as the blankets.

2. Transport of *Staph. aureus* to Other Individuals

In view of the wide dissemination of *Staph. aureus* on the skin, clothing, bedding, etc., of carriers, it is possible that other individuals may acquire the organisms as a result of direct contact with such surfaces. It can, however, be shown that the organisms may be liberated into the atmosphere by different forms of activity, so that transportation by air currents is an obvious alternative. This may be demonstrated in a variety of ways.

(a) From Skin

Both nasal carriers of *Staph. aureus* and non-carriers rubbed their hands together, and used the handle of a sterile scalpel to rub their chins or hair over an open culture plate immediately below. From Table IV it is clear that most of the carriers were able to dislodge some *Staph. aureus* from their skin or hair by these activities.

TABLE IV.—Release of *Staph. aureus* from Friction on the Skin

	No. of Persons	No. of Persons from Whom <i>Staph. aureus</i> was Obtained as a Result of:		
		Rubbing Hair	Rubbing Chin	Rubbing Hands
Nasal carriers	8	2	4	2
Non-carriers	6	0	0	1

Other experiments were carried out in a smaller version of the cubicle employed by Duguid and Wallace (1948). It was 6 ft. (183 cm.) high, the walls being 2 ft. 9 in. (84 cm.) and 2 ft. 6 in. (76 cm.) wide—that is, 41.25 cubic ft. (1.168 cubic metres). The walls consisted of plastic curtaining, the roof of three-ply wood, and the floor of moist butter muslin covering the hard surface of the laboratory floor. The whole of the interior surface was wiped down with cetrimide (1%), and the cubicle was left undisturbed for fifteen minutes before the experiments began. In each corner of the cubicle three culture plates were held horizontally, one being at floor level, another 1 ft. 9 in. (53 cm.) and a third 3 ft. 5 in. (104 cm.) above the floor. The temperature of the cubicle was usually 20–25° C. and the relative humidity 95 to 100%.

Control experiments showed that air movement *per se* does not bring to plates exposed in these situations more organisms than when it is still, the number of organisms obtained on culture plates exposed while a sterile gown, suspended from a coat-hanger from the ceiling of the cubicle, was agitated by pulling on pieces of string attached halfway down the sides, being approximately the same as on plates exposed while the gown was still.

TABLE V.—Release of Organisms into Free Air from Skin or Clothing as a Result of Movement

Geo	—	9.6	0.0	17.0	0.0	382.6	0.28	215.2	0.14

In this and the subsequent tables the figures give the total number of organisms or *Staph. aureus* falling on to 1 square foot (930 square cm.) in one minute. They are calculated from colony counts on 12 culture plates of the same size exposed horizontally at three different levels in the cubicle.

Subjects clad only in sterile bathing trunks, but with a mask over nose and mouth and a sterile cap over the hair, sat still for fifteen minutes in the cubicle while plates were exposed in the four corners. The plates were changed and the subjects then exercised by marking time and waving their arms about for a further fifteen minutes. After incubation, the total number of colonies and of *Staph. aureus* were counted. The results are given in the first part of Table V.

It is evident from this that during exercise some organisms are liberated into the atmosphere from the naked skin, and that if the individual is a carrier *Staph. aureus* may appear in appreciable numbers.

Staph. aureus may also be liberated into free air in droplets of water in the act of washing. Preliminary experiments showed that the relatively small amount of agitation of the skin and clothing resulting from the motion of the arms did not increase the number of bacteria in the atmosphere to any appreciable extent. But when the hands and arms were washed and scrubbed with toilet soap for five minutes, using clean water in a sterile bowl, the total number of organisms isolated on culture plates standing in the four corners of the cubicle were greatly increased. If the individual was a carrier, a large proportion of the colonies isolated were *Staph. aureus* (Table VI).

TABLE VI.—Release of Organisms from the Skin of Hands and Forearms into Free Air while Washing

		Total Orgs.	<i>Staph. aureus</i>	Total Orgs.	<i>Staph. aureus</i>	Total Orgs.	<i>Staph. aureus</i>
Ric	+	12.2	0	670.7	363.2	591.6	237.8
Win	+	35.4	0	998.5	6.56	680.8	38.75
Pri	+	25.8	0	1,762.2	323.9	1,456.1	300.5
Geo 1	—	16.4	0	607.6	0	669.9	0
2	—	6.4	0	383.7	0	421.5	0.41
Fos	—	21.1	0	983.2	0.21	712.8	0.42

Inspection of the plates immediately after exposure showed that many of them had actual droplets on the agar surface, and if the individual was a carrier large numbers of *Staph. aureus* appeared on these areas after incubation. Further experiments were carried out in which the subjects merely washed their hands without scrubbing. Almost identical results were obtained.

Thus friction, movement, and, perhaps most important of all, washing may disseminate large numbers of *Staph. aureus* from the skin of carriers into the neighbouring atmosphere.

(b) From Clothing

Previous workers (Green, Challinor, and Duguid, 1945; Bourdillon and Colebrook, 1946; Hare and Mackenzie, 1946; Duguid and Wallace, 1948) have shown that bacteria may be released into the atmosphere on particles of fluff or dust when clothing is shaken, but further experiments were undertaken to investigate the importance of this with staphylococcal carriers.

The clothing of carriers or non-carriers was accordingly suspended from a coat-hanger attached to the roof of the experimental cubicle. It was agitated for fifteen minutes by means of strings attached to the elbows of the coat and the knees of the trousers. The cubicle having been aired and its walls wiped down again with antiseptic, the subject then donned his clothes and exercised in it for fifteen minutes. The number of colonies developing on culture plates exposed during these activities is given in the second half of Table V.

It is evident from these experiments that while *Staph. aureus* and other organisms may be liberated into the atmosphere when the naked subject exercised in the cubicle, very much greater numbers reach free air from his clothing when agitated by itself or on the person of its owner.

Other experiments have been carried out in which the clothed subject sat still for 7½ minutes and then, for a further 7½ minutes, undressed and dressed again in the cubicle (Table VII). These experiments confirm the results

TABLE VII.—Release of Organisms into Free Air while Undressing and Dressing

obtained in the previous experiment, showing clearly that large numbers of organisms are liberated by agitation of ordinary clothing, and by dressing and undressing.

It is of some importance that the amount of air pollution by *Staph. aureus* from the clothing carriers, although always greater than that coming from non-carriers, varied considerably. The clothing of the carrier Pri, for example, consistently produced many more staphylococci than that of the other carriers. Indeed, in his case, *Staph. aureus* accounted for nearly 10% of the total organisms released into the atmosphere.

Phage-typing experiments with the strains isolated when the carrier Ric dressed and undressed in the cubicle showed that type 52/52A/80, which was present in one nostril and that type spread on his clothing, was also the predominant type released into the atmosphere. With the carrier Pri, on the other hand, who had type 29 in his nostrils and which was widespread on his clothing, it was found that only a few colonies on the plates belonged to this type. The majority were type 53, which was also found on some areas of his skin and clothing but which was not found in his nose.

In view of the large number of organisms liberated into free air from the clothes, further investigations were carried out to determine whether carriers wearing the type of clothing usual in operating theatres could contaminate the atmosphere.

Carriers and non-carriers accordingly exercised in the cubicle wearing trousers and shirt, or frock in the case of women, over which was placed a sterile gown with short sleeves, open at the back but secured by a tape round the waist. As will be seen from Table VIII, large numbers of organisms reached the exposed plates. This suggested that the gown conferred very little, if any, protection. For this reason, some of the subjects exercised while wearing their ordinary clothing and no gown. As will be seen from Table VIII, approximately the same number of organisms were liberated. Thus it must be concluded that the gowns worn by most persons on the floor of an operating theatre do not imprison the organisms on their clothing.

Those nearest to the patient in operating theatres leave their underclothing outside the theatre and wear clean, if not sterile, pyjamas under the gown, thus eliminating the source of some of the airborne organisms. Experiments were therefore carried out in which the subjects wore sterile pyjamas, covered by a sterile gown, and with sterile cap over the hair, mask over the face, and sterile boots on the feet. The results obtained are also given in Table VIII.

Fewer organisms were liberated than when the same subjects wore their own underclothing, but it is of some importance that the carrier Pri, to whom attention has already been drawn, was still potentially dangerous in that as many as 6.82 *Staph. aureus* were reaching 1 square foot (930 square cm.) in one minute in his vicinity.

(c) From Bedding

If, as shown in Table III, the bedding of carriers is contaminated by *Staph. aureus*, it is to be expected that this organism will be liberated into free air when the bed is made or is agitated in any way. Some provisional observations of ours confirm that this is so, but we have not investigated this problem in detail.

It is clear from these experiments that friction on the dry skin, washing or scrubbing with water, and agitation of the clothing may liberate comparatively large numbers of *Staph. aureus* from skin or clothing into the atmosphere if the subject is a nasal carrier.

3. Entry of *Staph. aureus* into the Tissues of the Recipient

This may occur as a result of direct contact between the organisms on the hands of a carrier or clothing, the respiratory tract of a normal person, an open wound, or the eyes and skin of newborn babies. But it is extremely probable that in most instances the organisms reach these areas by way of the atmosphere, particularly if the donor is a heavy carrier in active movement, with much shaking of the clothing.

Transmission of *Staph. aureus* from Septic Processes in Members of the Hospital Staff

When a localized infection of the skin, such as a boil or acne pustule, bursts or is opened *Staph. aureus* will almost certainly spread on to the skin in its immediate neighbourhood, and into whatever dressing may be applied. It is

extremely improbable that the infected area will come directly into contact with susceptible tissues in patients, or members of the staff, but the organisms may become widespread on the person in the same way as can *Staph. aureus* originating in the nose. Release as a result of friction or activity and transportation to others by air currents is therefore a possible alternative.

Skin and clothing surveys were made of 10 patients attending the casualty department with minor staphylococcal infections which, if on the person of members of the nursing or medical staffs, might not have necessitated their standing down from duty. All the lesions were discharging pus and none of the patients had received antibiotics. A comparable series of 14 patients without pyogenic infections were examined at the same time. The results are given in Table IX.

TABLE IX.—Presence of *Staph. aureus* on Skin and Clothing of Patients with and without Mild Local Sepsis

Six of the infected group and eight of the uninfected were nasal carriers of *Staph. aureus*, and many of them had this organism on different areas of skin and clothing. Although there was a tendency for the clothing in particular to be more widely contaminated when there was infection as well, it cannot be said that the difference was at all marked. There was much less contamination of the skin and clothing of the two groups who had no *Staph. aureus* in the nose, and no very definite evidence that the presence of a purulent infection increased this contamination to any extent.

An investigation comparable to the above was also carried out on a series of infants, aged 5–10 days, in a maternity ward. The results were similar—namely, that heavy staphylococcal contamination of the skin, clothes, and bedding occurred to about the same extent with healthy nasal carriers as with babies suffering from some form of sepsis.

Thus, although there is a possibility that *Staph. aureus* from a septic focus may be more pathogenic than when it is derived from a healthy nasal carrier (Barber and Burston, 1955), there is no evidence that particularly heavy contamination of the skin and clothing occurs.

Discussion

The results obtained in the experiments reported in this paper confirm those of Duguid and Wallace (1948), and show that the mechanism by which *Staph. aureus* is transmitted from the nasal cavity of carriers to other persons is very similar to that suggested for respiratory tract organisms in general by Hare and Mackenzie (1946).

This mechanism does not depend, primarily, on the expulsion into free air of *Staph. aureus* in droplets or droplet

nuclei coming from the anterior nares, but on outflow of this organism in the nasal secretions on to the upper lip or alae nasi. Its subsequent transfer to other persons then involves three separate and distinct steps.

The first step is the transport of the staphylococci by hands, handkerchief, or any object coming into contact with the nose to the skin, clothing, bedding, and other objects in the immediate vicinity of the carrier. The second step is the release of the organisms into the atmosphere. This may result from friction and dislodgment of dried particles from the skin or hair, from the spattering of water droplets in the act of washing, and from shaking of the clothing during activity. This may obviously occur anywhere in the hospital.

The third step involves the transport of these infected particles by air currents to other individuals in the neighbourhood. In this way the organisms may reach the anterior nares of normal persons to produce the carrier state in them, highly susceptible tissues such as the conjunctiva of the newborn infant, or, as probably occurs in operating theatres, open wounds, to produce, in due course, post-operative infection.

There is evidence that some carriers produce a much greater degree of air contamination in their vicinity from friction and movement of their clothing than do others. Such a carrier is probably much more dangerous in the hospital environment than is the member of the staff suffering from a minor staphylococcal lesion of the skin.

The application of these results to the prevention of staphylococcal infections in general is outside the scope of this paper, but, whatever alterations in technique be contemplated, cognizance should certainly be taken of the fact that direct expulsion of *Staph. aureus* into free air in droplets or droplet nuclei from the anterior nares is of much less importance than the almost inevitable presence of this organism on the skin and clothing of carriers, and its release on air-borne particles when the contaminated surfaces are subjected to friction and movement.

Summary

Experiments carried out with nasal carriers of *Staph. aureus* suggest that this organism is not transported from person to person by droplets or droplet nuclei but by an indirect route involving egress in nasal secretions, contamination of the skin, clothing, or bedding, release of the organisms by friction, movement, or washing, and transportation to others by air currents.

There is evidence that some carriers can contaminate the atmosphere in their neighbourhood with much larger numbers of *Staph. aureus* than the majority of carriers. Such individuals wearing a sterile gown over their ordinary underclothing may cause potentially dangerous degrees of air contamination during activity on their part; even when wearing a complete set of sterile operating clothes large numbers of *Staph. aureus* may still be detectable in the surrounding atmosphere.

These carriers are probably more dangerous in the hospital environment than the member of the staff suffering from a minor degree of skin sepsis.

We are grateful to the members of the medical and nursing staffs of this hospital for their help and co-operation, to the experimental subjects who have assisted us, and to Dr. R. E. O. Williams, of the Central Public Health Laboratory, for determining the phage-types of some of our strains.

STAPHYLOCOCCAL PNEUMONIA IN ADULTS

BY

W. HAUSMANN, M.D., M.R.C.P.

Physician, Reading Combined Hospitals

AND

A. J. KARLISH, M.D., M.R.C.P.

Consultant Chest Physician, Reading Combined Hospitals

Staphylococcal pneumonia has long been known as a complication of epidemic influenza. The fulminating, prostrating type encountered during the pandemic of influenza that followed the first world war was fully described in the writings of Chickering and Park (1919). At that time mortality rates of 80–90% were reported. In 1942 Finland *et al.* recorded a reduction in the death rate to 32%, which they attributed to the use of sulphonamides.

In sporadic form, however, staphylococcal pneumonia is widely regarded as a disease occurring mainly in infants. In these the prognosis is still grave. Recently, Wallman *et al.* (1955) reported 44 cases from Perth, Western Australia, with a mortality of 23%, a figure achieved by modern treatment with antibiotic agents.

In adults, relatively few cases unassociated with major influenza were reported before 1950. Heffron (1939), analysing 3,319 cases of lobar pneumonia, found only six that were considered staphylococcal. Among 298 cases of bacterial pneumonia admitted to the Central Middlesex Hospital in 1942–4, Humphrey *et al.* (1948) described seven which were thought to be staphylococcal. Only one had a history of preceding influenza-like illness.

During the last five years, however, several groups of cases have been reported. Of 110 cases of pneumonia admitted during one year to Hammersmith Hospital and reported by Crofton *et al.* (1951), 10 were considered to be staphylococcal and only two showed serological evidence of influenza B. Neither of these two patients was very ill. Grist *et al.* (1952) saw 10 cases of staphylococcal infection among 129 cases of pneumonia admitted to one hospital in Glasgow during a period of fifteen months. Serological evidence of recent influenza A infection was present in 5 of the 10 cases. Grant and Barber (1954) reported 15 cases from Belfast, constituting 3% of all pneumonia admissions. Only four cases occurred during an influenza outbreak.

Material.—This paper is based on a series of 18 cases of staphylococcal pneumonia in adults admitted to an acute medical unit in Reading during 1952–4. Many cases of pneumonia occurring in the area receive treatment at home, and, in general, only the severely ill patients not responding to penicillin and sulphonamides are admitted. There was no local influenza epidemic during the period under review, but virus studies were not made. The group formed 15% of a total of 122 consecutive patients admitted to the unit in whom the diagnosis of primary pneumonia was radiologically confirmed. There were 11 men and 7 women. Their ages ranged from 16 to 72, with an average of 51 years.

Diagnosis

The aetiological diagnosis of staphylococcal pneumonia is a matter of some difficulty and is often derived from a combination of clinical, radiological, and bacteriological

findings. In the series now reported the criteria adopted were those used by the Medical Research Council (1951) for the investigation of bacterial pneumonias—that is, “When *Staphylococcus aureus* (coagulase-positive) . . . [was] predominant in the sputum the pneumonia was regarded as staphylococcal . . . if this was clinically consistent, even when cultures from other sources were negative.”

Sputum from every case was cultured soon after admission and before the start of treatment if possible. From a number of patients minor growths of staphylococci were reported, together with non-pathogenic organisms, but, in view of the possibility of nasopharyngeal contamination of specimens yielding a few colonies only, such cases were classified as of uncertain origin and excluded from the series.

From 12 of the 18 cases reviewed staphylococci were isolated in pure culture. In the remaining six cases predominant growths of staphylococci were found, together with a proportion of non-pathogenic organisms such as *Streptococcus viridans* and *neisseriae*. In two cases coagulase-positive staphylococci were grown from the pleural fluid.

The organisms were reported to be penicillin-resistant in 10 cases, while results of treatment indicated that resistant strains were probably present in three other patients. Resistance to penicillin was estimated by the disk plate method, the disks being impregnated with 1.5 units of penicillin solution.

It is necessary to add that as most patients received some treatment at home it is impossible to say whether the organisms were resistant at the onset of the illness or became so only after penicillin had been given.

Clinical Features

Six of the patients gave a history of previous chest disease, such as chronic bronchitis, asthma, or recurrent pneumonia. There were serious associated conditions in two other cases— aortic stenosis in one and acute nephritis in another. Two cases occurred following abdominal operations; both later developed lung abscesses.

The duration of symptoms prior to admission ranged from two days to two months, with an average of three weeks. Pleuritic pain was complained of by 14 of the 18 patients. Rigors were present in four cases. Herpes labialis was noted in only one case. Sticky blood-stained sputum was produced by four patients.

Leucocyte counts were not found to be of great significance. They were done in nine of the cases, and the totals exceeded 10,000 per c.mm. in three.

With regard to anatomical distribution, postero-anterior and lateral x-ray films of the chest were available for all cases. The classification adopted was similar to that of Crofton *et al.* (1951). There were nine cases of lobar involvement, seven of lobular involvement, and two were segmental. This compares with the above authors' 10 cases, in which lobar distribution was seen in seven and lobular involvement in three.

The most outstanding features, however, were the severity of the clinical course and the number of serious complications. These were reflected in the duration of hospital stay, which averaged 38 days, compared with 19 days for the remaining 104 pneumonia cases admitted during the same period.

Six of the 18 patients developed abscess or empyema. Short summaries of these cases are given below. They included five men and one woman, their ages ranging from 21 to 72, with an average of 53 years. Their hospital stay averaged 58 days, with a range of 31 to 91 days.

Of the five cases of abscess, two were single and three were multiple. The abscess cavities were thick-walled and irregular, and none had the character of a thin-walled egg-shell cavity as described by Brock (1945).

In the three cases complicated by multiple abscess formation the pneumonia was of a “wandering” type, the consolidation moving from area to area and from one lung to

the other. One of the patients was admitted in a state of collapse, resembling the fulminating type of staphylococcal pneumonia described in association with influenza.

Empyema occurred in two patients. One of these, a woman of 21, developed pyopneumothorax, a complication occurring in 50% of staphylococcal pneumonias in infants but uncommon in adults. Sterile pleural effusions of moderate severity were noted in two patients. Delay in resolution of the pneumonia occurred in 12 of the 18 cases. There was no death in this series.

Treatment

After admission most patients were given penicillin while the results of sputum cultures were awaited, but it was supplemented with streptomycin for severely ill patients. Six of the 18 cases responded to penicillin, including one whose organisms were reported to be penicillin-resistant; seven responded to the tetracyclines (oxytetracycline or chlortetracycline); two to chloramphenicol; and two others to streptomycin. In one man erythromycin effected a dramatic improvement.

Only one of the 10 patients whose organisms were reported to be penicillin-resistant did, in fact, respond to penicillin treatment. On the other hand, three patients, including the case of pyopneumothorax, whose organisms were reported to be penicillin-sensitive responded to penicillin. It will be seen that the response to penicillin closely followed the results which sensitivity tests predicted, thus underlining the importance of such investigations. Of the five cases in which no sensitivity tests were done, three failed to respond to penicillin. These findings compare with those reported by Grant and Barber (1954), of whose 15 cases only six responded to penicillin.

Case 1

This patient, a man aged 64, had no history of past chest disease. Six weeks prior to his present illness he underwent an operation for inguinal hernia. On admission he complained of severe pleuritic pain in the chest and shortness of breath; his temperature was 106° F. (41.1° C.) and he had oedema of the ankles. His leucocyte count was 10,400 per c.mm. Radiography of the chest showed a left pleural effusion with consolidation and collapse of the left lower lobe, and a large abscess cavity with a fluid level. Aspiration of the left pleural space produced 4 oz. (114 ml.) of thick yellow pus which grew penicillin-resistant coagulase-positive staphylococci in pure culture.

Penicillin was first administered, without result; this was followed by tetracycline and later by chloramphenicol with moderate improvement. It then became clear that a broncho-pleural fistula was present, and rib resection with open drainage was performed (Mr. C. Grimshaw).

The patient was discharged fit after 60 days but returned a month later with recurrence of cough and purulent sputum. A small abscess was shown radiographically in the left upper lobe in a different position from the previous cavity, and staphylococci were again grown from the sputum. This time he responded well to chlortetracycline.

On the follow-up a year later there was still extensive pleural thickening over the left lung but no sputum or shortness of breath.

Case 2

In 1941 a diagnosis of ankylosing spondylitis was made in a man aged 52. Four days before admission he had a rigor with vomiting and pleuritic pain at both bases of the lung. Radiography of the chest showed partial consolidation in the right upper and left lower lobes. The right upper lobe was clear within three days, but by then there was consolidation at the base of the left upper lobe. The latter extended during the next fortnight with multiple abscess formation.

Sputum culture produced on two occasions profuse growths of staphylococci resistant to penicillin, streptomycin, and chlortetracycline. There was no therapeutic response

to penicillin combined with streptomycin or to chlortetracycline, and his condition grew steadily worse. Erythromycin was then tried with immediate and dramatic improvement, and he was discharged after 31 days.

Follow-up examination two years later showed fibrosis in the upper zone of the left lung and an obliterated left costophrenic sulcus. He was well and working, and had no sputum or dyspnoea.

Case 3

A man aged 72 had been unwell for two months; pain in the right chest and severe cough had been present for two weeks. On admission he was extremely ill with cyanosis, dyspnoea, and dry tongue. Blood pressure of 70/40 mm. Hg and a pulse rate of 130 a minute were recorded. Radiographs of the chest showed consolidation of the right lower lobe with partial consolidation of the right upper lobe. Three weeks later a single round abscess had formed in the right lower lobe, and this took a further six weeks to clear. Bronchoscopy revealed no evidence of new growth.

A profuse growth of penicillin-resistant staphylococci was obtained from the sputum. He was treated with combined penicillin and streptomycin without effect. Later he responded slowly to oxytetracycline and was finally discharged after 65 days, greatly improved in general condition, with a radiographically clear chest.

Case 4

This patient, a man aged 56, gave a month's history of cough and dyspnoea. Right-sided pleuritic pain had been present for two weeks, and frothy sputum for five days. On admission he was very ill, short of breath, and cyanotic. There were clinical signs of pneumonia at the right base, and a radiograph of the chest showed consolidation in the right lower zone. The leucocyte count was 18,000 per c.mm. Treatment was begun with penicillin, but sputum culture yielded coagulase-positive staphylococci resistant to penicillin and sensitive to streptomycin.

Six days later further radiographs showed some clearing of the right base with fresh consolidation in the left upper and lower zones. He was given streptomycin with little general improvement. After 10 days there was some clearing at the left base, but the left upper lobe had become densely opaque on radiographic examination. A week later there was extensive breakdown with multiple cavitation in the left upper lobe. Treatment was then changed to chlortetracycline, but this had to be stopped because of diarrhoea. Nevertheless, the left upper lobe gradually cleared and tomograms prior to discharge showed no cavitation.

He was further investigated; a bronchogram showed deficient filling of the left upper lobe bronchi, but bronchoscopy did not reveal any abnormality. His total stay in hospital was 91 days.

At a follow-up examination two years later he was well, but radiographs showed fibrosis in the upper zone of the left lung with ring shadows suggestive of cystic changes.

Case 5

In this case, that of a man aged 55, there was no history of chest disease. Following perforation of a sigmoid diverticulum he developed peritonitis, and at operation a left inguinal colostomy was formed, but his condition deteriorated and he was transferred to the medical ward.

On admission he was febrile and very ill. He had carious teeth and foul breath. Radiographs of the chest showed a right hilar opacity. This cleared slowly, but ten days later there was mottling at both bases. In spite of some clinical improvement the radiographic opacities extended. After another three weeks there was dense consolidation in most of the left lung, collapse of the left lower lobe, and multiple cavitations in the lingular segment of the left upper lobe. Slow resolution then began and proceeded steadily, but 60 days later cystic changes were still present at the site of the previous breakdown. Sputum examination revealed a

profuse growth of staphylococci resistant to penicillin but sensitive to chlortetracycline and chloramphenicol. He was treated with chlortetracycline and discharged after 36 days.

At a follow-up examination one year later he was well; there was no dyspnoea. A radiograph of the chest showed fibrotic changes at both bases.

Case 6

One week prior to admission a woman aged 21 developed a right lower lobe pneumonia which at first responded to sulphonamides at home, but was later complicated by pleural effusion.

On examination she was found to be very ill, short of breath, and cyanotic. A radiograph of the chest showed complete collapse of the right lung with air and fluid in the pleural space. Thick, blood-stained pus was aspirated and a profuse growth of penicillin-sensitive staphylococci was obtained on culture. She was treated with intramuscular penicillin daily, together with intrapleural injections of penicillin and streptokinase. She made an excellent recovery, and was discharged after 65 days. When seen three months later there was residual pleural thickening at the right base and in the interlobar fissures.

On a final follow-up examination two years later she was free of symptoms and radiographically the lungs were within normal limits.

Discussion

Staphylococcal infection to-day presents a major problem in the treatment of bacterial disease. The staphylococcus has shown such marked adaptability to antibiotic substances that within a few years of the introduction of penicillin it was found that a high proportion of these infections failed to respond to this drug.

In this country the majority of staphylococci are still sensitive to some of the broad-spectrum antibiotics, such as the tetracyclines, chloramphenicol, and erythromycin, but resistant strains are increasingly encountered in patients previously treated with these substances. In view of the recent tendency to treat chronic bronchitis with prolonged courses of tetracyclines many more resistant cases may be seen in future.

There is good evidence that the incidence of staphylococcal pneumonia is growing. Review of the literature in the last five years suggests that they now constitute from 3 to 10% of all cases of pneumonia admitted to hospital. This is probably an underestimate of the true situation owing to the difficulties in the way of an aetiological diagnosis already mentioned.

Most observers reporting large series of cases of pneumonia during the last ten years have noted the high proportion of patients whose sputum fails to grow pathogenic organisms. It is generally believed that this is due to chemotherapy before admission to hospital. Anderson (quoted by Grist *et al.*, 1952) studied a series of 500 patients between 1939 and 1941, and encountered only eight from whom pathogens were not isolated. Ten years later Crofton *et al.* (1951) were unable to identify an aetiological agent in 52 of the 110 cases of pneumonia studied at Hammersmith Hospital.

In our series of 122 cases of pneumonia admitted in 1952-4 an aetiological diagnosis was made in 50, of which 18 were staphylococcal. It is our belief that these 18 cases did not represent the total number of cases of staphylococcal pneumonia in the series. Staphylococci were, in fact, grown from the sputum of several other cases, but they were excluded because the evidence seemed inconclusive. Before admission to hospital most of the cases were treated with penicillin or sulphonamides, and some with oxytetracycline. Such treatment may have prevented the growth of the responsible organisms without effecting a cure. That this explanation for the failure to grow pathogenic organisms may not be the whole answer, however, is suggested by the

results of a recent investigation by Batty Shaw and Fry (1955) into 80 cases of acute chest infection in general practice. Eight general practitioners in South London, in association with the local hospitals, made every effort to obtain sputum or throat swabs from their patients before any treatment was started. In spite of this early collection of specimens pathogenic organisms were isolated only from 25 of the 80 cases.

Staphylococcal infection often directs its attack against damaged tissues and where local or general resistance is low. Such circumstances were present in 10 of the 18 cases in our series. It is significant in this respect that in fibrocystic disease of the pancreas, where recurrent chest infection is frequent, the staphylococcus is responsible for the majority of cases and accounts for a high proportion of deaths (Anspach, 1947; Shwachman *et al.*, 1949). It is also of interest that most cases of staphylococcal pneumonia in infants occur under the age of 6 months (Wallman *et al.*, 1955).

Reports already referred to and the results of our own review of 122 consecutive pneumonia admissions show that the average age of patients is over 50 years, and that a history of previous chest disease is obtained in at least 40% of the cases. It is not surprising, therefore, that the staphylococcus should play an increasing part in these infections.

Summary

Eighteen cases of staphylococcal pneumonia in adults are reported to have occurred in a series of 122 consecutive cases of pneumonia admitted to one medical unit in 1952-4. There was no epidemic influenza in the area during that period. The outstanding feature in these cases was the severity of the clinical course and the number of suppurative complications. All 18 cases recovered, but only six responded to treatment with penicillin.

There is some evidence that this form of pneumonia is becoming more frequent and that staphylococcal infections are responsible for a considerable number of cases where failure of response to penicillin is encountered. The important part played by pre-existing chest disease or reduced resistance is stressed. Tetracycline and erythromycin are suggested as the antibiotics of choice in these cases.

In future, staphylococcal infections are likely to present a major problem in the treatment of pneumonia.

We wish to thank Drs. A. Anderson, J. B. Bird, and L. M. Jennings for permission to include some of the cases under their care, and Drs. J. Mills and T. D. Martin for the results of bacteriological investigations. We are indebted to Drs. Harley Stevens and H. S. Le Marquand for help in the preparation of this paper, and to Mr. P. Barr and Mr. G. Luck, of the Oxford Regional Board, for assistance with the statistical aspect of the work. We are grateful to Dr. J. G. Scadding for his helpful criticism and advice.

HYPEREXTENSION AND
HAEMATOMYELIA

BY

P. N. ROBSON, M.B., F.R.C.S.

Senior Orthopaedic Registrar, Royal Victoria Infirmary,
Newcastle-upon-Tyne

Spinal cord injury occurring without radiological evidence of the corresponding bone injury constitutes a well-recognized picture. The majority of cases are diagnosed as haematomyelia and are seen in medical clinics with a partial or complete lesion of the cervical spinal cord and no radiological evidence of bone injury or dislocation. This paper attempts to explain the actual mechanism of cord injury in these patients.

Jefferson (1928) stated that "in hyperextension the articular processes of the cervical vertebrae lock together to form a solid column of bone which is resistant to injury, and therefore hyperextension injuries fall chiefly on the atlas and axis." Much work has been done on these latter injuries, but hyperextension injuries of the rest of the cervical spine are less generally recognized.

Walshe (1944) gave an excellent description of the clinical features of haematomyelia and stressed its association with closed cerebral injury, without any explanation of the actual mechanism. He also emphasized the frequency of the Babinski inversion of the supinator jerk in such cases as indicating a focal lesion of the cervical cord at the level of the fifth segment.

Natras (1944) described the case of a soldier who on D Day dived from a landing craft into shallow water. He struck his head on the bottom and an immediate weakness of the legs and arms ensued. X-ray films of the neck being normal, the patient was labelled hysterical. On his admission to a neurological unit the diagnosis of haematomyelia was made. Natras stresses the danger of regarding these cases as functional.

Barnes (1948) first described the mechanism of fatal cervical cord compression without radiological evidence of fracture or dislocation. In his cases there had been a dislocation of the neck in hyperextension with spontaneous reduction. The post-mortem findings were rupture of the anterior common ligament at the level of the injury with disruption of the intervertebral disk, the dislocation recurring in forced extension. Taylor and Blackwood (1948) described a similar case.

Taylor (1951) described a case in which quadriplegia and death followed a hyperextension injury of the neck, radiography demonstrating no bone injury. At necropsy there was crushing of the cervical cord but no evidence of bone injury, dislocation, or disk prolapse. Crushing of the cord by the ligamentum flavum, which bulges forward prominently in hyperextension, was suggested as the causative mechanism.

Mechanism of Cord Injury

It is suggested that in the absence of radiological evidence of skeletal injury the crushing of the cervical cord may be due to either of two mechanisms: (1) massive central disk prolapse, or (2) hyperextension injuries.

Massive Central Disk Prolapse

This is much rarer than the common cervical disk syndrome associated with root irritation. It is due to a flexion injury, and it is doubtful whether it can occur in hyperextension. Cramer and McGowan (1944) published serial x-ray films of the cervical spine demonstrating this.

To elucidate this point discograms of excised specimens of the cervical spine have been made. Fig. 1 shows tracings of a discogram in a young subject. In the neutral position the normal outline of the nucleus pulposus is shown. In extension the nucleus moved forward as the posterior angles of the vertebral bodies approximated; thus posterior prolapse of the nucleus seems unlikely in hyperextension injuries.

Hyperextension Injuries

There are two methods of spinal cord injury which occur with forcible hyperextension of the neck.

Type 1.—This is a transient dislocation with tearing of the anterior common ligament and disruption of the intervertebral disk, permitting separation of the vertebral bodies with crushing of the spinal cord. Fig. 2 is a post-mortem radiograph of the excised cervical spine from such a case, showing the mechanism of the injury. As soon as the hyperextending force is removed the dislocation is reduced by muscle pull exactly as in recurrent dislocation of the ankle due to rupture of the external ligament. In non-fatal cases repair of this lesion is by ossification of the torn anterior common ligament bridging the affected disk space. Fig. 3 shows two radiographs of a man who had a hyperextension injury of the neck. The first, taken immediately after the accident, shows avulsion of a flake of bone from the upper border of the sixth cervical vertebra by the torn anterior common ligament. The second film,

FIG. 2.—Excised cervical spine from a fatal case of a type 1 hyperextension injury, in the neutral and hyperextended positions.

FIG. 1.—Tracings made from discograms of a normal cervical spine. A. In the neutral position, showing the normal outline of the nucleus pulposus. B. In extension, showing the approximation of the posterior margins of the vertebral bodies and the squeezing forwards of the disks.

FIG. 3.—Lateral radiographs of a cervical spine following a hyperextension injury. A. Immediately after injury, showing avulsion of an osteophyte from the upper border of C6. B. Eight months later, showing repair by ossification of the anterior common ligament.

taken eight months later, shows ossification of the damaged ligament bridging the intervertebral space. Fig. 4 is an outline drawing of Fig. 3.

Type 2.—In hyperextension of the normal cervical spine the ligamenta flava between the laminae bulge forward prominently. If there is pre-existing cervical spondylosis with ridging at the posterior aspects of the intervertebral disks, the cord may be crushed between the ligamenta flava and the posterior ridge. Fig. 5 shows two moulds of the cervical spinal canal in forced hyperextension. The first is a normal spine from a young adult, and the mould shows ridging posteriorly where the ligamenta flava have bulged forwards. The second mould is from an older body in which there was cervical spondylosis. In this case the mould is markedly narrowed between the ligamentum flavum behind and the ridging at the intervertebral spaces in front. Had forcible hyperextension of the patient's neck occurred during life she must have sustained a cervical cord lesion.

Case Histories

All cases diagnosed as haematomyelia in a neurological clinic from 1939 to 1954 inclusive were reviewed. Twelve cases were available.

Case 1.—A woman aged 35 was admitted in 1946 with a three-months history of gradual onset of numbness in the

FIG. 5.—Photograph of moulds of the cervical spinal canal in hyperextension. A. From a normal cervical spine in a young man, showing ridging of the mould posteriorly (at arrow). B. From a woman aged 67. In this case there was spondylosis, and the mould is markedly narrowed. This is the mechanism of a type 2 hyperextension injury.

fingers of the left hand and difficulty in walking. She had noticed both legs to be weak. There was no injury. On admission the patient was found to have a left-sided Brown-Séquard syndrome. Present condition: She complains of numbness of the right side of the body. She can walk normally, but there is still some difficulty in running. On examination the cervical spine had a full range of painless movement. C.N.S.:

FIG. 4.—Tracing of Fig. 3. The arrows show: A, the avulsed osteophyte; B, the ossified ligament.

Cranial nerves, N.A.D.; sensory blunting and loss of pain sense below the fifth cervical segment of the right side; the only muscle-wasting found was the left first dorsal interosseus; reflexes were normal except for the loss of the abdominal reflex on the left side. Radiographs of the cervical spine showed nothing abnormal.

Case 2.—A man aged 47 was admitted in 1940 following an accident in the black-out. After having drunk some pints of beer he tripped over a low fence and fell, striking his forehead on the ground. He was unable to rise owing to weakness of the legs. On

admission he was found to have a spastic paraplegia with loss of pain sense on the left side of the trunk and in the left arm and leg. Atrophy of the small muscles of both hands rapidly followed. Radiographs of the cervical spine were stated to be within normal limits. He died of intercurrent disease eleven years after the injury.

Case 3.—A woman aged 54 was seen as an out-patient in November, 1939, with a history of having fallen downstairs some weeks previously, striking her forehead on a stair. She had noticed weakness of both hands. Examination confirmed the weakness of both hands, with hyperaesthesia. Present condition:—For several years after her injury she had considerable pain in her neck on movement. This cleared up spontaneously and she now has no symptoms. On examination the cervical spine had a full range of painless movement. C.N.S.: No abnormal physical signs were present. Radiographs of the cervical spine showed some neurocentral lipping and ossification of the anterior common ligament between the fifth and sixth cervical vertebrae.

Case 4.—Following an argument with a bus conductor in July, 1941, a man aged 61 received a blow in the face which jerked his head backwards. He was seen in the out-patient department some weeks later complaining of pain in the neck and difficulty in using the hands. On examination he was found to have astereognosis of the hands and gross painful limitation of neck movement. Radiographs of the cervical spine showed no evidence of fracture or dislocation. Present condition:—He complains of pain and clicking on neck movement. The difficulty in using the hands persists. On examination the cervical spine showed gross limitation of movement with severe pain on forcing. C.N.S.: No sensory loss or abnormality of reflexes was present. There was marked wasting of the small muscles of both hands and astereognosis persisted. Radiographs of the cervical spine demonstrated considerable spondylosis with some neurocentral lipping.

Case 5.—A man aged 73 fell forwards and struck his forehead on the ground in April, 1945. There was immediate weakness of both legs. He was seen in the out-patient department some weeks later complaining of weakness of both legs and difficulty in walking. On examination he was found to have a spastic paraplegia affecting both legs, with muscular weakness and wasting. There were no sensory changes found. Radiographs of the cervical spine showed slight posterior subluxation of the fourth on the fifth cervical vertebra with some spondylosis. An orthopaedic surgeon thought that these changes were part of a long-standing spondylosis. Present condition:—He com-

plaints of pain on neck movements and difficulty in walking owing to weakness of the legs. On examination the cervical spine had a full range of flexion, lateral flexion, and rotation. There was limitation of extension with pain on attempting this movement. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Marked interosseous wasting; weakness of grip; no sensory changes; reflexes were present but the right supinator jerk was inverted. Lower limbs: Wasting of all muscle groups with marked weakness; walking was only just possible; no sensory change; reflexes were present and equal and the plantar responses were flexor on both sides. Trunk: No sensory change; abdominal reflexes were present. Radiographs of the cervical spine showed marked cervical spondylosis with retrospondylolisthesis between the fourth and fifth vertebrae.

Case 6.—A man aged 62 was admitted in 1950 with a history that after having had several pints of beer in his workmen's club he bent down to pick up a threepenny-piece from the floor. He fell forward, striking his forehead on the floor. He was immediately paralysed, unable to move arms or legs, and unable to speak. He stated that his arms were flexed at the elbows. Next day he could again talk, and some power had returned to the limbs. On admission there was a paresis of arms and legs with loss of reflexes. During the ensuing four weeks, however, a partial recovery occurred, and at the time of his discharge from hospital, some five weeks after the accident, he was able to walk a few steps. **Present condition:**—He is barely able to walk with the aid of two sticks. On examination the cervical spine showed gross restriction of movement in all directions but no pain. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Wasting of all muscle groups in both arms, especially interossei; diminished power, with spasticity; reflexes increased; inversion of both supinator jerks; no sensory change. Lower limbs: Wasting of all groups, with weakness but only slight spasticity; reflexes increased; plantar responses—right extensor, left flexor. Trunk: Loss of abdominal reflexes on both sides. Radiographs of the cervical spine showed congenital fusion of the vertebral bodies of the second and third segments, also of the sixth and seventh with the first thoracic. There was ossification of the anterior common ligament between the fifth and sixth cervical vertebrae.

Case 7.—A man aged 54 was admitted after his motorcycle ran into a stationary car, causing facial lacerations and hyperextension of his neck. The lacerations were sutured and the following day he noticed weakness of both hands. On examination the cervical spine had a full range of flexion, lateral flexion, and rotation. Extension was limited and painful. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Wasting of interossei of both hands, with weakness of grip; sensory blunting in fourth and fifth fingers of the left hand; reflexes were present and equal, but the left supinator jerk was inverted. Lower limbs: N.A.D. Radiographs of the cervical spine showed a moderate degree of spondylosis, with fracture of an osteophyte at the upper anterior angle of the seventh cervical vertebra.

Case 8.—This patient, a woman aged 54, was seen in the out-patient department in 1941 four weeks after a fall downstairs. She was unable to give a clear history of the mechanism of the injury, and complained of pain in the neck and weakness of the left hand. On examination wasting of the muscles of the left hand and loss of thermal sensation were found. **Present condition:**—She has no symptoms referable to the accident. On examination the cervical spine showed slight limitation of the extremes of lateral flexion, otherwise there was full range of movement. C.N.S.: No alteration of sensation or muscle-wasting was found, but there was depression of the tendon reflexes of the left arm. Radiographs of the cervical spine showed moderate spondylosis and ossification of the anterior common ligament between the sixth and seventh vertebrae.

Case 9.—A woman aged 53 was admitted in 1943 after a fall downstairs in which she struck the back of her neck

on a stair. She was unable to move after her accident. On examination complete paralysis of all four limbs was found. **Present condition:**—For the first three weeks after the accident she remained completely paralysed, but there had been a gradual recovery over the next three months, and since then her condition has been static. She is able to walk slowly with some difficulty. On examination the cervical spine showed limitation of the extremes of lateral flexion and rotation. No pain on movement. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Wasting of the interossei of both hands, more pronounced on the right than on the left; no loss of sensation; tendon reflexes increased, with inversion of the right supinator jerk; mild spasticity. Lower limbs: Slight spasticity; reflexes present and equal; plantar responses flexor. Trunk: No sensory change; loss of abdominal reflexes. Radiographs of the cervical spine showed gross spondylosis with ossification of the anterior common ligament between the fifth and sixth cervical vertebrae.

Case 10.—This patient, a man aged 49, was seen in the out-patient department in 1947, some weeks after a mining accident in which he had been struck on the back of the neck by a fall of stone. He was complaining of severe pain in the neck and weakness of the limbs. On examination he was found to have a partial spastic quadriplegia. Radiographs of the cervical spine showed no evidence of fracture or dislocation. **Present condition:**—He complains of some pain in the neck on movement and of weakness of the legs and difficulty in walking. On examination the cervical spine showed limitation of extension and full range of other movements. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Slight spasticity; reflexes active and equal; no muscle-wasting or sensory loss. Lower limbs: Marked spasticity, with wasting of all groups; reflexes hyperactive; plantar responses extensor. Trunk: No sensory change; abdominal reflexes absent. Radiographs of the cervical spine showed a moderate spondylosis, most marked in the fifth/sixth region.

Case 11.—A man aged 49 was seen in the out-patient department in 1949, six months after a mining accident in which he received a heavy blow on the back of his neck. He immediately noticed numbness of his left hand. He was complaining also of pain in the neck. On examination he was found to have marked limitation of cervical spine movement. Muscle-wasting was present in the left hand, with some sensory blunting. Radiographs of the cervical spine were not taken at this time. **Present condition:** He complains of severe pain in the neck for which he has to wear a plastic collar; the numbness and weakness of the left hand persists. On examination the cervical spine showed gross limitation of movement in all directions, with severe pain. C.N.S.:—Cranial nerves: N.A.D. Upper limbs: Weakness of grip of the left hand with wasting of the first dorsal interosseous muscle; sensory blunting over the whole of the left hand except the index finger; loss of tendon reflexes in the left arm. Lower limbs: Blunting of sensation to pin-prick in the left leg; no wasting or loss of power; loss of left ankle-jerk; plantar responses flexor. Trunk: Sensory blunting of the left half; abdominal reflexes present. Radiographs of the cervical spine show marked spondylosis between the sixth and seventh vertebrae, with sclerosis of the adjacent surfaces of the vertebral bodies.

Case 12.—A man aged 46 was admitted in June, 1951, after having been hit by a locomotive. There was a traumatic amputation of the left foot and a complete quadriplegia below the sixth cervical level. Radiographs of the cervical spine were within normal limits. Death occurred two weeks later, and permission for a post-mortem examination was refused.

Review of Cases

These 12 cases fall into three groups: non-traumatic (1 case), history of hyperextension injury (6 cases), and no clear history of mechanism (5 cases).

Group 1.—This group contains only Case 1, and is outside the scope of this paper. Some other mechanism, such as an intramedullary angioma as described by Clark (1954), must have operated.

Group 2.—This group consists of Cases 2 to 7. In each instance the patient could clearly describe a hyperextension injury. Cases 2, 3, 5, and 6 followed falls on to the forehead, and in each there was local bruising. Cases 4 and 7 followed blows in the face. Particularly noteworthy is Case 6, in which a disastrous cervical cord lesion followed a very minor accident. The mechanical basis was limitation of extension of the cervical spine due to the congenital fusion between C2 and 3, and C6 and 7 and T1. As a result of this, in forced extension there was extreme stress of the remaining intervertebral spaces, and the anterior common ligament ruptured between the fifth and sixth cervical vertebrae. A feature of the history was the loss of speech in the early phase. This was probably due to a retropharyngeal haematoma from the torn ligaments.

Group 3.—This group contains Cases 8 to 12. None of these patients could give a clear history of the mechanism of injury. Cases 8 and 9, however, showed radiological evidence of ossification of the anterior common ligament and so were classified as type 1 hyperextension injuries. Cases 10 and 11 had exactly similar injuries—namely, a blow over the back of the neck. It seems more likely that this would produce hyperextension than flexion of the neck. These cord injuries may therefore have been due to a massive disk prolapse in flexion or, more probably, a type 2 hyperextension injury. Follow-up radiographs in both cases showed marked degenerative changes consistent with the latter diagnosis. Case 12 was unsatisfactory in that a post-mortem examination was not permitted, and there is no evidence to show which of the mechanisms of cervical cord injury operated.

Haematomyelia Due to Hyperextension Injuries

From the foregoing, at least eight and possibly more of these 12 cases of haematomyelia were due to hyperextension injuries. These eight cases were further studied to determine the frequency of the two types of hyperextension injury. In the follow-up radiograph those cases showing bridging of the disk space by ossification of the anterior common ligament were classified as type 1 hyperextension injuries.

Type 1 injuries ..	5 (Cases 3, 6, 7, 8, and 9)
Type 2 injuries ..	2 (Cases 4 and 5)
Died before follow-up ..	1 (Case 2)

The classification of Case 5 as a type 2 hyperextension injury is perhaps open to doubt, as from the original radiograph at the time of his accident there was found to be a retrospondylolisthesis of the third on the fourth cervical vertebra. This suggests a type 1 hyperextension injury with loss of the nucleus pulposus through the tear in the anterior common ligament, but the orthopaedic surgeon who originally saw the case thought these changes existed before the accident. Accordingly a type 2 hyperextension injury is more probable. Both of the cases classified as type 2 injuries thus had established degenerative changes in the cervical spine predisposing to this type of injury.

Treatment of Haematomyelia Due to Hyperextension Injuries

The primary object of treatment must be to prevent recurrence of cord compression. Two points bear on this: (1) In type 1 hyperextension injuries the displacement will recur in extension (Case 13) until reparative changes have restored stability. (2) In early cases it is impossible to distinguish with certainty the two types of hyperextension injuries. Although a type 2 hyperextension injury will not recur unless the original trauma is repeated, in view of the above it is suggested that all cases of haematomyelia following hyperextension injury should be immobilized for one month in a plaster-of-Paris collar with the neck in slight

flexion. Laminectomy is contraindicated except in the presence of a spinal block on lumbar puncture or myelography. The following case shows the unavoidable hazards of cervical exploration.

Case 13.—This patient was a man aged 59. Eighteen months previous to admission, while running forward with both hands in his pockets, he tripped and struck his forehead on the ground. A transient quadriplegia lasting some ten minutes followed, with a complete recovery except that in throwing his head back to drink his daily dose of quinine he had a brief weakness or sometimes paresis of one arm. Radiographs of the cervical spine were normal. Three months after the accident a cervical laminectomy, for a diagnosis of prolapsed disk, was carried out with negative findings. After the operation he noticed stiffness and weakness of the arms and hands. He was reinvestigated some three months later and myelography was done. This showed a block in the C6 region. Laminectomy was again undertaken, but the only finding was some scarring of the cord. After this operation the weakness and stiffness spread to the legs. When he came under our care he was having such severe burning pain in the left hand that he was unable to bear even the bedclothes on it. He was barely able to walk.

On examination a scar midline in the cervical region and gross restriction of neck movements were found. Upper limbs: Weakness and wasting of all muscles, especially intrinsic of left hand; spasticity of all groups, with increased reflexes; no reversal of supinator jerk; left hand showed diminution of sensation in palm and radial aspect of dorsum, redness of the skin of the thenar eminence and the pulps of the fingers with extreme hyperaesthesia. Lower limbs: Weakness and spasticity all muscle groups; increased tendon reflexes with extensor plantar responses; sensory blunting of sole and dorsum of right foot. Abdominal reflexes were absent. Sensation of trunk normal. It was considered that further recovery of the cervical cord was unlikely, and treatment was directed to muscle re-education. The pain in the left hand being temporarily abolished on three occasions by local block of the stellate ganglion, a cervical sympathectomy was carried out on the left side with relief of the causalgic pain in the left hand. No further cervical exploration was considered, as lumbar puncture showed normal pressure and no evidence of spinal block.

Summary and Conclusions

In hyperextension of the neck the spinal cord may be injured in one of two ways: (1) transient dislocation across a disk space, spontaneously reduced by muscle pull and gravity, or (2) crushing of the cord between the ligamentum flavum, which bulges forward on hyperextension, and the posterior lippling associated with pre-existing spondylosis. In both injuries immediate radiographs of the cervical spine show nothing abnormal. The type 1 injury repairs itself by ossification of the anterior common ligament; this may be seen on later radiography.

All cases diagnosed as haematomyelia in a neurological clinic between 1939 and 1953 were reviewed to see how many were due to these injuries. Twelve cases were available. Of these, eight were certainly due to hyperextension injuries, two were doubtful (both blows over the back of the neck), one patient died without being able to give an adequate history and a necropsy was not carried out, and one case was non-traumatic. It would appear, therefore, that most cases of haematomyelia can be accounted for by the known mechanisms of cervical spine injury, but that there is still a small percentage in which other mechanisms operate.

In view of the difficulty of making a firm early diagnosis of which type of hyperextension injury has

occurred, it is suggested that all cases should be immobilized in a short plaster-of-Paris collar for one month, as the type 1 injury will recur if the neck is forcibly extended (see Case 13).

Laminectomy is contraindicated unless spinal block is shown on lumbar puncture or myelography.

I am indebted to Professor F. J. Nattrass for permission to publish these cases, and to Dr. Whately Davidson for permission to reproduce the radiographs. I am grateful to Mr. J. K. Stanger for his help and advice in the preparation of this paper.

PELLAGRA CAUSED BY ISONIAZID

BY

R. J. HARRISON, M.R.C.P.

Physician, St. James' Hospital, London, S.W.12

AND

M. FEIWEL, M.B., M.R.C.P.

Dermatologist, St. James' Hospital, London, S.W.12

In 1913 pellagra occurring in Britain was the subject of articles appearing in the *British Medical Journal* (Box, 1913; Mott, F. W., 1913; Sambon, 1913; Hammond, 1913); and the *Lancet* (Blandy, 1913). At that time Thomas (1913) suggested that certain sedative drugs such as trional and sulphonal, then in common use in mental asylums, might produce pellagra by "intoxication."

The concept of secondary pellagra, as distinct from the endemic disease, was reviewed by Bean, Spies, and Blankenhorn (1944), who listed a large number of abnormal conditions and diseases which rendered the body susceptible to this deficiency syndrome. On the other hand, pellagra was mentioned only rarely as a sequel to the use of chemical compounds.

An observation that isoniazid seemed to be of benefit in disseminated sclerosis (Kurtzke and Berlin, 1954) led to further trials of this drug.

Dr. D. B. Handley gave isoniazid in combination with pyridoxine to a number of patients with disseminated sclerosis. One of these patients, who had been existing on an inadequate diet, developed a typical pellagrous dermatitis. Three weeks after stopping the drug, while still taking the same poor diet, her symptoms persisted. There was a rapid response to nicotinamide therapy.

Case History

A spinster aged 45 had suffered from disseminated sclerosis for twenty years. Her first symptoms occurred at the age of 25, with paraesthesiae in the legs and hands. There was a constant sensation of pins-and-needles in both legs up to the groins and in the hands and fingers up to the wrists. She also noticed that she could not appreciate hot water as acutely as before, but nevertheless never burnt herself because of this. Pin-prick, too, did not feel quite so sharp as formerly. There was no weakness of the legs, but she often felt as though she was walking on air.

After eighteen months these sensations passed off, and were later followed by pains in the legs, chiefly in the knees and calves, which were present day and night throughout the year. Then came some weakness and stiffness of the legs, especially on going upstairs. However, she could still

walk long distances if she wished. On direct questioning she said that she had never had any visual or auditory symptoms, no double vision, and her speech had always been normal. There was no dyspepsia, her bowels were opened regularly, and she had never had difficulty with, or precipitancy of, micturition, or any urinary incontinence.

In 1950 she had been investigated in a neurological centre, and a diagnosis of disseminated sclerosis had been made.

History.—Her appetite had always been poor. She would have only a cup of tea and a biscuit for her breakfast, and the same again at noon. She would take a very light lunch, with little meat and fish. At tea-time she would again have tea and biscuits, and nothing further until next morning. There was no family history of fits, faints, or neurological or mental disease. Her two brothers were both well. Her father died at the age of 60 (carcinoma); her mother died aged 70 (following a stroke). At school she was reasonably intelligent, and reached the senior class. Later she worked for ten years as a bookbinder. However, for the last few years she had been doing light work in a chemist's shop, chiefly dispatching and bottling medicines. She smokes little, and drinks no alcohol.

Development of Pellagrous Dermatitis.—In May, 1955, 300 mg. of isoniazid was given daily, together with 20 mg. of pyridoxine three times a day. She took her usual inadequate meals, as her appetite did not improve. She pursued her normal activities, and did not expose herself unduly to the strong sunlight, but it was an exceptionally fine summer. During July she experienced burning sensations in the hands and feet, and the typical symmetrical pellagrous dermatitis developed on the hands and feet.

On examination her intelligence was not high; she was quite co-operative, but did not give a very good history. She was a thin woman, height 5 ft. 2 in. (157.5 cm.), weight 8 st. 2 lb. (51.7 kg.). **Special Senses.**—No anosmia. Visual acuity, good; visual fields, full to confrontation; fundi, disks normal; retinal vessels, normal; no haemorrhages or exudates. Hearing normal. Taste, normal. **C.N.S.**—Cranial nerves, normal. Motor system: nutrition of limbs—rather thin, but no wasting; no fasciculation; slight hypotonia of arms; slightly increased tone in the legs, no clonus. Power in arms, normal; both legs could be raised from the bed simultaneously. Other movements within normal range except for moderate weakness of dorsiflexion of the right ankle. **Co-ordination.**—Finger-nose test performed well, but on each side some clumsiness, especially on the left when performing repetitive movements; finger flexion normal. The impression was of slight ataxia on the left. **Co-ordination of legs** within normal limits. **Reflexes.**—Arm reflexes brisk and equal; abdominals sluggish; knee- and ankle-jerks brisk and equal; plantar responses extensor—the responses being obtained from the foot only. **Sensations.**—Pin-prick and cotton-wool were normally appreciated. Two-point discrimination, within normal limits. Postural sensibility, normal. Projection of one limb towards another with eyes closed was well performed. Vibration sense, normal. No rombergism.

Her legs were held stiffly, especially the right. Although she was a little unsteady on turning, there was no marked ataxia. The skull was normal, no bruits. Spine: no scoliosis or kyphosis; full range of movements. Heart normal in size; sounds normal, no murmurs; pulse regular; blood pressure, 105/75. The respiratory system and abdomen were normal.

Skin Manifestations.—There was a typical pellagrous dermatitis, chiefly affecting the dorsal surfaces of the hands and dorsa of the feet. Around the mouth was a fine branny desquamation. The neck was not affected. The hands and feet showed a reddish-brown colour with coarse scaling, the upper boundary of the involved skin was sharply demarcated from the normal, as in the classical case (Figs. 1 and 2). The tongue was normal but angular stomatitis was marked. There was some fine scaling of the lips. Although the drugs were stopped her symptoms persisted; there was no change in her appetite or diet.

Three weeks after the drugs were discontinued she was given 1,000 mg. of nicotinamide daily. The burning sensations in her limbs rapidly lessened; her dermatitis also quickly improved, and within eighteen days the skin appeared normal.

Investigations.—Blood count, normal. Plasma protein, normal. Fractional test meal, normal. Serum cholesterol, 159 mg. per 100 ml. Urine, no porphyrins. An E.E.G., taken on August 22 by Dr. J. A. Irwin, showed that the dominant activity in the post-central areas was an 8-9 c/s alpha rhythm which was blocked by eye-opening. On these occasions a lower-amplitude 11-12 c/s rhythm was visible. Traces of low amplitude 4-5 c/s activity were mixed with the alpha rhythm and blocked by it. Overbreathing increased the amount of slow activity, and a small amount of low-amplitude 3 c/s activity was seen in the posterior temporal regions. This record is abnormal, containing an excess of theta activity and an unstable hyperventilation response.

Discussion

Although our patient's intake of food was poor it was sufficient for her ordinary needs; at least, it did not lead to a recognizable vitamin deficiency. She continued with this diet while taking isoniazid and developed pellagra. Since

Fig. 1.—Showing typical pellagrous dermatitis affecting the hands.

Fig. 2.—The involved skin of the feet is seen to be sharply demarcated from the normal.

the symptoms appeared during the isoniazid administration there would seem to be a causal relationship, and her improvement after nicotinamide treatment would be proof that she had been deficient.

That isoniazid may lead to the development of pellagra in poorly nourished patients was also observed by Wood (1955). Bantu out-patients with pulmonary tuberculosis receiving isoniazid developed pellagra within a few weeks and required admission to hospital. Wood also found that patients who had both pulmonary tuberculosis and pellagra could not be treated satisfactorily on a good diet, even with vitamin supplements, if isoniazid were given concurrently; in fact, clinical deterioration occurred in some cases.

In this country McConnell and Cheetham (1952) observed the occurrence of pellagra in a patient receiving isoniazid for abdominal tuberculosis, a condition known to predispose to secondary pellagra.

In our case pyridoxine was given together with isoniazid, as previous studies (Biehl and Vilter, 1954) suggested that peripheral neuritis, a common complication of isoniazid therapy when large doses are given, was due to an effect on pyridoxine metabolism.

Our patient was given the standard dose of isoniazid (5 mg. per kg. body weight). The development of pellagra suggested a nicotinamide deficiency, which raises the question of a metabolic antagonism between isoniazid and nicotinamide.

Reports of an antagonistic action between nicotinic acid and sulphonamide drugs led Bean *et al.* (1944) to use pyridone-3-sulphonic acid, related to nicotinic acid as sulph-anilamide is to para-aminobenzoic acid, in three patients with subclinical pellagra on a vitamin-B-free diet for a two-weeks period. Under these circumstances pellagra did not occur, but those workers thought that larger doses for longer periods were necessary before conclusions could be drawn.

Nicotinamide is an integral component of the pyridine nucleotides (P.N.) and the co-enzymes diphosphopyridine nucleotide (D.P.N.) and triphosphopyridine nucleotide (T.P.N.), which play an important part in cellular metabolism. McConnell and Cheetham suggest that the pellagra-producing effect of isoniazid depends on the patient's original nicotinamide level being low; the amount of isoniazid which would compete successfully with nicotinamide in the formation of co-enzyme depending, by the law of mass equilibrium, on their relative concentrations and their relative affinity for the co-enzyme residue.

However, the mechanism of the biological activity of isoniazid is not yet known; the highly specific action against *Mycobacterium tuberculosis* suggests interference with an essential metabolite. It is established that there is a high concentration of nicotinic acid in the tubercle bacillus (Pope and Smith, 1946; Bird, 1947).

The structural similarity of isoniazid to both pyridoxal and the pyridine nucleotides has suggested that it may act by competing with structurally similar essential co-enzymes in the organism.

Zatman *et al.* (1953) observed that certain D.P.N. nucleotidases cause an exchange of isoniazid for the nicotinamide portion of D.P.N. Their preliminary experiments indicated that the acetylpyridine analogue of D.P.N. can be synthesized in the whole animal, and especially in tumour tissue, with the administration of acetylpyridine, which is closely related to nicotinamide. They thought it possible that the synthesis of the analogue in the intact animal might be a factor in the toxicity of the compound, which could lead to symptoms resembling nicotinamide deficiency (Kaplan *et al.*, 1954).

However, to date Kaplan and his co-workers (1955, personal communication) have not been able to show any direct relationship between nicotinamide and isoniazid in animals.

Also with regard to pyridoxal, A. Albert (1955, personal communication) states that the biological antagonism between isoniazid and pyridoxal would seem to be due to the

ordinary chemical reaction (hydrazone formation) between a substituted hydrazine and an aldehyde, which occurs readily at room temperature in dilute aqueous solution; this would be sufficient explanation for pyridoxal deprivation.

Fisher (1954) showed that haemin antagonizes the effect of isoniazid; however, Albert and Rees (1955) and Knox *et al.* (1955) proved that haemin catalyses the oxidative destruction of isoniazid even in the absence of tubercle bacilli.

Recent work by Cyerman-Craig *et al.* (1955) presents experimental evidence that the action of isoniazid appears to include an essential chelation step, but this is not the whole story.

Summary

Pellagra developed in a woman who was receiving isoniazid for disseminated sclerosis. Her intake of food was poor. The dermatitis appeared during a particularly sunny summer.

Isoniazid was stopped. During the next three weeks her symptoms persisted. She continued to take the same inadequate diet. The burning sensations in both hands and feet were so severe that they caused her great distress. She was unable to sleep at night with her limbs covered. These latter symptoms were quickly relieved when nicotinamide was given. The dermatitis cleared completely in just over two weeks.

As the symptoms of pellagra came while isoniazid was taken, there seemed to be a causal relationship.

Other clinical observations are mentioned which point to isoniazid being a contributory factor in producing pellagra if the patient is in a pre-pellagrous condition.

These clinical findings suggest a possible metabolic antagonism between isoniazid and nicotinamide. Isoniazid bears an undoubted structural similarity to nicotinamide, which is an integral component of an essential oxidation-reduction co-enzyme—that is, D.P.N.

Experimental work has shown that it is possible by enzyme action to cause an exchange of isoniazid for the nicotinamide portion of D.P.N., which points to a mechanism whereby isoniazid might produce nicotinamide deficiency; but in experiments on the whole animal this has not yet been demonstrated. The biological antagonism between isoniazid and pyridoxal is due to a purely chemical reaction.

The suggestion that the pellagra-producing effect of isoniazid depends on the patient's initial level of nicotinamide being low would cover the facts observed in our case.

The interest of these observations is not so much the causation of pellagra as the demonstration of an apparent relationship between isoniazid and a condition which is caused specifically by a nicotinamide deficiency; this would therefore point to an interference by isoniazid in nicotinamide metabolism; as an integral component of D.P.N., nicotinamide has its most important known metabolic function. The question remains whether these observations are a reflection in the human of the mechanism whereby the tubercle bacillus is inhibited by isoniazid.

The photographs were taken by Miss E. Mason, St. James' Hospital

CASE OF FETISHISM TREATED BY AVERSION THERAPY

BY

M. J. RAYMOND, M.R.C.P.Ed., D.P.M.

First Assistant, Department of Psychiatry, St. George's Hospital, London

Fetishism, or more accurately "erotic fetishism," is the tendency to be sexually attracted by some special part or peculiarity of the body or by some inanimate object. Of all the sexual aberrations, fetishism is one of the most intriguing, perplexing, and varied. The literature is rich in detailed case reports and in speculation about theories of causation. I have been able to find, however, only three apparently successful results in established cases; one attributed to a co-operative wife (Hirschfeld, 1939), one to psycho-analysis (Romm, 1949), and the third to temporal lobectomy (Mitchell, Falconer, and Hill, 1954). I have been unable to find any previous record of a fetishist who responded favourably to aversion therapy. The following case is also of interest in that the fears implicit in psycho-analytical theory, and stressed by East and Hubert (1939), of releasing homosexual or sadistic drives, have not so far been confirmed.

Case Report

The patient, a married man aged 33, was referred in November, 1954, from the out-patient department of a mental hospital for consideration of a prefrontal leucotomy after he had attacked a perambulator. This was the twelfth such attack known to the police, and because of the previous incidents they were taking a serious view of his recent actions in following a woman with a perambulator and smearing it with oil. Since his first involvement with the police his career had been as follows.

First Charge (six incidents).—In September, 1948, whilst in the R.A.F., he slashed two empty prams on a railway station before setting them on fire and completely destroying them. He also admitted five other incidents involving cutting or scratching prams, which had been the subject of police investigations over a period of months. He was convicted of causing malicious damage and put on probation to accept medical treatment. He then left the R.A.F. and was in a mental hospital from March to April, 1949, before being transferred to a neurosis unit, where he stayed for a further month. The view was there expressed that he was unsuitable for psychotherapy, was potentially dangerous, and should remain in a mental hospital.

Seventh and Eighth Incidents.—He did not remain in a mental hospital, and early in 1950 he smeared some mucus from his handkerchief on to a handbag and also damaged a pram by scratching and cutting it. He was not charged, but was admitted to a mental hospital and stayed there from February, 1950, until June, 1951.

Second Charge (ninth incident).—In April, 1952, he deliberately rode his motor-cycle combination into a perambulator with a baby in it. He swerved at the last moment but hit the perambulator and damaged it. He was convicted of careless driving and was fined.

Third Charge (tenth incident).—In August, 1952, he damaged a pram and a woman's skirt and stockings by squirting oil on them. He was convicted of causing malicious damage and was fined.

Fourth Charge (eleventh incident).—In 1953 he rode his motor-cycle through a muddy puddle, splashing a pram and its coverings and the woman who pushed it. He was charged with driving without due care and attention, but the court gave him the benefit of the doubt.

Fifth Charge (twelfth incident).—In September, 1954, came the first incident mentioned. He was charged and convicted of causing wilful damage, and was put on probation to accept medical treatment.

During the court proceedings arising from his latest escapade, the prosecuting counsel, while stressing that the accused deserved sympathy, had said nevertheless that he was still a menace to any woman with a pram. He went on to speak of "a real fear that he may cause serious injury to a baby or mother unless he is put under some form of restraint."

The patient said that he had had impulses to damage perambulators and handbags since about the age of 10, and that, although the police knew of only twelve perambulator attacks, the number of times he had so indulged was legion. He had sometimes made several attacks in one day, but he estimated the average at about two or three a week, fairly consistently. With the handbags he was usually satisfied if he could scratch them with his thumbnail, and as this could be done unobtrusively, a handbag had only once led him into trouble with the police.

He had received many hours of analytical treatment and had been enabled to trace his abnormality back to two incidents in his childhood. The first was when he had been taken to a park to sail his boat and had been impressed by the feminine consternation manifest when he struck the keel of his yacht against a passing perambulator. The second was when he became sexually aroused in the presence of his sister's handbag. He had been led to see the significance of these events and to understand that perambulators and handbags were for him "symbolic sexual containers," but the attacks continued.

His mother was a paraphrenic who was certified at the age of 54 (when he was 12) and died aged 66. His father died aged 66 (when the patient was 15). His work took him away from home for long periods. There was one sister, twelve years his senior, who had played the maternal role, and to whom he was much devoted.

Personal History

His physical health as a child had been good, and his schooling had been normal. He left at the age of 14, having reached the top standard.

Occupational.—After leaving his elementary school he attended a technical school for three years before, joining the R.A.F. as an engine fitter. He served for ten years and was then discharged because of his fetishism. Since then he had worked well at a job requiring a degree of mechanical skill and ingenuity, and also a facility for making personal contacts. He was industrious and successful, and his employers thought well of him.

Sexual and Marital.—From the age of about 10 he had masturbated, with fantasies of prams and handbags, and particularly of damage being caused to them by their owners. He first had sexual intercourse after his marriage at the age of 27; but intercourse, he said, was only possible with the aid of fantasies of handbags and prams. There were two children, and his wife said that he was a good husband and father. The domestic perambulator and his wife's handbags, however, were not immune from attack.

and a handbag filled to capacity and bulging often provided piquancy to his masturbation. While it was true that handbags and perambulators aroused him sexually, his attacks upon them were never accompanied by emission, though he was usually conscious of release of tension.

He described himself as a good mixer, but said he was never perturbed by solitude, and had always been a day-dreamer. He read a good deal, especially adventure and crime novels, and he was keen on gardening and woodwork. His knowledge of perambulators and handbags was considerable, and there was no doubt that a good deal of his leisure time was devoted to them.

Treatment

On examination he was found to be a man of good intelligence, who showed no psychotic abnormality. He said he was depressed because he doubted whether anyone could help him, and though he said self-reproachfully that his trouble was lack of will power, it was noticeable that he gave his history in a facile way, and, it seemed, with a certain amount of relish.

In reflecting upon this man's plight, the despair of his family, and his poor response to treatment previously given, the idea was conceived that he might benefit from aversion therapy similar to that used in the treatment of alcoholism.

It was explained to the patient that the aim of treatment was to alter his attitude to handbags and perambulators by teaching him to associate them with an unpleasant sensation instead of with a pleasurable erotic sensation. Though he was frankly sceptical about the treatment, he said he was willing to try anything, for his despair had been deepened by recent sexual arousals when handbags appeared in the ward on visiting-day, and by illustrated advertisements in newspapers.

A collection of handbags, perambulators, and coloured illustrations was obtained, and these were shown to the patient after he had received an injection of apomorphine and just before nausea was produced. The treatment was given two-hourly, day and night, no food was allowed, and at night amphetamine was used to keep him awake. At the end of the first week, treatment was temporarily suspended and the patient was allowed home to attend to his affairs.

He returned after eight days to continue the treatment, and he reported jubilantly that he had for the first time been able to have intercourse with his wife without use of the old fantasies. His wife said that she had noticed a change in his attitude to her, but was unable to define it. Treatment was recommenced and continued as before, save that emetine hydrochloride was used whenever the emetic effect of apomorphine became less pronounced than its sedative effect.

He was asked to write an account of the attractive qualities of perambulators and handbags, and this he did between treatments, writing at considerable length and with a wealth of technical detail. He also wrote an account of the ways in which they are commonly and carelessly misused. At this stage his difficulties were discussed, and attention was chiefly directed towards the pride with which he had always cherished his eccentricity, the exhibitionistic element in his attacks on perambulators, and ways in which they had become a threat to his liberty. After five days he said that the mere sight of the objects made him sick. He was now confined to bed and the prams and handbags were continually with him, the treatments being given at irregular intervals. On the evening of the ninth day he rang his bell and was found to be sobbing uncontrollably. He kept repeating, "Take them away," and appeared to be impervious to anything which was said to him. The sobbing continued unabated until the objects were removed with ceremony, and he was given a glass of milk and a sedative. The following day he handed over a number of photographic negatives of perambulators, saying that he had carried them about for years but would need them no

longer. He left hospital but continued to attend as an out-patient.

After a further six months it was decided empirically to readmit him for a boosting course of treatment. He agreed to this, although he did not consider it at all necessary. A coloured cinematograph film was made of women carrying handbags and pushing prams in the careless, provoking ways which he had described previously. The film was started each time just before the onset of nausea produced by an emetic and was continued throughout the period of nausea. He was also given handbags to handle.

When asked to write an account of any change which he thought had taken place, he said that he no longer regarded himself as an expert on perambulators, and often made mistakes about them in the street. He wrote: "The will power had been there all the time, but before treatment prams and handbags had a fascination for me which my will power was too weak to overcome." The fascination, he said, had become much less because his will power had "matured."

Progress

Nineteen months after he first had aversion therapy he still appeared to be doing well.

Patient's Report.—He says that he no longer requires the old fantasies to enable him to have sexual intercourse, nor does he masturbate with these fantasies.

Wife's Report.—She says that she is no longer constantly worrying about him, and about the possible imminence of police action against him. Their sexual relations have "greatly improved."

Probation Officer's Report.—He says that the patient has made "very noticeable progress" and that "his general attitude to life, his conversation, and his appearance have all shown a marked improvement."

Work Record.—He has been promoted to a more responsible job.

Police.—He has not been in any trouble with the police.

Literature

Among the earliest speculations on this subject are those of the French philosopher Descartes, who was himself a slight fetishist. In 1649 he wrote: "From whence came those extraordinary passions which are peculiar to certain men? There is so close a union between mind and body that once we have combined a certain action with a certain thought, the one never subsequently presents without the other." Referring to strange aversions (anti-fetishisms) that some people have, he concluded that they may well have formed in early infancy to "remain imprisoned in the brain until the end of life."

Binet (1888), however, first gave the term "fetishism" its sexual connotation, defining it as the erotic idolatry of something which cannot directly satisfy the ends of reproduction. He stressed that everyone was to some extent a sexual fetishist and that the difficulty was in knowing where the normal became abnormal. Fetishism, he said, arose from an "accident acting on a predisposed subject," and the predisposition was in the form of a general nervous hyperaesthesia. According to Binet the form taken by any sexual perversion was determined purely fortuitously by an external event, and he stated that "the man who can love only men could easily have been a nightcap fetishist or a shoe-nail fetishist." He distinguished a minor and major fetishism. In minor fetishism some effective detail or object was the centre of attraction, but did not overshadow the person to whom the love was gradually transferred. In major fetishism there was no such transference. Minor fetishisms, he said, were not at all obvious or easy to recognize, but in them lay the secret of many strange loves and astonishing marriages.

Krafft-Ebing (1939) accepted Binet's conclusion that in connexion with the first awakening of the fetishist's sexual life some event determined the association of lustful feeling

with a single impression. The fetishist's abnormality, according to Krafft-Ebing, lies not in what stimulates him, but in what does not stimulate him—that is, in his limited sex interest. He classifies fetishes according to the type of fetish object: (1) part of female body, (2) part of female clothing, (3) special materials, (4) animals. Group 1 may be physiological or pathological, but the other three are always pathological.

He stresses its *forensic importance*, because it may present as strange acts aimed at defiling the object or at its theft, and its importance as a *cause of impotence*.

Havelock Ellis (1906) states that fetishism tends to occur in sensitive, nervous, timid, and precocious individuals, and can usually be traced to a definite starting-point in some sexually emotional episode in early life. The degree to which this influences an individual's subsequent life depends on his "morbid emotional receptivity."

Hirschfeld (1939) elaborates Binet's theory and says that the predisposition is not a generalized nervous hyperaesthesia but a specific psychological make-up and that it is only a certain type of "accident" which is capable of arousing fetishism. In summary, he says that "fetishism is based on a conscious or unconscious associative absorption of sensual perception that is in accord with the individual's psycho-sexual constitution."

Freud's (1928) views may be briefly, and no doubt inadequately, summarized as follows. A fetish object is a substitute for the woman's (mother's) phallus in which the boy once believed. It remains as a triumph over the castration threat, and saves the fetishist from becoming homosexual by endowing women with the attribute which makes them sexually acceptable. The object may, however, symbolize the boy's last impression before the traumatic discovery which it screens from his conscious memory.

Stekel (1930) states that fetishism can be totally explained as flight from the woman, and in his experience homosexuality was the end of every case. It is, he says, a complicated compulsive neurosis giving rise to impulsive, often sadistic, acts carried out in a twilight state and expressed in symbolism which can be interpreted only by psycho-analysis. Stekel stresses the fetishist's pride in being unusual, his psycho-sexual immaturity, his harem cult, and his impulses to exhibitionism.

Karpman (1934) states that sadism is the root of fetishism, though sado-masochistic fantasies may not be present. Common to sadism and fetishism are predominance of fantasy life, depreciation of the sexual partner, and incestuous attachment.

Rarity in Females.—All authorities agree that fetishism is predominantly a male disorder. Krafft-Ebing (1939) considered that pathological fetishism had been observed only in men, and Havelock Ellis (1906) noted the "great rarity of fully developed fetishism in women" but thought that slight degrees might occur. Stekel (1930) stated that it was "generally a male disease," and Fenichel (1945) that it was "very rare" in women. Kinsey *et al.* (1953) state that it is "an almost exclusively male phenomenon." Of 7,789 females, they reported only two or three who were regularly aroused by objects not directly connected with sexual activity.

Fetishism in Homosexuality.—East (1949) states that fetishism is not confined to heterosexuals, for in rare cases it is associated with homosexuality. Thoinot and Weyse (1920) recorded the case of a male homosexual fetishist who was erotically excited by contemplating the patent-leather shoes of other men.

Frequency as a Primary Medical Problem.—In a series of 4,000 patients seen in private practice, Curran (1954) found only five cases in which fetishism was the primary problem. None of these was on a charge.

Frequency as a Legal Problem.—Fetishism, according to East (1949), is seen infrequently in the criminal courts. It is also quite rare in divorce proceedings (R. Ormerod, 1956, personal communication).

Discussion

To use aversion therapy in treating this patient seemed a logical approach if one believed that the results obtained in alcoholism are not dependent upon the specific biochemical changes produced by any drug but upon the establishment of a conditioned response. The fetishist's predisposition propounded by Binet as a general nervous hyperposition may well be expressed as an unusual capacity for forming conditioned responses, and this capacity might prove as great an asset in treatment as it was a liability when the fetish was formed. To use nausea and vomiting as a means of producing the aversion was clearly less appropriate than in alcoholism, but familiarity with the procedure, the ease of administration, and reluctance to use other available stimuli favoured its use. Also the modification of attitudes and psychological conversions are more easily obtained in states of exhaustion and hunger, and from that point of view the technique was suitable.

It was thought that should aversion be successfully established there might be some risk that impotence would ensue. According to Freud's (1928) view, overt homosexuality might emerge if the protective fetish objects were removed; while Stekel's (1930) experience suggested that this would happen anyway. East and Hubert (1939) stress the danger of changing a sexual fetish into strong homosexual or sadistic drives by treatment. So far none of these eventualities has arisen.

Romm's case is interesting because apparently the impulses to aggressive action disappeared or were controlled, although unusual interest in what had been the fetish object still remained, and was even occasionally used in fantasies.

Much of what our patient says—for example, that he makes mistakes about perambulators—also indicates the habits of observation persist to some extent. He insists, however, that observation is more casual, and that sexual stimulation never occurs as a result.

Summary

A report is given of a case of fetishism believed to be unique in that the patient responded favourably to aversion therapy. A brief review of the literature is given and discussed in relation to the treatment of this case. It is suggested that the predisposition to fetishism, first discussed by Binet, may lie in an unusual capacity to form conditioned responses, and that this capacity may be used as an asset in treatment.

I am indebted to Dr. Desmond Curran for the opportunity to treat this patient, and for permission to publish this report. I also thank him and Sir Paul Mallinson for much helpful criticism and advice in the preparation of this paper. It is a pleasure to acknowledge the help and co-operation of the nursing staff at Atkinson Morley's Hospital.

ACTION OF DIBENYLIN ON THE PERIPHERAL CIRCULATION

BY

R. S. DUFF, M.D., F.R.F.P.S., M.R.C.P.

From the Cardiological Department, St. Bartholomew's Hospital, London

"Dibenyline" (phenoxybenzamine hydrochloride) is chemically related to though much less toxic than "dibenzamine." It has been thought to cause increased blood flow in many tissues by an action mainly involving the vasomotor nerves. Studies with dibenyline in patients with peripheral vascular disease have yielded conflicting results. Moser *et al.* (1953), Haimovici (1951), Friend and Edwards (1954), and Wertheimer *et al.* (1954) found it valuable when given intravenously or orally in the treatment of vasospastic disorders, causalgia, and acrocyanosis. Wertheimer *et al.* (1954) claimed some benefit in arteriosclerosis obliterans, but most workers consider the drug to be less efficacious in organic vascular disorders.

Animal investigations have suggested that the vascular response to dibenyline is largely dependent upon an adrenergic blocking action on the sympathetic nervous system (Nickerson *et al.*, 1953; Green *et al.*, 1954; Harvey and Nickerson, 1954).

The present investigation was designed to assess the effect of the drug on diseased blood vessels and to study the role of the sympathetic nerves in the response to dibenyline in man.

Subjects and Methods

The blood flow responses of 22 sympathectomized limbs to dibenyline were studied. Most patients were given dibenyline while still in hospital in the immediate post-operative period following surgical sympathectomy. A few were tested with the drug as out-patients after sympathectomy.

The subjects belonged to one of two fairly distinct categories: (1) patients with hyperhidrosis or uncomplicated Raynaud's phenomenon who had no evidence of organic vascular disease and were therefore considered to have comparatively healthy blood vessels (eight limbs); and (2) patients with arteriosclerosis, scleroderma, or Raynaud's disease with ischaemic lesions, in whom there was undoubtedly organic vascular change (14 limbs). The effects of intravenous and of intra-arterial dibenyline were separately investigated.

The blood flow in the limbs was measured in each case by venous occlusion plethysmography, under standard conditions (Barcroft and Swan, 1953). Each limb under observation was enclosed in a neatly fitting thin rubber sheath and inserted into a plethysmograph of appropriate design. Throughout every test the temperature of the water surrounding the segment of limb in the plethysmograph was kept at $34 \pm 1^\circ \text{C}$; the room temperature was maintained between 23° and 25°C . Regular measurements of blood flow were made at intervals of half to one minute; the systemic blood pressure was recorded with a sphygmomanometer every five to ten minutes.

Control observations of blood flow were made for at least ten minutes. An intravenous or intra-arterial infusion of saline was then set up, using a power-driven infusion apparatus delivering saline at a constant rate of 3 ml. a minute (Duff, 1952). Saline alone was infused for ten minutes; the desired amount of dibenylin was then added, after which the plain saline infusion was resumed. Blood flow was measured regularly throughout the entire period.

In the studies in which dibenylin was given *intravenously* the total dose was determined by the size and condition of the patients, and was between 25 and 60 mg. The drug was infused at a rate of 0.5 to 1 mg. a minute.

In the study of *intra-arterial* dibenylin unilateral infusions were given into the brachial artery just above its bifurcation. The total dose was under 0.5 mg., given at a rate of 50 to 200 μg . a minute.

Evidence that the vasomotor nerves had been effectively interrupted in the investigated limbs was provided both clinically and by the use of the plethysmograph. Increased warmth of the skin and absence of sweating were noted; in addition Horner's syndrome was observed in those having stellate ganglionectomy. In most subjects an increase in blood flow was recorded soon after operation; however, a failure to induce vasodilatation after indirect warming of the body was regarded as the most reliable indication of successful sympathectomy (Landis and Gibbon, 1933).

Effects of Intravenous Dibenylin on Sympathectomized Vessels

Healthy Vessels

Results of a typical experiment are portrayed in Fig. 1. Bilateral cervicodorsal ganglionectomy had been performed seven days previously in a young woman with uncomplicated Raynaud's phenomenon. Soon after the start of the dibenylin infusion the blood flow in the hand increased from about 8 to over 25 ml. per 100 ml. a minute. The flow was still elevated three hours later. However, 24 hours later the

Fig. 1.—Blood flow in hand and forearm of a woman aged 27, with uncomplicated Raynaud's phenomenon, on seventh day after sympathectomy, during infusion of saline (shallow block) and dibenylin (deep block). With dibenylin the circulation increased greatly in hand, slightly in forearm. One month later blood flow in both tissues was below control level.

mean hand blood flow had returned to about the resting (pre-dibenylin) level. The increased blood flow was therefore of comparatively brief duration, and at an examination one month later the blood flow was still low.

Increased blood flow through comparatively healthy vessels after intravenous dibenylin is also shown in Fig. 2. This subject, a woman aged 37, had had bilateral cervico-

Fig. 2.—Circulation in sympathectomized hands of a woman aged 37 during continuous intravenous saline infusion. Dibenylin given between 40th and 70th minute (dotted line) was accompanied by some increase in flow in both hands, especially the right.

dorsal ganglionectomy ten days previously. A mean increase in hand blood flow of between 50 and 100% was recorded during the infusion of 45 mg. of dibenylin.

Diseased Vessels

Dibenylin caused little or no increase in blood flow in some of the subjects in this group. Findings in a man aged 53 with intermittent claudication due to arteriosclerosis of the lower limbs are illustrated in Fig. 3. Five days previously bilateral lumbar sympathectomy had been performed.

Fig. 3.—In this patient, a man aged 53 who had undergone sympathectomy for intermittent claudication, 60 mg. of dibenylin failed to influence the blood flow in the feet.

A slight increase in the blood flow in the feet had resulted from the operation. No further increase in flow occurred with intravenous dibenylin even when 60 mg. had been given. Seven weeks later the blood flow in both feet was at the pre-operative level.

In other subjects with organic vascular disease dibenylin did increase the blood flow. The circulatory response in the hands to an infusion of 25 mg. of dibenylin in a woman with scleroderma is shown in Fig. 4. An increase in flow

Fig. 4.—Intravenous dibenylin caused some increase in flow in both hands of a woman aged 65 with diseased blood vessels.

of approximately 100% occurred in both hands. The flow was no longer raised two months after the infusion. This patient had obtained little or no symptomatic relief from bilateral cervicodorsal sympathectomy nine years previously, or from vasodilator drugs such as tolazoline hydrochloride. She claimed considerable relief from a subsequent course of oral dibenylin.

Effects of Intra-arterial Dibenylin

In this series a regular infusion of saline into the brachial artery of the right arm was maintained continuously. At half-minute intervals the blood flow was measured simultaneously in both hands. After a control period of five to ten minutes dibenylin was added to the infusion in an amount sufficient to produce a concentration between 50 and 200 μg . a minute. This was given for four minutes; then, after a further control period on saline alone, a second infusion of dibenylin was given.

The total amounts of dibenylin were too small to have any measurable effect on systemic blood pressure or on blood flow in the non-infused left hand.

Healthy Vessels

Dibenylin caused a marked increase in blood flow in the infused right hand without affecting the level of flow in the left hand.

Fig. 5 illustrates the response in a man of 48 with coronary disease but otherwise healthy blood vessels. Six days before the test bilateral cervicodorsal ganglionectomy had been performed, and Horner's syndrome and anhidrosis of the denervated areas had resulted. The blood flow in the infused right hand averaged 7 ml. per 100 ml. a minute during the initial saline control period. Soon after adding dibenylin at a concentration of 100 μg . a minute the blood

flow in the right hand rose to between 12 and 13 ml. On resuming the plain saline infusion the flow in that hand fell slightly, but when dibenylin was given again, at 200 μg . a minute, a further increase in flow occurred, to between 14 and 16 ml.

Fig. 5 illustrates the important control provided by the non-infused left hand which failed to exhibit any increased flow. This confirmed that the dibenylin did not escape from the right hand into the blood stream in an amount sufficient to cause systemic effects on the peripheral circulation. No change in heart rate or arterial blood pressure was recorded during the intra-arterial infusions of these small amounts of dibenylin.

Fig. 5.—Two infusions of dibenylin into the right brachial artery caused increase in blood flow in the right hand of a man aged 48, with angina, on the sixth day after bilateral cervicodorsal sympathectomy.

Diseased Vessels

Similar responses were recorded in patients sympathectomized for peripheral vascular disease of the upper extremity. The results of one such test are illustrated in Fig. 6. The blood flow was measured in both hands of a woman of 39 who had had bilateral cervicodorsal ganglionectomy eight days previously. A continuous infusion into the right brachial artery was maintained throughout the period of observation. During the initial saline control period the blood flow in the right hand averaged about 12 ml. per 100 ml. a minute. Soon after adding dibenylin to the intrabrachial infusion (at a rate of 100 μg . a minute) the flow in the right hand rose to over 20 ml. This marked

Fig. 6.—Intra-arterial dibenylin caused vasodilatation confined to the infused hand of a woman aged 39, with Raynaud's phenomenon and calcinosis, sympathectomized eight days previously.

increase in flow with dibenylin was not invariably found. A young girl of 15 was studied five days after cervicodorsal ganglionectomy for hyperhidrosis. Only a slight increase in flow accompanied infusions of dibenylin in concentrations of 50 and 200 μg . a minute. In none of the tested subjects, however, was dibenylin associated with a reduction of flow in the infused hand, and the common response, irrespective of the condition of the blood vessels, was a distinct increase in blood flow.

Discussion

This study has shown that in man dibenylin is capable of increasing the blood flow through vessels surgically deprived of their sympathetic innervation. The increase in flow after intravenous dibenylin was generally greater in subjects with little or no organic arteriolar narrowing than in those with structural ischaemic change. The volume of blood flowing through any part of the arterial tree is determined by the "perfusing" pressure and by the vascular resistance. In these experiments there was no increase in pressure; on the contrary, the blood pressure generally fell a little with the intravenous infusions of dibenylin. The increased flow was therefore due to a lowering of resistance—that is, to an increase in mean vascular calibre. Since the blood vessels had been denervated the increased flow was not due to any effect of dibenylin on the sympathetic nerves. The vasodilatation could therefore be attributed to an action of the drug at the periphery or to the systemic release of some vasodilator substance by the intravenous dibenylin.

The mechanism was further elucidated by the studies using intra-arterial dibenylin. Dilatation during infusion of the drug into the brachial artery was confined to the corresponding hand. This demonstrated that the vasodilatation with dibenylin can result from a purely peripheral action without involving any systemic or central effect. This peripheral action presumably involves the receptor elements or the contractile muscle of the arterioles.

In subjects with intact vasomotor nerves this action is no doubt reinforced by the effects of the drug (when given orally or intravenously) on the sympathetic nervous system. It has been demonstrated that dibenylin is capable of dilating blood vessels by peripheral action beyond the sympathetic terminals. This is of particular importance in patients in whom the vasomotor nerves have been ablated by surgery or impaired by metabolic or nutritional disorders. Dibenylin is specially indicated in acute ischaemia of an extremity, for it may be infused directly into the artery of any limb to which the vascular disturbance is confined. It is effective in doses that do not influence the blood pressure or systemic circulation.

If two or more limbs are involved the drug may be given intravenously in larger amounts (25–60 mg.). By this route its systemic actions, especially its tendency to lower the blood pressure, may be a disadvantage.

Undesirable effects tend to occur with intravenous doses of over 40 mg. of dibenylin. The most serious of these—tachycardia and hypotension—are related to the widespread vasodilatation produced. The drug is therefore best withheld from people known to have heart disease. After intravenous administration all patients should be kept in bed for 24 to 48 hours, and the heart rate and blood pressure carefully watched. Some drowsiness and lethargy is to be expected during this period, but requires no treatment. Nasal stuffiness due to congestion of the mucosae is common, but rapidly passes off. If dibenylin is given continuously by mouth, especially in daily doses greater than 20 mg., nasal congestion, lethargy, and giddiness may occur, but considerable relief is usually afforded by the use of an amphetamine inhaler and small doses of dexamphetamine sulphate tablets, B.P.C.

Summary

It has been shown that dibenylin is capable of increasing the blood flow in the limbs by a peripheral action independent of any effects it may have on the sympathetic nervous system.

The vasodilatation from a single injection is of rapid onset and persists for several hours.

The drug may be of particular value in treating acute ischaemia of a limb, for it is effective when infused intra-arterially in doses (under 0.5 mg. into the brachial

artery) that do not appreciably affect the general circulation.

Dibenylin is effective even in patients in whom the integrity of the vasomotor nerves has been lost.

However, it must always be remembered that the extent to which any blood vessel may dilate with dibenylin or with any other agent is determined ultimately by the degree to which disease has induced structural change in the vessel wall.

The patients were investigated by courtesy of Professor Sir James Paterson Ross, Professor J. B. Kinmonth, and Mr. G. W. Taylor, to whom I am much indebted. For valuable encouragement and advice I am grateful to Dr. Geoffrey Bourne and Dr. Graham Hayward, of St. Bartholomew's Hospital, and to Professor Henry Barcroft and Dr. Jean Ginsburg, of St. Thomas's Hospital Medical School. I would like also to thank Dr. Kenneth Carter and the secretarial staff of Smith, Kline and French International Co. for supplies of dibenylin and for secretarial help.

CARDIOVASCULAR COLLAPSE DURING APOMORPHINE TREATMENT

BY

DENIS PARR, M.D., D.P.M.

Department of Psychiatry, St. George's Hospital, London

Apomorphine treatment for alcoholism is being used on an increasingly large scale, and published reports suggest that it is effective and safe. In principle, the method, which was introduced by Dent in 1934, consists in giving drinks of alcohol together with subcutaneous or intramuscular injections of apomorphine repeatedly over a few days. There has recently been a trend, expounded chiefly by Feldmann (1952), of Geneva, towards long and intensive courses of treatment, such as apomorphine 1/10 gr. (6.5 mg.) by injection and alcohol by mouth, two-hourly day and night for six to ten days, during which time other foods and fluids are absolutely withheld.

In view of the safety claimed for this treatment, it is thought worth publishing the following observations on a patient who showed an anomalous and dangerous reaction to apomorphine. In spite of his experiences under therapy, he generously volunteered to have further doses of the drug experimentally, and thereby made it possible for the nature of this unusual reaction to be more accurately defined.

Case History

The patient, a man of 32, was of markedly asthenic physique and had a thoracic kyphoscoliosis. He had a history of repeated attacks of intestinal colic, which had not been cured by a reconstruction operation carried out on the hypothesis that an aberrant mesenteric vessel might be responsible. He came under psychiatric treatment because of a confusional state provoked by drugs and alcohol. The most notable feature in his drug-taking history was the injection of pethidine in doses up to 2,500 mg. daily, intermittently

over nine months with periods of freedom from the drug of up to three weeks. In addition, he had on rare occasions taken intravenous thiopentone in such dosage as 0.5 g. His drinking history was less remarkable, amounting to frequent symptomatic excess rather than confirmed and continuous addiction, his daily intake being of the order of 3 pints (1.7 litres) of beer and nine whiskies. His confusion cleared before admission.

Before starting on apomorphine treatment, a course of modified insulin was given to improve his general physical condition. He proved to have a high insulin tolerance, taking as many as 440 units without losing consciousness.

Treatment by apomorphine was started on the 57th day after admission. The patient, who was anxious and apprehensive, had a B.P. of 120/60 and a pulse rate of 96 a minute. In accordance with the method of Feldmann (1952), he was then given an initial dose of 1/10 gr. (6.5 mg.) of apomorphine subcutaneously, with 20 oz. (570 ml.) of beer. After 10 minutes he experienced nausea, and after 15 minutes he vomited copiously, whilst his pulse rose to 126. Twenty minutes after the injection he suddenly became pale and cyanosed. Profound cardiovascular collapse followed, with cessation of respiration, absence of radial pulse, loss of consciousness, and an appearance of extreme prostration. Artificial respiration and oxygen were given and the return of shallow irregular respiration and of a slow pulse was accompanied by generalized clonic jerking. He recovered consciousness within a minute or so, but with some transient confusion. He was then restless and agitated, but within 15 minutes of the collapse his physical condition no longer gave cause for concern.

In view of this severe and dangerous collapse the treatment was withheld for a week. During this time an E.E.G. showed mild bilateral dysrhythmia of constitutional type, but no evidence of epilepsy. An E.C.G. revealed a sinus bradycardia of 50 a minute, with flat P waves in all leads, but the curves were considered to be within normal limits. The bradycardia was an isolated finding, his usual pulse rate being 70 to 80. It was decided to proceed cautiously with the treatment. He was watched very closely after each dose of the drug and means of immediate resuscitation were kept at hand. His reactions to subsequent doses are summarized in the Table.

Reactions to Apomorphine				
Days after Admission	Time	Dose of Apomorphine	Vomiting	Cardiovascular Effects
64	6.55 p.m.	gr. mg. 1/40 1.6	After 5 mins.	Nil
64	9.05 "	1/30 2.2	" 5 "	(1) Fall of pulse from 84 to 48 after 10 mins. (2) Malaise, shock, pallor, cyanosis after 15 minutes. B.P. 70 systolic. Nikethamide 5 ml. given i.m. (3) Improving 20 minutes after injection. Pulse 84. B.P. 95/50
65	10 a.m.	1/60 1.1	Nil	Nil (difficulty in focusing after 5 mins.)
65	12 noon	1/50 1.3	Nausea only after 6 mins.	Nil
65	1.30 p.m.	1/40 1.6	Nil	Yawning and fall of B.P. from 110/75 to 90/50 after 20 mins. Nil else.
65	3 "	1/30 2.2	Nausea after 6 mins. (retching)	Pulse steady
65	4.10 "	1/20 3.2	After 5 mins.	Malaise and fall of B.P. to 95/60 after 13 mins. Pulse steady
65	8.08 "	1/20 3.2	" 5 "	Pulse 46 after 10 mins. Pallor and collapse after 12 mins. requiring oxygen and nikethamide
66	10 a.m.	1/30 2.2	Nil (nausea after 5 mins.)	Nil significant (facial flush and blurred vision after 15 minutes)

Because of its manifest hazards in this case, apomorphine treatment was abandoned. The patient agreed, however, to have further doses of the drug under experimental conditions so that electrocardiographic recordings could be made.

Experimental Observations

The patient was given a series of injections of apomorphine, each on a different day. Tracings were taken as indicated by a Cambridge Electrite cardiograph, lead II being used throughout. In the following summaries of the observations made, the times noted refer to the interval after injection, and letters A–F to the series of E.C.G. tracings (Fig. 2) corresponding to the points on the pulse chart (Fig. 1) for the third experiment.

First Experiment (71 days after admission).—Resting E.C.G. normal. Pulse 75, regular. Apomorphine 1/40 gr. (1.6 mg.) subcutaneously. 9 minutes, slight malaise. 13 minutes, yawning. No vomiting. No significant change in E.C.G.

Second Experiment (78 days after admission).—Resting E.C.G. normal. Pulse 88, regular. Apomorphine 1/25 gr. (2.6 mg.) subcutaneously. 9½ minutes, vomiting followed by malaise. No significant change in E.C.G., pulse, or blood pressure.

Third Experiment (83 days after admission).—Resting pulse 97. B.P. 120/70. (A.) Apomorphine 1/20 gr. (3.2 mg.) intramuscularly. 4 minutes, subjective flushing. 7½ minutes, vomiting. 8–9 minutes, rapid fluctuations in size of pupils. 10 minutes, onset of malaise. 15 minutes, slight conjunctival injection. 16 minutes, further vomiting; pupils reacting briskly to light, sluggishly to accommodation. 18 minutes, inability to focus; much more severe malaise; a floating feeling. 19 minutes, increasing malaise, restlessness, and pallor. 20 minutes, onset of severe collapse. (B.) 21–26 minutes, cyanosis and profound collapse; oxygen and nikethamide given. (C. D. E.) 29 minutes, rapidly improving; B.P. 110/50. 30 minutes onwards, steady and uninterrupted recovery. (F.) 45 minutes, hiccuping and drowsiness; B.P. 115/60.

FIG. 1.—Pulse chart showing third experiment. A–F refer to times at which the electrocardiographic tracings shown in Fig. 2 were taken.

The urgent need for resuscitative measures made it impossible to take blood-pressure readings while he was collapsed, and the state of the pupils was also neglected. For similar technical reasons, there were short breaks in the E.C.G. tracing between points B and C, and C and D. Fig. 1 shows the changes in pulse rate. Representative sections of the E.C.G. are reproduced in Fig. 2.

This series of electrocardiographic changes supports the clinical diagnosis of a severe vasovagal syndrome, the gravity of which is well illustrated by the tracings C and D. The rapid return of the E.C.G. to normal is regarded as evidence against the possibility of a direct toxic action of apomorphine on the heart.

Discussion

The pharmacology of apomorphine was extensively reviewed by Sumwalt (1943), while, of the standard works of reference, those of Drill (1954) and of Goodman and Gilman (1955) give comprehensive accounts of the drug's actions. Apomorphine is, of course, a central emetic which acts

selectively (according to Borison and Wang, 1953) on a chemoreceptor trigger zone in the floor of the fourth ventricle, separate from the emetic centre in the fasciculus solitarius. Vomiting occurs 5 to 15 minutes after a dose of 2 to 8 mg. in most adults. Emesis is not the only excitatory effect of the drug; restlessness, tremor, polypnoea, and even convulsions have occasionally been reported. There is, in addition, a central depressive action, manifest usually by

FIG. 2.—Electrocardiographic findings (third examination). A. (Time zero.) Normal E.C.G.; rate 97; P-R interval 0.16 second. B. (20 minutes.) Rapidly increasing bradycardia; rate regular, 75-50; P-R interval 0.12 second. QRS complex normal. C. (21½ minutes.) Extreme slowing and irregularity; rate 26; P-R interval 0.12 second; QRS complex normal. D. (23½ minutes.) Regular bradycardia; rate 39; all P wave activity suppressed; idioventricular rhythm; QRS complex normal. E. (26 minutes.) Regular bradycardia; rate 52; normal P wave re-established; P-R interval 0.12 second; QRS normal. F. (30 minutes.) Normal curves; rate 71; P-R interval 0.14-0.16 second.

fatigue and somnolence after vomiting. According to Drill, central depression of vasomotor tone, causing momentary syncope, occurs in 1 to 5% of patients having the drug, and in rare cases there is fatal cardiovascular collapse. No reference to E.C.G. changes in humans has been found, but Crittenden (1932) reported cardiographic evidence of heart block and cardiac arrest in unanaesthetized animals given subcutaneous apomorphine. The wide range of variation in individual susceptibility to apomorphine has been generally stressed.

Apart from the uses to which it has been put by psychiatrists, apomorphine has few therapeutic applications. It is recommended, traditionally but with great caution, as an emetic in alcoholic intoxication and other instances of acute poisoning, and as a remedy for paroxysmal tachycardia (Finkle, 1939). Apomorphine has less often and with doubtful effect been tried as an analgesic in obstetrics, as premedication for emergency operations in delirious patients, and to reduce tremor in Parkinsonism. In experimental pharmacology it has been found useful in the evaluation of anti-emetic substances.

The apparent efficacy of apomorphine in the treatment of alcoholics depends, in part, on the production of conditioned aversion to alcohol. Psychodynamic processes such as expiation of guilt by submitting to such unpleasant treatment may also be important. There is, however, some evidence that the main action of the drug is not in effecting psychological changes in these ways, but in correcting physiological abnormalities causally underlying the alcoholism. Feldmann (1955), who has treated over 3,400 patients (not all alcoholics) with apomorphine, inclines to this last view.

Feldmann (1955) carries out preliminary physical assessment in every case, but says that apomorphine treatment given for alcoholism by his rigorous technique has "absolutely no contraindication." He and Dent, in personal communications, regard the case here reported as quite exceptional (as do we, from our much smaller experience of the method at the Atkinson Morley Hospital). In Feldmann's clinic,

apomorphine treatment has been given without mishap to cases of severe cardiovascular degeneration, including six patients with bundle-branch block. It would, however, be unfortunate if the confidence felt in such a large and well-staffed clinic was casually assumed and misapplied elsewhere.

As to the dangerous idiosyncrasy exhibited to apomorphine by our patient, it might be postulated that he possessed inherently abnormal autonomic lability. The rapid fluctuations in pupillary size following injection would support this hypothesis, as would the history of attacks of intestinal colic. On the other hand, anomalous responsiveness to other drugs was shown by the high pethidine and insulin tolerance (the latter being a common incidental finding in psychiatric patients). A year after these experiments he developed minimal but definite signs of thyrotoxicosis in the inexplicable presence of a blood cholesterol of 405 mg. per 100 ml.

Aside from such speculations, the clinical and electrocardiographic observations in this case leave no doubt that apomorphine is a potentially dangerous drug in certain individuals. Whenever it is given, the patient should be under very close observation for at least 30 minutes after each dose. It is best to start with a small dose, such as 1/30 gr. (2.2 mg.) in case of idiosyncrasy, and oxygen and restoratives should be at hand for immediate use. Malaise and restlessness after vomiting (instead of the usual nauseated drowsiness and relaxation) are danger signals. Syringes should be sterilized by boiling, since alcohol destroys apomorphine, perhaps making it more difficult to judge dosage. Finally, if any green coloration is seen in the prepared injection it should be discarded and fresh supplies obtained.

Summary

The case is described of a man of 32 who showed profound and dangerous cardiovascular collapse with therapeutic doses of apomorphine. Electrocardiographic findings following experimental administration of the drug to the same patient are described and illustrated. It is suggested that the traditional caution of pharmacologists and physicians in the use of apomorphine should not be disregarded now that the drug is finding a new and promising application to psychiatric problems.

I am grateful to Dr. Alastair Hunter for interpreting the electrocardiograms; to Sir Paul Mallinson, under whose care the patient was admitted, for criticizing the manuscript, and to Dr. John C. Pittman for his invaluable assistance. Special thanks are due to Miss J. Hurst, of the E.C.G. department of St. George's Hospital.

In his report for the second quarter of 1956 the city analyst of Birmingham, Mr. H. H. BAGNALL, reports that "an ointment and medicine prescribed by another of the pseudo-medical geniuses with whom the country appears to be infested were, as usual, the cheap common articles that one has come to expect in such cases." The patient treated by this person (at 3 guineas for a consultation and 13s. 6d. a month for medicines) was said to be suffering from spinal injury and gravel on the kidney. The ointment was kaolin poultice and the medicine a dilute laxative syrup. The cost of the two specimens would be less than 1s., reports Mr. Bagnall, and he remarks on "the apparent ease with which effrontery of this kind is able to impose on a certain section of the population."

B.C.G. VACCINATION AFTER REPLACEMENT BLOOD TRANSFUSION

BY

ARCHD. S. HUTCHESON, M.B., Ch.B., D.P.H.
Consultant Tuberculosis Physician, County of Argyll

AND

PETER MACPHERSON, L.R.C.P.&S.Ed., L.R.F.P.S.
Tuberculosis Physician, County of Argyll

B.C.G. vaccination has been performed for a number of years in many maternity hospitals in this country and Gaisford (1955) has suggested that it might with advantage become an accepted part of the care of the "new-born" in such hospitals. In spite of the number of publications on the subject we have not seen direct mention of B.C.G. having been given to a baby within a short time of its receiving replacement transfusion.

Case Report

A baby suffering from haemolytic disease was born in a Glasgow maternity hospital on March 24, 1955, and a replacement blood transfusion was carried out the same day. B.C.G. vaccination was given on March 28. One week later the reaction had so far progressed that there was an indurated area 8 mm. in diameter, with a small ulcer crater in the centre from which there was watery discharge. During the next two weeks the ulcer became slightly larger and there was slight discharge of yellowish pus. The ulcer crusted frequently, only to break down again, but it healed finally at about three months. A few weeks later the mother noticed a small lump in the axilla. This was ignored until the middle of October, when it was felt to be larger. At that time it was a rubbery swelling 19 by 15 mm., with no definite fluctuation, though the skin over it was rather telangiectatic. The child's general condition was excellent and x-ray examination of his chest showed no evidence of past or present pulmonary tuberculosis. The Mantoux test, using 1/1,000 dilution, gave a strong positive reaction. There was an area of erythema extending to 38 mm. diameter with a central induration of 21 mm. diameter.

The swelling was kept under observation, and by November 11 it had increased to 25 by 18 mm. Definite fluctuation was now present and the pus was aspirated, with streptomycin replacement. The pathological report on the pus was: "Exceedingly scanty acid- and alcohol-fast bacilli present; no growth obtained on culture."

The x-ray film of the mother's chest showed no evidence of pulmonary tuberculosis and her Mantoux (1/1,000) reaction was negative.

At the replacement transfusion 540 ml. of blood was withdrawn from the baby and 600 ml. administered. Of the latter, 540 ml. was received from donor A and 60 ml. from donor B. In each case the blood had been donated on March 22. The donors have subsequently been examined. Their x-ray films show no abnormality. Donor A proved negative to a 1/10,000 dilution tuberculin test, but developed positive induration of 20 mm. diameter with the 1/1,000 strength. Donor B gave a positive result with induration of 7 mm. diameter with the 1/10,000 and of 10 mm. with the 1/1,000 dilution.

Discussion

The following is an extract from Irvine (1954): "When introduced into the skin of a tuberculin-negative person in a suitable dose, nothing appears to the naked eye for two to three weeks. . . . At the end of this time a small area of induration may be felt at the site of the vaccination which gradually increases to a lump or papule, usually about the

size of a split pea. Between the fourth and sixth weeks a bleb appears on top of this papule in the majority of cases." Another baby from our area was vaccinated in the same hospital on the same day and with the same batch of B.C.G. In this case the papule began to appear on the fourteenth day and pursued the usual course.

The following factors are worthy of consideration.

(a) *Secondary Infection.*—The rapidity with which the ulcer formed must suggest the possibility of secondary infection at the time of vaccination. However, the whole course of eruption was normal, apart from the unusually short time taken to reach this stage. Further, the subsequent glandular enlargement and the pus therefrom were identical with those of B.C.G. adenitis.

(b) *Rate of Evolution of Lesion Altered by Maternal Influences.*—There is at present a diversity of opinions whether or not children born to tuberculous mothers respond more quickly or more slowly to B.C.G. than is normally the case. Gaisford (1955) found that 97% of contact infants had converted by four weeks, compared with 81% in the non-contact cases. Hewell and McClellan (1954) reported similar findings. However, Hagberg (1954) reported that the conversion rate was much slower than in the non-contact group. Roloff and his co-workers (1954) are in agreement with this latter view, believing that there is passively transferred antibody, but that this does not pass across the placenta. Ström (1950) has shown that even the newborn possess the ability to localize the B.C.G. organisms to some extent at the site of the inoculation. This supports the view that there may be some passively transferred immunity. The baby under consideration here has shown no evidence of congenital tuberculosis and was breast-fed for the first six weeks. The x-ray film of the mother's chest showed no abnormality and her Mantoux reaction was negative. These factors indicate that the baby could not have been "tuberculin positive" at birth and was unlikely to have received any passive immunity from the mother.

(c) *Rate of Evolution of Lesion Altered by Blood Received from a Tuberculin-positive Donor.*—When B.C.G. inoculation of a tuberculin-positive person occurs, a Koch phenomenon and possible local glandular reaction are to be expected. Zammit-Tabona (1952) reported that the commonest finding in the Koch phenomenon was a darkish circular ulceration, with a tendency to sloughing at the vaccination site three to six days after inoculation. His other findings sometimes included concurrent enlargement of lymph nodes in the axilla on the side of vaccination. There is no doubt that a circulating antibody exists which may give passive immunity, but there are conflicting opinions concerning the allergic state. Harries and Mitman (1947) state: "Like immunity, hypersensitivity may be induced actively or passively. Almost all clinical examples of hypersensitivity are active. Passive sensitivity follows the injection of serum from a sensitized animal. The state develops more rapidly and passes off quickly."

Hadfield and Garrod (1947) state: "The serum of a sensitized animal will render a normal animal anaphylactic—whereas no amount of serum from an allergic animal will confer on a normal animal the capacity to react allergically. Anaphylaxis thus depends on the presence of circulating antibody, and allergy does not." However, they go on to quote Rich and Lewis (1932), who claim to have proved that the change is in the cells themselves. Tissue cultures were prepared from the leucocytes and spleen of guinea-pigs sensitized by an injection of avirulent tubercle bacilli. To these cultures were applied various dilutions of tuberculin, which were found to kill the cells while they had no effect on the cells of similar cultures prepared from a normal animal.

Rich (1951) states: "In contrast to the anaphylactic type, the tuberculin type of hypersensitivity cannot be transferred to a normal individual by an injection of the serum of a hypersensitive one. The reported exceptions to this rule are so rare and irregular that it is evident that in this type of

Medical Memoranda

Herpes Zoster

Between October 1, 1948, and October 1, 1954, I attended 72 patients with herpes zoster (41 females, 31 males). Their ages ranged from 13 to 88 years, and more of these patients were over than under 50 (Table I).

TABLE I.—Ages in Decades

	1-9	10-19	20-29	30-39	40-49	50-59	60-69	70-79	80-89
No. of cases	0	4	5	2	5	15	20	16	5

The distribution of the rashes was as follows: trigeminal first division, 7 cases; second division, 2; third division, 3; cervical roots, 16; dorsal roots, 35; lumbar roots, 3; sacral roots, 6. There was some overlapping, as adjacent roots were often affected, and in one third-division trigeminal case the second cervical root was also involved.

Pre-herpetic pain varied from nil to severe, and was variously described as itching, irritation, "like a needle," neuralgia, burning, soreness, shooting, crushing bones, stomach-ache. Pre-herpetic symptoms were absent or negligible in 44 cases, slight or moderate in 21, and severe in 7. The longest period of pain before the onset of the rash was 10 days, the usual being two to three days (Table II).

TABLE II.—Pre-herpetic Pain in Days Before the Onset of the Rash

Days	Nil	1	2	3	4	5	6	7	8	9	10	Total
No. of cases	44	1	12	9	1	1	0	3	0	0	1	72

Pain during the stage of eruption varied from slight discomfort to severe pain, and the same descriptions were applied as for pre-herpetic pain where it had occurred. Eruptive pain was experienced by some patients who had had no pre-herpetic pain, and vice versa. The amount of rash varied within wide limits, but no relation was noticed between the extent of rash and the degree of pain. One man aged 26, with left intercostal (D 5) herpes, was dyspnoeic on exertion during the eruptive stage. Eruptive pain usually corresponded with the distribution of the rash, but in two supra-orbital cases the main pain was in the mastoid region. Two males with S 4/5 involved had painful and difficult micturition during the eruptive stage.

Treatment was mainly symptomatic with powder, calamine lotion, or collodion, and aspirin, aspirin compounds, or "nepenthe" as required. Four cases received ultra-violet rays, three systemic penicillin (two oral and one parenteral), and one chloramphenicol at the onset of the rash. The reasons for giving these additional treatments were more experimental than clinical. In no case was the course of the disease apparently altered thereby, but it is interesting to note (see below) that two cases treated with ultra-violet rays developed post-herpetic pain and two did not, and the one case treated with parenteral penicillin developed post-herpetic pain, as did also the one treated with chloramphenicol.

The vesicles dried into scabs which separated in from five days to six weeks. Although the cases often appeared in batches of two, three, or four, with intervals of up to six months without a single case, no association was established with known chicken-pox epidemics.

Pain lasting more than six weeks from the onset of the rash, and severe enough to require advice or treatment, occurred in five cases—that is, one in 14. Three were males and two females. In each case this post-herpetic pain was a continuation of the eruptive pain and was of the same nature. In these five cases the ages and situation of the rashes were: aged 73, maxillary; aged 70, supraorbital; aged 70, occipital; aged 68, intercostal; aged 56, intercostal.

hypersensitivity the serum rarely contains sensitizing antibody in amount sufficient to sensitize the previously normal body." He further quotes the work of Chase (1945), who reported that guinea-pigs injected with a leucocytic peritoneal exudate derived from tuberculous hypersensitive guinea-pigs acquired, within one to three days, the capacity to react to tuberculin. This reactive capacity was of brief duration, and, curiously, could be conferred only by living cells. Freezing the cells of the exudate, or heating them to 48° C. for fifteen minutes, destroyed their sensitizing power.

The prompt reaction to the B.C.G. with local tissue destruction in our patient, who received *whole blood*, was identical with the Koch reaction, which is usually ascribed to a state of hypersensitivity (Rich and McCordock, 1929; Rich, 1930). Clawson (1933) found that the lesions produced by intravenous B.C.G. were more extensive and severe in previously sensitized rabbits than in the control animal.

Apart from the speeding up of the appearance and stages of the local reaction which we describe, there is no definite evidence that the B.C.G. vaccination was more pathogenic than usual. The subsequent gland abscess could fairly be regarded as a typical accepted complication. However, the extent of the induration (21 mm. diameter) resulting from 1/1,000 tuberculin is much in excess of the average seen after B.C.G. conversion. The glandular complication was not prevented by passive immunity, though the local fixation effect of agglutinating antibody received from the donors might have waned before a natural cellular reaction had time to develop.

Conclusion

In a case such as we have described one has to decide which of the following factors played a part: allergy and/or immunity; if allergy, from the cells and/or serum of a tuberculin-positive donor; if immunity, from a passive humoral agglutinating antibody reaction, with or without a cellular reaction.

Having regard to the opinions quoted above and to our investigations, the reaction appears to have been an immediate allergic phenomenon without obvious evidence of immunity, and was probably induced by the cells in the 600 ml. of refrigerated, but not frozen, blood received from the tuberculin-positive donors.

When, as at present, the study of allergy is of such general interest and importance, and when, in addition, immunization as a preventive measure on the one hand and desensitization as a therapeutic measure on the other are being advocated, this case, though a single one, seems to be worthy of record and consideration.

It is hoped that parallel findings by others will also be reported.

We wish to thank Dr. John Wallace, regional director, Glasgow and West of Scotland Blood Transfusion Service, for his willing help, and our colleagues in the Lanarkshire Tuberculosis Service for carrying out the examination of the donors.

In the supraorbital case it has so far lasted for over three years, but in the others it tended to remit within 18 months. Two of these five had severe pre-herpetic pain, the other three had none.

No effective treatment for post-herpetic pain was discovered. The methods tried were analgesics, including aspirin and its compounds, opium, nepenthe, levorphanol tartrate, pethidine, local injections of procaine, deep x rays (two cases), short-wave therapy, ultra-violet rays, ultrasonics (one case), E.C.T. (one case), liver, posterior pituitary injection, ergotamine tartrate, dextroamphetamine sulphate, the chlorpromazine. The deep x-ray therapy was given to the supraorbital and one intercostal case, the ultrasonotherapy and E.C.T. to the supraorbital case, the latter on account of mental depression. No relief of pain resulted.

Of these five cases with post-herpetic pain, as stated above, two had ultra-violet rays at the onset of the rash, one had parenteral penicillin at the onset, and one had chloramphenicol at the onset. No significance is attached to this, except to indicate that these measures did not prevent the development of post-herpetic pain. Four of the five were emotionally unstable individuals, and the fifth developed generalized neurodermatitis 18 months after the shingles. Eight others, in whom post-herpetic pain did not occur, were also regarded as neurotic or emotionally unstable.

I am indebted to Sir Charles Symonds for advice and criticism.

L. J. BARFORD, D.M.

Herpes Zoster after Fractured Spine Complicating E.C.T.

Since its introduction by Cerletti and Bini in 1938 electric convulsion therapy (E.C.T.) has been used widely and increasingly in the treatment of various forms of mental illness. Although vertebral fractures are now a well-recognized complication of E.C.T. they were not described until four years after its inception, because they are largely symptomless and discoverable only by radiography (Cook, 1944). The *British Medical Journal* (1954) states that the incidence of vertebral fractures as a result of unmodified E.C.T. is high, and Lingley and Robbins (1947) and Meschan *et al.* (1950) give the incidence as 21.3% and 35.4% respectively. All workers agree that complications of the vertebral fractures are extremely rare (Kitching, 1954). A case is described below in which herpes zoster appeared after a fractured spine resulting from E.C.T. I have been unable to trace any record in the literature of the occurrence of this particular sequence.

CASE REPORT

A man aged 29 suffering from schizophrenia was admitted to hospital on June 6, 1955. He was recommended for a course of E.C.T. Routine radiography of the spine showed no abnormality. He received his first treatment on June 27. After the third treatment, on July 1, he complained of pain in his back, and lateral and antero-posterior x-ray films were taken of his thoracic spine.

The x-ray report stated: "There is a slight upper dorsal scoliosis and there is wedging of the bodies of D 4 and 5 and to a lesser extent of D 3, the appearances being of a compression fracture. D 3 is certainly involved, as there is some irregularity of its anterior margin. In the antero-posterior projection there also appears to be minimal lateral wedging of D 6."

No further E.C.T. was given and the patient was seen by the orthopaedic surgeon, who advised no special treatment. The pain in the back gradually spread to the front of the chest, and on July 8 the patient reported the appearance of a rash running from the middle of his chest under the left armpit and on to the middle of the back as far as the spine. On examination there was an eruption of grouped vesicles upon an inflamed base involving the left second and third intercostal nerves. A diagnosis of herpes zoster was made. One week later the lesions were crusted for the most part, but the patient still complained of pain

which was severe enough to require an analgesic to enable him to sleep. By the end of July most of the crusts had fallen off and the pain had practically gone. However, the patient refused any further treatment, although his mental condition had not yet cleared up.

COMMENT

Herpes zoster appearing after injury to the vertebrae in the region of a ganglion was observed by Mitchell and Keen as far back as the American Civil War (Klauder, 1947), and Roxburgh (1941) states that it often follows injuries to the spine. In view of the vast number of patients treated with E.C.T. in the last 17 years and the high incidence of vertebral fractures as a result of this therapy it is rather surprising that there have been no cases similar to the one described above. It must be mentioned, however, that Kitching (1954) was impressed by the discrepancy of the figures given by different investigators for the occurrence of fractured spine following E.C.T. He says that these figures show all too convincingly that the radiological diagnosis of vertebral fractures is by no means an exact science.

As regards the zoster being a chance occurrence, Chalker and Martin (1932) formulated two circumstances in order to associate trauma with the presence of herpes zoster. Firstly, herpes zoster should appear in the region or within the range of the injury. Secondly, the disease should appear within one day to one month after the injury. These two conditions were satisfied in the above case.

The appearance of zoster following trauma to a nerve ganglion is ascribed to the awakening into activity of a dormant chicken-pox virus within the ganglion (Sequeira *et al.*, 1947), and in the case here described there was a history of chicken-pox occurring at about 8 years of age.

Finally, it may be mentioned that Meschan *et al.* (1950) reported that the incidence of vertebral fracture (radiologically shown) was reduced from 35.4% to 19.5% when curare was administered, and Kitching (1954) states that in all situations where time and space permit modified E.C.T. should be encouraged. In my case the use of modified treatment would possibly have prevented the occurrence of the fractured spine and hence averted the resulting herpes zoster.

I thank Dr. Edward Marley for his valuable advice in the preparation of this report.

The Food and Agriculture Organization has established a number of fellowships with the object of fostering research in the field of food and agriculture. These fellowships will be called after André Mayer, who was closely associated with scientific research in France as well as with work in the international field, particularly in relation to F.A.O. The fellowships will be awarded for advance training in research work in fields of particular interest to member countries and to F.A.O. as a whole. Only persons with the highest qualifications who have already shown a strong inclination and a real aptitude for research and who would benefit from additional training will be selected. Five or six fellowships will be offered in 1956 and will be spread over the whole field covered by F.A.O.—i.e., agriculture, agricultural economics and statistics, fisheries, forestry, and nutrition. Further information can be obtained from the Secretariat of the F.A.O. National Committee for the United Kingdom, c/o Ministry of Agriculture, Fisheries, and Food, 10, Whitehall Place, London, S.W.1.

Reviews

SECRETION OF URINE

Modern Views on the Secretion of Urine. The Cushny Memorial Lectures. Edited by F. R. Winton, M.A., M.D., D.Sc. (Pp. 292+vii; illustrated. 30s.) London: J. and A. Churchill Ltd. 1956.

Modern Views on the Secretion of Urine is a series of ten lectures delivered last year at University College, London, to commemorate the work of Cushny, who occupied the Chair of Pharmacology at University College from 1905 to 1918. Naturally the lectures are mainly physiological (it should cause no surprise nowadays that some were given by clinicians), but they are readable and almost wholly understandable by any physician interested in renal function, and there is important material here for anyone in any branch of medicine wishing to revise his knowledge of renal physiology. Some of the lecturers (Dicker on clearances; Nabarro on the adrenal cortex and renal function, for instance) have summarized the present knowledge of their subject. Others (such as McCance and Widdowson on renal function in the first two days of life, and Harris on genetic aspects of tubular function) have dealt with an aspect of renal function to which they have themselves made major contributions. L. E. Bayliss on the process of secretion gives the most fundamental lecture and perhaps the most difficult for the pure clinician, though this is no criticism of its exposition. The editor, Professor Winton, includes in his own lecture on "Pressures and Flows in the Kidney" a very interesting account of Pappenheimer's cell-separation theory of autoregulation in the kidney. This is the first readily accessible account of this interesting work. According to this theory the vascular system of the kidney is so designed that the plasma and cells of the circulating blood become separated to a variable degree, the plasma-rich blood being skimmed off to perfuse the glomerulo-tubular systems, while the viscous, concentrated cell suspension is shunted through shorter channels. There is a good deal of evidence to support this idea, which would explain some peculiar facts of renal blood flow, including its virtual independence, within a wide range, of the systemic blood pressure; for rise of blood pressure would increase the separation of cells and plasma and thereby steeply increase the viscosity of the cell-rich stream, thus increasing the vascular resistance.

The last two lectures are closest to the direct concern of the clinician—namely, Rosenheim on renal failure and Bull on osmotic diuresis in tubular necrosis. In a short review it is not possible to discuss the book in any greater detail, but, having referred to eight of the ten lectures, it seems a pity not to complete the table of contents by mentioning the excellent contributions of Grace Eggleton on tubular reabsorption and secretion, and of Mary Pickford on anti-diuresis.

ROBERT PLATT.

BACTERIAL ENDOCARDITIS

Subacute Bacterial Endocarditis. By Andrew Kerr, Jr., M.D. (Pp. 343+xviii. 47s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This monograph in the American Lecture Series reviews the whole subject of subacute bacterial endocarditis exhaustively, and the 800 references, from many of which there are quotations in the text, illustrate the author's industry in collecting in one volume nearly all the published facts about this disease. The approach to the clinical manifestations is historical, and the author is at pains to establish priority of description of the various eponymous signs such as Osler's nodes and Roth's spots. The difficulty of differential diagnosis of bacterial endocarditis and rheumatic fever in young adults is emphasized, though the statement that anaemia is more severe in bacterial endocarditis is contrary to most experience in this country. The difficulty of diagnosis of bacterial endocarditis, particularly in elderly patients when signs of renal or central nervous system involvement

may predominate, is discussed, but the section on differential diagnosis is short, the author preferring to treat patients early with full doses of antibiotics if there is a reasonable clinical possibility of this disease being present. Treatment is planned according to the clinical response of the patient, and little reliance is placed on laboratory tests of sensitivity of the infecting organism. There are detailed instructions for treatment of the different bacteriological types of bacterial endocarditis, but it would seem difficult to justify the routine use of streptomycin with penicillin for all cases. In all other respects the treatment advised is in accordance with the usual practice in this country, and the danger of using predominantly bacteriostatic antibiotics such as chlortetracycline, chloramphenicol, and oxytetracycline is stressed. The mortality from subacute bacterial endocarditis is still high, although failure to control the infection is uncommon, and the emphasis throughout this book on early diagnosis and treatment should help to decrease the incidence of heart failure, vascular catastrophes, and renal failure, which are now the chief causes of death.

This book can be recommended both as a work of reference with an excellent bibliography and also to provide practical help in the diagnosis and treatment of bacterial endocarditis.

GRAHAM HAYWARD.

ELECTROCARDIOGRAPHY

Clinical Electrocardiography. Part I. The Arrhythmias, with an Atlas of Electrocardiograms. By Louis N. Katz, A.B., M.A., M.D., F.A.C.P., and Alfred Pick, M.D. (Pp. 737; illustrated. £6 10s.) London: Henry Kimpton. 1956.

Although this volume is really the first section of the third edition of *Electrocardiography*, now divided into two parts, it is virtually a new book and should be regarded as such. The change of title to *Clinical Electrocardiography* emphasizes the fact that it is not just another atlas of electrocardiograms illustrating the arrhythmias, but a monograph on the subject as a whole, the electrocardiograms serving to illustrate the text. This is a refreshing change which should have put electrocardiography in its proper place as a clinical tool, but one is left with an uneasy feeling that the graphs are still pre-eminent and the patient little more than a volume conductor. A glance at the 16-page index emphasizes this point. As a descriptive atlas the book is excellent in respect of both the many illustrations and their detailed captions; as a monograph on the arrhythmias from which so many patients suffer it is too incomplete to be really helpful. Nevertheless this new edition has an improved shape, and can be highly recommended to students of electrocardiography, and to clinicians who feel in need of an advanced refresher course in the electrocardiographic diagnosis of the arrhythmias.

PAUL WOOD.

PRACTICAL HAEMATOLOGY

Practical Haematology. By J. V. Dacie, M.D., M.R.C.P. Second edition. (Pp. 229+vii; illustrated. 20s.) London: J. and A. Churchill, Ltd. 1956.

A comparison of the first and second editions of Dr. Dacie's book shows how greatly haematology has increased in complexity, even in the last quinquennium. Less than half the book is occupied by the classical methods of counting and staining the blood cells and marrow smears. A wide range of serological techniques has been devised for the study of the haemolytic anaemias, radio-isotopes are routinely used for the estimation of the blood volume and the red-cell survival, and plasma proteins and haemoglobin are studied by electrophoresis and chromatography. A battery of tests has been devised for the investigation of the haemorrhagic disorders, and blood grouping can at times be a highly elaborate procedure needing the resources of a reference laboratory. Dr. Dacie has achieved a miracle of compression in bringing so much precise knowledge in such a small volume. There are over 350 references, so that it is easy for anyone who wishes to consult the original papers. This is not only a practical book, but a book of great scholarship, and Dr. Dacie has once more put haematologists in his debt.

L. J. WITTS.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 13 1956

TROUBLESOME STAPHYLOCOCCI

Staphylococcal infections are fast becoming the most troublesome and disturbing with which the epidemiologist and clinician have to contend. The staphylococcus has almost entirely replaced the haemolytic streptococcus as a cause of epidemic hospital sepsis. One reason for this is clear—that streptococci are unable to acquire resistance to antibiotics, whereas staphylococci have an almost unparalleled capacity for doing this. Few hospitals can have been so fortunate as to escape trouble of this kind, particularly in their surgical and maternity units; in many the results have been highly inconvenient and in some frankly disastrous. Dr. Walsh McDermott, of Cornell University Medical College, New York, one of the leading authorities in the United States on the clinical use of antibiotics, considers this situation from a detached and philosophic standpoint in a paper published in our opening pages this week. He rightly points out that this and two other infections which are rather less amenable to treatment have been thrown into high relief by the therapeutic triumphs of the past few years. He then asks whether the present ravages of staphylococci are attributable to a change in them or change in the patient. In favouring the second hypothesis, he observes that patients are now being subjected to many new surgical and even some medical procedures calculated to diminish their resistance to infection. Perhaps not everyone will agree on whether he is right in concluding that the properties of staphylococci have remained unchanged. There is at least a strong suspicion that antibiotic-resistant staphylococci have a greater capacity for epidemic spread than sensitive strains and perhaps a different capacity for producing lesions. This was expressly postulated by C. W. Howe¹ on the basis of his study of the increasing incidence of surgical infections. Antibiotic resistance is not an entirely independent character unrelated to all others; a large majority of resistant strains belong to one of the main phage groups. Further, there is at least a suspicion that acute membranous staphylococcal enterocolitis, perhaps the most serious of all these infections, can be caused only by certain

strains and not by others, just as only certain strains form enterotoxin and can thus cause food-poisoning. There is a lot to be said for the idea that the use of antibiotics is selecting a tougher race of these organisms than those with which we had to contend before. It is also possible, though difficult of experimental proof, that the appetite of the staphylococcus grows by what it feeds on, for frequent transference from host to host enhances the virulence of haemolytic streptococci, and to a less striking degree that of other species as well.

McDermott does not believe that staphylococcal pneumonia is increasing in frequency. This belief is contrary to the experience of Drs. W. Hausmann and A. J. Karlish, who record on p. 845 this week that 18 out of 122 consecutive cases of pneumonia treated in Reading during 1952–4 were due to this infection. These occurred apart from any known epidemic of influenza, to which staphylococcal pneumonia is so often secondary. This series of cases strongly emphasizes the value of bacteriological examination of sputum and of determinations of antibiotic sensitivity in a species in which this property is so variable. But for assiduous work of this kind, all these patients might not have recovered.

In another paper on these troublesome organisms, at p. 840, Professor Ronald Hare and Dr. C. G. A. Thomas, of St. Thomas's Hospital, describe an experimental study of one of the mechanisms by which hospital cross-infection takes place. It is well known that in any unit where this infection exists large numbers of the staff may be entirely symptomless nasal carriers. Precisely how they disseminate the organisms is a matter of much importance. The usual belief is that they are expelled in droplets of secretion, and masks are extensively worn with the object of preventing this. Hare and Thomas's work shows that their distribution on the person of the carrier is widespread and that dissemination must be largely by particles of dust from contaminated skin and clothing. Whereas breathing, coughing, talking, and even sneezing expelled few staphylococci from the noses of carriers, the organisms were frequently recovered from various areas of skin, always from handkerchiefs and the pockets in which they were kept, and often from items of clothing on not only the upper but the lower part of the body. The shedding of staphylococci from these surfaces was studied under various conditions in a cubicle in which culture plates were exposed. Even an almost naked subject liberated them, but much larger numbers were liberated when clothing was shaken or merely moved to the extent required in dressing and undressing. Perhaps the most disturbing result of these experiments was to

¹ Howe, C. W., *New Engl. J. Med.*, 1954, 251, 411.

² MacCabe, A. F., and Gould, J. C., *Scot. med. J.*, 1956, 1, 223.

show that wearing a sterile gown over ordinary clothing does not prevent dissemination of infected particles. Another highly disquieting observation was that the act of washing the hands scattered water droplets containing staphylococci, which were cultivated in large numbers on plates exposed in the four corners of the cubicle.

These observations demand a wholesale revision of our ideas about the effects of the nasal carrier state. They may seem also to require an intensification of aseptic precautions, especially in operating theatres. It would certainly be better if more were known about the factors underlying the development of the nasal carrier state, and if measures could be devised for preventing its development. Alternatively it may be susceptible to treatment. The use of most of the major antibiotics for this is inadvisable because of the danger of inducing resistance, but A. F. MacCabe and J. C. Gould² mention having cleared up two carriers by the application of 1% "hibitane" cream, and advise this treatment for carriers of antibiotic-resistant strains. Some such method which goes to the root of the matter would be far preferable to the elaborate precautions which these new observations seem to demand, at least when any surgeon or nurse is a carrier.

ANAESTHETIC DEATHS

The number of deaths every year associated with anaesthesia is sufficiently large to be a matter of some concern. Indeed, the latest report of the Chief Medical Officer of the Ministry of Health¹ for the first time devotes a section to this problem: in 1953 there were 562 deaths associated with anaesthesia, or about 1 per 1,000 of all deaths in the population.

The circumstances surrounding such deaths have in the past often eluded exact definition. The causes indicated on the death certificate sometimes fail to give a clear lead, since they may come from persons not in possession of the full details of the anaesthetic procedure and thus unable to fill in the pharmacological and physiological background to the death. Nor has public inquiry by coroners' courts advanced scientific knowledge of these deaths. Simple analyses of mass statistics also seem unlikely to yield helpful information. In one such analysis² relaxant drugs appeared to be incriminated, but criticism of this investigation not only pointed to the unreliability of

such methods in these circumstances but emphasized the importance of considering many factors, often intangible, connected with the administration of anaesthetics. Thus the experience and training of the anaesthetist, and whether proper efforts at resuscitation were carried out, are as important as what particular anaesthetic drugs were used. Fully aware of their responsibilities in this matter, the anaesthetists themselves, through the Association of Anaesthetists of Great Britain and Ireland, initiated in 1949 a scheme to encourage the voluntary reporting of anaesthetic deaths. A standard questionnaire was made available to anaesthetists, who were invited to return details of anaesthetic deaths with which they were connected. The reports were anonymous but signed by local senior anaesthetists to vouch for authenticity.

A committee was set up to consider these deaths, and it has now issued its report³ on the first thousand collected. In nearly 600 of these cases the death is considered to be entirely or to a large extent the result of anaesthesia. The report discusses with great clarity and pungency, but with commendable restraint, the various categories into which these deaths fall. Opinions and facts of far-reaching importance are put on record, and it is to be hoped that every doctor and hospital administrator will read the report in its original. It is to be reprinted separately.

Certain parts of the report stand out. The danger of inhaling vomit has always been known. The extent to which this cause—the commonest single one—is still responsible for death is striking. A particularly distressing occasion is during labour. Indeed, in operative obstetrics anaesthesia has now become the commonest cause of maternal death.^{4 5} The report also reveals the frequency with which the intravenous barbiturates cause death. This is the price being paid by the community for its insistence (real or assumed) on an intravenous induction of anaesthesia. Insufficient care of the patient in the post-operative period also takes a heavy toll; death is then usually due to such causes as respiratory obstruction or depressed breathing. Many other less common causes of death are given. Pre-operative obstruction of the respiratory tract, endotracheal anaesthesia, convulsions, the administration of antidotes and stimulants, the induction of hypotension and spinal anaesthesia—these are but a few of the many occasions or causes listed and discussed.

Few readers will disagree with the report when it repeatedly points to lack of skill, poor equipment, and insufficient medical or nursing supervision as paramount factors that lead to so many deaths. Too often

the acute observer can see unconscious patients left unattended or in the care of a junior probationer, wards without the means of efficient suction, powerful drugs given without enough thought to their pharmacological effects, or outmoded techniques used. British anaesthesia stands exceptionally high in world esteem, and this report is an indictment which must be taken note of. In the first place a detailed review is required by regional hospital boards of their arrangements for providing anaesthesia in the hospitals. In doing this certain pertinent questions might be asked: Is the number of specialist staff adequate? Are too many junior trainees being employed without sufficient supervision? Is every modern requirement for safety, such as suction, and proper means of ventilation of the lungs in cases of respiratory failure, available wherever anaesthetics are administered or unconscious patients treated? Is there sufficient staff, both anaesthetic and nursing, to supervise these patients? Is the anaesthetic staff consulted about the arrangements for providing service and have their recommendations been considered? Ultimately the prevention of anaesthetic deaths will be a matter for better training of anaesthetists and nurses—particularly the former, for the report makes clear that more skill and experience would have averted many of those recorded. Anaesthetists have realized that all is not well with the training of young specialists, and a welcome novelty was the holding of a symposium on anaesthetic teaching at the Postgraduate Medical School recently. Meanwhile, good is certain to result from the publication of this report.

A NEW LEASE OF LIFE

C. S. Beck and his colleagues¹ recently reported that a doctor suffering from ischaemic heart disease who died from a sudden heart attack at the moment of leaving hospital had been successfully resuscitated by cardiac massage and defibrillation. He finally left hospital feeling fit enough to return to his practice. Another similar case was reported by L. B. Reagan and his colleagues,² in which ventricular fibrillation developed during the recording of an electrocardiogram and the patient was resuscitated by cardiac massage and defibrillation. With the rapid development of new techniques in cardiac surgery, the treatment of cardiac arrest and ventricular fibrillation has become of increasing importance, and much experience in treating these conditions has been gained, both in animal experiments and

during cardiac operations. The possibility arises of applying this experience to the treatment of cardiac arrest and ventricular fibrillation when these occur spontaneously in patients with ischaemic heart disease or Stokes-Adams disease, and Beck and Reagan and their colleagues and also P. M. Zoll and colleagues³ have now demonstrated that resuscitation from these terminal arrhythmias is possible.

The restoration to life of a patient who in normal circumstances with conservative treatment would certainly have died raises the question how far such treatment is generally applicable. Two main problems have to be considered—first, the feasibility of the method, and secondly the chances of successful resuscitation in each individual patient. Whatever the method of resuscitation, immediate treatment is of vital importance, and it is the lack of time for organization or preparation which more than anything else will limit the general applicability of the method. Cardiac massage through the open chest requires oxygen given under positive pressure by intratracheal tube, and it will only be possible to begin treatment within five minutes of the onset of the arrhythmia by a fortunate coincidence of circumstances or when the arrhythmia has been anticipated and a trained team is ready to begin resuscitation immediately. In addition an electrical defibrillator must be available without too long a delay. It would obviously be preferable to resuscitate the patient in an operating theatre, as in the case of Beck's patient, but patients only rarely collapse immediately outside an empty operating theatre. An attempt to carry out resuscitation by such means in the open ward might well prove intensely distressing to other patients in the ward and could certainly not be envisaged as a routine procedure: the privacy of a side room would appear essential. It seems, therefore, that this method of resuscitation could be carried out in hospital only in exceptional circumstances. Another method of resuscitation which has recently been used successfully is the application of the external cardiac pace-maker and the external defibrillator described by Zoll and his colleagues.^{3 4} This method has the advantage that it can be applied direct to the intact skin and there is no necessity to open the chest. On the other hand the apparatus and facilities for using it must be immediately available if successful resuscitation is to be achieved, and it is likely to be of use only when a fatal arrhythmia has been anticipated and preparations for resuscitation already made.

The second important consideration in deciding whether to attempt resuscitation must be the underlying pathological process responsible for the terminal arrhythmia. If it is known that the patient has had an extensive cardiac infarct, the chances of successful defibrillation must be small. In addition there is the possibility that, even if cardiac resuscitation is successful, the patient may be left with permanent mental impairment or indeed may never recover consciousness as a result of the prolonged period of cerebral anoxia. In some patients with ischaemic heart disease, on the other hand, who die suddenly and unexpectedly, the

heart at necropsy shows only small scattered fibrotic lesions with no major occlusion of a coronary artery and no clear area of cardiac infarction. These patients almost certainly die from ventricular fibrillation or cardiac arrest, and if this terminal arrhythmia can be aborted the heart should be capable of return to normal function. The report of these cases of successful resuscitation serves to emphasize that, though spontaneous cardiac arrest and ventricular fibrillation are usually terminal, they need not necessarily be so if facilities for courageous and energetic treatment are at hand.

ANTIBIOTICS AS FOOD PRESERVATIVES

Several uses have been found for antibiotics apart from the treatment of disease in man, animals, and plants. They are extensively used as food supplements for accelerating growth in young farm stock and poultry, an effect which is still imperfectly understood, although it appears to depend on some change in the intestinal flora. Again, as discussed at a recent conference in Rome and reported at p. 879 of the *Journal* this week, another use is for arresting or delaying the bacterial growth responsible for food spoilage. An odd example of this which has been suggested, though not, it would seem, adopted, is the addition of subtilin to canned foods to inhibit the growth of *Cl. botulinum*.¹

The principal field for this sort of treatment is meat, and there are several possible methods of applying it. The animal can be given a therapeutic dose of the antibiotic before slaughter, or the carcass can be perfused with a solution. No doubt the penetration so achieved would be most effective, but a simpler process has been found satisfactory and is now widely used in the United States, which is simply to dip meat and poultry in a solution. The most effective antibiotics, presumably because of their wide antibacterial spectrum, are chlor- and oxytetracycline (aureomycin and terramycin). The former is the active constituent in the "acronize" process, which includes citric acid as a stabilizer. The solutions contain 5 to 10 parts per million, and treatment with them prolongs the storage life of meat and poultry considerably. It is claimed that the minute amounts used are harmless to the consumer, and in any case are destroyed by cooking; that it would be necessary to eat an entire uncooked steer to get a therapeutic dose of the antibiotic, or to eat 2 lb. (0.9 kg.) of chicken daily for 70 years (whether cooked is not clear) to obtain half such a dose. Even shrimps and eggs are mentioned as benefiting from such treatment, and an important application is certainly the preservation of fish. The addition of chlortetracycline to the ice in which fish are preserved in trawlers should enable voyages to be extended by 7-10 days. The Department of Scientific and Industrial Research recently announced that this process was to be applied experimentally to the catch in a trawler which would subsequently visit Aberdeen, Grimsby, and Hull so that the trade could judge its effects.

¹ Anderson, A. A., *J. Bact.*, 1952, 62, 145.

The present law does not permit this process, but medical authorities may well be asked in the near future to decide whether it should do so. Apart from a general uneasiness about the increasing application of artificial processes in the food industry, or about entrusting such potent substances to people ignorant of their properties, is there any objection to the preservation of meat, poultry, and fish with antibiotics of the tetracycline group? It is true that the dose capable of being taken in a meal is very small, and there is no evidence—although perhaps this should be verified by *ad hoc* experiment—that exposure to minimal concentrations can elicit bacterial resistance. It seems unlikely that the consumption of such minute amounts could induce sensitivity, though this again seems to need confirmation. On the other hand, it is far from certain that the consumption of even minute amounts would be harmless in a person already sensitized by therapeutic doses. Possibly American experience will provide an answer to these questions before a decision is made here.

COLONIC MOTILITY

The colon is normally in a state of more or less continuous muscular activity as judged by the pressure changes recorded by small balloons introduced into it or by the more satisfactory system of open-ended tubes filled with saline and connected to electro-manometers. In 1941 H. F. Adler, A. J. Atkinson, and A. C. Ivy¹ showed that the human colon displays three different types of pressure waves, which correspond closely to what had been found earlier in the dog's colon.² Type I waves are simple monophasic waves lasting from 5 to 20 seconds and of low amplitude. Type II are also simple monophasic waves but of longer duration (12 to 60 seconds) and of greater amplitude. They are the major manifestations of muscular activity in the normal pelvic colon, occurring throughout two-fifths of the time of observation. It is probable that they represent localized circular contractions of the colonic wall which produce the appearances of "haustation" in barium enema radiographs. Type III waves are complex, with a change in the basal pressure, regarded as a "tonus" change, and with Type I or II waves superimposed on this. They occur only infrequently in the normal colon and last from one to four minutes. They are thought not to be propulsive waves but possibly to assist in absorption by changing the hydrostatic pressure.

Similar studies made on patients with ulcerative colitis have yielded a picture which differs sharply from the normal.^{3,4} The three types of wave observed in normal subjects are either absent or much reduced in number. However, another type of wave (Type IV) is present in these patients. These are unusually large waves, which are apparently propulsive in nature and directly related

⁷ Lium, R., *Arch. Intern. Med.*, 1939, 63, 210.

to the occurrence of diarrhoea. The absence of the normal Types I, II, and III waves is regarded as responsible for the lack of haustration usually noticed on barium enema films of patients with active ulcerative colitis.

Recent studies at Cornell by M. Davidson and colleagues^{5,6} extend these observations to children. Data obtained from 40 normal children agree closely with those for adults. In cases of acute infantile diarrhoea these workers observed the characteristic propulsive waves already noted in adults with ulcerative colitis. They also observed similar waves among those children who responded to oral magnesium sulphate, subcutaneous mecholyl, or the introduction of iced water into the rectum by developing abdominal pain followed by defaecation. On the other hand they did not find these waves in seven children with ulcerative colitis of at least one year's duration. However, none of these seven children was suffering from diarrhoea at the time of study, though three of them were passing blood in the stools and all had characteristic sigmoidoscopic appearances. It would thus appear that Type IV waves are not an essential feature of ulcerative colitis but are to be found whenever diarrhoea occurs in this and other diseases. This is of interest in relation to the view originally put forward by R. Lium⁷ that ulcerative colitis may be due to muscular spasm of the colon with secondary necrosis and ulceration of the mucosa. The findings of Davidson and his colleagues would favour the view that the excessive colonic propulsive activity which results in diarrhoea is the consequence of an inflamed colonic mucosa and not the cause of it.

INFANTILE GENETIC AGRANULOCYTOSIS

From time to time doctors are puzzled by an undue, and indeed fatal, susceptibility to infection occurring in several members of a family. One disorder of this kind has now been defined as agammaglobulinaemia, in which the essential anomaly is an absence of gamma-globulin; in the idiopathic form this is probably due to a sex-linked recessive gene.¹ Another disorder has recently been defined in an isolated district of Sweden. In 1950 R. Kostmann² reported a sibship with congenital agranulocytosis; one infant, a girl, was fully studied, but three elder children had presented a similar clinical picture. There were also six normal children in the family and the parents were third cousins. He concluded that the disease was a hereditary "reticulosis" due to a recessive gene. Two earlier reports^{3,4} are clinically very similar, but in each case only one child in the family was affected. An extensive study of all branches of Kostmann's original family, recently reported by J. A. Böök and Kostmann,⁵ revealed three other branches of the family with a child who was affected and had been fully investigated; three further branches contained a child who died with essentially the same clinical picture,

⁶ *ibid.*, 1956, 45, 34, Suppl. 105.

though not fully investigated in hospital. No fewer than 10 children, all of the same generation, were affected with this rare disease in this family, which stemmed from common great-great-grandparents and was much inbred. Two further families, one with one affected child and one with two affected sibs, were found in Sweden which were not clearly related to the original large family, but the parents in each case were blood relations and came from the same district as the large family. The proportions affected in these families leave little doubt that a recessive gene with full penetrance in the homozygous state is responsible for the condition. No evidence was found that the heterozygous parents were in any way abnormal.

Clinically the picture is uniform. In a few weeks or months the children develop multiple abscesses, mainly in the skin, and die within the first year. The infection can be temporarily controlled with antibiotics. Blood smears show agranulocytosis or severe granulocytopenia. The bone marrow shows an arrest of maturation of granulocytes at the myelocyte stage. This arrest is also seen in marrow cultures in the patient's plasma, but not in plasma from a normal child. The essential nature of the metabolic error is suggested by the finding originally made by B. Vahlquist and C. M. Plum that the maturation defect seen in culture in the patient's plasma may be corrected by adding the sulphur-containing amino-acid cysteine to the culture medium.⁶ The obvious next step is to try the effect of giving this amino-acid to a child suffering from the condition. An interesting point is why this rare and lethal recessive condition should be relatively common in one geographical area. It is presumably a chance effect; the recessive gene mutation occurred in a remarkably fertile family in this isolated area, which in the next few generations indulged in much cousin marriage, bringing the mutation to light.

PARALYTIC POLIOMYELITIS AND PHYSICAL ACTIVITY

Since the outbreak of poliomyelitis in 1947 there have been some changes in the epidemiology of this disease in Britain. The average age of the patients is higher than formerly and it seems that the involuntary muscles are now paralysed more often than when the disease was described as infantile paralysis. At one time it was very rare for more than one in a family to be attacked, but now multiple cases in a family are not uncommon. In some large localized outbreaks which occurred during the epidemic in 1947 it was found that the attack rate varied in different social groups, a higher proportion of children in the residential areas being infected than the children in the crowded central areas. This trend was not apparent in subsequent outbreaks and now environment is not thought to be a factor of any importance in the attack rate. Another belief that seemed to be well established was that paralysis was particularly likely to develop in patients who over-exerted themselves at the onset of the attack. Doubts of the truth of this hypothesis have been raised by the results obtained by I. N. Sutherland¹ from a

¹ Sutherland, Ian N., *Brit. J. prev. soc. Med.*, 1956, 10, 58.

large inquiry into the experience in Scotland during the four years 1950 to 1953. The number of cases of poliomyelitis in this series was 1,718, and consequently he was able to subdivide them by age groups and by degree of activity at onset of attack. In the younger children no association was found between physical activity after onset of illness and the degree of paralysis. Sutherland suggests that the apparent relationship between over-exertion and paralysis was due to age, since with increasing age there is a trend towards more severe illness, with greater physical activity before symptoms appear and less rest after the onset of symptoms.

THE KING'S FUND

King Edward's Hospital Fund for London has greatly varied and enlarged its beneficence, even as the problems with which it has to deal have changed their form since, nearly sixty years ago, the prince who afterwards became Edward VII established the Fund to help the metropolitan hospitals. Formerly its grants were made largely with a view to the promotion of the material efficiency of hospitals—uniformity of accounting, for example, and the drawing up of architectural codes. In more recent years it has recognized that its resources could be invested in people as well as in materials. It has taken to heart Sir Richard Livingstone's declaration that the growth of colleges and centres for adult residential study is one of the most interesting developments of post-war Britain, and it has established bursaries and training centres for ward sisters, hospital administrators, cooks and caterers, and, finally, for matrons, for whom it provides four-week refresher courses. Another piece of useful work is the nursing recruitment service which was established by the Fund sixteen years ago. Perhaps the most urgent nursing problem of the moment is the staffing of mental and mental-deficiency hospitals, and it is acknowledged that the recruitment service, while giving what help it can, is no more able to solve it than the hospitals themselves. Some idea of the urgency of the need may be gained from the fact that, while there are over 91,700 beds for male patients in mental and mental-deficiency hospitals, only 460 male nurses qualified in 1954. Last year was notable in the history of the Fund for the exceptionally large allocation of grants to mental hospitals. The amount granted was £250,000, to be used over the three-years period 1955-7, and a new chapter in the relationship between the Fund and the mental hospitals has thus been opened.

The Fund, as shown by its latest annual report, assists in many other directions, among them the personal aid service for the elderly. The emergency bed service is also a special feature of the Fund. It was founded twelve years ago and now has had over half a million applications. About 1,250 calls a week are accepted, varying very much, of course, with the season, and it is its proud boast that the average time required to see a successful admission through from the general practitioner's initial call is 27 minutes, not including the cases of infectious disease which are comparatively

easy to admit. It would be a great thing if this service merely resulted in saving the practitioner's time and vexation of spirit, but it has also proved an indispensable link between two partners of the medical service of London. Moreover, the calls upon the service provide an index of any rise or fall of sickness among the people of London, and thus serve to give the medical administrator timely warning of trouble ahead.

FLUOROHYDROCORTISONE

The substitution of a fluorine atom for a hydrogen atom in the hydrocortisone molecule has yielded 9 α -fluorohydrocortisone, or fludrocortisone, which turns out to differ from hydrocortisone in some important respects. First, its effect on the excretion of sodium and potassium is so marked that it is doubtful whether systemic administration is ever likely to be indicated. Secondly, it is remarkably more effective quantitatively than hydrocortisone when applied to the skin. Fludrocortisone lotion and ointment, now appearing on the market in Britain, have been available for nearly two years in the U.S.A. and have been carefully assessed by various workers, whose results have reached close agreement.^{1,2}

The optimum concentration of the hormone in either lotion or ointment is 0.1%. In this concentration it has been found effective slightly more often than 1% hydrocortisone, but the range of disorders in which it is beneficial is exactly the same. (The cost of 0.1% fludrocortisone is also about the same as that of 1% hydrocortisone.) Individual cases respond differently, however, some doing better on fludrocortisone, and some, though fewer, on hydrocortisone. The base also may have considerable influence, so that a trial of local steroid therapy in any case should not be abandoned until both compounds in various bases have been given. Broadly, the best results are obtained in localized anogenital pruritus, otitis externa, and eczemas of all kinds, including infantile and atopic eczema. Eruptions of the hands and feet do not usually respond so well, psoriasis and lichen planus not at all.

An advantage of hydrocortisone locally applied is that systemic effects are never seen; the same cannot be said of fludrocortisone, the systemic effects of which may be troublesome if large areas are treated, particularly if the skin is denuded. These effects may be countered by a low-salt diet and the administration of potassium, but in general it is evidently better to avoid fludrocortisone when large areas are affected and also in cases of heart failure, renal disease, or when some other condition likely to cause oedema is present.³

Combinations of steroids with antibiotics are still under trial. Such applications may be useful in cases where superficial infection is superadded, and there is no serious objection to them.

REFERRALS IN GENERAL PRACTICE

BY

PHILIP HOPKINS, M.R.C.S., L.R.C.P.

General Practitioner, London

The primary objects of the investigation described in this paper were two in number: (1) to examine the reasons for which patients may be referred by a general practitioner to his consultant and specialist colleagues; and (2) to discover what functions are most required by the patient and his doctor from the hospital service.

Analysis of the results has not only answered these questions, it has also provided further evidence of the high incidence of psychoneurosis and stress disorders. This study was based on a single practice.

The Practice

The practice is centred on a part of London where all social classes are represented. A near-by colleague and I deputize for each other for one half-day each week, alternate week-ends, and holidays, and with this arrangement it is a simple matter to keep complete records.

There is a fairly large turnover of patients, as people are constantly moving into and out of this district, and this may account for the high percentage of the practice population seen each year. A number of temporary residents are included in the study.

Table I shows the size of my National Health Service list for the three years 1951, 1952, and 1953, and Table II shows the number of patients entering and leaving the practice during this time. I estimate that some 85% of the practice population consult me each year.

TABLE I.—Number of Patients on National Health Service List, and Temporary Residents for 1951-3

For Quarter Ending:	1951		1952		1953	
	On List	Temp. Res.	On List	Temp. Res.	On List	Temp. Res.
Mar. 31 ..	1,217	18	1,339	19	1,409	19
June 30 ..	1,265	15	1,355	18	1,425	11
Sept. 30 ..	1,272	11	1,341	17	1,486	19
Dec. 31 ..	1,272	15	1,386	11	1,515	12

Average No. of patients "at risk" each year=1,370-1,355 on list and 15 temporary residents.

TABLE II.—Number of Patients Joining and Leaving List in 1951-3

	1951	1952	1953
Joining list ..	376	430	401
Leaving list ..	250	314	272

In an analysis of the clinical records of eight practices during the period April, 1951, to March, 1952, Logan (1953) found the number of consultations per 100 practice population to vary from 287 in a rural practice to 468.9 in a "lower working-class neighbourhood."

If this method of expressing the rate of consultations is used in my practice it works out at 321 consultations per 100 practice population. In Logan's survey the two practices with rates per 100 nearest mine were in North-east London (338.8) and in "a better working-class practice in Norwich" (331).

The number of consultations in my practice made during the years 1951-3 is shown for each year and place of

TABLE III.—Number and Place of Consultations for each Year

Consultation	1951	1952	1953	Total	%
In surgery ..	3,125	3,328	3,648	10,101	76.5
On visit ..	919	1,021	1,167	3,107	23.5
Total ..	4,044	4,349	4,815	13,208	100

consultation in Table III. It is interesting to note that the average number of consultations per 100 practice population per annum for the three years is 330.

Logan found that for all eight practices in his survey the average attendance rate at the doctor's surgery was 68%. From these figures it would seem reasonable to say that the behaviour of my patients is very similar to that in the practices which formed the basis for Logan's survey. It is certainly true that the general incidence of illnesses classified in the usual groups is much the same in my practice as in others that have been recorded and published.

The Investigation

My daybook contains a record of all patients seen, and the material for this investigation was obtained from this source.

By "referral" I mean that a patient was referred to a consultant or specialist at a hospital or clinic, or in a small number of instances by private arrangement between the patient and the consultant. In all cases, however, the patients were registered with me under the National Health Service. A patient seen by a consultant with me at a domiciliary visit is also here accepted as a referral. Patients referred to a casualty department of a hospital are also included under this term.

Throughout this paper the figures given (unless otherwise stated) are for referrals and do not indicate actual patients. All such referrals during the three years 1951-3 were determined from the daybook, and total 1,225. Table IV shows their distribution as in-patients, out-patients (including those referred to casualty departments), and those seen on domiciliary visits; the figures are given separately for medical and surgical conditions.

TABLE IV.—Analysis of 1,225 Referrals, According to Sex, as In- and Out-patients, and Domiciliary Consultations, for Medical and Surgical Conditions during 1951-3

Total ..	11.8	54.7	22.7	10.8	100

During the three years under review the actual number of patients referred was 860. Their distribution according to sex and age group is shown in Table V. The percentage incidence of patients according to sex and age group in the practice population was recently calculated in preparation for participation in the Morbidity Survey which is being conducted by the College of General Practitioners (1955) in collaboration with the Registrar-General's Department. The findings are shown in Table VI. Comparison of these

figures shows a fairly even distribution of all age groups among the referrals, there being only a slight relative reduction in the number of males in age group 45-64, with a slight increase in the males in age group 65+ referred.

The large majority of these 860 patients referred attended hospital only once or twice each; only a small number were referred three or more times each. The figures are shown in Table VII.

TABLE VII.—Number of Patients Referred One to Six Times each

No. of Patients			Times Each was Referred	Total No. of Referrals

1	5	6	5	30
1	3	4	6	24
385	475	860		1,225

In the medical literature available to me I have been able to find very little reference to the subject of referrals from general practice, and even this has been confined only to actual statistics.

Pemberton (1949) published a survey of illness occurring in eight practices in Sheffield. He reported that 2% of the 4,656 consultations resulted in referral to a hospital out-patient department, in 0.16% to an in-patient department, and in 0.2% to a local authority clinic.

Fry (1952) described the work in his practice for the year 1951. Of the 4,456 patients on his list he referred 307 for consultant's opinion (6.9% of practice); 240 for radiological investigation (5.4% of practice); and 220 for pathological investigation (4.9% of practice). No mention is made of patients referred to hospital for treatment.

Logan (1954) summarized his findings in a survey of the work of eight practices during the year April 1, 1951, to March 31, 1952, and he gives a detailed statistical analysis of the numbers of patients referred to hospitals as in- and out-patients, and also of those seen on domiciliary consultations and by private arrangement. He reported that two-thirds of the total lists of the eight practices were seen. In all, 19,000 patients were seen for 105,000 consultations. Over 4,300 referrals were recorded, an average of 15.8 per 100 patients on the combined lists or 4.1 per 100 consultations given. Logan comments on the "startling differences" between the referral rates in the eight practices—the rate ranged from 32.1 per 100 patients in Polegate to 6.4 in Walthamstow. There is no indication, however, of the types of cases referred or the reasons for their referral.

Referral for Treatment

Examination of the reasons for referring patients is more revealing than a simple statistical analysis. It is fully appreciated that individual practitioners may vary widely in their approach to their patients and in their methods of treatment, but it is more than likely that there may be factors common to all. The commonest reason for referral of patients during the three years 1951-3 was for some form of treatment requiring a special technique, and of the 1,225 referrals under discussion 660 (53.8%) were for treatment. Some had already been investigated in order to confirm a provisional diagnosis before referral, or to exclude possible underlying physical disease before referral for psychiatric treatment. Very often the actual treatment is decided by the general practitioner when he chooses the specialist to see a particular patient.

Analysis of the 660 referrals for treatment is shown in Table VIII. Out-patient referrals are more numerous than in-patient referrals; for referrals to physicians the ratio out-patient:in-patient is approximately 2:1. As might be expected, in the case of surgical referrals the ratio of out-patient:in-patient is nearly 5:1. The proportion of females:

Figures in parentheses denote number seen on domiciliary consultation.

males is practically 1:1 for medical referrals, and nearly 2:1 for surgical referrals, where the referral is for treatment.

The commonest cause for admission for in-patient treatment is acute appendicitis (10 female and 6 male), and a further 11 female and 6 male referrals were made to surgical out-patient departments for consideration for interval appendicectomy where there had been recurrent appendicitis.

The largest number of referrals for medical treatment were psychiatric, and consisted mainly of cases of severe psychoneurosis and of psychosis (see Table XIII).

The next two largest groups referred for medical treatment were for general medical conditions (including chest affections) and dermatological complaints. The latter referrals included most of those patients who were referred to specialists in response to their own request—a valid reason for referral in those illnesses known to be chronic and difficult to treat successfully.

Among the surgical referrals for treatment the largest group were for orthopaedic conditions, although many of them could have been referred direct to a department of physical medicine for the required physiotherapy had this been available. Fortunately there has been a change since this survey was completed, and patients may now be referred direct for physiotherapy in this district.

It is perhaps surprising how many patients consult their doctor when they require dental attention, although they often present with acute submandibular adenitis and require the combined attention of dental surgeon and doctor.

Referral for Special Investigation

The second most common reason for referral was for special investigations in order to confirm a provisional clinical diagnosis, or in many cases to exclude possible underlying physical disease when the diagnosis was a psychoneurosis. Often the real reason for this latter type of referral is one's own anxiety—it is so often said that "organic disease" may be missed if patients are "labelled" neurotic, and as this is one of the most common diagnoses it is hardly surprising that it becomes necessary "to make sure" nothing is being overlooked.

There is no doubt that the standard of general practice will be improved only by allowing the family doctor full facilities for properly investigating his patients in order to reach an accurate diagnosis. It is only by this means that adequate treatment may be started. This means there must be open access to pathological laboratories and radiological depart-

ments, and although some hospitals have shown their willingness to co-operate with the general practitioner there are many that have not. The argument usually put forward is that there is not the room or the staff to deal with the extra work involved. This is nonsense, as shown by this investigation. Table IX shows the number of referrals for pathological investigations, and Table X shows the number of referrals for radiological investigation. In both cases the majority had first to be referred to a consultative out-patient department.

Hunt (1951) described a diagnostic unit he had built in the first five years after the war, and his discussion of the work carried out during that time shows the high standard of practice made possible by having available the facilities for pathological and x-ray investigations. This unit was outside the National Health Service, but its excellence should be the aim of the general practitioner within the National Health Service. During the years 1948, 1949, and 1950 7,020 pathological investigations were carried out, and 1,476 sets of x-ray films taken. Hunt had consultants in pathology and radiology to advise him. The number of patients seen in the three years is not stated, but in five years 3,864 patients were treated. This implies a high incidence of investigations per patient, but the standard of practice was such that he wrote: "This unit has enabled work to be done in general practice which would have been very difficult without these facilities."

Since the present survey was completed one hospital in the area in which I practise has opened its pathological and x-ray departments to general practitioners; my referral rate to consultative out-patient departments has dropped because of this, as might be expected from the results of this study. There are other hospitals, however, also serving this area, whose pathological and x-ray departments are still closed to general practitioners, so that there is a tendency to overburden the special departments of the hospital with open access. Clearly it is necessary for all hospitals to play their part in co-operating with the general practitioner—and the teaching hospitals should lead the way.

Referral for Consultant's Opinion

During the three years under review out of the 1,225 referrals only 183 were for a consultant's opinion about the diagnosis or for advice and guidance with regard to further management of the patient. An analysis of these 183 referrals is shown in Table XI.

These figures show almost equal numbers of surgical and medical referrals, but with a ratio of nearly 2:1 of females:

It will be noticed that nearly one-third of these referrals for an opinion took place on domiciliary consultation—a

method which I think is of the utmost value to all concerned. It permits a proper consultation to take place between the family doctor and the consultant; the patient is often saved a long wait for an out-patient appointment, or indeed he may avoid being admitted to hospital; the family have the opportunity of seeing the specialist, and are able to ask their questions; finally, the consultant gains by seeing the patient in his own home environment—a sick person among his family in his own home, and not a patient in hospital.

Domiciliary Consultations

Analysis of the 80 domiciliary consultations is shown in Table XII. There is here a majority of females, due mostly to the number seen by a psychiatrist. Perhaps in this branch

of medicine more than in any other is the domiciliary consultation of value. So often the patient cannot be persuaded to go to hospital to see a psychiatrist, but he can be helped by the psychiatrist coming to see him. Again, there is the advantage of the psychiatrist seeing the patient in his normal environment, and also of being able to discuss the case with the family.

Apart from the 26 referrals by domiciliary consultation with a psychiatric consultant, 34 other patients were referred to psychiatrists, some of them more than once each. Table XIII shows the diagnosis in the 60 patients referred to psychiatrists, the majority of them being for severe psychoneuroses and psychoses. The small number admitted is to the credit of the consultants concerned, as out-patient treatment was arranged for many cases in spite of the difficulty in getting a patient adequate psychotherapy under the National Health Service. Because of this I have taken on a

much larger number of patients for psychotherapy than I referred, and I have discovered that in fact, contrary to the opinion of some psychiatrists, the family doctor is exceptionally well placed to treat patients by this method. Not only does he know his patient's home background, he already has the trust and confidence that is so necessary if psychotherapeutic methods are to succeed. Even those patients who say they do not "believe" in psychology can be treated without their even realizing it—and later, when they come to see how they have responded to this type of approach, their gain in insight is often remarkable.

The largest group of patients seen on domiciliary visits by the surgical consultants was the orthopaedic one; mostly the referral was for a patient with severe acute back pain, the most frequent cause being a disk lesion. Occasionally a plaster-of-Paris jacket helps the patient get about; more often, however, it is useful as a means of setting the wheels in motion for routine x-ray examination of the back in order to estimate the extent of spondylosis—and to exclude any other possible pathological condition. Also, arrangements can be made for suitable physiotherapy to be started at the optimum time during the period of recovery. In this way the delay (which may be as long as four to six weeks) in waiting for an out-patient appointment is avoided.

Table XIV shows the numbers of referrals according to sex, and whether for medical or surgical conditions, for each of the four main reasons for referring patients to hospital. It will

TABLE XIV.—Numbers of Referrals According to Sex, and whether for Medical or Surgical Conditions, for each of the Four Main Reasons for Referring them

be seen that just over 50% are for treatment, usually by some special technique which the general practitioner is not normally expected to do. The ratio of out-patients to in-patients for males is 3.5:1, and for female referrals it is 6:1. The ratio of surgical:medical referrals is 3:2 for males, and nearly 2:1 for females.

Other Reasons for Referral

There are lesser reasons for referral which may be recognized. One is the doctor's own anxiety to "make sure" no physical disease has been missed. Taylor (1954), in a report of a survey, states: "Claims that as many as a third of the

G.P.'s patients are suffering from neurotic illness appear to have arisen mainly because organic complaints have not been diagnosed." In fact, I have personally always been apprehensive lest this happen in my practice: perhaps this is why my referral rate is so high when compared with others (see Logan, 1953). Nevertheless, in spite of careful physical examination, together with special investigations, the incidence of neurotic illness found among my patients is over 40% when the generally accepted stress disorders are included (Hopkins, 1955).

A reason commonly claimed for many referrals to hospital is that the patient requested that he be x-rayed or that he should see a specialist. In my experience this is a very infrequent reason for referral—provided always that one can give the patient who makes this type of request the necessary time in which to express his fears and anxieties, and to make a thorough clinical examination in order to be certain of the diagnosis before embarking on any form of treatment.

One further reason not yet mentioned is to obtain help in the "disposal" of a patient. I have been fortunate in not having had to do this more than three times, and on each occasion the need for this action was entirely due to the patient being entirely alone in the world, having no family or friends to look after her.

Comment

In my experience there is quite clearly a simple answer to the first object posed at the beginning of this paper: I believe that the family doctor should play a major part in the care of his patients, and that only when they require treatment not available in general practice should referral to hospital for treatment be made. In the main, this applies to surgical illness. Here, then, is the first part of the answer to the second question set out above—the hospital should provide the staff and facilities for prompt and efficient treatment for those patients in need of it.

The second requirement is for adequate facilities for proper investigation of the patient in the pathological laboratory and in the x-ray department—without the patient needing to see any other specialist apart from the pathologist or radiologist. Taylor (1954) provides the answer for those who cry out that this is impossible: "As with pathological open access, it can be argued that radiological open access does not add to the total volume of work done. Indeed, if in a hospital inexperienced house officers are allowed to order x-ray films, it can be claimed that the more experienced G.P.s are likely to ask for less on the same patients."

An important point arises here, however, since the general practitioner must be prepared and able to continue treating his patients—so long as the treatment required is within his competence. The all-important factor therefore is time, and it is here that the possibilities for the doctor fall away if he has a large National Health Service list, even if he has ancillary help. Simple mathematics show how much time can be given to each patient when the numbers of patients and the available time are known.

Finally, the hospital's functions must include consultative facilities. Again time is all-important. If the huge numbers of out-patient attendances to consultative clinics for pathological and x-ray investigations were reduced, the consultants would more easily be able to see patients by appointment—and this in turn would make it possible for the general practitioner to attend the consultation. This fulfils the meaning of the word, which essentially is a consultation between the family doctor and the consultant-specialist about the patient. This is at present possible on a domiciliary consultation, as described above.

Of course, the hospital has its part to play in furthering the education of the family doctor, and keeping him abreast of modern advances, but this is not the place to discuss that.

Reference has been made to the incidental finding of fresh evidence of the high incidence of psychoneurotic illness and

NEW ACADEMIC YEAR UNIVERSITY COLLEGE HOSPITAL

The Doctor's Double Role

At the opening of the new session of University College Hospital Medical School an address was delivered by Sir ARTHUR FFORDE, headmaster of Rugby School, and the prizes were presented by Lady FFORDE. Sir CHARLES HARRINGTON, F.R.S., chairman of the school council, who presided, referred in fitting terms to the retirement of the vice-dean, Professor S. J. COWELL, who for sixteen years had been primarily responsible for the selection of students and the instruction of deans in their duties and responsibilities, and also to the retirement of Mr. ALAN SHEFFORD, the vice-dean for dental students, who had been at the school since 1913.

The Dean, Dr. J. D. S. FLEW, gave a brief account of the school year. During the session the total entry of undergraduate students taking the full course was 92; the total number of undergraduate students in attendance was 277, and of postgraduates 63.

Sir ARTHUR FFORDE said that no sensible person in these days could possibly be without a lively consciousness of and real gratitude for the enormous advances of medical science and the swift development of medical practice and technique. Nor could one fail to be aware of the degree of self-sacrifice and devotion with which in this country we were blessed in the general practitioner and nursing services. Yet it must be the case that, for anyone in present circumstances who was embarking upon the profession and art of medicine, it was the difficulties and responsibilities and restrictions of the task in its present framework that loomed larger at times than the vast accumulation of knowledge, skill, and prestige which he or she had to rely on at call. It was not so much the endless procession of examinations and the profound and detailed knowledge which it was necessary to acquire in order to pass them, but the sense that, as soon as one was beyond the beaten track and the well-practised techniques, one was holding in one's hand an individual life, and it was assumed by others that one knew precisely what one was doing, even though in one's own heart there was uncertainty. That was likely to be the burden and the challenge, as the discharge of it was truly the glory, of the medical vocation. It was this which distinguished it from all other vocations, with the possible exception of the priesthood.

"How much does it matter, do you think, to me personally as your prospective patient whether you did or did not win a particular prize on a particular occasion or whether you do or do not keep yourself abreast all the time of the latest developments in medical science? You will probably say that it matters a great deal more than you suspect me of thinking. . . . Nevertheless, prize winner or not, if it should turn out that I am later to be your patient, I am more than half inclined to say that the *sine qua non* of that relationship over and above your knowledge of modern techniques was expressed many centuries ago by Bianor, who indeed wrote in Greek, for that was his language, but who, if he had known English, might have put it something like this, 'Behold, I tell you a mystery. This, this nothing, this meanness, this indeed slave, even this man, is loved and is the lord of the soul of another.' I, your patient, am not a thing, but a person, and you must know it and remember it, and make me feel that you do."

Sir Arthur fford went on to say that in order to maintain this personal relationship, given as must be assumed the best and completest knowledge of the scientific side of medicine, the main difficulty that nowadays one was likely to encounter was what he called the Civil Service difficulty. The doctor had to be part of a large organization, not yet very fully and completely established, in which, in contradistinction to other forms of Civil Service, all the eventual actions were related to particular people rather than to classes of persons. But in relation to this problem he was an optimist. From the point of view of those people who in the past

stress disorders as a result of this study. It is reasonable to expect that among the number of referrals to hospital would be found the more seriously ill patients, and this was so. Nevertheless, when those who were referred for treatment (excluding the psychiatric referrals) are deducted from the total number of referrals 615 remain. Of these 615, over one-half—that is, 31.3% of the total number of referrals—were found to be suffering from psychoneurotic illnesses and stress disorders. In the time that has passed since this survey was planned and carried out a careful check has been made and only two patients have been found whose diagnoses were not correct. In both cases, however, referral to hospital had been made and full investigations carried out (in one case a barium-meal examination which was repeated twice, and still reported negative), but the physical disease was missed. It so happened that when, later on, the diagnosis was properly made and treatment completed, it was still obvious that there was serious psychoneurotic illness present. In short, even when physical disease is found there may be no connexion between it and the patient's symptoms, or even when treated for his physical illness the patient still retains those symptoms due to the coexisting psychoneurosis. These findings are at complete variance with Taylor's observation that: "There is a substantial element of truth in the hypothesis that the better the clinician, the less often does he diagnose neurosis."

Conclusions

In analysing 1,225 referrals to consultants and specialists over a period of three years (1951-3) from a single general practice certain facts emerge. Just over half of the referrals (53.88%) were for treatment requiring special techniques not within the general practitioner's competence. Of the remainder, the majority (31.1%) were for special investigations, in the pathological laboratory or the x-ray department. In only 15% of the referrals was there need for an opinion from a consultant, or advice and guidance for further management of the patient.

Arising from these facts it is possible to emphasize the need for provision of facilities to help the family doctor reach an accurate diagnosis and, where required, to provide consultative out-patient clinics where recommendations for further treatment by the family doctor can be obtained. To burden the hospitals with more than this is to increase the amount of unnecessary work for the staff, and also to deprive the family doctor of his responsibility for and to his patients.

In my experience the incidence of illness due to psychoneurosis and stress disorder is high—over 40% in my total practice and just over 30% of all referrals to hospital. This perhaps points to the need for more facilities for the treatment of large numbers of patients by psychotherapeutic methods—both at hospital and by the family doctor.

I would like to take this opportunity to express my grateful thanks for the ever-ready help that I receive from my consultant and specialist colleagues, and also for the co-operation of the many generations of residents at the hospitals I usually use.

had the family doctor at call, the new system was in many ways a deprivation. But for the general run of the population of this country it was difficult to feel that the change had been anything other than of benefit. He supposed there had never been a time in the past when the medical services had been as available to the population in general as they were now.

The students before him were to become part of a body of men and women pursuing under various delegations of authority, some of them remote, a science and art and vocation the whole of which had to do with individuals one by one, and therefore with a person in the immediate proximate foreground. On the other hand, they could not forget that they belonged to an increasingly organized and very large undertaking. But, if they allowed that fact with its remoteness to destroy the essential proximity between themselves and their particular individual patient, then neither they nor the organization was doing the thing which the organization was set up to facilitate, and that they themselves, when they recognized their vocation, found themselves called upon to do.

The problem was not a new one, though it might be new to the medical profession. But just as a soldier when he became involved in an army, or a priest became involved in a church, was still concerned with the individual human being, and had to learn by experience how to combine the two duties, so the doctor had primarily all the time to do that same thing. To protect oneself, one had to adopt a certain detachment, a certain case-hardening, to dissociate oneself, emotionally at least, from those with whom one was concerned to deal. Yet such was the mystery of life that these combined yet dissimilar operations could in fact be accomplished without detriment to the wholeness of life itself.

ROYAL FREE HOSPITAL SCHOOL OF MEDICINE

The Vocation of Medicine

In his inaugural address to the Royal Free Hospital School of Medicine on October 5 Sir FRANCIS WALSH spoke on "The Vocation of Medicine." He returned to the eternal truth that the practice of medicine was a way of life with an ethos of its own, and that it transcended the making of a living or of a career. It was an exacting calling, demanding all one had to give of mind and heart, of knowledge and of wisdom.

Much criticism of medical education was misplaced and derived from a false notion of what could be taught by formal methods. There were things which could be learnt only in the hard school of responsible experience. The popular nostrum for the rapid seasoning of the young doctor was a course of lectures upon normal psychology—two dozen easy lessons in wisdom. This was completely silly.

Doctor and Patient

The doctor-patient relationship had been very much a weapon of debate in recent years, but it had won doctors no political victories, and it had perhaps emerged from their unequal struggle with the politicians a somewhat tattered notion. At its best it was a more complete human relationship and a more responsible one than any other profession or occupation was called upon to enter into. The conditions essential to the optimal development of this necessary confidence between patient and doctor were no longer so favourable as they were, for the State threw its long, interfering shadow over them, and there were many to-day who thought of the doctor as no more than another amenity in that vast day nursery called the Welfare State. But apart from all this there were essential elements of instability in the relationship. The doctor must keep emotionally independent to retain his freedom and avoid being hurt when those whom he had striven to help proved unreasonable, thankless, or even vindictive.

Doctors had been recently admonished by a learned judge that they must always tell the truth; but what, in the relevant connexion, was meant by "truth"? It generally meant telling the patient the full nature of the prognosis. Suppose the case was inoperable and the prospect of survival was to be measured in weeks or months. How much was it necessary or expedient to say? The patient's relatives would almost certainly be against giving the patient a realistic account of his situation. There were many patients with the courage and the wish to know the facts, but not all men and women might safely be assumed to wish to know the worst, or to react with prudence and fortitude if they were told.

The lawyer interpreted and applied a statute, and assumed it was the citizen's duty to know the law and obey it. Doctors lived in no such realms of simplicities but at the heart of human life, knowing that they could not act by rule of thumb but only with due respect for the individual human person and with appreciation of human weakness and limitations. It might often be, then, that an economy of truth was demanded on some occasions.

Apart from these grave situations there was a widespread tendency to-day not to tell the patient as much as one should about his illness. Time given in simple explanation was never wasted. Sir Francis warned, however, that doctors could not live other people's lives for them; he suggested, for instance, that it was wrong to tell a young woman showing initial signs of disseminated sclerosis that she must not marry and have children. Happiness in married life was not necessarily or usually shattered by the illness of one partner. Health and happiness were not always to be equated.

Each doctor, he concluded, must discharge his conscience according to a considered judgment of each particular case.

School Scholarships

In her report the Dean, Dr. KATHARINE LLOYD-WILLIAMS, discussing the quinquennial policy for 1957-62, said that the school and hospital were in complete agreement. The establishment of professorial units would involve additional building. The scholarships committee had introduced new schemes so that students who for one reason or another were not eligible for the large State grants now so readily available could compete for school scholarships, and in some cases awards had been combined to provide more valuable postgraduate awards, for which the need was urgent. An adviser to the men students had been appointed, an appointment made necessary by the increase in numbers from one in 1947 to over 100 at present.

The chair at the ceremony, which was held in Senate House, was taken by the chairman of the school, Sir FRANCIS LASCELLES, whose wife presented the prizes.

MEDICAL PROTECTION SOCIETY

The annual meeting of the Medical Protection Society was held on October 3 at Victory House, Leicester Square, with Sir ERNEST ROCK CARLING, the president, in the chair. In presenting the sixty-fourth annual report of the council, Sir Ernest said that the year had been entirely uneventful. The Society continued to prosper. The number of new members elected during the year was 1,529, and the total membership stood at 29,638. Over 2,000 members sought the advice and assistance of the Society during 1955. The council had been a little disturbed, as had other like bodies, at the continuance of such accidents as swabs left in the body after operation. It had occurred to him that possibly something more ought to be done about new residents. Perhaps there ought to be a more regular overhaul of the

human factor, just as the engineer made an overhaul of apparatus. He also touched upon the need for scrupulous hospital recording.

Mr. W. M. MOLLISON, honorary treasurer, said that the financial report showed a substantial increase in the reserves of the Society. The income for the year was up by nearly £4,000, and expenditure was less, indicating a reversal of the trend of the last few years of increasing expenditure, though it should be stressed that the full effects of inflation had yet to be felt, and also that there were many serious cases *sub judice* which might prove to be very costly. The funds available for the protection and defence of members' interests now exceeded £220,000, and the Society was reinsured with Lloyds underwriters for a considerable sum.

Mr. DOUGAL CALLANDER proposed the re-election of Sir Ernest Rock Carling as president, and this was carried unanimously. The vice-presidents and retiring members of council and other officers were also re-elected.

Claims against Hospitals

In a report which was presented to the meeting by the Society's solicitors (Messrs. Le Brasseur and Oakley) it was stated that the view expressed last year that the number of legal actions and claims against doctors, dentists, and hospital authorities had reached its peak was borne out by the most recent experience. Although actions and claims were still running at a disconcertingly high level compared with a decade or more ago, there were indications that the growth had been arrested at least for the time being. But the situation was still very serious and demanded the constant vigil of the professions and of those charged with the protection of their interests. The procedure agreed on by the three defence societies with the Ministry of Health for dealing with claims made or actions brought against hospitals or members of their medical staff continued, it was said, to work smoothly. It had to be emphasized that the new arrangement applied only to doctors who were members of, and whose defence was undertaken by, one of the three societies. Membership of one or other of them was therefore of particular importance to doctors employed by hospital authorities, since for doctors not so protected the Ministry's policy was that steps should be taken in appropriate cases to obtain contributions or indemnity from them.

CANNED FOODS

[FROM A SPECIAL CORRESPONDENT]

Several topics of importance to public health were discussed at the third International Congress on Canned Foods held in Rome from September 24 to 28. The most striking feature of the bacteriological session was a demonstration by Dr. D. A. A. MOSSEL (Utrecht) that in the examination of batches of cans for any particular condition only very large numbers of cans will give statistical significance to the results. This led inescapably to the conclusion that the absence of *Clostridium botulinum* from a batch of cans could not practically be assured by bacteriological examination, whether this took the form of direct search for the particular organism or for similar anaerobes whose occurrence would imply the possibility of its presence. The same arguments applied equally to all methods of examination or to any species of micro-organism. Hence the only really satisfactory solution was to rely on a canning process which would ensure the killing of all unwanted microbes in the product. This should be coupled with prevention of their re-entry by strict attention to the integrity of can seams and the use of sterilized cooling water. The real function of bacteriological examination was to provide the manufacturer with an assurance, with a particular confidence

limit, against the spoilage of the product, and this degree of confidence was a direct function of the cost of the examination, which might well exceed 25% of that of the product itself.

Safety in Acidity

This point of view reappeared several times. Discussing bacteriological classification of canned foods, Dr. R. BUTTIAUX (France) emphasized the difference between canned foods with a pH more acid than 4.5 and those less acid. In the former, as is well known, *Cl. botulinum* is inhibited by the acidity, so they are subjected to much less severe processing. Dr. Buttiaux suggested that, from the standpoint of public health, they might for the same reason be sampled on a system giving much lower degrees of confidence. Several speakers confirmed that this is in fact done in commercial practice. For example, Mr. T. E. BASHFORD stated that the percentage of cans examined was commonly only half as great for fruits as for meats. Dr. BUTTIAUX, however, complicated the argument by the assertion that, contrary to general belief, viable cells of *Salmonella* occurred not infrequently in acid preserves, citing citrus juices and jams in particular. Though the acidity prevented multiplication of these bacteria, they could remain viable. He suggested that they might be introduced after the heat treatment of the products. Other speakers contested these assertions strongly, notably Mr. P. H. LEFEBVRE (Belgium).

Such occurrences would place special emphasis on plant sanitation, and this topic was discussed in a separate section, most succinctly by Mr. J. M. HEINEN (U.S.A.). He listed the following as having, in recent years, helped to "make in-plant sanitation a reality": use of stainless steel and monel metal, welded crevice-free construction, organic detergents, improved fumigants and insecticides, ultra-violet light, and chlorinated water. The problems in designing equipment for the sanitary processing of food were considered more fully by Mr. C. K. WILSON (Costa Rica). Mr. HEINEN affirmed too the value of the U.S. Food and Drug Administration's system of resident plant inspectors; and it was interesting to hear this opinion confirmed by other representatives from the traditional land of unrestricted enterprise.

Disposal of residues, as one of the most serious problems of cannery operations, was also discussed by several speakers in a separate session. MM. MAILLET, HUGUES, and ENGINGER (France) described in detail the various by-products derived from the residues from meat canning. The only satisfactory way of dealing with the waste was to convert as much as possible of the organic content into useful by-products—for example, into cattle fodder, fertilizer, or fermentation products—and to dispose of the effluent liquor by irrigation of land and not by discharge into rivers. Professor R. S. INGOLS (U.S.A.), after comparing different irrigation systems, concluded that much the most effective was the irrigation of woodland, though it had the disadvantage of yielding no immediate cash return.

Antibiotic Dangers

The use of antibiotics as an aid to preservation was mentioned several times. Mr. HEINEN referred to numerous American experiments, covering a wide range of antibiotics, which had so far failed to reveal a method which was of practical value in canning. Dr. M. JUL (Denmark) thought that, though antibiotics might lead to improvement in the handling of fresh meat, they would not compete with canning. Most outspoken against their use in any foodstuff was Professor A. BASERGA (Italy), who thought that many antibiotics interfered with the mitotic processes necessary for the regeneration of the mucosa of the tongue and gut, causing damage which might not become evident for some time.

The undesirability of using chemical preservatives to stabilize preserves was emphasized by speakers from various countries, leaving the impression that such practices are much more common than is known or desirable. The impossibility in general of detecting the wide variety of such substances by chemical means was regarded as making it necessary to seek them by more generalized methods of biological assay; and it was suggested that positive results in such assay tests should now be regarded as sufficient legal justification to condemn the food, even though the preservative cannot be precisely identified.

MANAGEMENT OF THE GANGRENOUS FOOT

On October 3 the Section of Surgery of the Royal Society of Medicine met for the first time under its new President, Mr. ERIC A. CROOK, to discuss the management of the gangrenous foot.

In the opening paper Professor C. G. ROB spoke briefly first of gangrene due to venous thrombosis, a type seen usually in patients debilitated by other diseases such as carcinoma or ulcerative colitis. Anticoagulant therapy and elevation were indicated; amputation should be avoided as long as possible, since the line of demarcation tended to become more peripheral. But it was gangrene due to arterial disease which was much the more common and important. In 145 cases at St. Mary's Hospital seen since 1950 atherosclerosis had been responsible in 125. In 90 of these the occlusion had been in a large vessel (aorta, iliac, femoral, popliteal), and in a further 24 cases main trunk and small vessels were occluded. Turning briefly to gangrene in diabetic patients, Professor Rob said he did not believe in diabetic gangrene as such. Atherosclerosis, infection, and neuropathy were responsible for most cases, and these were much commoner in diabetics than normal people. Important among conservative measures for gangrene were cooling the affected part to room temperature, to reduce metabolic needs, while warming the rest of the patient to promote reflex vasodilatation. Alcohol had been found very useful, both to relieve pain and, by vasodilatation, to aid the collateral circulation. Means to improve the general health, such as the correction of anaemia, anticoagulants, and the prevention of deformities were further conservative measures.

Discussing the surgical treatment, Professor Rob said the essential thing was to diagnose the level of arterial block, and whenever possible to reconstruct the artery. Arteriography was an essential preliminary to an arterial reconstruction operation in these patients. In 30 cases—about 20% of the series—arterial reconstruction had been carried out, with a successful result in 20. The best type of reconstruction operation had been found to be the by-pass graft popularized in Britain by Cockett. Having reconstructed the artery, one should be conservative with the gangrenous part itself. Healing with minimal loss occurred following successful operations, and formal amputations could be avoided. Local removal of dead tissue was all that was required. It had been their experience, Professor Rob continued, that in cases in which the graft subsequently became blocked gangrene did not necessarily reoccur. This suggested that arterial reconstruction did not have the damaging effect on collateral circulations which had been claimed. Only in one case of thromboangiitis obliterans had he found it possible to do an arterial reconstruction for established gangrene (because usually small peripheral vessels were thrombosed), and it had been well worth while.

Sympathectomy had been carried out in 81 of the cases, with valuable improvement in 55. He believed that the level of the operation should be planned to fit the level of the arterial occlusion. For popliteal occlusions excision of the second and third lumbar ganglia was adequate, but the first should be included for mid-thigh blocks and up to the tenth dorsal ganglion for high occlusions such as the origin

of the common iliac arteries. After sympathectomy again, amputation should be as conservative as possible. The most satisfactory operation of all, though not often indicated, was thrombo-endarterectomy.

Amputations had had to be performed in 94 of the 145 cases. In 34 the level had been above-knee, in 26 below-knee, whilst in the remainder it had been successful at lower levels.

Diabetic Gangrene

Dr. W. G. OAKLEY confined his remarks to the lesions seen in diabetic patients. He agreed with Professor Rob that there was no demonstrable difference between diabetic and senile gangrene. Gangrene was, however, six times more common in diabetics than in other people, and in his clinic at King's College Hospital, in a three-year period, 146 cases had been seen. Age was an important factor, for none was less than 40, and the incidence of foot troubles increased steadily with advancing years. They had not been able to find any significant relationship between occlusive vascular disease and the duration of the diabetes. Where sepsis and perforating ulcers occurred in young patients the common defect was diabetic neuropathy.

Dr. Oakley said that the gangrenous lesions in diabetics were of four types, according to the cause—septic, neuropathic, ischaemic, and combined lesions. Sepsis required standard treatment, though it might complicate ischaemia or neuropathy. In neuropathic lesions it was the loss of appreciation of pain which was particularly important. A characteristic deformity of the toes, with dorsal dislocation, tended to occur, and local gangrene due to trauma might result, even in the presence of a good blood supply. There were two main manifestations of ischaemia in diabetes—pain and gangrene. Usually the patients were old and both feet commonly were affected. The painful feet were cold, pink, and very painful, especially at night. Vasodilator drugs had not been effective, and, though sympathectomy relieved pain in some cases, amputation was usually necessary. Indeed, it was often requested by the patient.

Turning to gangrene, Dr. Oakley said he was strongly opposed to waiting for natural separation. If the patient was kept in bed there was a danger of gangrene of the heel, and, if allowed up, of injury causing rapid spread, whereas amputation of a gangrenous toe often was followed by healing. Gangrene of the fifth toe presented special problems. It was difficult to obtain skin cover on the outer border of the ischaemic foot, and this lesion often led to below-knee amputation. The big toe was less of a problem, and local disarticulation often gave good results. If two or more toes were affected, it was usually wisest to amputate all five. Amputation through the tarsal and metatarsal regions had been disappointing, for it was rarely possible to obtain skin closure without tension. When gangrene in diabetic patients spread beyond the toes, below-knee amputation was necessary.

Concluding, Dr. Oakley described a method for preventing heel gangrene in recumbent patients. The legs were suspended just off the bed in canvas slings, lined by orthopaedic felt, by means of springs. He had found it most effective.

Condition Before Gangrene

Mr. G. E. MAVOR read a paper dealing chiefly with two matters—the pathological anatomy of the disease, and some aspects of by-pass operations. An analysis he had made of 223 cases of peripheral ischaemia of the lower limb showed atheroma with secondary thrombosis to be the cause in 203. It was important, he said, to consider the events which preceded the onset of gangrene. In 92% of cases the disease affected a main vessel. Initially thrombosis was limited in extent and in 83% of cases occurred in the femoral artery, most commonly in the region of the opening in the adductor magnus muscle. From here it spread proximally to be halted at the orifice of the profunda femoris artery. In 10% it was the popliteal artery which

was affected, and the initial thrombosis then occurred in the proximal part of the vessel, whence it spread downwards to the bifurcation. In main vessels thrombus propagation was the principal method of spread, thrombosis at a fresh site in a main artery being uncommon. It had occurred in only 3% of his cases.

Mr. MAVOR discussed then the role of the lower leg vessels. While rarely the site of initial thrombosis, they became thrombosed secondarily. It was the extent of main vessel thrombosis which largely determined the manifestations of the disease. In 60% gangrene was the culmination of years of increasing peripheral vascular insufficiency, and surgically the problem was often best dealt with before its onset. Once the stage of femoro-popliteal thrombosis was reached, the time for surgery was limited, as most patients with pain at rest and skin changes in the foot developed gangrene within six months.

Mr. MAVOR then described experiences with the by-pass graft. Its greatest advantages were that the anastomosis could be made of reasonable size and that the best points for insertion of the graft could be selected. At the same time collateral branches were preserved. Arterial homografts were to be preferred. In cases with femoral artery thrombosis the proximal anastomosis should be made proximal to the origin of the profunda femoris; the distal could be made to the proximal popliteal artery, if it were healthy, but was probably better fashioned to the terminal segment of popliteal artery at or below knee-joint level, as this segment of vessel was generally healthy and free of inconvenient branches. But in femoral-popliteal thrombosis there was no choice in the siting of the anastomosis. So far the longest follow-up he had made of a by-pass graft had been 11 months, and Mr. MAVOR thought the justification for grafting procedures for limited thrombosis was still open to question. Collateral channels might be reduced and the long-term future of arterial homografts was still unknown. However, he felt there was adequate justification for interference in cases with femoral-popliteal thrombosis.

In Nigeria, "active opposition to vaccination, particularly by local vested interests such as a gerontocratic oligarchy of 'juju' priests, fetish men and witch doctors, is, happily, a thing practically of the past; and, thanks largely to the efforts of that great Nigerian physician and pioneer in maternity and child welfare work, Dr. O. Sapara, the menace of dangerously hostile smallpox secret societies, such as the 'sopono' cult of the Yoruba country in Western Nigeria, now no longer stalks the land as it did two or three generations ago. The story of this feat is interesting and perhaps worth retelling. Dr. Oguntola Sapara, I.S.O., L.R.C.P.&S.Ed., was a medical officer in the Nigeria Medical Service from 1896 to 1927. The 'sopono' cult (now proscribed by law) was a powerful and dreaded secret society of the large and influential Yoruba tribe. The method of operation of its members was to infect with smallpox virus a person or household whom they had unsuccessfully attempted to blackmail: this they did by the application of scrapings of the skin of actual smallpox cases, or of other fomites. Previous vaccination would of course protect the prospective victim from attack from smallpox as intended—hence the cult's opposition to vaccination. Often also, by deliberately disseminating infective variolous matter, they artificially created epidemics of smallpox in order to increase their clientele and produce numerous patients for them to 'cure'—and vaccination would stop all that! At great personal risk Dr. Sapara, himself a Yoruba, joined the cult incognito, learnt their secret, and later helped Government to introduce legislation which banned the cult as an illegal organization. Our problem, now, is different: it is not so much one of opposition by the people to vaccination as the need to find a thermo-stable smallpox vaccine which will retain its potency for long periods under 'bush' conditions, and particularly in the dry and hot climatic conditions of our most northerly territories."—*Annual Report on the Medical Services for the Year 1953-4*, Federation of Nigeria.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Treatment of Intracranial Metastases

SIR—I read the article on adrenalectomy for intracranial metastases from carcinoma of the breast, by Mr. Allan-Clain and Mr. Alan H. Hunt (*Journal*, September 15, p. 627), with much interest. I am, however, in some doubt about their conclusion that the "operation of bilateral gonadectomy and adrenalectomy is at present the only possible treatment of value for patients with intracranial metastases from cancer of the breast." The following case history shows that radiotherapy in conjunction with hormone therapy may also cause regression of an intracranial metastasis.

A woman aged 45 had a radical mastectomy in April, 1953, for an anaplastic small duct carcinoma of the left breast. She remained well until the autumn of 1955, when she began to suffer from pain in both groins. She was admitted to hospital in December, 1955, complaining of headaches, inability to concentrate, a feeling of pressure on top of the head, pain in the upper part of the back encircling the chest, in the lower part of the back and in both groins, and also of severe thirst. She looked ill and pale and was unable to move without severe pain. She was passing large

FIG. 1

FIG. 2

amounts of urine. An x-ray of the skull (Fig. 1) showed expansion and almost complete destruction of the sella turcica. The most painful lesions in the dorsal spine and pelvis and also the region of the pituitary gland were treated with x-ray therapy. Four weeks after the beginning of the x-ray treatment to the pituitary gland the thirst became less severe; ten days later it was completely relieved and she was passing a normal amount of urine. When the patient was discharged three weeks later the headaches and the feeling of pressure on top of the head had subsided, the power of concentration had improved, and the pain in the back and groins was less severe. She was then given methyl-androstanolone for five months. There was a steady improvement in her condition, she put on 1½ stones (9.5 kg.) in weight, and an x-ray of her skull (Fig. 2) showed recalcification of the sella turcica. When the patient was seen last month, her general condition was good and there were no further symptoms of diabetes insipidus.—I am, etc.,

London, W.C.1.

GWEN HILTON.

Glycyrrhetic Acid

SIR,—Correspondence regarding glycyrrhetic acid ointment reveals a difficulty which often attends the introduction of new remedies. Extracts of liquorice were shown to have certain cortisone-like properties when given internally, though not sufficient to be of much therapeutic value. Early this year a circular from a manufacturer informed us that glycyrrhetic acid was an active principle and that local application was effective in diseases of the skin. Ointment and lotion containing glycyrrhetic acid were recommended for a wide variety of skin disorders, though there was apparently no experimental work to support this claim. About this time I accepted the invitation of the makers to carry out clinical trials with an ointment and a control base which they supplied, and I have since learned that several of my colleagues did the same. In June I had assessed the ointment in 22 patients and had failed to show that it was at all superior to the control base. The makers were informed that my results were not promising but that I wished to continue the trial. However, they informed us that the composition of the ointment had now been altered and that it was shortly to be put on the market, prescribable on E.C.10.

Speaking generally, the effectiveness of a new ointment is usually very easily established if it is really much use. The astonishing value of hydrocortisone ointment can be strikingly shown in a very small series of suitable cases and leaves nobody in doubt. When an ointment such as glycyrrhetic acid fails to show convincing results in as few as 20 cases, one cannot of course say that it has proved to be inactive, and a series of this size with negative results seems hardly worth publishing; it is very much more difficult to prove a negative than a positive in this respect. But surely even such limited experience indicates that the ointment is not likely to be of much practical value. Certainly one wonders why glycyrrhetic acid was released for prescribing at public expense at a time when not a single favourable report on clinical trials had been published. This is not to argue that clinical trials with glycyrrhetic acid should proceed no further. The ointment may at last be shown to have some unexpected action or some slight clinical value, though it seems certain that this will be of only academic interest; but until larger series have produced some positive results it seems reasonable to confine prescribing to clinical trials.—I am, etc.,

London, W.1.

F. RAY BETTLEY.

Sickling in an African Community

SIR,—Dr. W. A. Wilson (*Journal*, August 25, p. 481) has criticized our article (*Journal*, August 11, p. 333) in which we discuss the mechanics of balanced polymorphism in the Baamba tribe. He differs in the calculation of the mortality of normal (non-sickling) homozygotes which he assesses at

27% as opposed to our 24.2%. Dr. Wilson's figure is based on the assumption that 157 deaths occurred in a "mean population"—i.e., one falling from 648 to 491. A cumulative death rate is, however, calculated upon the original population, and in our example is therefore 24.2% of the normal homozygotes born. We were concerned to show that in two situations the relative genetic fitness of the normal homozygote could be the same (in our example expressed by a loss in each case of 24.2% of the normal homozygotes exposed to the selective process), and yet the actual number of observable deaths from the selective factor could be quite different.

Dr. Wilson devises a formula for measuring malarial and non-malarial mortality at any given time. He assumes that the decline of population follows similar curves in both, and hence concludes that the proportional loss of life from malaria would be constant at any given mortality. Our argument is, however, based on the accepted view that at one period of childhood malarial mortality occupies far the greatest part of the total mortality, but that it is of less importance before and after that age (10–36 months).

Lastly, Dr. Wilson sees "a big gap to be closed between the 24% reduction in population needed by this hypothesis and the 7% or so which malaria can effect." The figure of 7% refers to all children, sicklers and non-sicklers alike, the 24% refers to non-sicklers only, and represents an observable loss of life from malaria between 6.9% and 15.7% of all children born. We gave reasons for expecting the actual death rate in Bwamba to be nearer the lower limit. Thus there is indeed little "gap" left, barely enough for Dr. Wilson to extract his "red herring."—We are, etc.,

A. B. RAPER.

Medical Education

SIR,—May I please beg space in your columns to reply to the letter by Mr. John B. Williams (*Journal*, September 29, p. 767)? He suggests that there is an element of "unrealism" about my scheme for the education of the "compleat doctor," in that such a scheme would mean that a doctor would be in his thirties by the time he was established, and he implies, I think, that this is in part due to my recommendation in respect of the statutory period of National Service.

Several points arise. First, I would question whether being in one's thirties on becoming established is necessarily evil: there is nothing new in this, and I feel that to fulfil a family doctor's role adequately before the age of 30 is unusual. Secondly, I would question whether this is in fact demanded by my recommendations: my own experience was to become established as a principal at 31, in spite of more than six years' war service, but I quite realize that this was in exceptional circumstances. But if a man qualifies at 24 he should be in a position to enter practice at 28, and he would do so very much better fitted to his task than is now customary. Thirdly, on entering practice as either principal or assistant, the young doctor would have been earning for a full four years, so that the question, "Who pays?" scarcely arises. Fourthly, marriage really cannot be considered in the production of good family doctors: again I quote from experience—I married at 25, still a junior student, with no capital whatsoever, and I would hesitate to suggest that this has in any sense impeded my professional career. Finally, I would stress that the reasons for my recommending the early undertaking of National Service were twofold; not only to use it as a ready-made course in "lifemanship," but to avoid the likely waste of time and frustration accompanying its intrusion into his professional life at a later date; and the time at which he does his National Service will not affect its duration, so that it can have no bearing on his age at entry into practice. I trust none of your readers read into my words any suggestion that manhood could be achieved in no other way.—I am, etc.,

Upton, Hunts.

JOHN K. PATERSON

History of Medicine in Medical Education

SIR,—In all the recent discussions on medical education the importance of the history of medicine in the building up of the physician has been sadly neglected. History is, however, a vital factor, as much for the understanding of scientific principles as for developing the ability of independent thinking, of spiritual steadfastness, of constructive criticism and moral courage. The old saying *Historia vitae magister* applies to medicine as well as to life in general. I am not advocating new chairs, or matter for examinations, but an attitude of mind.

History of medicine allows us to understand thoroughly our contemporary medical problems. In the original Greek, history means "investigation" and not the recording of things past, which is only an aid to investigation. History of medicine is therefore investigation of our medical problems in the light of what has been thought about them in the past, and this allows for the perfect understanding of these problems. In science, to repeat the words of Benedetto Croce, the highest form of knowledge is historical knowledge.

History gives to the physician the general unified view of medicine and thus counterbalances the negative effects of specialization and ultra-technology that threaten to disrupt our great science. It thus plays a great role in the integration of medicine, which is dominating contemporary medical thinking. A most important aspect of this integration consists in the link between the natural scientific basis of medicine—physiology, pathology, nosology—and its cultural scientific basis—psychology, sociology, history and philosophy. Medicine is not only a natural science but also a cultural science, because we have to deal with man, and man is not only body but also mind and spirit. History shows us medicine in its humanistic and social aspect as well as in its scientific aspect and thus helps us towards an effective practice.

The growing interest in history of medicine shows that medical men feel the need of the historical attitude of mind. We have, however, to distinguish the real history of medicine from the philology of medicine, which consists of the study of the lives and works of the physicians of the past. This is a necessary discipline, but it is the investigation of medical problems in the light of those who have thought about them in the past that constitutes the real historical attitude of mind. It is not a matter of special chairs or examinations but an attitude that should permeate clinical teaching, as it has permeated the teaching of a William Osler, of a Clifford Allbutt, and of many Continental teachers at whose feet I have sat years ago.—I am, etc.,

London, W.1.

A. P. CAWADIAS.

Abuse of Antibiotics

SIR,—I was most interested to read Dr. A. Fry's letter (*Journal*, September 1, p. 551) on the abuse of antibiotics. I fear we are often little better in this country. I have for some time tried to make my registrars and housemen realize that antibiotics are dangerous and risky drugs and should only be used if there is some real indication and a safer treatment is not available. My specialty is urology, and in cases of this sort antibiotics are frequently misused. I consider that antibiotics should never be given to a case of urinary infection until the urinary tract has been shown to be free of any abnormality which could cause persistence of the infection, the only exceptions being if a patient's life or a kidney is in danger.

In the *Lancet* there appeared recently¹ a leading article on the increasing incidence of bacterial resistance to antibiotics. Routine prophylactic treatment with antibiotics and indiscriminate and inadequate administration are the chief cause of resistant strains. There are other grave disadvantages to antibiotics. In the *Journal of Urology* of June this year² a case is reported of fatal moniliasis after prophylactic antibiotics to newborn caesarean babies at a clinic in the U.S.A. There have been many other reports of fatal moni-

liasis in American literature. It would appear that since the advent of antibiotics many organisms previously practically non-pathogenic are causing fatal infections. I have had a fatal case of septicaemia with proteus following the treatment of a urinary infection with antibiotics.

I believe that the medical profession are not the only abusers of antibiotics. Farmers feed them to livestock, and lately I hear that meat and fish have been preserved with antibiotics. Is this wise? I would be the last to deny their value, but I do feel that unless we are more careful in their use they may cease to be effective and may do more harm than good. I cannot condemn too strongly their routine prophylactic use and indiscriminate administration, and I do hope that the medical profession in this country will set an example in the proper use of these drugs, which have been one of the greatest blessings to mankind.—I am, etc.,

S. HENRY C. CLARKE.

Hove, Sussex.

SIR,—For some time now I have watched with interest the views of your contributors and correspondents on the abuse of antibiotics. The recent attack by Dr. E. O. Evans (*Journal*, September 22, p. 712) on the policy of many of our American colleagues would seem to warrant a reply. There is much to be said for those American doctors who supply their patients with oxytetracycline or other broad-spectrum antibiotics to take should they get a cold, cough, sore throat, or other readily curable condition of this type, because it is quite clear from our journals that their patients will not receive them from most general practitioners in this country for complaints of this nature.

Only a few of us on this side of the ocean seem to realize that parenteral administration of drugs is undesirable when an oral route is possible and patients do not like feeling ill unnecessarily, therefore penicillin and the sulpha drugs are as out of date as leeches. One of the greatest assets of some of the newer antibiotics (particularly the tetracyclines) is that they can be used with little or no inconvenience to the patient to achieve a rapid cure of many minor ailments, to prevent the onset of major illnesses, and to reduce the number of patients needing hospitalization. The small doses (often no more than 750 mg. a day for not more than three days) generally prescribed for this method of self-treatment are frequently successful if begun at the first sign of an illness.

I will answer in advance the numerous critics who will assert that this line of treatment is likely to give rise to resistant strains of staphylococci by saying the bulk of the literature shows clearly that resistant strains are carrier spread in closed communities and that their occurrence among the general public in America is not excessive.—I am, etc.,

Droitwich.

G. B. LEYTON.

SIR,—Dr. Joan M. Curtis (*Journal*, September 29, p. 767) is very much against the abuse of antibiotics, but apparently has different views about the abuse of general practitioners. It seems to me that no good can come of this miscalling of one section of the profession by another. We all make our mistakes, not only with antibiotics, but surely tolerance and understanding are preferable to reviling our fellows in print. When all is said and done there are those in the ranks of the consultants who are not averse to prescribing vast quantities—one thinks of patients in some wards receiving penicillin routine no matter what is wrong—but no good will come of bickering among ourselves about it.

There is no question that all branches of our profession must consider the problem more from the financial aspect than from any other, because economy now rules the day. Recently, having become involved in the problem of over-prescribing, I have been cutting down on all prescribing in my practice and I have been watching to see what the effect is. To my surprise there has been no marked change at all. No patients have died of lack of drugs and none

has suffered from no antibiotics—except for some of the septic hands, which obviously would have benefited if I had given a suitable drug at the beginning instead of later on when I was forced to do so. Apart from these cases, there appears to be no disadvantage in practising the methods I used before the war when antibiotics had not been discovered, but I cannot help feeling that to go back 18 years cannot be considered progress, even although it is cheaper.

We must find some solution to this problem, some set of rules or recommendations that will enable us to work out when an antibiotic is needed and when it is being wasted. Would it not be a good idea for some young registrar to analyse the results of treatment in representative surgical and medical wards to show the length of treatment, the incidence of complications, and the final results of treatment, comparing a pre-war year with perhaps the past twelve months? In this way we might be able to evaluate the effects of antibiotic treatment, other circumstances being equal. We might even discover that the liberal use of these drugs in hospital has saved vast numbers of man-hours by returning patients to their work earlier than before, and perhaps it might transpire from a similar inquiry in general practice that vast numbers of men return to work without ever being near a hospital, where formerly weeks were spent draining septic tendon sheaths and healing the stumps of amputated fingers, making disfiguring incisions for breast abscesses, and guiding the critically ill patient through the dangers of lobar pneumonia.

If such inquiries are held and do prove these suggestions of mine, we should point out to the Minister that solid gain has been made, that the health of the people has improved, and that economies made in this way must be placed beside the increased cost before a balance is drawn. In addition, we must remember that we are a great and noble profession, that the vast majority of us, in all sections, are honest men and women striving to do our best for our patients and our Government—in that order—and that it is a mistake to conclude that all men are fools because one meets an error from a hard-pressed practitioner, probably overworked, and doubtless underpaid as well.—I am, etc.,

Tarbert, Argyll.

A. C. MAYER.

Watery Eye Drops

SIR.—The recent incident at an eye clinic emphasizes the dangers inherent in the use of watery eye drops in children. In this case hyoscine hyd. 2% was dispensed instead of the 2% homatropine hyd. which had been ordered. The drops were made up in distilled water.

Watery solutions rapidly pass into the nose and nasopharynx and are soon absorbed. Fatal cases of atropine poisoning have been reported in babies who had been treated with regular instillations of a 1% solution of the sulphate in water. Drugs incorporated in an oily or ointment base are retained in the conjunctival sac; absorption is local and so limited that systemic symptoms do not occur. This retention has the additional advantage that the ocular effect is more profound and prolonged.—I am, etc.,

London, N.4.

E. M. G. GALTON.

Speech Therapy

SIR.—The last sentence of Mr. H. St. John Rumsey's letter (*Journal*, September 29, p. 768) suggests malpractice by speech therapists. If that was the meaning, it is a serious charge which I hope will be withdrawn.

One has to agree that it is a pity that there are not more mature women entering the profession, and that in the U.K. there are so few male speech therapists. In other countries the proportion of men in the profession is much higher. As to the rest of the letter, it is largely based on an old gentleman's misapprehensions. Stammerers are not crowded out of speech therapy clinics in favour of cases of very minor defects, such as "slurred" s; sometimes patients are taken on "first come, first served" principles, at others priority is given to the more urgent and serious cases—but

never preference to the so-called easy ones. A sigmatism can be related to other conditions; schoolteachers and parents cannot always do the job on the strength of a single explanation; and as to the cost of training, it costs as much to train as a teacher of speech training as it costs to train as a speech therapist.

Mr. Rumsey seems to be unaware of the existence of aphasics, laryngectomized patients, recurrent laryngeal nerve palsies, high frequency deafness, and the numerous other disturbances of speech and voice to be dealt with, if he believes only backward speakers, stammerers, and spastics come into the picture.—I am, etc.,

London, N.W.11

JOAN H. VAN THAL,
Speech Therapist,
St. Bartholomew's Hospital.

SIR.—I was glad to see that Mr. H. St. John Rumsey in his letter (*Journal*, September 29, p. 768) endorses the view that stammering cannot be treated as if it were merely a matter of correct enunciation. His assertion that boys of 12 should not be treated by a "young woman" gives the weight of his reputation to my view that a stammer is essentially a symptom of, or a form of, neurosis. I often have cause to notice the extent to which damned-up aggression, usually against the father, contributes to the inhibition of speech.

This raises the point as to whether the average speech therapist, in spite of her long and difficult training, is the best person to deal with stammerers, or whether we should not make yet another specialty and train men for that specific purpose. The rare female stammerer can usually adjust herself to either male or female therapist. In every case, unless the stammerer is leading an independent life away from home, the domestic atmosphere must be inquired into and the parents' responsibility for the condition brought home to them. In many cases (as often happens with married couples) the wrong person is brought for treatment, and it will be found that one or both parents exhibit some serious personality defect to which the stammer is the reaction.—I am, etc.,

Scarborough.

R. MACDONALD LADELL.

SIR.—Mr. H. St. John Rumsey (*Journal*, September 29, p. 768) states that it is "extremely difficult to be really conscientious about wasting time when working by paid sessions" and thus seems to arraign in principle the world economic system, but since he is here attacking speech therapists may I be allowed to reply on their behalf?

We are accused of wasting time on the lighter kind of case. Case selection in a speech clinic presents great difficulties because of the different amount of time allotted to each type of defect, and when a single short appointment time is vacated only one demanding a similar time for treatment can be taken in. This is the only likely reason for jumping any case on the waiting-list even temporarily, but the opposite is more likely to be true, that complicated adjustments are made to allow a severe case demanding a longer treatment time to be brought forward. There are, of course, many other categories of case, mild and severe, than those mentioned by Mr. St. John Rumsey, but speech therapists have the needs of stammerers very much in mind. Minor defects, however, have major consequences, and most people would agree that we are not wasting our time in treating them.

Let me now face the other way and meet the charge that, after all, the greater number of speech therapists, who happen to be women, should not treat stammerers at all. It seems that the patient-therapist relationship is a very individual matter, and the scientific management of this aspect apart, one boy of 12 might respond better to a man (the right man) where another would respond better to a woman even if young. An eminent psychiatrist recently expressed surprise at the "excellent results achieved by these young girls." In any case the "bossing about" mentioned would be a very faulty technique. The one generalization about stammering seems to be that no generalizations are possible. Mr. St. John Rumsey scatters them broadcast.

Sir, human frailty is common to all mankind, but, apart from that, let me assure you that speech therapists are trying to do conscientious and honourable work in relieving suffering, and would do whether they were paid for it or not. They are, of course, paid very, very little, which is no doubt the reason why we have so few male therapists to carry out the valuable work that Mr. St. John Rumsey would like them to undertake.—I am, etc.,

London, W.2.

PEGGY CARTER,
Press Officer,
College of Speech Therapists.

Clinical Psychologist in the Mental Hospital

SIR.—Dr. Ralph Hetherington, in his plausible advocacy (*Journal*, September 22, p. 708) of the significance of a psychologist—as psychotherapist—"based on the ward," cites a postulate which he deems favours his contention. On page 709 he writes, "Whereas the doctor and nurse are inevitably in positions of authority, the psychologist is not so. He is not required, nor is it necessary, for him ever to give orders to the patient or to anybody else. His advice may often be sought, but he never assumes authority. This often provides opportunities for the patient to work out his problems when he needs some non-authoritarian figure to consult."

A doctor and a nurse, working in a ward, are responsible: they are not authoritarian. It is a medical adage that clinicians and nurses who look after patients, and specialists who practise a particular technique—as for instance psychotherapy—should be held directly responsible for the care and treatment they provide. Dr. Hetherington's identification of an age-honoured tenet of responsibility with authoritarianism provides him with an untenable postulate; and the consequent standpoint, as to the function of doctor and nurse, is founded on such a false premise as to render his contention, so far as this aspect of the argument is concerned, *eo facto*, invalid.—I am, etc.,

London, W.1.

MURDO MACKENZIE.

Prefrontal Leucotomy

SIR.—Will you allow me some comments on the article on prefrontal leucotomy by Drs. A. Elithorn and E. Slater (*Journal*, September 29, p. 739) and also on your annotation on that subject (p. 760)? My experience is based on personal observations on some 230 cases on whom I carried out—I hope you will forgive the term for want of a better one—psycho-surgical operations. Unlike the series described by Elithorn and Slater, the vast majority of our cases were certified chronic psychotics. The material is now undergoing analysis, but I can support wholeheartedly the statements made by the two above-mentioned authors. To speak, in the case of chronic psychotics with "disintegrated" or "dilapidated" personalities, of undesirable post-operative changes shows that those who say so do not appreciate the extent of the problem as it exists in our mental hospitals. To speak of exaggerated fear of the operation reflects merely the fact that the procedure has not been adequately explained to either the patients or the relatives, and is more often than not based on rumour. It rarely takes more than two or three days for any one patient to recover from the immediate post-operative effects, which are no different from any other minor surgical procedure.

There appears to exist amongst many doctors the belief that a violation of the integrity of the skin must cause serious damage; they forget that procedures such as electro-convulsive therapy also have their effects on tissues, which I have been able to inspect and trace over months and years with the E.E.G. machine. The "personality defects" so often described are, I am sure, frequently due to inadequate rehabilitation or re-education: after many years of institutional certified life it is surely expecting too much that the patient should, when returned home early after the operation, behave with perfect manners. In our experience at this hospital it is not unknown to find that a stable state in which there are no further mental changes, favourable or

unfavourable, is not needed until 18–24 months after operation.

Finally, one word about your annotation. It is my impression that leucotomy and kindred operations should be advised and carried out in the light of a careful selection of the cases and that each operation should be fitted to the case. A fair range of modifications has now been practised and associated adequately with individual needs. This attitude, I venture to suggest, would be a better one than to consider leucotomy a last straw when everything else has failed; the duration of the illness and any other treatment the patient has had during his illness has a marked effect on the prognosis. The very fact that other means of physical treatment have failed makes it doubtful that the last straw will prove to be a life-saver. I believe it was Dr. Slater himself who stated at a meeting on leucotomies at the Royal Society of Medicine that the proper diagnosis and selection of each case should determine therapy rather than try each method in turn and leucotomy last.—I am, etc.,

Colchester.

S. L. SHERWOOD.

SIR.—I do not want to add fuel to the controversy for or against leucotomy. The article by Drs. Alick Elithorn and Eliot Slater (*Journal*, September 29, p. 739) gives a very practical approach to the assessment of results, though it might be asked whether leucotomized patients and relieved relatives would show penetrating judgment. It seems to me that part of the doubt in the minds of the critics is due to the frank difference in approach between psychiatrists interested in "depth" psychology and psychiatrists studying the more widespread field of symptoms. The annotation on response to leucotomy (p. 760) is a case in point, though admittedly what is quoted has a special reference. It is stated: "Many neurotic illnesses turn out to be atypical depressions . . . and most neurotic illnesses have high remission rates whatever the type of treatment given." This last may be statistically true, but could well imply an attitude which overlooks the individuality of the patient.

Is it really suggested that with any given case of neurosis a competent therapist could equally well use long-term analysis, hypnosis, support and sedation, relaxation exercises, or a variety of physical methods? Perhaps not, but the implication to the general reader might be that it does not much matter. Equally, because the majority may tend towards self-cure—which after all is a tendency noted in many illnesses—is there no importance in trying to assess which patients are liable to become chronic? Certainly the bane of the therapist's life is to be constantly receiving cases which should have been treated years back, before the situation is complicated by secondary elaborations and ingrained psychosomatic disturbances, which may even have led to operation. By that it is not implied that all such would have been curable.

To my mind there is no doubt that in certain cases prefrontal leucotomy offers far the best chance. But the expert in leucotomy may fail to understand the point of his critics, because he is not primarily interested in the quality of human experience. As leucotomy so often is only resorted to in order to save a psychiatric disaster, the pros and cons are perhaps better argued in each special case, rather than as a matter of principle. Nevertheless, it is fundamentally slipshod not to face the philosophical implications involved, in what is, at least potentially, a maiming of the personality. Lastly, if it is really true that most neurosis tends toward recovery, why is such satisfaction still felt at the early treatment of war neurosis, often largely by physical means, in the second world war, compared with the more delayed treatment in the first world war?—I am, etc.,

London, W.1.

ALAN MASON.

SIR.—The paper by Drs. A. Elithorn and E. Slater (*Journal*, September 29, p. 739) and your annotation (p. 760) show the very doubtful results to which some statistical approaches in psychiatry can lead. A brain operation of ill-defined physiological and psychological effect is carried out on 103 patients who suffer from a diversity of symptoms such as intractable

pain, inability to bear tinnitus or involuntary movements, anxiety states, depression, and schizophrenia. Some patients are apparently mentally healthy, others obviously mentally ill to a varying degree. They are all lumped together, and the opinions of patients who feel that they are better or worse after the operation, and the opinions of relatives, are given *en bloc*. Then the authors, and you in your annotation, come to certain conclusions on the basis of those findings.

The many questions that such an investigation must arouse are not answered, nay, they are not even asked. What do mentally healthy and mentally sick people mean by, "I have or have not noticed a change in my personality"? To what extent has the pro-leucotomy attitude of the physicians influenced the answers of the patients and of the relatives? What do we know of the family setting of the 103 patients, of the attitudes of the relatives to the patients? What values and meanings are attached to the relatives' statements that the patient is or is not better? We all know that there are some patients who demand and some who apparently benefit for a while from punitive measures of a social, medicinal, or surgical kind. How far have such traits influenced the result of the investigation? Little doubt, there will be patients who feel better after leucotomy. Many patients say they feel better after taking valerian mixtures. Neither statement adds to our understanding of the patient, the illness, or the therapeutic procedure, except in the very crudest pragmatic sense.

Any views whatsoever on the hotch-potch of opinions on superficial label diagnoses with which we are presented can hardly be called an empirical approach to leucotomy, as you call it in your annotation. All we have really learned is that some people who thought they were a nuisance to themselves, who probably were a nuisance to their doctors, and who were a nuisance to their relatives, think now that they are either less or more of a nuisance to themselves, and some of the relatives do or do not think on similar lines. An operation that might be defensible in a moribund patient in intractable pain might not be desirable at all in patients to whom we attach the label of "chronic anxiety or tension state," a label that is hardly more of a fundamental medical diagnosis than "chronic pyrexia." Maybe we are not able yet to formulate our psychiatric diagnoses better. But then we cannot usefully evaluate statistically groups of patients under that heading any more than we could evaluate treatment methods for groups of patients under the headings of "fever," "cough," or "headache."

Any method of treatment which might alleviate human suffering and reëstablish health deserves to be studied without bias. The opinion of the patient on the effect of treatment is of vital importance, and the opinion of a relative may be of value in this connexion, too. But the patient must know what we are talking about, and we must understand what the patient is talking about. To draw conclusions from the opinions of an undifferentiated mixture of mentally healthy and mentally disturbed patients, without distinction and without investigating what exactly the questions and answers mean to the patient, can hardly throw any light on the value of leucotomy or on our conceptions of mental illness or mental processes. Such pseudo-scientific and pseudo-statistical studies, under whatever aegis they may be issued, will certainly not "stop scare stories about this operation" (your annotation), and can hardly give confidence to doctors or patients.—I am, etc.,

Southall, Middlesex.

M. B. CLYNE.

Medical Evidence at Inquests

SIR,—Dr. W. Maxwell Penny (*Journal*, September 29, p. 767) does not appear to have much confidence in the pathologists in the county of Kent, nor does he appear to think coroners are interested in obtaining a precise and exact cause of death in cases submitted to them. As a county coroner, to whom 800-odd cases per annum are reported, I am of the opinion that a coroner's certificate based upon a pathologist's report is of much more value to the Registrar-General than the average death certificate.

May I take this opportunity of putting on record that I always receive a great deal of willing co-operation from every pathologist I call upon, and I am quite certain this is true of the coroners in the county of Kent? Furthermore, I would suggest that Dr. F. M. Rose (*Journal*, August 11, p. 356) acquaint himself with the facts before he writes about coroners being unwilling to obtain and/or pay for reports, etc., from general practitioners and house officers. By far the majority of coroners—if not all—are reimbursed for all witness expenses paid by them; many coroners are in fact provided with an imprest account for such expenses. It is, of course, the general custom of a coroner to acquaint himself with information from all sources, and he is only too willing to hear the point of view of the general practitioner—that is, if he has something material to say. Whether he can pay for such information or not depends on the schedule issued by the county or borough authority—not on the personal inclination of the coroner.—I am, etc.,

East Grinstead, Sussex.

A. C. SOMMERVILLE.

SIR,—I read with some surprise the experiences of your correspondent Dr. W. Maxwell Penny (*Journal*, September 29, pp. 767) with regard to coroners' necropsies. In view of recent trends in forensic pathology, I felt it necessary to make inquiries into the circumstances of the cases and found that, in fact, the later two incidents took place some 20 years ago. One can only hope that Dr. Maxwell Penny's more recent experiences have been less unhappy.—I am, etc.,

London, W 1.

FRANCIS CAMPS.

Doctors in Hungary

SIR,—During the past two and a half months I have spent a total of seven weeks investigating political, social, and economic developments in Hungary. On the evening of September 26 Mr. Marosan, a deputy Prime Minister of the Hungarian Parliament, drew my attention to an item of medical news in your September 8 issue headed "Doctors in Hungary" (p. 611).

It said that professionally educated persons in Hungary who prior to the present regime elected private practice rather than Government employment, were now reduced to a status of extreme poverty and many of them are literally starving to death. The fact is that every doctor receives a salary from the State. He may then increase his income in a number of ways, such as an appointment to a hospital, clinic, or factory. But by far the most lucrative way is to establish a private practice. The number of people able to obtain a doctor's services through the national insurance scheme has increased from approximately 1 million before the war to 5 million. The rest of the population requires doctors' services in a private capacity. A doctor in Hungary is not only able to work privately but in any case has a basic State salary. It is true to say that doctors are among the most highly paid, and, indeed, in our hotel (the best in Hungary) more than half of the Hungarian residents were in the medical profession. Should a student doctor, having qualified, decide to do intensive research in order to become a specialist later on, he may well take no other job and live on the State salary. He would not live well in making the same sacrifices as are made by similar-minded students in any country in the world. But nobody starves in Hungary, and my family and I saw no sign of poverty.

Incidentally, we have good reason to know something of Hungarian health services. One of my sons was ill in our hotel and was seen by three doctors on holiday there and two local doctors. My youngest son was taken to a hospital seriously ill. There are 20 doctors in the hospital, all receiving a State salary. Before the present regime only five of the twenty were paid.

I am assured by the professor who attended my son that no longer do young doctors have to take jobs as bus conductors through lack of remunerative professional practice. Maybe the case-history mentioned in the article is dated pre-1939.—I am, etc.,

House of Commons.

RON LEDGER, M.P.

Obituary

Dr. J. L. KYDD died in Glasgow on September 13 at the age of 55. James Lowdon Kydd was born at Falkirk on July 16, 1901, and was educated at Stirling and Wishaw High School, before proceeding to Glasgow University, where he graduated M.B., Ch.B. in 1926. After a short time in Newcastle and Wales, he went to Easington, County Durham, in 1928, where he married and remained as an assistant until 1931. At the beginning of that year he returned to Scotland, to Bellshill, where he succeeded to the practice of Dr. J. H. Clifford, and began what was to be a quarter of a century of hard, unremitting work. The early years were marred by trade recession and bad times in the district, rendering his task a difficult and uphill struggle. In the late 'thirties conditions improved, but, as if fate were against him, he and his whole family contracted scarlet fever, and this severe illness affected his heart. On return to work he found that he could no longer carry on alone. To his first assistant, who stayed with him for nearly three years, Dr. Kydd's devotion to his patients became more and more obvious. Nothing that was for their welfare was too much trouble, and at this time too he instituted and built up a very fine electrotherapeutic practice, which he ran in conjunction with the ordinary every-day work of his general practice. When the second world war came along he became senior medical officer of the first-aid service in the area and also medical officer to the Home Guard. This extra work entailed many sleepless nights and worry, and there is no doubt that it told on his health. After the war he was appointed factory doctor for the Bellshill area, and he also became active in the Lanarkshire Division of the British Medical Association, of which he was chairman in 1944-5. In the last three years his health had not been good, and latterly it required a great effort of mind and body to overcome his disability so that he might continue to help and treat his patients. Indeed, at times he was so ill that those who knew him best marvelled that he was able to go out at all. Only his great determination and strength of purpose kept him alive, because he refused to ease the strain on himself. In the end his death was sudden and came as a great shock to all his patients and friends. He is survived by his wife and four children, to whom our deepest sympathy is extended in their great loss.—A. Y.

The tragic death on September 19 of Dr. D. R. SYRED, after a short illness, has come as a shock to his medical colleagues. He was 41 years of age. Deryck Ralph Syred was born at High Wycombe on September 4, 1915, and was educated at Caterham and at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1940. With just over a year's hospital experience, he joined the R.N.V.R. in July, 1941. His active service was only too short. His destroyer was torpedoed in the second battle of the Java Sea, and after 24 hours in the water he was picked up by the Japanese, in whose hands he remained as prisoner of war for three and a half years. His native ingenuity was severely taxed to improvise and extend his miserable medical supplies to the utmost benefit of his fellow prisoners. Close contact has been maintained with a number of the survivors of those years, and his good work under difficult circumstances earned a mention in dispatches in 1946. On discharge from the Navy he trained in radiology at the Middlesex Hospital, obtaining his D.M.R.D. in 1948. Dr. Syred then went to Northampton as senior registrar, and since 1951 had held a consultant radiodiagnostic appointment with the Northampton and Kettering Hospital Groups. His work was characterized by diligent application to detail, and careful questioning appraisal of the clinical problems presented. His prisoner-of-war experiences had left their mark, but his assurance and confidence were gradually restored, reflecting the increasing respect shown for his opinion. His main outside interest was sailing, with swimming as a necessary

associated accomplishment. Withal we shall remember him for his sincerity, his hard work, his quiet charm, and occasional more boisterous outbursts of laughter, and we deeply regret his untimely death. He leaves a widow, two sons, and a daughter, to whom we extend our heartfelt sympathy.—G. H.

Dr. WILLIAM CUTHBERTSON died on September 19 at his home at Leyton, after a long and tedious illness. He was 59 years of age. William Cuthbertson was born on June 17, 1897, and studied medicine at Glasgow University, graduating M.B., Ch.B. in 1924. He entered into partnership with a fellow Scot in 1927, and conducted a very busy general practice in the Walthamstow, Leyton, and Woodford districts, running the practice single-handed during the second world war. He leaves a widow, a son, who is a final-year medical student, and a daughter.

Dr. N. A. THORNE writes: William Cuthbertson was a practising Christian and a good man in the true sense of the word. As one who had known him for almost thirty years, both as a patient and then as a colleague, I am certain that he will be truly missed. His patients have lost a tireless friend and comforter, as well as a most competent general practitioner. He always put his duty to his patients before his personal convenience. His special interest was in children, and for many years he acted as honorary physician to the Walthamstow Child Welfare Society, doing pioneer work in the days when the public health service was less highly organized than it is now.

By the death of Dr. D. W. A. BULL on September 24 Stony Stratford, Buckinghamshire, has lost a prominent townsman and a highly respected medical practitioner. He was 76 years of age. Douglas William Anderson Bull was born at Stony Stratford on April 7, 1880, the son of Dr. W. H. Bull, and was educated at the old St. Paul's College, Stony Stratford, and Lancing College. He then went on to Gonville and Caius College, Cambridge, receiving his clinical training at St. George's Hospital. He qualified M.R.C.S., L.R.C.P. in 1906, obtaining the degrees of M.B., B.Chir. two years later, and proceeding to the M.D. in 1915. After qualification he held a number of house appointments at St. George's before joining his father in practice. After the death of his father in 1921 he was joined in the practice by two other doctors, and was senior partner until he retired in 1950. From 1919 until last year he was medical officer of health for the Wolverton Urban District Council, and for some time he was a member of the Bucks County Panel Committee. Appointed a justice of the peace in 1924, he was chairman of the Stony Stratford Bench from 1945 until last year. His great interest was in the work of the St. John Ambulance Brigade, an interest encouraged by his father, who inaugurated the movement in Stony Stratford in 1886. For many years he was a lecturer and an examiner, and he coached the Wolverton Railway Carriage Works team which won the Railway Shield and the Dewar Shield on many occasions. In 1937 his team won a competition in which Dominion teams took part, the Wolverton team having the honour to be in Westminster Abbey at the coronation of King George VI. For his services to the St. John Ambulance Brigade he was appointed a commander of the Venerable Order of St. John of Jerusalem. A keen sportsman, he represented his college at tennis, hockey, cricket, and football, and he played tennis for Buckinghamshire for several years. He married Miss Eileen Waddell in 1909, and she survives him with one son, now consultant radiologist at St. George's Hospital, and one daughter, who is the wife of Dr. J. S. Minett.

Dr. L. M. V. MITCHELL, formerly honorary physician and bacteriologist to the Royal Northern Infirmary, Inverness, died suddenly at his home at Inverness on September 28 at the age of 69. Lachlan Martin Victor Mitchell was born on March 24, 1887, and was educated at Edinburgh University, where he graduated M.B., Ch.B. in 1909. After

graduation he settled in practice at Inverness, becoming also medical officer to the burgh tuberculosis dispensary and assistant surgeon at the Royal Northern Infirmary. Shortly before the outbreak of the first world war in 1914 he was appointed medical superintendent of Inverness Infectious Diseases Hospital. During the war he served as a captain in the R.A.M.C. with the 1/1 Highland Mounted Brigade Field Ambulance, and later attained the rank of major. For his war services he was appointed O.B.E. in 1919. On return to civilian life he obtained the Aberdeen D.P.H. with honours in 1920, and then became bacteriologist to the Royal Northern Infirmary. A member of the British Medical Association for forty-four years, he was chairman of the Inverness Division from 1926 to 1928 and again in 1933-4, and president of the Northern Counties of Scotland Branch from 1949 to 1951. He leaves a widow.

Dr. J. RONALD writes: I would like to pay personal tribute to the late Dr. L. M. V. Mitchell, whose passing has deprived the Highlands of a physician of exceptional quality. "Dean of the Faculty" in the north, and a man of great personality and variety of gifts, he used his talents well and generously, combining innate kindness with knowledge and wisdom. Widely travelled, cultured, and uncompromisingly honest, he had an analytical mind and an intellectual curiosity which rendered his opinion of the utmost value to patients, colleagues, and friends. His shrewd clarity of expression had something in common with Voltaire's crispness and the irony of Anatole France, but was illumined and warmed by a very human, and sometimes Rabelaisian, humour. Though gifted and accomplished, he was yet gentle and tender; the wealth of kindness he gave to his fellows can never be fully known, but will never be forgotten. Warm-hearted and courageous, loving and loved, he was indeed *fortunae majoris honos, erectus et acer*.

Medico-Legal

MEDICAL EVIDENCE ON APPEAL

[FROM A CORRESPONDENT]

In a recent case in the Court of Criminal Appeal a man convicted of murder was acquitted on admission of new medical evidence. Apart from its considerable medico-legal importance, the case has raised a number of issues of far wider general interest.

At first sight the facts are simple enough. The victim was stabbed in the stomach during a fight in a café in Hull. He was taken at once to hospital, where an operation was performed, and after eight days died with bronchopneumonia. The man who attacked him was charged with murder and found guilty. After this trial, however, one of the doctors who had observed the victim's treatment in hospital said that in his opinion death would not have occurred if certain errors in treatment had not been made. On the strength of this evidence an appeal was allowed. The defence then sought to prove that death was in fact the result not of the original injury but of two errors in treatment—the incorrect use of oxytetracycline and the administration of excessive quantities of fluid. Two expert medical witnesses supported the defence. The appeal was allowed and the conviction quashed.¹ As a result of the suggestion that the patient had not been correctly treated in hospital, Leeds Regional Hospital Board set up a committee of inquiry, which included three independent medical assessors. They reported unanimously that they had no fault to find with the patient's treatment, which they in fact described as devoted and exemplary.²

So we are faced with two flatly contradictory views of the case. A conflict of medical evidence is nothing new, but in this case the differences between the experts are peculiarly subtle. No one would deny that death from fulminating

enteritis may occur after abdominal operations, especially though not uniquely following the use of broad-spectrum antibiotics, or that patients can be killed by administration of excessive amounts of fluid as well as by dehydration. Either of these treatments could have caused death, but the evidence that they in fact did so is by no means complete. There was apparently no evidence of infection by drug-resistant staphylococci, such as would be expected if oxytetracycline had really been responsible. Nor was there any oedema of the lungs or other evidence of overhydration such as would have been expected if excessive amounts of fluid had been given. So from the purely medical point of view the cause of the victim's death remains obscure.

But the fact remains that the victim was stabbed with a knife—and if he had not been stabbed he would probably still be alive. If an intention to kill could be inferred from the nature of the weapon and the wound, then the original charge of murder was right, as would have been a charge of attempted murder if the victim had survived. If the wound had been trivial or if it could be shown that there was no deliberate intention to kill, then the right charge was one of manslaughter, and the original conviction for murder was wrong. Common sense suggests that the rightness or wrongness of the original verdict should be treated on its own merits, and the question whether the medical treatment was right or wrong does not enter into it. The appeal, however, was allowed, apparently on the ground that if the evidence submitted later about the medical treatment had been available at the first trial the jury might not have been satisfied that death was due to the stab wound, and might have brought in a different verdict. If there had been any likelihood of that happening, then since a second trial was out of the question the appeal had to be allowed. But was there any likelihood of that happening? It is hard to see why technical arguments about the correctness of the medical treatment should have in any way affected the case for or against regarding the crime as murder.

Criticism of the treatment the patient received in hospital was a necessary corollary to the successful appeal. The appeal was allowed only because it was possible to argue that death was due not to the wound itself but to complications caused by incorrect treatment. This is especially unfortunate, since there can be little doubt that a great deal of care was devoted to the patient's treatment. The whole case leaves us with a feeling of confusion and incompleteness. We may perhaps have heard the truth and nothing but the truth, but where lies the whole truth?

THE SEXUAL OFFENCES ACT, 1956

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The statute law of England has grown piecemeal since Angevin times into a luxuriant jungle which is nearly as daunting to lawyer as it is to layman. Into this jungle light is being gradually admitted by the devoted efforts of the parliamentary draftsmen charged with the consolidation of the law into more logical and compendious statutory form.

A good example of the process is to be found in the Sexual Offences Act, 1956, which will come into force on January 1, 1957. According to its "long title" this is an Act to consolidate with corrections and improvements the statute law of England and Wales relating to sexual crimes, to the abduction, procurement, and prostitution of women and to "kindred offences," and to make the necessary consequential alterations to existing statutes. The object of the exercise is not to alter the law but to streamline it and make it readily accessible.

The numerous offences with which the consolidating statute deals are culled from some 16 statutes beginning with the Offences Against the Person Act, 1861. Six statutes are involved in consequential alterations. The second schedule to the Act consists of a table of the offences dealt with, showing how they are prosecuted and what penalties and alternative verdicts are available; this runs to 36 separate

items ranging from rape to the crime of tenants permitting premises to be used for prostitution. An attempt to commit most of these offences is an offence in itself, sometimes involving different prosecution procedures and always different penalties. The provisions enabling a landlord to get rid of a tenant who has been convicted of using the premises let to him as a brothel involve cross-referencing the Act with the flourishing thicket of the law of landlord and tenant.

Doctors should find it easier as a result of the new Act to find out what the law on sexual offences really is. When its reform has been achieved the statutory thicket, now neatly pruned, will at once start growing again.

Vital Statistics

Eire in Second Quarter

In Eire in the second quarter of 1956 the number of births registered was 16,840, giving a rate of 23.3 per 1,000 population, which was 0.4 above the corresponding rate last year. The number of deaths registered was 8,595, giving a rate of 11.9 per 1,000 population, and 1.4 below the rate for the second quarter of 1955. Deaths from respiratory tuberculosis numbered 155 and from other forms of tuberculosis 39; corresponding figures for last year were 198 and 38 respectively. Deaths from infectious diseases included 2 from streptococcal sore throat, 3 from diphtheria, 14 from whooping-cough, 2 from meningococcal infection, 2 from acute poliomyelitis, and 4 from measles; tetanus caused 3 deaths, rubella 2, and herpes zoster 1. The infant mortality rate was 33 per 1,000 registered births, and was 3 below the corresponding figure for last year.

Week Ending September 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 447, whooping-cough 1,765, diphtheria 8, measles 1,396, acute pneumonia 292, acute poliomyelitis 131, dysentery 457, paratyphoid fever 9, and typhoid fever 5.

Infectious Diseases

The largest rises in the notifications of infectious diseases in England and Wales during the week ending September 22 were 150 for measles, from 932 to 1,082, 69 for dysentery, from 321 to 390, and 63 for scarlet fever, from 313 to 376; the only large fall was 423 for whooping-cough, from 2,271 to 1,848.

The rise in the incidence of scarlet fever was largest in London and the south-east counties, where 64 cases were notified compared with 37 in the preceding week. The incidence of whooping-cough fell throughout the country; the largest falls were 52 in Kent, from 140 to 88, 50 in Yorkshire West Riding, from 216 to 166, and 48 in Essex, from 200 to 152. Only small changes were reported in the local returns of measles. 6 cases of diphtheria were notified, being 1 less than in the preceding week; 2 of the cases were notified from Kingston-upon-Hull C.B.

111 cases of acute poliomyelitis were notified, and these were 7 fewer for paralytic and 7 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 26 (Manchester C.B. 17, Salford C.B. 2, Stretford M.B. 2); London 13 (Kensington 2, Paddington 2, Wandsworth 2); Cheshire 8 (Stockport C.B. 4, Macclesfield R.D. 2).

The largest centres of infection of dysentery were Yorkshire West Riding 78 (Leeds C.B. 25, Sheffield C.B. 16); Lancashire 77 (Manchester C.B. 13, Blackpool C.B. 11, Liverpool C.B. 10); London 39 (Fulham 13); Surrey 35 (Esher U.D. 22); Warwickshire 26 (Coventry C.B. 17).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

² *Ibid.*, September 22, 1956, p. 716.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 22 (No. 38) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Smoke Control.—Regulations prescribing authorized fuels to be used in areas of smoke control are being prepared, and the Minister of Housing and Local Government intends to interpret strictly the section of the Clean Air Act which enables him to exempt from control methods of firing, industrial or domestic, which are either not producing any smoke or not producing a substantial quantity of smoke. Mr. ENOCH POWELL, Parliamentary Secretary of the Ministry of Housing and Local Government, said this when he addressed the National Smoke Abatement Society's conference at Southport on October 3. Although the provisions for the prevention of dark smoke, grit, and dust—provisions mainly affecting industry—would not come into force until the spring of 1958, people must not suppose that they could wait until then to do something about their problems. Neither should they assume that the seven-year period of grace allowed any general exemption from the prohibition of dark smoke during the period. It would afford only a limited defence—limited in scope and limited in time. To establish the defence it would be necessary to prove that the emission of dark smoke was due to the nature of the building or its equipment, and not to lack of maintenance or improper use, and that the necessary alterations or new equipment could not have been completed by the time the contravention occurred.

Pneumoconiosis.—A new edition of the booklet first issued in 1952 by the Ministry of Pensions and National Insurance, *Pneumoconiosis: Procedure for Claiming Benefit*, has been sent to all doctors in coalmining areas. The booklet explains what to do to help patients suffering from pneumoconiosis (including silicosis and asbestosis) to claim the benefits to which they are entitled. Doctors in England and Wales who would like a copy of this booklet should apply to the Ministry of Pensions and National Insurance, 10, John Adam Street, London, W.C.2; doctors in Scotland should apply to the Central Office for Scotland, 39, Drumsheugh Gardens, Edinburgh, 3.

Chartered Society of Physiotherapy.—The annual congress dinner of the Chartered Society of Physiotherapy was held at the Café Royal, London, on October 5, with the president of the Society, Sir CECIL WAKELEY, presiding. Sir ARTHUR PORRITT, proposing the toast of the Society, recalled Hippocrates' dictum that "a physician must be experienced in rubbing," and quoted the great man's views on the art of massage. The audience's amusement was clear enough evidence that some at least of them were not outdated. After congratulating the Society on the fact that all three fighting Services had now adopted the Society's training as the standard for their physiotherapists, Sir Arthur spoke of the relationship of doctor and physiotherapist. Both were members of a team, he said. It was the doctor's legal, ethical, and moral right to be captain, but the doctor would be quite useless without the team, in whose skill he trusted completely. It seemed to the speaker unnecessary therefore to squabble over precise definitions of status. The profession of physiotherapy had other more important things to think of and one of them was research. Miss PEGGY BARRON, vice-chairman of the Chartered Society, responded, and the toast of the guests, proposed by Sir CECIL WAKELEY, was wittily replied to by the principal guest of the evening, Air Marshal Sir JAMES KILPATRICK. The Founders Lecture, given the following day by Sir RUSSELL BRAIN, P.R.C.P., brought to a close a full three-day programme of lectures and demonstrations.

Cathedral Service for Disabled.—The Provost of Southwark, The Very Reverend H. E. ASHDOWN, has co-operated with the Disabled Persons' Choral and Musical Society (Harrow) to enable them to hold for the first time a special service for disabled persons at Southwark Cathedral on Sunday, November 11, at 6.30 p.m. The Provost will

conduct the service and the choir taking part will be composed entirely of disabled persons, who after the service will give a programme of songs in the Chapter House lasting half an hour. Those wishing to attend should communicate before November 1 with Miss ROSE TAAFFE, 57, Grant Road, Wealdstone, Middlesex.

Medical Research Council Members.—The Committee of Privy Council for Medical Research, after consultation with the Medical Research Council and the President of the Royal Society, has appointed as members of the M.R.C. Professor G. PAYLING WRIGHT, Sir William Dunn professor of pathology in the University of London at Guy's Hospital Medical School, and Dr. DENIS HILL, senior lecturer in clinical neurophysiology, Maudsley Hospital, London, and physician and lecturer in psychological medicine at King's College Hospital. The committee has reappointed the Earl of LIMERICK and Sir GEOFFREY VICKERS, V.C., to the Council for a further term of office.

Manchester Northern Hospital.—The Manchester Northern Hospital, which celebrates its centenary this year, as described in the *Journal* of January 7, p. 42, has published an illustrated booklet giving a brief history of the hospital and details of the work of the various departments. To mark the centenary, verandas on two of the wards have been converted into day rooms, which were officially opened by the Earl of DERBY on October 9.

Medical History.—A new quarterly journal, *Medical History*, is to be published from January next by Messrs. Wm. Dawson and Sons (4, Duke Street, Manchester Square, London, W.1). The journal will be international in scope and is intended to provide a medium for papers on all aspects of the history and bibliography of medicine and related sciences. It has already been adopted as the official organ of several medico-historical societies, both in Britain and abroad; it will be edited by Mr. W. J. Bishop, formerly Librarian of the Wellcome Historical Medical Library. Annual subscription is £2 10s. (£2 to society members).

Christmas Seals.—The National Spastics Society has produced an attractive booklet of Christmas seals for sticking on parcels and envelopes. By charging a penny per seal the society hopes to raise £350,000 to maintain its centres and to society hopes to help spastic children and adults. The open new ones to help spastic children and adults. The seals are being put on sale in different kinds of shops and are obtainable from the society at 28, Fitzroy Square, London, W.1.

Postgraduate Education at R.C.S.—A useful pamphlet describing the exceedingly varied postgraduate activities of the Royal College of Surgeons has been prepared by its deputy secretary, Mr. W. F. DAVIS, from whom further information may be obtained. The pamphlet, which is illustrated, begins with a summary history of the College and then goes on to describe the various departments for research and teaching, the scholarships offered, and the courses of instruction held.

Medical Golfing Society.—The winners at the society's autumn meeting were as follows: Canny Ryall cup, Dr. C. CARRON BROWN; Lindsay Rea cup, Dr. A. J. MAY; Creasy salver, Dr. M. J. HEALY; Milsom Rees cup, Dr. J. G. H. McNabb; Bathurst cup, Mr. NILS L. ECKHOFF and Dr. A. WINGFIELD.

COMING EVENTS

Television.—First of three television outside broadcast visits to St. Mary's Hospital, London, W.2, will take place on October 18 at 7.30 p.m.

U.C.H. Medical School.—A series of postgraduate demonstrations will be held on October 18-19, followed by the annual dinner for past and present students at 7.30 for 8 p.m., on October 19, at the Savoy Hotel, Strand. A symposium on the management of advanced malignant disease will be held on the Friday afternoon at 2.15.

St. Luke's Day Catholic Service.—Mass will be celebrated in the crypt of Westminster Cathedral on Sunday, October 21, at 8.45 a.m.

French Scientific Films.—A programme of French scientific films will be held at the French Institute, Queensberry Place, London, S.W.7, on Wednesday, October 24, at 8.15 p.m. Synopses of films in English.

John Matheson Shaw Lecture.—Dr. W. FERGUSON ANDERSON will deliver the John Matheson Shaw lecture at the Royal College of Physicians of Edinburgh on November 9 at 5 p.m. His subject will be "The Care of the Elderly Sick in General Practice."

Maudsley Lecture.—Dr. JOHN R. REES, Director, World Federation for Mental Health, will deliver the thirty-first Maudsley lecture at the Royal Society of Medicine, 1, Wimpole Street, London, W.1, on November 16 at 2.15 p.m. His subject will be "Psychiatry and Public Health."

NEW ISSUES

British Journal of Pharmacology and Chemotherapy.—The new issue (Vol. 11, No. 3) is now available. The contents include:

PHARMACOLOGICAL STUDIES ON HEMLOCK WATER DROPWORT. H. F. Grundy and F. Howarth.
THE ACTION OF ATROPINE AND HEXAMETHONIUM IN COMBINATION ON GASTRIC SECRETION AND MOTILITY. A. W. Kay and A. N. Smith.
EFFECT OF ANAESTHETICS AND HAEMORRHAGE ON THE RELEASE OF NEUROHYPOPHYSIAL ANTIDIURETIC HORMONE. Michael Ginsburg and Lucy M. Brown.
ANTIDIURETIC ACTIVITY OF POSTERIOR PITUITARY PREPARATIONS. Michael Ginsburg.
THE SPERM-SHEDDING RESPONSE OF MALE TOADS AND TREEFROGS AFTER THE INJECTION OF TWO TYPES OF GONADOTROPHIN. J. F. D. Frazer.
EXPERIMENTAL DESIGN FOR BIOASSAY OF A MATERIAL INDUCING STRONG TACHYPHYLACTIC EFFECT (ANAPHYLATOXIN). M. Rocha e Silva and A. M. Rothschild.
THE EFFECT OF ACETAZOLEAMIDE, AN INHIBITOR OF CARBONIC ANHYDRASE, ON GASTRIC SECRETION. L. Poller.
THE PHARMACOLOGY OF BENZOYLCHOLINE DERIVATIVES AND THE NATURE OF CARBONYL RECEPTORS. W. E. Ormerod.
THE MODE OF ACTION OF SOME NON-SPECIFIC ACETYLCHOLINE ANTAGONISTS. A. R. Timms.
ASSESSMENT OF DEPRESSOR ACTIVITY AND MYDRIATIC ACTIVITY OF HEXAMETHONIUM ANALOGUES. J. G. Blackman, F. N. Fastier, C. M. Patel, and L. C. K. Wong.
THE EFFECTS OF 5-HYDROXYTRYPTAMINE AND ITS ANTAGONISTS ON TIDAL AIR. H. Konzeit.
CHEMICAL REACTIVATION OF PHOSPHORYLATED HUMAN AND BOVINE TRUE CHOLINESTERASES. F. Hobbiger.
ACTION OF COMPOUND 48/80 ON THE MAST CELLS AND HISTAMINE CONTENT OF GUINEA-PIG TISSUES. I. Mota and I. Vugman.
THE SPECIFICITY OF BRAIN CHOLINE ACETYLASE. A. S. V. Burgen, G. Burke, and Marie-Louise Desbarats-Schonbaum.
THE ANTAGONISM BETWEEN 5-HYDROXYTRYPTAMINE AND CERTAIN DERIVATIVES OF LYSERGIC ACID. E. C. Savini.
ANTAGONISM BETWEEN CHLORPROMAZINE AND NORADRENALINE IN BLOOD VESSELS OF THE HANDS. Robert S. Duff and Jean Ginsburg.
OCCURRENCE OF A SUBSTANCE P-LIKE POLYPEPTIDE IN FISH INTESTINE AND BRAIN. U. S. von Euler and E. Ostlund.
THE EFFECT OF CORTISONE ALONE AND IN COMBINATION WITH ISONIAZID ON EXPERIMENTAL MURINE LEPROSY IN MICE. M. Naguib and J. M. Robson.
TRYPANOCIDAL ACTION OF PHENANTHRIDINE COMPOUNDS: EFFECT OF CHANGING THE QUATERNARY GROUPS OF KNOWN TRYPANOCIDES. G. Woolfe.
TRYPANOCIDAL ACTION OF PHENANTHRIDINE COMPOUNDS: FURTHER 2:7-DIAMINO PHENANTHRIDINIUM COMPOUNDS. G. Woolfe.
SOME ACTIONS OF CHLORPROMAZINE. R. W. Ryall.
THE EFFECT ON RESPIRATION OF INFUSIONS OF ADRENALINE AND NORADRENALINE INTO THE CAROTID AND VERTEBRAL ARTERIES IN MAN. D. R. Coles, F. Duff, W. H. T. Shepherd, and R. F. Whelan.

Issued quarterly; annual subscription £4 4s.; single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Thorax.—The new issue (Vol. 11, No. 3) is now available. The contents include:

PERCUTANEOUS LEFT VENTRICULAR PUNCTURE IN THE ASSESSMENT OF AORTIC STENOSIS. Sir Russell Brock, B. B. Milstein, and D. N. Ross.
AN INVESTIGATION INTO THE LYMPHATIC AND VASCULAR SPREAD OF CARCINOMA OF THE BRONCHUS. H. C. Nohl.
THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS IN CHILDHOOD AND ADOLESCENCE. D. W. Huish.
BASAL PLOMBAGE. J. K. Clarendon and W. P. Cleland.
MULTIPLE SPUTUM CULTURES IN THE ASSESSMENT OF PULMONARY TUBERCULOSIS. D. R. Hay.
SUBPHRENIC ABSCESS. Geoffrey H. Wooler.
THE DIRECT INTERPRETATION OF THE FAST VITAL CAPACITY RECORD. R. J. Shephard.
RHEUMATOID ARTHRITIS WITH LUNG LESIONS. T. M. L. Price and M. O. Skelton.
THE RADIO-THERAPEUTIC AND RADIOLOGICAL ASPECTS OF RADIATION FIBROSIS OF THE LUNGS. William M. Ross.
ACQUIRED AND CONGENITAL OESOPHAGO-BRONCHIAL FISTULAS. A. Duprez, F. Wittek, and A. Dumont.

Published quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, October 15

- HUNTERIAN SOCIETY.—At Talbot Restaurant, E.C., 7 for 7.30 p.m., dinner meeting. 8.30 p.m., Presidential Address by Dr. C. D. Coyle: The Changing Hospital.
- MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. J. L. Moreno: Psycho-drama and Sociometry.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. I. C. Gilliland: Exophthalmos.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. B. N. Brooke: Colitis; 6.30 p.m., Professor B. W. Windeyer: Malignant Tumours of Bone.

Tuesday, October 16

- BRISTOL UNIVERSITY.—At Wills Physics Building, 8.15 p.m., 45th Long Fox Memorial Lecture by Dr. A. M. MacLachlan: A Doctor's Visit to the U.S.S.R.
- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. K. M. Smith, D.Sc., F.R.S.: Electron Microscope in the Study of Viruses.
- ILFORD MEDICAL SOCIETY.—At King George Hospital, 8.45 p.m., Dr. Horace Joules: Air Pollution and Prevention of Chest Diseases (with film). Members of Stratford Division, B.M.A., are invited.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. J. M. P. Clark: Treatment of Poliomyelitis; 6.30 p.m., Mr. J. P. Hosford: Cholelithiasis.
- ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. J. Suchet: Appraisal of the Results of Treatment of Infertility.
- SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Dr. J. Tudor Lewis: Prevention of Poliomyelitis.
- WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. N. G. Hulbert: neurological demonstration.

Wednesday, October 17

- BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At Charing Cross Hospital Medical School, 5.30 p.m., Mr. K. S. Duncan: A Layman Looks at Athletics.
- EUGENICS SOCIETY.—At Royal Society, 5.30 p.m., symposium: Artificial Insemination (Donor). Speakers: Dr. Margaret C. N. Jackson, Dr. P. M. Bloom, Dr. C. P. Blacker, Dr. A. S. Parkes, Sc.D., F.R.S., and Mr. Cecil Binney, M.A.
- GLASGOW OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.—At Royal Faculty of Physicians and Surgeons of Glasgow, 5 p.m., William Smellie Memorial Lecture by Professor S. J. Cameron.
- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. S. Pegum: Hair Growth.
- INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. R. W. Riddell: Fungus Infections of the Lung.
- INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. Harland Rees: Differential Diagnosis of Frequency of Micturition.
- LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Middlesex Hospital Medical School, 8 p.m., Mr. T. Holmes Sellors: Surgery in Diseases of the Lung.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor A. Neuburger, F.R.S.: Proteins of Connective Tissue.
- ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Professor C. A. Wells: Conservation of Renal Function.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. Osmond-Clarke: Treatment of Osteoarthritis of the Hip Joint; 6.30 p.m., Mr. R. H. Franklin: Non-malignant Conditions of the Oesophagus.
- ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3 p.m., Bengué Memorial Award Lecture by Dr. Peter M. F. Bishop: The Problem of Obesity.
- ROYAL MICROSCOPICAL SOCIETY.—5.30 p.m., Dr. R. Barer: Further Developments in Quantitative Microscopy.
- WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, 8.45 p.m., Dr. Freida Young: The Haemorrhagic Diseases and Coagulation Defects.

Thursday, October 18

- BRITISH INSTITUTE OF RADIOLOGY.—7.30 p.m., special general meeting; 8 p.m., Dr. R. I. Roberts: Mechanism of Pharyngeal Deglutition in the Normal; Dr. G. M. Ardran and Dr. F. H. Kemp: Swallowing Defects After Poliomyelitis.
- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. F. H. C. Crick, Ph.D.: Structure and Function of Small Viruses.
- HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., annual general meeting. Dr. W. Moodie: Planned Research in the Future of Hypnototherapy.
- LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. A. W. Howel-Evans: Tylosis and Oesophageal Cancer—A Family Study; Dr. A. H. Cruickshank: Diagnostic Difficulties in Buccal Facial Biopsy.
- LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Presidential Address by Dr. I. Gordon: Hazards of Drug Therapy.
- NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Clinical Theatre, Manchester Royal Infirmary, 5 p.m., Dr. V. Cotton-Cornwall: 1945, 1955, a Comparison.
- NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Professor J. Trueta: Study on the Aetio-pathology of Perthes' Disease.
- ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Aspects of Refraction Work—(2) Formation of the Images.
- ST. ANDREWS UNIVERSITY.—At Physiology Department, Queen's College, Dundee, 5 p.m., Professor Dorothy S. Russell: Hormonal Activities of the Pituitary in Relation to its Cytology.
- ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. J. Williams: neurology demonstration.

Friday, October 19

- BRITISH INSTITUTE OF RADIOLOGY.—3 p.m., meeting of medical members.
- FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Radiodiagnosis Section Meeting. Dr. J. Sutcliffe: Hypophosphatemia; Dr. L. J. Sandell: Congenital Insensitivity to Pain; Dr. J. W. Laws: Dissection of the Aorta as a Complication in Lumbar Aortography; Dr. M. Simon: Pulmonary Veins in Mitral Stenosis.
- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. T. Brain: Skin Diseases in Children.
- INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.
- INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. D. M. Stern: Pre-eclamptic Toxaemia.
- KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. J. P. Hosford: Experiences in Biliary Surgery; 4 p.m., Sir Stanley Davidson, P.R.C.P.: Changing Views of the Clinical Picture and Treatment of Blood Diseases.
- ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., combined meeting with Edinburgh Medico-Chirurgical Society. Discussion to be opened by Mr. K. Paterson Brown, Dr. H. Kennedy, and Mr. F. H. Roberts: Abdominal Emergencies.

Saturday, October 20

- WEST MIDLANDS PHYSICIANS' ASSOCIATION.—At Dudley Road Hospital, Birmingham, 10.45 a.m., autumn meeting.

APPOINTMENTS

- HYND, ROBERT STEWART, M.B., Ch.B., D.P.H., Divisional Medical Officer (South Hertfordshire Division), Hertfordshire County Council.
- NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—A. M. Jelliffe, M.D., F.F.R., M.R.C.P., D.C.H., D.M.R.T., Consultant Radiotherapist, Middlesex Hospital and Mount Vernon Hospital (joint appointment with Board of Governors of Middlesex Hospital); S. Catterall, M.D., D.P.M., Consultant Psychiatrist and Deputy Medical Superintendent, Hill End Hospital; S. Mattingly, M.B., B.S., M.R.C.P., D.Phys.Med., Consultant in Physical Medicine, Mid-Herts and Luton and Hitchin Groups and Garston Manor Rehabilitation Centre; T. O. Garland, M.D., D.P.H., Consultant Physician to organize and develop a Department of Industrial Medicine based on Central Middlesex Hospital; D. M. Foubister, M.B., Ch.B., F.F.Hom., D.C.H., and W. T. Walker, M.D., F.F.Hom., Consultant Homoeopathic Physicians, Royal London Homoeopathic Hospital; I. Sutton, M.D., D.P.M., Consultant Psychiatrist and Superintendent, Friern Hospital; A. de B. Joyce, M.B., B.Ch., D.O.M.S., Ophthalmologist (S.H.M.O.), Nottingham School Treatment Centre; G. E. B. Scott, M.R.C.S., L.R.C.P., D.P.M., Assistant Psychiatrist (S.H.M.O.), Cell Barnes Hospital, including duties of Deputy Medical Superintendent.
- SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—M. G. Thorne, M.D., M.R.C.P., Consultant Physician, Torbay Hospital, Torquay; Brenda Grant, M.B., Ch.B., Registrar in Psychiatry at Bristol Mental Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Camac.—On September 20, 1956, at Burton Nursing Institution, to Joyce (formerly Swift), wife of Dr. J. C. Camac, a daughter—Ailsa.
- Craig.—On October 2, 1956, at Southmead Hospital, Bristol, to Jean (formerly Simpson), wife of Dr. R. A. Craig, a daughter.
- Donohoe.—On September 29, 1956, at the Maternity Hospital, Loveday Street, Birmingham, to Dr. Ursula Donohoe (formerly Wilkin), wife of Dr. T. W. G. Donohoe, a third daughter—Rosemary Ailsa.
- Fleischl.—On September 11, 1956, at Napier, New Zealand, to Charmian (formerly Quinton), M.B., B.S., wife of Peter Fleischl, M.B., M.R.C.P., M.R.A.C.P., a daughter.
- Hirst.—On September 25, 1956, in Trinidad, British West Indies, to Anne (formerly Jordan), M.B., B.S., wife of Major David Hirst, a son—David Richard Jordan.
- Mann.—On September 28, 1956, at Aberdeen Maternity Hospital, to Dr. and Mrs. A. B. Mann, of 458, King Street, Aberdeen, a daughter.
- West.—On September 27, 1956, at the General Hospital, Sault Ste. Marie, Ontario, Canada, to Kathleen (formerly Stanhope), wife of Michael H. West, M.D., M.R.C.P., of 125, Simpson Street, Sault Ste. Marie, a daughter.

DEATHS

- Chapman.—On September 14, 1956, at his home, Trederwyn, Heatherdune Road, Bexhill, Sussex, Philip Francis Chapman, C.I.E., M.B., C.M., Colonel, I.M.S., retired, late of Fanans, Taynuilt, Argyllshire, aged 86.
- Edwards.—On September 21, 1956, Dennis Raymond Edwards, M.B., Ch.B., of 47, English Coombe Lane, Bath, Somerset, formerly of Darlington, Co. Durham.
- Gotelee.—On September 21, 1956, at his home, "Chalcots," Fleet, Hants, Hugh Evelyn Gotelee, M.R.C.S., L.R.C.P., D.P.H., aged 74.
- Hutchesson.—On September 23, 1956, at Pinetrees, Braidley Road, Bournemouth, Hants, David Albert Hutchesson, M.D., D.P.H., formerly of Aberdeen.
- Kydd.—On September 13, 1956, at Victoria Infirmary Annexe, Glasgow, James Lowdon Kydd, M.B., Ch.B., of Bellshill, aged 55.
- Langhorne.—On September 20, 1956, at his home, Burfield, Bosham, near Chichester, Sussex, Douglas Alfred Langhorne, M.B.E., T.D., F.R.C.S.Ed., aged 51.
- Mathieson.—On September 21, 1956, in a nursing-home, Dumfries, Alexander Lewis Mathieson, M.B., C.M., late of Viewmount, Moffat, Dumfriesshire.
- Murray.—On September 20, 1956, at Raigmore Hospital, Inverness, Andrew Rowand Murray, M.B., Ch.B., of The Anchorage, Bruchladdich, Isle of Islay, Argyll.
- Romanes.—On September 9, 1956, at Noys End, Brockham Green, Betchworth, Surrey, Jean Lauderdale Romanes, M.B., B.S., aged 34.
- Worger.—On September 20, 1956, at Suva, Fiji Islands, William Worger, M.R.C.S., L.R.C.P., late of Radstock and Burnham, Somerset, aged 67.
- Yavagal.—On September 9, 1956, Shivalingappa Shivappa Yavagal, M.B., B.S.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Pica in a Child

Q.—What are the causes of pica in children? How should an intelligent and apparently happy girl of 8 be managed who has been eating dirt and earth from the garden all her life? When indoors she will even scrape the bottoms of shoes to satisfy her appetite. The home is good, the mother understanding, and the child does well at school and seems free from anxiety.

A.—It is an unusual problem that an intelligent and happy girl of 8 years should be so persistently wanting to eat dirt. Tradition has it that this condition often goes with worms, but, as intestinal worms are such a common infestation, it is difficult to know whether the connexion is real or apparent. However, it would obviously be a sensible precaution, and quite a simple one, to see that no such infestation is present. It might even be helpful to take the child into hospital for a week—provided she went into a happy ward where well children are catered for and understood—to see if the habit persists, and to observe her ordinary behaviour with food, her appetite in a general sense, and her attitude towards other children. If this confirms her apparent normality, and if the habit persists in all circumstances, I would have thought it merited careful investigation from the psychological point of view at a child guidance clinic.

Perverved appetites very commonly symbolize a need for love, and are a sort of substitution for more normal gratifications. A child guidance clinic would want to know about her early habit training, about whether the normal baby's interest in excreta was present to any marked extent, how it was satisfied, and how she was helped to pass from it to other kinds of creative play with her hands. I would be surprised if such an investigation did not suggest some way of relieving the condition.

Alcoholic Excess and Mucous Colitis

Q.—After over-indulgence in spirits, a man of 40 has attacks of diarrhoea in which patches of intestinal mucous membrane are passed. How seriously should this be regarded? Is the condition due specifically to the excessive intake of alcohol, or could some other predisposing factor account for it? Short of cutting out alcohol, which would be difficult in this case, what management is advised?

A.—It seems most unlikely that patches of actual intestinal mucosa are being passed when this patient suffers from diarrhoea after heavy spirit-drinking. It is much more probable that the patches are composed of mucus, which in may occasionally be passed in sheets, as, for example, in the so-called "muco-membranous colitis." Microscopical study of the material would settle this point.

Mucus may be passed per rectum in liquid gobs or as strands or flecks of coagulated mucus which appear white or greyish. Large membranes of coagulated mucus may occasionally be passed, as mentioned above. The passage of excessive mucus, either with faeces or on its own, is commonly met with in nervous diarrhoea. It may also occur in constipated patients following the taking of a purge, and in patients who are sensitive to particular foodstuffs, and in patients with ulcerative colitis in a very mild stage. Strong alcoholic drinks damage the surface epithelium of the stomach and are very apt to cause a gastro-enteritis, so that transient diarrhoea is a fairly common feature on "the morning after the night before." The passage of mucous flecks or sheets has no special significance beyond this fact. A kaolin or bismuth mixture may be found helpful in relieving

the symptoms, although it is questionable whether a physician should acquiesce in the patient continuing to over-indulge in spirits to the extent that his gastro-intestinal tract obviously rebels. One possibility might be to put the patient in touch with Alcoholics Anonymous (BM/AAL, London, W.C.1).

Effect of Truss on Subsequent Herniorrhaphy

Q.—As an industrial medical officer I am perturbed by the long interval between the diagnosis of inguinal hernia and operation. Such patients are often recommended for light work during the whole of this waiting period and until six months after operation. Is it not possible for these men to wear a truss until operation, or does this increase the surgeon's difficulties?

A.—The wearing of a truss for long periods certainly induces local atrophy of fat and a degree of fibrosis of the muscles in the area where the pad has been pressing. In long-standing cases, therefore, this may make the operation a little more tedious and the result less certain and permanent. It would not apply, however, in cases where a truss had been worn for shorter periods of, say, six months to a year; the writer has not met with any additional difficulties in such cases and can see no reason why a truss should not be worn during the waiting period. So far as aftercare goes, if the operation has been quite straightforward and satisfactory, three months' abstention from really heavy work should be all that is needed. There will obviously be exceptions to this, especially in the case of direct herniae, and then the surgeon's knowledge of the conditions found at operation will be the best guide.

Long-distance Cycle Racing

Q.—What food is advised for a competitor in a long-distance cycle race? Are stimulants advised? The race is 150 miles (about 240 km.).

A.—In long-distance cycle racing the physiological factor limiting performance is the rate of supply of glucose, the substrate for oxidative breakdown to provide energy. If adequate supplies of glucose are available, then nervous fatigue is the ultimate limiting factor. Hence the food taken during the race should be glucose, which provides carbohydrate in the most easily assimilated form. If the amount which it is necessary to take (about a pound—0.45 kg.—spread over the second half of the race) is nauseating, then the equivalent should be taken in the form of some other carbohydrate food. Fruit juice makes the glucose mixture more palatable.

Other dangers of long-distance racing are dehydration and salt depletion, due to excessive sweating. Thirst is a safeguard against undue dehydration, but 2–3 g. of sodium chloride, as salt pills, should be taken before the race, in addition to the normal dietary intake of salt.

I am not in favour of taking stimulants during a race, because their use cannot be repeated without danger of ill effects.

Procaine Sensitivity and Heart Block

Q.—Signs of sensitivity to procaine amide have developed in a patient being treated for partial heart block. There is swelling of the right eye and irritation each time the drug is used. What should be done in this case?

A.—There are two points to be considered in this question. The first is that no anti-fibrillatory drug such as procaine amide or quinidine should be used in the treatment of heart block. There is no indication for it and the results are nearly always disastrous. The administration of quinidine or oral procaine amide will depress spontaneous rhythm and result in the onset of idioventricular rhythm. This may well take the form of ventricular tachycardia or fibrillation. In partial degrees of heart block the effect of these drugs is usually to increase the degree of block. In conditions such as bundle-branch block procaine amide may be used, but with great caution, because the heart in these

4998

A young woman was admitted on account of haematemesis and the amount of blood lost reported as having been about two pints (1.14 litres). The diagnosis on admission was gastric ulcer. Her excessive degree of drowsiness, lack of restlessness, and forceful cardiac impulse rang no warning bell in the minds of those who first saw her. A physician with a sense of smell and mental acuity undimmed by tobacco recognized uraemia as the causative disease.

My third example illustrates the danger of incomplete viewing of the body merely because the diagnosis appears to be firmly established. A middle-aged woman who had seen several practitioners and a consultant for anaemia had been treated for seven years as a case of pernicious anaemia. The somewhat unusual fluctuations of the disease in spite of liver treatment were attributed to faulty extracts. It appeared that intractable ulcers on the legs had not been observed by those she consulted, and she had come to regard them as part and parcel of her general ill-health. When they became extremely painful she sought further advice, which promptly led to the diagnosis of acholuric jaundice. Failure to expose fully the body of the patient is a relic of Victorian prudishness.

I have stressed the value of visual appraisal of abnormalities, but there is a reverse side to be considered. Two pitfalls come to mind which have caught the unwary; they are the lack of plumpness and yellowness in the aged with pernicious anaemia, and the rarer absence of abnormal pigmentation in Addison's disease. The former often presents as a case of cryptic fever; the latter as gastro-intestinal disease by virtue of vomiting and diarrhoea. The absence of abdominal pain and tenderness is a warning signal both of this disease and of uraemia.

That efficiency demands that the diagnostician should be possessed of the senses unimpaired would seem to be a self-evident proposition. So indeed it is if we consider the case of the general physician, but increasing specialization has made him a rarity. For the more specialized physician, some bodily infirmities may determine his sectional interest, in which he can excel. Most of us can recall instances of severe deafness which, though barring the doctor from detailed study of the diseases of the heart and lungs, may coexist with great achievement in other branches of medicine. Disabilities acquired later in life are more apt to lead to diagnostic errors than those which are already present at the beginning of the career. I well remember a consultation which threatened to become heated on the question of whether there was or was not an aortic systolic thrill. To one it was obvious, to the other it did not exist. The puzzling difference of opinion was not explained until six months later, when the negatory physician was found to have cervical tabes.

Percussion; Auscultation; Palpation

Percussion is rapidly becoming a lost art; in fact, one must admit that even in its heyday it often provided an impressive though unreliable accompaniment to the overall appreciation of probabilities already clear to the acumen of the physician. The widespread use of x-ray films is responsible for its perfunctory performance, and it cannot be denied that, especially in the realm of cardiology, this form of examination has often proved inaccurate. On the other hand, percussion will reveal clearly the presence of pulmonary disease where x-rays fail or only hint at the true state of affairs. Early pulmonary collapse, lobar pneu-

monia, and small pleural effusions provide a more reliable percussive response than do the more complex, expensive, and disturbing examinations by Roentgen rays.

A yet stronger claim can be made with justice for auscultation. It still holds its own in examination of the heart, but there is a dangerous tendency to place little faith in it when it comes to diseases of the lungs. This swing away from older methods was started by the realization that, especially in tuberculosis, the x-ray appearances gave far more information than could be gained by clinical examination. On the other hand, lobar and bronchopneumonia, bronchiectasis, and bronchitis are recognizable with certainty by the traditional methods of examination, whereas the x-ray picture may reveal remarkably little. It is strange to note the readiness with which some announce a diagnosis of bronchopneumonia on the strength of x-ray films in the face of apyrexia and signs consistent with severe bronchitis only.

Even the simple procedure of palpation, so far as the thorax is concerned, seems to be treated with contempt. Candidates for higher qualifications probably do not know that their failure is rarely due to their lack of knowledge of the complexities of disease but more often to inability to elicit straightforward physical signs.

For how many centuries have we failed to palpate the carotid artery in search of a cause of focal cerebral disturbance? How many such simple manoeuvres still elude us?

Radiology

Radiology, which has taught us much and which has corrected many false beliefs, is nevertheless a dangerous master. There are few branches of medicine in which it has not added appreciably to our knowledge of pathological processes and our powers of diagnosis.

The commonest radiological pitfall is provoked by the radiologist's report. This to the majority of doctors and all laymen is infallible. It is noteworthy that the more skilled the radiologist the more cautious he is in stating his conclusions. He will report on what he sees, but he will state that his findings are so-and-so, and suggestive of this or that but nothing more. In the other and more heavily loaded scale are those who have embraced the specialty without adequate grounding in medicine and surgery. It is from these that we receive lengthy documents detailing normal and allegedly abnormal appearances, diagnoses sometimes correct and often utterly wrong, and, worst of all, advice as to treatment. There are still many practitioners who were brought up in the days when x-ray films were used but rarely except for surgery, and have had no experience in their interpretation. They are necessarily dependent on the report, but their number is steadily diminishing. To counteract this, however, a deplorable form of officialdom has arisen since the inception of the National Health Service, for this seems to put every possible obstacle in the path of the practitioner to seeing the films of his patient taken at a hospital. Harassed, overworked, and discouraged, it is not surprising that he gives up the unequal struggle.

Even highly skilled radiologists share with physicians and surgeons a liability to make mistakes. They are often unaware of the limitations of their craft. For instance, visible peristalsis, a succussion splash, and copious vomiting led, in an instance which I witnessed, to the not improbable diagnosis of obstruction due to chronic duodenal ulceration. A highly skilled radiologist reported that there was no obstruction because the emptying rate was normal. He claimed that there was no ulcer, although in fact, owing to its backward direction, the duodenal cap could barely be seen. Three months later the emaciated patient was induced with difficulty, because of the report, to have his much-needed operation. Extreme duodenal stenosis and an extensive ulcer were revealed.

It is not perhaps as widely known as it should be that in such cases a barium meal encourages the stomach to exhibit powerful peristalsis, so that it ejects the meal at normal speed, especially in the first hour of observation,

even though there may be quite well-marked stenosis. On the other hand, a fractional gruel test-meal, which approaches much more closely to the normal stomach content, will nearly always confirm the clinical appraisal of the symptoms and signs I have mentioned.

Although increasing alertness has led to the discovery of hiatus hernia in ever-increasing numbers, a new hazard has arisen in that it is often found that a sliding hernia through the diaphragm is confused with the normal ampulla of the oesophagus. The actual x-ray appearances are remarkably similar, and in some perfectly normal people the dilatation of the lower end of the oesophagus is well marked. A single picture, therefore, may be most misleading, and there are many who are not aware of this point of differential diagnosis. In fact, the ampulla fills up in full inspiration, and will therefore have disappeared in x-ray pictures in other phases of respiration.

Dysphagia, that most ominous of symptoms, should alert both physician and radiologist to the most intensive search for an organic cause. In hundreds of hospitals the so-called "barium swallow" observed in the erect patient is regarded as a satisfactory examination, and so the early growth is missed. The mucosal pattern should be viewed in the recumbent patient with the same care as that of the stomach, and a solid opaque bolus should replace emulsion if this has revealed no abnormality. It is only with such care that we can hope to detect disease early enough to give the surgeon the opportunity to cure.

There is an area of radiological romance which is bounded above by the pylorus and below by the ileocaecal valve. This stretch of gut, as yet inaccessible to even the most determined endoscopist, provides material for the doubtful claims of duodenitis, jejunitis, and ileitis. Once these labels have been accepted by doctor and patient the incentive to search for a rational explanation of symptoms wanes and search for a condition which seldom exists. Not many years ago gastritis was confidently diagnosed on radiological observation of the mucosal pattern, but it was fortunately put into right perspective by the advent of the gastroscope and mucosal biopsy. In short, it takes many years for us to find the limits of normal in respect of any new mode of assessment, be it radiological or biochemical.

Specialization without extensive knowledge of general medical and surgical diagnosis endangers efficiency, and no more so than in radiology. The leaders of this specialty, already men of wide culture, are crying out for recruits with higher medical and surgical qualifications. This should be encouraged with all the influence we can command to ensure financial support. Only thus will the country be provided with physicians or surgeons who have specialized in radiology to replace the many who as yet see through a glass darkly.

Biochemistry

The enormous increase in our knowledge of biochemistry is, alas, providing pitfalls in the diagnostic path. Few practitioners can be expected to grasp the significance of all the reports they receive. It behoves the less experienced pathologist to avoid the flattering invitation to make a diagnosis, or even to suggest treatment, on the strength of blood analyses of patients whom he may not even have seen. I have seen three such reports bearing a confident diagnosis of pancreatitis because of high serum amylase figures. In each case the cause of the abnormality was morphine addiction, with consequent spasm of the sphincter of Oddi. This as yet little-known effect has led to fruitless laparotomy followed by further morphine administration; pethidine may also act in this way.

Anamnesis

The more experienced physicians devote a greater time to the taking of history than to physical examination. Failure to do so leads to more mistakes than any other error of approach. But even this must be guided by experience, which alone allows us to sift the relevant from the irrelevant. That process cannot be taught but must

be achieved afresh by each succeeding generation. Above all, the initial symptoms of disease are so important. They may be transitory and thus omitted from the account, especially if there be a sense of hurry at the consultation. For that reason, the study of symptomatology is often best carried out in the peaceful atmosphere of the consulting-room rather than in an out-patient department, where the silent pressure of an overfilled appointment list exerts a sense of urgency which is incompatible with clear thought. Pyrexia of unknown origin which has at times brought humiliation to most of us exemplifies the value of the premonitory symptom.

For instance, a man of 40 had been admitted to hospital on two occasions on account of pyrexia lasting for a week at intervals of three months. Reading through the notes, it appeared that his only symptom had been a feeling of feverishness and slight nausea. Physical examination had been unhelpful. A polymorphonuclear leucocytosis was, however, observed. Spontaneous recovery led to his discharge on two occasions. The third attack, six months later, drew to him a physician who took a history in which he covered hour by hour the development of each bout. He elicited that in fact on each occasion the bowels had been copiously evacuated on the first day. Arguing that there must be an inflammatory lesion and this presumably within the abdomen, and that in all probability it involved the large gut, he diagnosed the most common lesion in an uncommon position—namely, an inflamed retrocaecal appendix. And so it proved to be; in fact, an abscess here, giving rise to no tenderness or guarding, was evacuated and cure followed. Like Columbus's egg, it is all so simple, but it is the ability to recognize the signposts which places some men in the upper ranks of diagnosticians.

Others with more knowledge of diseases may for ever flounder in the morass of differential diagnosis. To consider at length the diagnostic possibilities of a case is academically interesting but laudable only if at the end the physician commits himself to a firm opinion. Intellectual dishonesty is easily acquired. It is so facile to say later, "I did mention that as one of the possibilities." This is, after all, no help to a general practitioner and receives no credit from the patient. Furthermore, the physician is establishing a precedent for himself, and he may go through life as a differential diagnostician, albeit with an exiguous practice.

One of the great advantages of being on the staff of a teaching hospital is that the consultant is constantly liable to be subjected to criticism by his colleagues, his registrars, house officers, and students. We have not allowed, as yet, the development of the teutonic professorial infallibility supported by sycophantic juniors whose only hope of preferment lies in bowing to the pontifical utterances of the great chief. We should not allow ourselves to pass from one bed to the next without pronouncing a diagnosis, or saying quite frankly that we do not know. If we prove to be wrong we must learn to eat our words and try again, but the words must be recorded by the ward clerk so that there shall be no escape. In this way we learn. "Experience," wrote Oscar Wilde, "is the name everyone gives to his mistakes."

A useful exercise in the wards is to take the students step by step through the history of a patient and limit the initial examination to inspection. It is remarkable how often the correct diagnosis can be reached. Such training helps to emphasize the relative importance of the clinical approach to the innumerable special investigations which are used so prodigally at this time.

The difficulties which beset the general practitioner are in many respects different from those which await the consultant. In the case of the former there is lack of time, the wider field of knowledge to be embraced, and a year-long familiarity with the patient. There are but few occasions on which a general practitioner can devote twenty minutes or more to history-taking, yet most mistakes in diagnosis are due to inadequate anamnesis. In the last few years this obstacle has been increased to an alarming

extent by the paramedical duties inflicted on him by the Health Service. To the consultant this difficulty does not exist in private practice. The general practitioner, has, furthermore, to exercise reasonable knowledge and skill in medicine, surgery, and obstetrics. In thus doing, his overall efficiency is greater than that of the consultant or specialist. It is to be hoped that Her Majesty's judges will not fail to make this clear to juries in the litigation which threatens to deter our young men from acceptance of responsibility.

Familiarity with a patient, especially if she be of neurotic temperament, tends to lower one's guard. Even a hypochondriac may develop a carcinoma of the stomach, and indeed the fable of crying "Wolf" too often might have been written for our benefit.

Difficult Relatives

Consultants have less excuse for making mistakes, yet we all make them, and it behoves us to find out why. In our case it is not perhaps so much a matter of scamping the taking of a history as failing to attach importance where it is due. We are often hampered by the presence of relatives, and indeed that worst pest of all, the uxorious husband. He is the most difficult of relatives to expel from the waiting-room, yet his answers to every question addressed to his wife, even on the most intimate matters, are often useless apart, of course, from the light they shed on the domestic background. It comes as a surprise to many a young consultant to find that patients of good upbringing, and allegedly excellent educational training, can be as muddled in their thinking and in their answers as the most exasperating out-patient from the lowest social stratum.

We have also to cope with that strange state of mind which deliberately withholds symptoms for fear of learning the truth. Others, we must remember, genuinely fail to understand questions which to us appear to be clear enough. A very human reaction is to truncate the history-taking in despair and to proceed to examination. Unfortunately so many diseases present no physical sign in their early stages that the diagnosis may well escape us through impatience. I have already said that a scamped history is the commonest cause of failure. One of the most important influences leading to this pitfall is fatigue. In the intensely interesting and full life we lead, fatigue is apt to pass unnoticed, yet it insidiously undermines our efficiency. We tend to think, as spoke Bismarck, "I have no time to be tired." But if we find that our quota of mistakes is expanding, or if we hear ourselves issuing platitudes on a ward round, that is an indication for rest which can only be disregarded at peril to our patients and to our reputation.

Although it is clear that with increasing experience a consultant is likely to gain more from a history than he did in his formative years, yet he runs a risk of a certain rigidity of his mental associations. Think of the centuries during which countless doctors had studied case histories before a flash of insight exposed the hazards of German measles to the unborn child and the, in retrospect, so obvious mechanical cause of sciatica. There is no reason to suppose that we are not still shutting our eyes to the obvious in many of our present-day problems. Just as thirty years ago the advance of medicine was arrested by the theory of focal sepsis, so to-day the search for truth may be imperilled by the parrot-cries of "adaptation reactions" and "collagen diseases." It is so easy to slip into unhelpful pseudodiagnoses such as "cerebral catastrophe" or "acute abdomen," or the latest futility, "cardiac episode."

Mistakes of the Experienced

Paradoxical though it may be, experience may at times hamper a physician in coming to a correct conclusion. He is tripped up, as it were, by the vast impedimenta of his knowledge, whereas his junior may see the goal clearly. Bias, produced by specialized knowledge, may play havoc with a physician's reputation. It disturbs at once the ability to assess the relative importance of all the features of the

diagnostic problem, which is the hall-mark of the sound clinician. Many recent examples of this have been seen since the importance of a lesion of an intervertebral disk has been revealed. The pathology and symptomatology of this new conception impressed those who studied it most, and for this very reason threw them off their balance. It has been said that any man may make a mistake once, but only a fool makes the same mistake twice. I doubt if this is true, for often the making of the same mistake is an indication of a logical train of thought diverted from the path of truth by the attachment of undue importance to perhaps one symptom.

For instance, malignant metastases of the spine were wrongly attributed to prolapse of an intervertebral disk on the strength of sudden onset of pain, normal x-ray appearances, and no obvious primary growth. But the interrogation had not gone far enough. Carcinoma of the uterus and of the prostate would, in many instances, have been revealed if a biased approach had not diverted attention from the pelvis.

There are vogues of bias in which large sections of the medical world lose their balanced judgment and go chasing after false diagnostic gods. Thus we have seen peaks of diagnosis of focal sepsis, intestinal intoxication, disk protrusion, and polyarteritis nodosa, to quote but a few of the fashions of the last thirty years. In some instances the rise in diagnostic incidence has been justified by a true increase in the disease or a sudden understanding of its nature, but even then there is always an over-swing of its application due to prejudice and mental laziness.

A Constant Danger

There is, however, one constant danger which besets us, and that is to attribute to the mind diseases of the body; in short, to label as neurotic a patient with organic disease. On analysis, I suppose it is evidence of conceit; a feeling that if no cause of symptoms has been found then the physician cannot have missed anything and thus the patient's symptoms are imaginary. The trouble is that they often are so, but the gravest mistakes are being made by all of us no matter how experienced we may be. There are but few patients whose history may not reveal unreasonable obsessions, phobias, and anxieties in the course of their life which in the last resort cannot be called in to explain apparently otherwise inexplicable symptoms. Perhaps we are all potential neurotics.

A woman whose outrageous behaviour and revolting gluttony had led to years of domestic unhappiness eventually consented to in-patient treatment for her obesity. A stream of complaints that she was starved, failing in strength, and suffering from headache was unimpressive when it was found that she was bribing menials to smuggle food into her locker. Six months after discharge, as uncooperative, she died of an expanding Rathke pouch cyst.

A middle-aged man developed depression and backache after his son committed suicide. The backache was constant. No investigation was spared to find its cause, but all to no avail. Three months later he developed jaundice from the spread of a carcinoma of the body of the pancreas to its head.

The tragedy is that carcinoma stands very high in the list of mistakes of this sort. Some of them are no doubt unavoidable; others might be averted by constant preoccupation with the fact that one may be wrong. Metastases in the spine, though giving rise to excruciating pain aggravated by all movements of the trunk, by sneezing, or by coughing, may yet for many weeks produce no abnormality in the x-ray picture. The reason is clear in that the deposits may occupy the cancellous centre of the vertebrae, causing pain by expansion, and it is only later that the cortex undergoes erosion. To give an illustration, of which I see many examples: A man of 60 years of age was subjected to prostatectomy. Sections of the prostate showed benign enlargement. Six months later he was seized by intense pain in the upper lumbar region. After

being treated as a case of acute lumbago for three weeks, he was finally x-rayed and a normal spinal picture obtained. In increasing agony he turned to a medical manipulator, whose onslaught caused such horrible pain that the man thought he must die. In the next week he saw a physician who, appreciating the nature of the pain and the fallibility of prostatic microscopy, passed his finger into the rectum and found that the prostatic bed was stony hard. Fresh x-ray films now revealed extensive metastases in the spine and there was elevation of the serum acid phosphatase. Six years have since passed, and the patient is in good fettle, thanks to stilboestrol, the outcome of the genius of a Fellow of this College.

This case illustrates to perfection the dangers of relying on two of the most exact ancillary sciences in the face of symptoms pointing to the truth, but only for those who have ears to hear.

In May, 1954, a woman aged 75 developed pain in her left thigh and lumbar region. In June the spine was x-rayed and showed widespread osteoporosis, with no evidence of the malignant deposits which had been suspected. The blood count, erythrocyte sedimentation rate, and serum calcium at that time were normal. With rest and treatment for senile osteoporosis, the pain subsided and she again became mobile but never completely lost the backache. Early in October of 1955 the pain became more intense and was felt in both buttocks. A month previously an x-ray film again showed osteoporosis but also partial collapse of the fifth lumbar vertebra. The pain being intense, yet another x-ray film was taken, and this showed the same diffuse osteoporosis, but now there was extensive collapse of the fifth lumbar vertebra, much of which had in fact disappeared. She was strikingly anaemic, with a leucocyte count of 15,000, and the sedimentation rate by the Westergren method was 106 mm. at one hour. From that time the course of events was steady emaciation, pain which could be controlled only by large doses of suitable drugs, and death in December of 1955.

The remarkable feature of this case was that for over a year, although the woman must have had a carcinoma involving the spine, there was no unequivocal radiological evidence of it, yet there was temporary and appreciable improvement simply as the result of treatment for osteoporosis. This is the longest period I have heard of in which malignant disease has been masked in x-ray films of the spine, but six to nine months is by no means unknown, at a point which should be more widely appreciated, as lack of knowledge of it has led to a large number of mistakes in diagnosis.

We may ask ourselves how far does our duty compel us to carry out special examination of patients in our care.

To the symptomless patient asking for a routine overhaul, do we do our duty by confining this to a thorough clinical examination, or should he be subjected to extensive x-ray examination, or should he be subjected to extensive x-ray search, blood examinations, and so forth which are popular in the U.S.A. and certain Continental countries? A dogmatic answer to this question would be unwise; such factors as age, occupation, and environment might well call for more extensive search. On the other hand, we can all recall the valetudinarian whose yearly dossier of investigations is proudly presented, and who is eventually found to be suffering from advanced carcinoma undetected at his routine overhaul only a few months previously. Yet apparently trivial symptoms such as unwonted lassitude must put us on our guard. I have notes, for instance, of five patients in whom this was the only symptom and in whom lymphatic leukaemia was discovered by blood examination and was revealed in no other way.

Iatrogenic Diseases

The therapeutic nihilism which characterized the turn of the century has given place to exuberant enthusiasm which, though laudable, in the main has brought a trail of iatrogenic diseases with it. The disastrous results which may arise from the use of various medical and surgical pro-

cedures, though by no means unknown to our forefathers, have gathered momentum with the appearance of chemotherapy, antibiotics, and active principles of the endocrine glands. Even the hitherto harmless oxygen has by improved efficiency of administration caused that most terrible of therapeutical diseases, retrolental fibroplasia. Generations of bacteria with ever-increasing resistance to our drugs are threatening to overwhelm the human race, which at the moment is only one step ahead in ingenuity to thwart the infinite adaptability of the microbial kingdom.

There is yet another danger, and that is to be taken in by a sudden inspiration, that flash of insight which sweeps away our difficulties and resolves our problems.

Those with mercurial minds are most likely to be granted such revelations, often in the still hours of the night. In that way are born such fancies as the psychogenic origin of ulcerative colitis, stress reactions as the cause of rheumatism, or degeneration of Auerbach's plexus as the prime factor in cardiospasm. The critical faculty wobbles, discordant facts are suppressed, and practitioners of ancillary sciences are hypnotized into finding supporting evidence, while medical literature is pressed into the service of an ill-conceived child born of ambition and unreason.

Further risks of failure are encouraged by coming to conclusions based on insufficient number of cases. I need hardly remind you of the claims for complete safety of various drugs which have ultimately proved to be dangerous to the few. Amidopyrine, pethidine, chloramphenicol, come to mind as examples of the risk of forming conclusions on a few hundred cases.

The explanation of symptoms may in fact suffer the same way. The best example of that is perhaps proctalgia fugax. When I first described this in 1928, I referred to the remarkable symptom of intense pain felt as it were in the rectum, its liability to come on in the early hours of sleep, its proneness to be provoked by extreme fatigue, sexual excess, sitting on hard seats, and constipation. Although I had listened to these symptoms from many patients at that time I had had the opportunity of obtaining information from only one in respect of investigation at the time of the attack. Examining the rectum in a bout, it was noted that it was contracted and the sphincter taut. I wrongly attributed the condition to rectal spasm. Since that time the literature on this peculiar and widespread malady has confirmed the precipitating factors, and it is generally agreed that the application of intense heat to the sacrum, or pressure upwards on the perineum, and the injection of air or warm water into the rectum will cut short an attack. But it is still widely held that it is due to spasm of some part of the lower bowel; this I believe to be untrue. Among the numerous examples which I have since collected, I have ten doctors who have examined at my request the rectum during a seizure, and not one has borne out the findings in my original report that there was any trace of unusual resistance on the part of the sphincter or any sign of contraction of the walls of the rectum. They all agreed, however, that on one or other side of the rectum a firm band was felt apparently lying outside the wall, which was tender, and heavy pressure here would often relieve the pain. The statement that the pain must be of alimentary origin because it disappears if the patient takes anything to eat or drink is, I know, incorrect. I have notes of several who have been seized with the pain during a meal, and who have been hard put to it to maintain their composure and their table conversation in the face of this deep-seated agony. It is to be remembered also that the substances which will relax spasm of unstriated muscle, notably the nitrites, have no effect on it. The evidence then suggests that it is produced by cramp of a portion of skeletal muscle, possibly a part of the levator ani, more likely the coccygeus.

It may seem strange to present as a hazard the discovery of some abnormality in the course of a search for diagnosis. The risk I am referring to lies in assuming that a structural departure from the normal is necessarily the cause of the illness being investigated. In this respect, I

think the surgeons are the greatest sinners. Most of us can recall instances of the removal of septic tonsils for rheumatoid arthritis with no benefit, or again the excision of a kinked and possibly infected appendix for symptoms which proved later to be due to duodenal ulceration.

Of recent years, I have noted two false linkages surprisingly frequently. In the one the finding of a true but mild hydronephrosis on the right side has led to the entirely unnecessary loss of the kidney in a psychoneurotic. The other is the exploration of the abdomen for pancreatic adenoma on the strength of low blood-sugar levels—for example, 50 to 60 mg. per 100 ml.—after an initial high peak in the glucose tolerance curve. These patients do not give the typical history of hypoglycaemia. They are often flabby, tired female psychoneurotics, rejoicing in the claim that their endocrine system is at fault and that they suffer from low blood pressure.

Their lassitude, low blood pressure, low blood sugar, and lag curve were in fact all due to too little food, no exercise, and barbiturate addiction. We are as a profession not nearly sufficiently alive to the mental and physical changes which are produced by the constant taking of therapeutic doses of barbiturate, an addiction which is doing far more harm to the efficiency of the upper social classes than are the more dramatic and better-known forms of addiction.

When we think of the multitude of impediments to our smooth passage along the road to diagnosis it may make us wonder at times that we are so often right. The patient's mental ability, his level of intelligence, his attitude towards his symptoms, his fear of disease, his inability to express himself clearly, the different meanings which people apply to the same word, the jumble of symptoms mixed up with irrelevancies, all produce a mountainous hazard to success. This is increased yet further by the vagaries of disease, often shown in most misleading guises, seldom reproducing itself faithfully in one patient after another, and liable to throw out symptoms and signs like sports in evolution. For instance, attacks of gall-bladder colic which are felt entirely in the left hypochondrium are rare, but when they occur they give rise to the greatest difficulty in diagnosis. I have met this condition twice only, the first in a young married woman of some 30 years of age who had had two children, and who had five attacks of acute abdominal pain, felt entirely on the left side and lasting for several hours. I witnessed the fifth attack and found that, although the pain was still in this position, tenderness was striking in the usual position of the gall-bladder. The usual investigations led to the discovery of gall-stones, and the removal of the gall-bladder terminated the attacks.

The second instance was in a woman of some 40 years of age whose pain was a little lower. It spread from the left hypochondrium towards the anterior superior spine. These bouts over many years had been attributed to colon spasm. Removal of her gall-bladder, full of stones, resulted in recovery.

What the mechanism is which gives rise to this anomaly has never, so far as I know, been discovered.

The layman has difficulty in understanding that the specialist or consultant can make a mistake; in fact, he goes further, and is only too apt to attack him and his general practitioner in the courts of law, not because he is necessarily aggressive but because he is ignorant in that he will compare the machine which can be taken to pieces with the infinite and variable complexity of the human body. However, we should not allow the criticism of fools to disturb us, provided that we preserve intact our mental discipline and self-respect. Mistakes are inherent in the pursuit of a progressive science, and not to admit them spells death to any hope of advancement in learning.

To be ruthlessly critical of one's own theories is one of the most difficult tasks we have to accomplish; for, as Bacon remarked, "A mixture of a lie doth ever add pleasure." In some walks of life, especially in politics, this does not matter, but in medicine it will not do.

[The second lecture will appear in our next issue]

DIAGNOSIS AND TREATMENT OF SARCOIDOSIS

BY

D. GERAINT JAMES, M.D., M.R.C.P.

Leverhulme Scholar, Middlesex Hospital Institute of Clinical Research

It is difficult to dogmatize on the management of sarcoidosis, a disease whose cause is undetermined, whose clinical manifestations are protean, whose natural history is unpredictable, and whose specific therapy is unknown. The diagnosis rests on a combination of clinical, radiological, and histological features, which together provide the maximum information at present available.

This report is based on the findings in a series of 150 patients with clinical or radiological features of sarcoidosis supported by histological evidence of sarcoid tissue. Many patients with good clinical, radiological, and immunological evidence of sarcoidosis have been excluded because there was no accompanying histological confirmation. Likewise, patients with histological evidence of sarcoid tissue have been excluded if this was a local reaction unaccompanied by evidence of generalized involvement.

Clinical Features

The lesions caused by the granulomatous process or its fibrotic sequelae are so widespread that clinical manifestations may embrace any branch of medicine (Table I). Its

TABLE I.—Showing Widespread Clinical Manifestations

Chest Physician:	Routine chest x-ray changes
	Breathlessness
Dermatologist:	Nodules, papules, vesicles, scars
	Lupus pernio, keloid formation
Ophthalmologist:	Uveitis
	Enlarged lacrimal glands
	Sjögren-like syndrome
	Glaucoma
Cardiologist:	Pulmonary heart disease
Gastro-enterologist:	Splenomegaly
	Diagnostic liver biopsy shows granulomata
Neurologist:	Eye changes
	Meningitis
	Isolated cranial nerve lesions
	Space-occupying lesion
	Pituitary involvement
Surgeon:	Diagnostic lymph-node biopsy
E.N.T. Surgeon:	Nasal granulomata
	Laryngeal plaques
Obstetrician:	Should pregnancy continue?
Radiologist:	Chest x-ray changes
	Bone cysts
General Physician:	All the above referred for "sorting-out"
	Atypical mumps
	Acute rheumatism
	Lymphadenopathy
	Hepatosplenomegaly
	Nephrosis
	Hypercalcaemia
	Renal calculi

masquerades are reminiscent of those of syphilis in the pre-penicillin era. The modes of presentation indicate the diversity of onset (Table II). Further examination frequently revealed involvement of other organs or systems.

Sarcoidosis most commonly presents with intrathoracic involvement, either by routine radiography, possibly in a symptom-free and apparently healthy young adult, or,

TABLE II.—Major Presentations of 150 Patients with Histologically Confirmed Sarcoidosis

Aspiration liver biopsy	2
Meningitis	1
Nephrosis	1

alternatively, because of breathlessness or signs of pulmonary hypertension and cor pulmonale due to long-standing fibrotic pulmonary sarcoidosis.

At some stage of the disease skin lesions developed in 67 (45%) patients. They may be transient lesions such as erythema nodosum and vesicular eruptions, or persistent bluish-red plaques, lupus pernio, or knee scars which may remain unchanged for years. Keloids, infiltrated with sarcoid tissue, may develop insidiously in operation scars, in vaccination sites, or simply following trauma.

Ophthalmic changes occurred in 42 (28%) patients. They may, like the pulmonary changes, progress relentlessly to fibrosis, with final blindness. The most pronounced early change is iridocyclitis. This may be acute and transient or insidious and persistent. Cells appear in the anterior chamber, and fine cellular deposits on the posterior corneal surface enlarge to form greyish keratic precipitates resembling mutton fat. Eventually the iris may adhere to the lens, and obstruction of the angle of the anterior chamber results in secondary glaucoma. In addition, involvement of the choroid and retina may signify a panuveitis. The fundus oculi should always be examined in addition to routine slit-lamp investigation; any chronic granulomatous uveitis suggests sarcoidosis. In two patients, lacrimal gland involvement causing keratoconjunctivitis sicca, with a dry mouth due to salivary gland involvement, presented a clinical picture resembling Sjögren's syndrome. In all, there was involvement of the parotid glands in seven and of the lacrimal glands in four patients, but these were not always the major presenting features. At some stage in the disease there were enlarged peripheral lymph nodes in 56 (37%) and a palpable spleen in 27 patients (18%). These tended to subside spontaneously unless the spleen was greatly enlarged.

On two occasions aspiration liver biopsy, undertaken for the diagnosis of hepatosplenomegaly, revealed miliary granulomata, and this was, in fact, the mode of presentation. The nasal mucosa was involved in three patients and sarcoid-like plaques were seen on the larynx in another.

The general surgeon may be confronted with a histological report of sarcoid tissue in the lymph nodes draining a carcinoma or Hodgkin's tissue. Since the sarcoid reaction is limited to the lymph nodes draining the cancer or malignant reticulosis, it is presumably a local reaction and should not be confused with generalized sarcoidosis.

Neurologists are most likely to see cranial nerve palsies, subacute meningitis, or pituitary lesions due to sarcoidosis. In this series, Bell's palsy, occurring in four patients, was always transient and cleared without treatment. It was associated with parotitis and/or uveitis.

To the general physician are referred many of the above problems for "sorting-out," and in addition he is liable to encounter acute polyarthritides preceding or accompanying erythema nodosum.

Circumstantial Evidence

The clinical features may be augmented by evidence which, although not specific, suggests sarcoidosis.

Serial Chest Radiographs.—These are indispensable (Table III). The changes include bilateral hilar lymphadenopathy and/or diffuse lung mottling, or, even at the

first examination, there may be a more advanced stage of pulmonary fibrosis with cavitation. The hilar lymph nodes are affected first, and they may be accompanied by paratracheal lymphadenopathy. These enlarged lymph

TABLE III.—Initial Chest Radiographic Changes (150 Cases)

Bilateral hilar lymphadenopathy	58

Diffuse pulmonary mottling	45
Pulmonary fibrosis ± cavitation	5
Clear chest radiograph	14

nodes may regress completely or they may be accompanied or followed by diffuse pulmonary mottling. This parenchymal involvement, in turn, may regress or progress to irreversible fibrosis. In view of the changing radiological features, any attempt at subdivision into different stages is therefore arbitrary.

Radiographs of Hands and Feet.—Jüngling (1920-1) drew attention to cystic bone changes, and radiographs of hands and feet became a popular ancillary investigation. These changes have been observed in only eight patients, all of whom had persistent cutaneous plaques or lupus pernio. X-ray films of bones did not give diagnostic information not afforded by examination of the skin.

Tuberculin Reaction.—The tuberculin test is almost invariably performed, tuberculin insensitivity being commonly regarded as a cornerstone of the diagnosis. Cutaneous anergy is not, however, confined to tuberculin sensitivity, since delayed skin-test reactions to various other antigens, including mumps virus, pertussis agglutinin, *Candida albicans* extract, and trichophyton are also depressed (Friou, 1952; Sones and Israel, 1954). Furthermore, depression of skin sensitivity to tuberculin is not restricted to sarcoidosis but is also observed in Hodgkin's disease and other reticuloses (Hoyle, Dawson, and Mather, 1954).

In this series the Mantoux reaction was negative in two-thirds of patients tested with 100 T.U. In positive reactors it was frequently negative at higher dilutions, and 100 T.U. was necessary to elicit a positive response. However, when 5 T.U. was incorporated in an oily delaying vehicle and injected intradermally, a further two-thirds of the negative reactors displayed tuberculin hypersensitivity (James and Pepys, 1956). This is of some practical importance in the interpretation of negative tuberculin tests in patients suspected of having sarcoidosis. A negative aqueous tuberculin test implies that the patient may be completely insensitive to tuberculin because he has never been infected with the tubercle bacillus or, alternatively, because he is suffering from sarcoidosis or Hodgkin's disease. A positive depot tuberculin with a negative aqueous tuberculin test suggests sensitivity and implies depression of the normal skin response.

Mumps Skin and Complement Fixation Test.—Although patients with sarcoidosis may fail to show skin sensitivity to various intradermal antigens, their ability to produce circulating serological antibodies remains unimpaired. This dissociation between cellular and circulating antibodies is the basis of an ingenious diagnostic aid (Quinn, Bunch, and Yagle, 1955). Mumps virus is chosen as the test antigen because most normal adults display both a positive complement fixation test and a positive skin test. Sarcoidosis is suggested when a negative skin test is associated with a positive complement fixation test. Similar results are encountered in Hodgkin's disease (Schier *et al.*, 1956). This test cannot therefore be used to distinguish sarcoidosis from other reticuloses with skin anergy.

Serum Globulins.—Since Salvesen (1935) drew attention to raised serum globulins in sarcoidosis this observation has been repeatedly observed and correlated with activity of the disease. Electrophoretic analysis of the serum proteins has shown that the involved fractions are the α - and γ -globulins. In this series, 14 of 50 electrophoretic patterns showed raised α and/or γ -globulins. This was of little diagnostic value because these fractions tend to be raised non-specifically in many infections; an increase, however, indicated activity of the disease.

(3) Patients with sarcoidosis do not require sanatorium treatment with its unwarranted exposure to tuberculosis and the associated psychological trauma. The patient should be speedily rehabilitated to his normal occupation even when receiving steroid hormones.

(4) The majority of patients enjoy a spontaneous and permanent remission without treatment. The cortisone group of drugs have undesirable side-effects and should be reserved for the minority with a definite indication.

(5) When sarcoidosis is suspected, histological confirmation should be sought by all available means. This applies especially to the patient with bilateral hilar lymphadenopathy in whom malignant reticulosis may be confused with sarcoidosis and unnecessary radiotherapy contemplated.

Summary

One hundred and fifty cases are described in which clinical or radiological features of sarcoidosis were supported by histological evidence of sarcoid tissue. Diverse modes of presentation include intrathoracic, cutaneous, ophthalmic, glandular, hepatic, renal, and cerebral manifestations. Radiological and immunological aids to diagnosis are discussed. Histological evidence of sarcoid tissue remains the most satisfactory confirmation of the disease. In 100 patients it was obtained by biopsy of lymph node, skin, liver, or other affected tissues, and the Kveim test was positive in 83 of 110 subjects examined.

Antituberculous drugs did not affect the course of the disease and need not be given routinely. In the early stages the cortisone group of drugs have a beneficial effect on the clinical, radiological, and histological changes. Results of treatment are disappointing in the chronic fibrotic stage. Steroid treatment is given only when specifically indicated and is directed towards the prevention of these late sequelae.

I am grateful to Dr. H. L. Marriott and Professor A. Kekwick for their constant support and advice and to other clinicians who have referred patients. I am indebted to Dr. Louis Siltzbach, New York, for drawing my attention to his technique for skin biopsy with the Hayes-Martin drill, and to Dr. A. D. Thomson, Bland-Sutton Institute of Pathology, for histological interpretations.

RESPIRATORY SYMPTOMS AND PULMONARY DISABILITY IN AN INDUSTRIAL TOWN

SURVEY OF A RANDOM SAMPLE OF THE POPULATION

BY

Medical Research Council, Pneumoconiosis Research Unit,
Llandough Hospital, near Penarth

Interest is increasing in the prevalence and causes of chronic bronchitis. Bronchitis was the commonest cause of spells of sickness incapacity in males reported to the Ministry of Pensions and National Insurance during 1953-4 (M.P.N.I., 1955), and accounts for about 10% of all claims.

Diseases that are generally prevalent can be considered to be influenced by occupation only if their occurrence among workmen differs from that found in the general population. Respiratory symptoms and pulmonary disability are common in coal-miners, but before we can attribute them to mining we must first show that their prevalence is higher in miners than in non-miners. The ideal investigation would require a random allocation of school-leavers to mining and other occupations, and subsequent comparison of the incidence of respiratory diseases in the two groups. In default of this we can only study the prevalence in already constituted groups as comparable as possible in age and all environmental conditions except those associated with mining. It is then always necessary to remember that their comparability is but an assumption and that the voluntary choice of occupation may itself be related to the medical status of the men.

In November, 1954, the Pneumoconiosis Research Unit carried out a survey of the 55- to 64-year-old male population of Leigh in Lancashire. One of the objects of this survey was to compare the prevalence of respiratory symptoms and disability in miners with that found in men who had worked only in other occupations.

Leigh was chosen for a number of reasons, including the expectation of finding approximately equal numbers of miners and non-miners in the older age group. It is not an area where coal-miners' pneumoconiosis is a particular problem. It is 13 miles west of Manchester, about in the middle of the Lancashire/Cheshire conurbation of towns—a region with a high mortality from bronchitis (Lane, 1954). It is, however, relatively circumscribed and away from the area of heaviest pollution.

This paper gives the results of our investigation and suggests a possible approach to the difficult problem of controls.

The Sample

At the time the survey was planned the only information available about the age and sex distribution of the population of Leigh was that given by the Registrar-

General (1949) from estimates obtained from the National Register in December, 1947. According to these the male population of Leigh was 22,909, of whom 2,341 were between 55 and 64. A sample of about 250 men in this age group, or roughly one in ten, was considered adequate.

The only list from which sampling could be carried out was the Electoral Roll. This gives the names of those eligible to vote at the time of compilation. It appears as a list of streets, with the occupants of each house listed alphabetically within houses, in the order of the houses in the street. Within each ward the occupants of houses are given a serial number.

As a basis for a random sample of individuals the Electoral Roll is unsatisfactory, since the population of the town at the time of the survey may differ from that at the time of compilation of the list. However, it is satisfactory as a basis for a random sample of houses, provided a supplementary list of new houses is available. The procedure adopted was to sample at random from the serial numbers of individuals, to regard the selected numbers as selecting a house, and to include in the final sample all men in the chosen houses who were of the correct age. By this method the chance of selecting a house is roughly proportional to the number of its inhabitants, so that, again roughly, each individual has the same chance of being included in the sample. Each new house was arbitrarily allotted two serial numbers since the vast majority were in a new "residential neighbourhood unit" built by the borough council and occupied by young married couples.

The principal deviation from randomness to be expected in this method of sampling is that all relatives of the right age group living together in a chosen house were automatically included in the sample. Thus if there is any tendency for relatives to resemble each other in their sickness experience the sample would tend to be less diversified than a truly random one. In fact, it was seldom that more than one man of appropriate age was found in a chosen house. Samples of 100 houses from the whole of Leigh were chosen in this fashion in succession. The visiting in each sample was completed before the next was begun. After fifteen such samples had been visited 245 men between 55 and 64 had been found, and the sampling was stopped. Since 14% of males over 20 were aged 55-64 in 1947 it was expected that about 14% of houses would yield a suitable subject; in fact, 16% (245 in 1,500) did so.

Of the 245 men chosen, 24 (9.8%) refused to co-operate in the survey. The sample was divided according to occupation as in Table I. In different electoral wards the lapse rate ranged from 0 to 31%.

TABLE I.—Random Sample of Men Aged 55-64

Group	Examined	Lapsed	Total
Miners and ex-miners	135 (92.5%)	11 (7.5%)	146
Non-miners	86 (86.7%)	13 (13.1%)	99
Total	221 (90.2%)	24 (9.8%)	245

The difference in lapse rate is insignificant (0.30 > P > 0.20).

The wards differ in their level of prosperity. The proportion of electors entitled to be called for jury service (which has been suggested by Gray *et al.* (1951) and Corlett (1952) as an index of the economic status of a district) ranges in different wards from 1.4 to 62.3 per 1,000. The correlation between lapse rate and jury index was, however, quite insignificant.

Procedure and Method

Every male inhabitant aged 55-64 of the selected houses was interviewed personally by a member of the Field Survey team. He was asked to co-operate in an investigation into the effect of dust on the lungs. Each man who consented was given an appointment to attend at a central hall where the various investigations were carried out. Transport was offered. Whether or not he consented he was asked if he had ever worked for one year or more in mining or cotton, to enable a provisional occupational classification to be made. Any man who failed to keep his appointment was promptly revisited, usually on the same day. He was either persuaded to accompany the home visitor immediately, or was given another appointment. The following were the methods adopted.

1. Occupational histories from the time of leaving school were taken.

2. Respiratory symptoms were recorded, using a questionnaire (see Appendix). Particular attention was paid to a history of chest illness during the past three years, to the constant occurrence of cough and phlegm, and to wheezing and tightness in the chest. Breathlessness was graded, using the questions recommended by Fletcher (1952). In addition, questions relating to some aetiological factors thought to be important in causing bronchitis were asked. All the questionnaires were completed by one observer to avoid the differences in recording level that are known to occur between different observers (Cochrane *et al.*, 1951).

3. Sitting height to the nearest half-inch and weight to the nearest pound were measured.

4. Ventilatory capacity was measured by recording the volume of air expelled in the first 0.75 second of a forced expiration, using a modified Gaensler (1951) apparatus. The mean of three or four readings was taken (excluding the first) and the resulting volume was expressed in litres/minute as the maximum voluntary ventilation (M.V.V.) (indirect) in the way described by Kennedy (1953).

5. A postero-anterior x-ray film of the chest was taken of each man, using a mobile x-ray van. Duplicate x-ray readings were carried out according to the practice adopted at this unit.

Results

Exclusions.—We have excluded from the analysis those men whose chest x-ray films showed significant disease, other than coal-miners' pneumoconiosis and emphysema, that might be expected to affect the ventilatory capacity. There were five such men: three miners and two non-miners. The reasons for their exclusion and the mean value of various measurements are shown in Table II. The exclusion of these men makes no material difference to the general results.

TABLE II.—Mean Measurements of 5 Exclusions

Group	No.	Age (Years)	Sitting Height		Weight		M.V.V. (l./min.)
			in.	cm.	lb.	kg.	
Miners and ex-miners	3*	57.7	34.5	87.6	136.0	61.7	74.0
Non-miners	2†	61.0	33.3	84.5	152.5	69.2	69.5

* One case each of bronchial carcinoma, general cystic disease of the lungs, and extensive pleural thickening.

† One case each of extensive pleural thickening and category 2 simple pneumoconiosis in an engine-driver.

Men with Exposure to Cotton Dust.—24 miners and 28 non-miners had worked for one or more years in cotton (average period 16 years). The average working time of those who had worked only in cotton was 25 years, and all except two were spinners. Most of those with a mixed occupational history had worked in dustier parts of the mills, but their mean exposure was only six years. The mean values of the main measurements are given in Table III. The results do not differ significantly from those found in men who had never been exposed to cotton dust. It therefore seems justifiable to include them in their appropriate groups.

Prevalence of Pneumoconiosis.—Among the miners and ex-miners there were 31 men whose x-ray films showed

TABLE III.—Mean Values of Those Men who had Worked in Cotton

	No.	Age	Sitting Height		Weight		M.V.V. (l./min.)	Bronchitis
			in.	cm.	lb.	kg.		
Miners	24	59.4	34.0	86.3	142.4	64.6	71.5	7 (29.2%)
Non-miners	28	59.4	33.6	85.3	141.5	64.2	87.1	3 (10.7%)

pneumoconiosis, a prevalence of 23%: 21 (15.6%) had simple and 10 (7.4%) complicated pneumoconiosis. These figures may be compared with a prevalence of 30.3% simple pneumoconiosis and 21% progressive massive fibrosis found in the 55-64 age group by Cochrane *et al.* (1952) in the Rhondda Fach Valley, in South Wales. The miners with pneumoconiosis are analysed separately. There are therefore three groups for comparison: (1) 84 non-miners, (2) 101 miners or ex-miners without pneumoconiosis, and (3) 31 miners or ex-miners with pneumoconiosis. Their mean ages, weights, and sitting heights are given in Table IV.

TABLE IV.—Mean Anthropometric Measurements of the Three Groups (Aged 55-64)

Group	No.	Age (Years)	Sitting Height		Weight	
			in.	cm.	lb.	kg.
Non-miners	84	59.4	33.9	86.1	145.6	66.0
Miners without pneumoconiosis	101	59.1	34.2	86.8	147.8	67.0
Miners with pneumoconiosis	31	58.6	34.1	86.6	152.4	69.1

Prevalence of Respiratory Symptoms.—Table V shows the prevalence of respiratory symptoms found in each of the age groups (simple and complicated pneumoconiosis being differentiated). As the number of men with pneumoconiosis was small the results in this group should be interpreted with caution. The first two grades of breathlessness in Fletcher's classification require the subject to estimate his performance in walking uphill. In the flat country in and around Leigh answers to such questions are of doubtful validity. Only those men who were unable to keep up with other men of their own age on the level (Grade 3 or more) were therefore considered to be breathless.

Non-miners and Miners Without Pneumoconiosis.—In every case the miners recorded a higher prevalence of symptoms than the non-miners. The difference was greatest in the case of breathlessness, the miners recording a prevalence more than three times as high as the non-miners ($P < 0.01$). Cough and sputum and wheezing and tightness were recorded approximately twice as frequently among the miners ($P < 0.01$).

Miners With and Without Pneumoconiosis.—A similar prevalence of chest illness and of wheezing and tightness in the chest was found in these two groups. Cough and sputum, on the other hand, were recorded less often among those with pneumoconiosis and only slightly more frequently than among the non-miners. In the miners with simple pneumoconiosis the prevalence of breathlessness was only slightly higher than that found in the non-miners (9.5% compared with 7.2%); in those with complicated pneumoconiosis the prevalence of breathlessness was higher than in any other group—namely, 40%.

It is clear, therefore, that miners, irrespective of the presence of pneumoconiosis, had a higher prevalence of all symptoms and were more breathless than the non-miners.

TABLE V.—Prevalence of Respiratory Symptoms in the Three Groups (% in Parentheses) (Aged 55-64)

Group	No.	No Symptoms	Chest Illness	Cough	Sputum	Cough and Sputum	Yellow Sputum	Wheeze	Tightness	Wheeze and Tightness	Breathlessness
Non-miners	84	30 (35.7)	17 (20.2)	25 (29.8)	28 (33.3)	15 (17.9)	10 (11.9)	32 (38.1)	30 (35.7)	19 (22.6)	6 (7.2)
Miners and ex-miners category 0/-/-	101	20 (19.8)	32 (31.7)	49 (48.5)	57 (56.4)	38 (37.6)	22 (21.8)	59 (58.4)	53 (52.5)	43 (42.6)	25 (24.8)
Miners and ex-miners with pneumoconiosis	31	7 (22.6)	10 (32.3)	9 (29.0)	13 (41.9)	6 (19.3)	6 (19.3)	17 (54.8)	14 (45.2)	14 (45.2)	6 (19.3)
Simple pneumoconiosis	21	4 (19.0)	7 (33.3)	7 (33.3)	9 (42.9)	4 (19.0)	5 (23.8)	11 (52.4)	8 (38.1)	7 (33.3)	2 (9.5)
Complicated	10	3 (30.0)	3 (30.0)	2 (20.0)	4 (40.0)	2 (20.0)	1 (10.0)	6 (60.0)	6 (60.0)	5 (50.0)	4 (40.0)

Prevalence of Chronic Bronchitis

There is no generally accepted definition of chronic bronchitis, though cough, sputum, and disability are usually implied. German authorities reviewed by Worth and Schiller (1954) stress the importance of physical signs in the chest in addition to cough and sputum; but they also point out that added sounds may be evanescent. In view of the unreliability of physical signs in the diagnosis of chronic bronchitis (Schilling *et al.*, 1955), we omitted a clinical examination and based the diagnosis on answers to the questionnaire.

For this analysis we have defined chronic bronchitis as the constant production of phlegm and one or more chest illnesses during the past three years. Table VI shows that by this definition the miners had more than twice as much bronchitis as the non-miners—23.5% compared with 10.7%.

TABLE VI.—Prevalence of Chronic Bronchitis

	No.	Chronic Bronchitis
Non-miners	84	9 (10.7%)
Miners	132	31 (23.5%)
Without pneumoconiosis	101	27 (26.7%)
With	31	4 (12.9%)

The prevalence of bronchitis in the miners without pneumoconiosis (26.7%) was the cause of most of this difference. In those miners with pneumoconiosis the prevalence of bronchitis was only slightly higher than in the non-miners (12.9% compared with 10.7%). The difference between the non-miners and the miners without pneumoconiosis is highly significant ($0.01 > P > 0.001$); that between the non-miners and all the miners, irrespective of x-ray category, is also statistically significant ($0.05 > P > 0.01$).

The radiographs were classified for emphysema on the usual criteria—a low diaphragm, narrow vertical heart, abnormal vascular pattern, and bullous changes (Simon and Galbraith, 1953). The prevalence of emphysema was not significantly different in miners and non-miners; however, the detection of the early stages of emphysema radiologically is unreliable (Knott and Christie, 1951) and we had no lateral films.

Ventilatory Capacity

The ventilatory capacity measurements according to occupation and x-ray category are shown in Fig. 1. The mean value for the non-miners was 85 litres/minute, and for the miners without pneumoconiosis 76 litres/minute. The difference is highly significant ($0.01 > P > 0.001$). The mean M.V.V. of all miners irrespective of pneumoconiosis was 77.3 litres/minute, and the difference between this and the non-miners is also significant ($0.05 > P > 0.01$).

The effect of pneumoconiosis on the ventilatory capacity is also shown in Fig. 1. A reduction of 6 litres/minute for each category of simple pneumoconiosis was observed. A further reduction of 7 litres/minute was found in the mean M.V.V. of miners with P.M.F.

Fig. 2 shows the percentage frequency distribution of the ventilatory capacity for the non-miners and the miners without pneumoconiosis. The distribution in the miners is displaced to the left. Thus the percentage of men with values of less than 50 litres/minute was 7.1% in the non-miners, compared with 16.8% in the miners. It is our clinical impression that those with an M.V.V. of less than 50 litres/minute are usually definitely crippled by their respiratory insufficiency.

The men with chronic bronchitis are indicated by the black columns. Bronchitis is associated with a low ventilatory capacity. Thus the mean of the non-miners with bronchitis was 60 compared with the group mean of 85 litres/minute ($P < 0.001$); that of the miners with bronchitis was 65 compared with the group mean of 76 litres/minute ($0.01 > P > 0.001$).

Chronic bronchitis as we have defined it has a greater effect on ventilatory capacity than one category of simple pneumoconiosis (Table VII). The mean M.V.V. of miners with bronchitis was 65 litres/minute and for those without bronchitis about 80 litres/minute—a difference of 15 litres compared with the 6 litres/minute per category of simple pneumoconiosis.

Fig. 1.—Relationship between x-ray category and maximum voluntary ventilation. (Age 55-64.)

Fig. 2.—Frequency distributions of M.V.V. Men with chronic bronchitis are indicated by black columns.

TABLE VII.—Mean M.V.V. (Indirect) in Litres/Minute in the Three Groups, Showing the Effect of Bronchitis on the Ventilatory Capacity

	Group Mean	Without Bronchitis	With Bronchitis
Non-miners	85	88	60
Miners and ex-miners, category 0/-/-	76	80	65
Miners and ex-miners with pneumoconiosis	82	84	65

Analysis by Social Class, Smoking Habits, and Dust Exposure

Our survey also enabled us to investigate the possible aetiological importance of a limited number of other factors.

Social Class.—Table VIII shows the number of men in each group in each of five social classes. Social class as classified on the Registrar-General's scale was determined from the occupations in which a man had spent most of his working life. This may differ from that obtained by the Registrar-General based on occupation at the time of the census. This difference may be of some importance, because

TABLE VIII.—Social Class

	Registrar-General's Social Classes			Total
	III	IV	V	
Non-miners	56	11	9	76*
Bronchitis	5	2	1	8
Miners and ex-miners category 0/-/-	34	52	15	101
Bronchitis	14	10	3	27
Miners and ex-miners with pneumoconiosis	18	12	1	31
Bronchitis	1	3	0	4
Total	108	75	25	208
Bronchitis	20 (18.5%)	15 (20.0%)	4 (16.0%)	39 (18.8%)

* 8 non-miners were in classes I and II.

those with severe bronchitis may be in a lower social class on account of their disability. The miners' social class was lower than that of the non-miners. Furthermore, the social class of the miners without pneumoconiosis was lower than that of the miners with pneumoconiosis (66.4% compared with 41.9% in classes IV and V). A relation between the prevalence of bronchitis and social class might therefore be inferred. However, the overall prevalence of 18.5, 20.0, and 16.0% in classes III, IV, and V suggests that there was in fact little relation between chronic bronchitis and social class in the group studied.

Smoking Habits.—Men have been classified according to the quantity of tobacco smoked. A smoker is defined as one who at any period of his life had smoked 1 g. of tobacco a day for a year. One cigarette a day is equivalent to 1 g. of tobacco a day; 1 oz. (28 g.) of tobacco a week is equivalent to 4 g. of tobacco daily (Doll and Hill, 1950). The results are shown in Table IX. The proportions in each group among miners and non-miners were similar.

Smokers were compared with non-smokers irrespective of occupation and x-ray category; there were no bronchitics among 28 non-smokers but 40 bronchitics among 188 smokers. The numbers expected in the two groups, assuming that there is no association between smoking and bronchitis, are 5.2 and 34.8. The observed differences from those expected are statistically significant ($0.02 > P > 0.01$). For all groups together a clear relationship between the amount of tobacco smoked (above 1 g. a day) and bronchitis is disturbed by the lower prevalence in those smoking the largest amount.

Dust Exposure.—Only indirect measures of dust exposure were possible—namely, the number of years spent (1) underground, and (2) on the coal-getting shift. The bronchitics among the miners without pneumoconiosis had spent an insignificantly longer time both underground and on the coal-getting shifts. Those men with category 1 and 2 simple pneumoconiosis and bronchitis had spent only a short time

TABLE IX.—*Smoking Habits Classified According to Number of Grammes of Tobacco Smoked a Day*

Group	No.	Smoking Habits (g. of Tobacco)				
		0	1-	5-	15-	25-

on the coal-getting shift. The numbers are, however, too small to draw any firm conclusions about the relation to dust exposure and bronchitis.

Discussion

Lapses

The homes of all those who lapsed from the investigation were visited. Some information was obtained either from the men themselves or from their wives. While information divulged through the crack of a closing door is of doubtful value, sufficient details were obtained to conclude that no great bias was introduced by the lapses.

Lapses could be reduced if the population sampled could be studied in their homes instead of having to attend at a central hall. Portable tests of ventilatory capacity now make this a foreseeable possibility. Radiography would, however, have to be omitted. Our results suggest that such an omission would not have affected our conclusions about miners and non-miners, but a diagnosis of pneumoconiosis would, of course, have been impossible.

Mortality Statistics

A high mortality from bronchitis for coal-miners was noted by Collis (1931), who also drew attention to the wide differences that occurred in different coalfields. In 1930-2 the S.M.R. from bronchitis and pneumonia for all coal-miners (ages between 20 and 65) working underground was 119, but for miners in Lancashire and Cheshire it was 165. In 1950 the S.M.R. for bronchitis in hewers and getters was 180; that in other mine-workers in coal was 98. It would appear, therefore, that the excess mortality due to bronchitis affects the former group. However, undoubtedly in the past deaths due to pneumoconiosis and even respiratory tuberculosis have been attributed to bronchitis (Cummins, 1935; Sen, 1937), and it is probable that some inflation of the bronchitis mortality statistics by faulty certification still occurs. Nevertheless, the figures do suggest that bronchitis may be more prevalent in miners than in the general population. It should, however, be noted that a high mortality due to bronchitis is found in those coalfields which are situated in areas where bronchitis death rates are high also in the non-mining population (Goodman *et al.*, 1953), and that the wives of coal-miners share this excessive mortality from bronchitis to a large extent (Registrar-General, 1938).

Morbidity Statistics

Remarkably few estimates of the relative prevalence of bronchitis in miners and comparable non-miners have been published. In 1924 Schurmann (quoted by Worth and Schiller, 1954) found that the prevalence of bronchitis in underground workers was double that of mine office workers who had never been exposed to dust. More recently Boehme and Lent (1951), in a large group of hospital patients, found an overall prevalence of bronchitis of 29.1% in miners compared with 15.5% in non-miners, the figures in the 50-60 age group being 32.6 and 14.6% respectively. Our findings in the 55-64 age group in a geographically defined community support these conclusions and indicate a close agreement in the magnitude of the difference found by Boehme and Lent.

Conflicting results have been obtained for the prevalence of bronchitis in miners with and without pneumoconiosis.

In this country Hart and Aslett (1942) found that among South Wales coal-workers aged 40-64 years the prevalence of chronic bronchitis increased with radiological category. In Germany, Trautmann (1949) found that in "silikose" stage I and II the prevalence of bronchitis was not especially high, but that in stage III it might reach nearly 60%. Beckmann (1951) found a higher prevalence of bronchitis in those with "silikose" than in those without; while Zorn (1949) and Worth and Dickmans (1950) noted an increasing prevalence of bronchitis with increasing grade of "silikose." On the other hand, Boehme and Lent (1951), in a group of miners who were no longer capable of full work, found a higher percentage of bronchitis in those without "silikose" than in those with stages I and II. The results of German investigations are reviewed by Frieboff (1952) and Worth and Schiller (1954). It is clear, as Boehme and Lent themselves realize, that the results may be greatly influenced by the population studied.

In the present survey chronic bronchitis was slightly commoner among the miners without pneumoconiosis than among those with pneumoconiosis, but the number of the latter was small and they mostly had simple pneumoconiosis. It is interesting to observe in this connexion that in their 55-year-old group Gilson *et al.* (1955) recorded a higher prevalence of cough and sputum in working miners without pneumoconiosis than in those with either simple or complicated pneumoconiosis.

The general prevalence of respiratory symptoms has seldom been published. Stuart-Harris (1954) reported cough and sputum in 55% of men aged 50-60 in an industrial population. Of these, 35.5% had a symptom group called the "triple complex," consisting of cough, sputum, and disability. An approximately comparable figure obtained from our results gives a prevalence of 26% for the three groups together, and 34% for miners and ex-miners without pneumoconiosis.

Ventilatory Capacity

Our findings of a significant reduction in ventilatory capacity in miners compared with non-miners are in agreement with the few other workers who have compared miners with men who have never mined (Vokac, 1950; Kadlec and Vyskocil, 1950; Salvini and Capodaglio, 1955). Significant differences in ventilatory capacity between miners without pneumoconiosis and non-miners of comparable age have been recorded previously at this unit (Gilson *et al.*, 1955).

The finding that miners with early simple pneumoconiosis recorded a higher mean M.V.V. than those without is discussed in detail in another paper (Carpenter *et al.*, 1956). Taken together with the observation that such miners appear to have fewer respiratory symptoms and less chronic bronchitis, the suggestion is made that the fitter men with the larger ventilatory capacities, who are more likely to work on the coal-face where the concentration of dust is highest, are consequently more liable to pneumoconiosis than their fellows.

The effect of simple pneumoconiosis on the ventilatory capacity of the sample studied was not great, and it seems unlikely that this form of pneumoconiosis *per se* causes much disability. The effect of chronic bronchitis and respiratory symptoms in reducing the M.V.V. were, how-

ever, more considerable. These findings support the conclusions of those workers who have found that disability in miners is related more closely to "emphysema" than to fibrosis (Wright, 1956; Lavenne and Belayew, 1953; Foubert *et al.*, 1954).

Aetiological Factors

Smoking.—Cigarette-smoking is generally regarded as aetiological important in the development of chronic bronchitis. Palmer (1954) found a significantly greater incidence of bronchitis in smokers than in non-smokers and noted an increase with increasing tobacco consumption. Oswald *et al.* (1953) considered that cigarette-smoking was an important aggravating factor.

Greene and Berkowitz (1954), using a "pre-operative test cough" of "proved sensitivity and reliability," recorded prevalences of "smokers' bronchitis" in 76-80% of people of either sex smoking 20 or more cigarettes daily. On the other hand, neither Fry (1954), in general practice, nor Gregory (1955), in a gas-workers' survey, was able to show a convincing relationship between smoking and bronchitis. Nor was there any association between the mortality rates of doctors due to respiratory disease other than carcinoma and their smoking habits (Doll and Hill, 1954). Differences may be due to the wide differences in diagnosis of bronchitis. Significant results are most likely to be obtained by those who include "smokers' cough" in their definition of bronchitis.

In a previous investigation in the Rhondda Valley we were unable to show a relation between smoking habits and bronchitis (Cotes *et al.*, 1956). In the present study, however, smoking appeared to be a possible factor. Smoking cannot, however, account for the differences either in respiratory symptoms of ventilatory capacity between miners and non-miners, since the smoking habits of the two groups were very similar.

Social Class

The relationship between bronchitis and social class is seen in the mortality statistics. These are considered in detail for 1930-2 by Goodman *et al.* (1953). The S.M.R.s for bronchitis in men aged 20-64 according to class in 1950 showed that there was no longer so great a difference between classes III and IV as there had been in 1930-2, and this was due to a reduction in the S.M.R. in class IV.

Oswald *et al.* (1953) were unable to show any close association between bronchitis and social class. Fry (1954) also failed to observe any relationship. Our findings indicate that the importance of social class could easily be exaggerated. Thus the higher prevalence of bronchitis among miners might be attributed to their lower social class. That this was not so is clear from the prevalence of bronchitis within the social classes, which showed no such relation.

Exposure to Dust

Since the main differences between miners and non-miners are life underground and exposure to coal-dust it is likely that one or both of these factors is associated with the differences that we have observed. Of the two, exposure to dust might perhaps be expected to be the more important. An association between dust exposure and bronchitis, based on the presence of rhonchi in the lungs, has been stressed by several authors (Dautrebande *et al.*, 1948; Lent, 1950; Dautrebande, 1952) but refuted by others (Beckmann, 1951; Pestiaux *et al.*, 1955; Worth *et al.*, 1955). In the present survey, no clear relation between bronchitis and dust exposure could be shown in the mining group. This may be because bronchitis is a condition in the cause of which many factors are involved. The interaction of these factors may tend to obscure the importance of any one of them. Alternatively, the general belief that dust is important in causing bronchitis may be mistaken.

The possibility that miners may be more apt than other members of the community to complain of symptoms has been suggested (Halliday, 1943; Heron and Braithwaite, 1953; Ross *et al.*, 1954). In a previous survey we observed a tendency for men who had been compensated to record a lower breathlessness grade than might have been expected

from their ventilatory capacity, and it seemed probable that other respiratory symptoms might be correspondingly exaggerated. In the present study, compensation issues were rarely raised and we had no evidence to suggest that miners were more symptom-prone than non-miners. Ventilatory capacity measurements supported the questionnaire findings.

Summary

A study of respiratory disability in 90% of a random sample of 245 men aged 55-64 in Leigh (Lancs) has been made.

Miners and ex-miners had significantly more "chronic bronchitis" and a lower ventilatory capacity than men who had never worked in the mines; and they also recorded a higher prevalence of all respiratory symptoms.

Miners without pneumoconiosis were on the average more disabled than those with early simple pneumoconiosis.

The differences between miners and non-miners could not be ascribed to differences in social class or smoking habits, and in the miners there was no obvious relationship between length of exposure to dust and bronchitis.

We are indebted to our colleagues at the Pneumoconiosis Research Unit for their help, advice, and criticism. The chest radiography was carried out by Mr. W. G. Clarke and the radiographic team, and much of the home visiting by the epidemiological team. The ventilatory capacity measurements were made by Mr. A. J. Merrick. We also wish to thank the Mayor and inhabitants of Leigh, without whose active co-operation this survey would not have been possible.

APPENDIX

RESPIRATORY SYMPTOMS

Name..... X-ray No.....

	Yes	No
I. During the past 3 years, have you been ill with your chest? If yes:— Once only? More than once? Did you have increased cough? Did you have increased phlegm?		
II. (a) Apart from chest illnesses, do you usually have a cough? If yes:— Do you suffer from a persistently troublesome cough? (b) Apart from chest illnesses, do you usually bring up phlegm? If yes:— In the winter? Throughout the year? Is the phlegm usually yellow? If not: Did it become so during your illness?		
III. Do you ever get wheezing in your chest? If yes:— Slight-moderate? Severe? With chest illnesses? Does your chest ever feel tight? If yes:— Slight-moderate? Severe? With chest illnesses?		
IV. Have you ever had:— Year: Pneumonia? Pleurisy? Acute bronchitis?		
V. Do you consider that you suffer from:— Chronic bronchitis? Asthma?		
VI. (1) Is your breath as good as that of other people of your own age at work, on walking, hurrying, climbing stairs, or hills? (2) Are you able to walk with normal people of your own age on the level, but unable to keep up on hills or hurrying? (3) Are you unable to keep up with normal people walking on the level but able to walk a mile or more at your own speed? (4) Are you unable to walk more than 200 yards on the level without a pause for breath? (5) Are you breathless on talking, after undressing, or at rest?		
VII. Have you had to change your job on account of being too short of breath when at work? If yes: Year changed..... Job at which you failed.....		
VIII. Smoking:— Have you ever smoked? Now? Amount smoked now:— Estimated average during past 10 years if different: Cigarettes per day..... Oz. tobacco/week (hand-rolled)..... Oz. tobacco/week (pipe)..... Age at starting:..... Age at stopping:.....		
IX. Does observer consider subject to be bronchitic?		
X. Are you getting a pension for any chest disease? Have you ever applied for a pension?		

IRRADIATION-INDUCED MALIGNANT
HYPERTENSION: CURED BY
NEPHRECTOMY

BY

W. M. LEVITT, M.D., F.R.C.P., F.F.R.

Associate Physician, Department of Radiotherapy,
St. Bartholomew's Hospital

AND

SAMUEL ORAM, M.D., F.R.C.P.

Physician, King's College Hospital

The following case is considered worthy of record as, to the best of our knowledge, it is the first example demonstrating the possibility of saving life by timely nephrectomy where renal damage produced by irradiation has resulted in malignant hypertension.

Case History

A man aged 33 had his left testis removed for seminoma in 1941. Soon afterwards he complained of abdominal pain and distension and began to lose weight. A mass was found in the upper abdomen, but nothing was done until May, 1943, by which time the mass had become very large, extending well across the midline. He was given deep x-ray therapy by one of us (W. M. L.) in May and June, 1943, following which the mass disappeared, and he returned to normal health and full work. The total dosage to the left renal region was under 3,000 r. He remained well and at full work until July, 1954, when he was seen by one of us (S. O.), complaining of severe splitting vertical midline headache which had begun about a year previously and which was relieved by aspirin after about half an hour. Some six months ago a second type of headache had appeared, which was associated with a bounding pulse. Two weeks prior to the consultation he had found difficulty with his vision.

Because of various medical examinations for insurance purposes his blood pressure in 1950 was known to have been 150/90 mm. Hg; in 1952 it was 160/90 and in 1953 165/95.

There was a history of scarlet fever at the age of 18, but this was not complicated by nephritis, and there was no past history of pyelitis or urinary infection. There was no family history of hypertension or cardiovascular disease, and both his parents were alive, his father aged 76 and his mother 74.

On examination on July 22, 1954, the positive physical signs were that his apex beat was 4½ in. (11.4 cm.) to the left of the midline in the fifth intercostal space, and a double thrust was visible and the cardiac impulse was forceful. A clear protodiastolic triple rhythm was audible, together with a faint systolic murmur at the apex. His aortic second sound was loud and musical. There were no aortic murmurs. His pulse was 78, of regular rhythm and large volume, but the vessel wall was not clinically thickened. His femoral, dorsalis pedis, and posterior tibial pulses were easily palpable. His blood pressure at rest was 215/130 mm. Hg.

On July 30 he was examined ophthalmologically by Mr. Ronald Crick, who reported some general retinal oedema with extreme attenuation of the arteries, which were hardly visible, and some dilatation of the veins. There was some deflection at the arterial crossings, with hard white exudate near the disk edges and more fluffy exudate farther out, with some flame-shaped haemorrhages. His disks showed a blurred margin, the right more than the left, with slight papilloedema. There was no nipping of the veins. The retinopathy was of Grade III-IV, and the whole process suggested a relatively acute and recent process.

There were no abnormal physical signs in the central nervous system, lungs, or elsewhere.

On clinical grounds, with knowledge of the gradual increase in blood pressure over the preceding three years, his

case was considered to be hypertension secondary to irradiation of the left kidney, rather than essential hypertension, and it was thought likely that he had suddenly entered a malignant phase over the previous six months.

In spite of complete bed rest and amylobarbitone sodium sedation, his triple rhythm persisted and the diastolic pressure did not at any time fall below 120 or the systolic below 180 mm. Hg.

Pre-operative Investigations

Teleradiograms of the chest in the antero-posterior and right and left anterior oblique views showed slight enlargement of the left ventricle.

The 12-lead electrocardiogram (July 22) showed severe ischaemia of the left ventricle as a result of hypertrophy of that chamber. The R wave was tall in leads V5, V6, VL, and standard lead I, and the S wave was deep in leads V1, V2, and V3. The T wave was inverted in leads V5, V6, VL, and standard leads I and II (see accompanying electrocardiograms).

An intravenous pyelogram showed delayed secretion of the left kidney with some deformity of the left lower calices. The right kidney was radiologically normal.

Chromocystoscopy by Mr. Yates-Bell showed slight delay on the left side, and micro-urea concentrations of ureteric urines showed slightly diminished concentration on the left side.

The blood urea was 44 mg. per 100 ml., and his urea clearance was 46% of the average standard normal. The urine showed a slight cloud of albumin with scanty red cells and pus cells and a few hyaline and granular casts. Urine culture was sterile. Haemoglobin was 108% and the red cells were normal.

Left nephrectomy was carried out by Mr. Yates-Bell on August 9. The perirenal fat was adherent and the ureter was found with difficulty among dense fibro-fatty tissue.

Pathological Report on Left Kidney (Professor H. A. Magnus).—The kidney weighed 84 g. The capsule stripped with some difficulty, revealing fine granulation of the kidney, especially on its greater curvature. On slicing, it was apparent that there was a very considerable reduction in the kidney substance with a corresponding increase in intrapelvic fat. At the lower pole there was one small cyst. The blood vessels were not unduly prominent and the renal pelvis appeared normal.

Sections showed numerous areas in which there was complete obliteration of glomeruli with marked arteriosclerotic changes in the associated blood vessels. These damaged areas of kidney tissue tended to have a linear distribution, but this was not a constant feature. In the areas of kidney tissue not involved the glomeruli were remarkably normal, but the arterioles and larger vessels still showed the changes of arteriosclerosis. Towards the medulla the larger vessels showed pronounced medial hypertrophy and some fibrosis.

The histological picture suggested some process of long standing, and it may well have represented the end stages of damage from x-ray therapy. Professor Magnus stated that he had never seen a kidney in this condition, so that he was unable to make any comparison. He did not think the histological picture was that of malignant hypertension, and it was certainly not that of chronic nephritis. The vascular changes present in this kidney were not recent, and it was probable that they did not give a picture of what the vascular system was like as a whole. Had he not known the clinical history of the patient he would have suggested that the lesion represented the end-result of a chronic pyelonephritis.

Post-operative Progress

The blood pressure on the day after operation fell at one time to 130/80, but within a week it had reached 180/120 and a canter rhythm at the apex became again audible. At the time of his discharge from hospital on the 22nd day after his nephrectomy the blood pressure had reached

180/100. On that day Mr. Crick reported slight diminution of the oedema of both retinae; no haemorrhages were visible and the exudates were slightly less and the arterioles fuller than previously. The conclusion was that there was slight general improvement in the fundus picture. By September 8 the patient's blood pressure had reached 210/140.

On September 30 Mr. Crick reported that without doubt there had been a recession in the papilloedema and there was less attenuation of the retinal vessels, particularly noticeable in the right eye. In addition, some of the sharply defined glistening exudates which formerly made up

Electrocardiograms showing reversion to normal in less than a year after nephrectomy.

the pattern of the macular fan in the left eye had disappeared, so that there was now only one streak left in this formation, together with a few dots. No haemorrhages were visible.

By October 15 the blood pressure had fallen to 172/104 and the electrocardiogram showed slight improvement. The T wave, which previously had been inverted in lead VI and standard leads I and II, had become just upright. It was, however, still slightly inverted in leads V5 and V6.

A month later the visual acuity was 6/6 in each eye and there was a further slight improvement in the appearance of the fundi.

By December 22 he was quite well and working a full day, and had had no further headaches or nocturia, and he realized for the first time that he had been dyspnoeic prior to his operation. His blood pressure was 200/110, but there was no albuminuria. The electrocardiogram showed some further improvement in that the previously inverted T wave in lead V5 had now become upright, although inversion of the T wave in lead V6 persisted; the amplitude of the T wave in leads I and II had improved.

When next seen, on March 16, 1955, he was working hard and had no symptoms whatsoever; the blood pressure was 190/110 and the electrocardiogram remained essentially unchanged, with slight inversion of the T wave in lead V6 still present. His fundus picture showed still further improvement, the disks being flatter, the exudates fewer, and the vessels less attenuated. In view of the blood-pressure figure it was thought justified to try the effect of "serpasil" orally, 0.25 mg. three times a day. By April, 1955, the reserpine had reduced his blood pressure to the range of 150-160/92-110.

On June 22 the 12-lead electrocardiogram had become completely normal and the blood pressure was 162/94; he was now taking 0.5 mg. of reserpine thrice daily. Mr. Crick reported that his fundi had also now become completely normal.

When last seen on March 28, 1956, the patient had no symptoms whatsoever, was taking only reserpine, 0.25 mg. three times a day, the blood pressure was 152/92, and his 12-lead electrocardiogram was still normal in all leads.

Discussion

Radiation damage to the kidneys was first described by Ralston Paterson in 1952, and the material upon which his communication was based was analysed in detail by Kunkler, Farr, and Luxton in the same year. All the patients in this series—over 30—had been treated for testicular tumours with a radiation dose of from 2,000-3,000 r, distributed to both kidneys. The onset of renal failure was comparatively early, the interval after treatment averaging about eight months. In a number of cases the renal damage proved fatal. However, it was found that even in severe cases a considerable degree of recovery was possible after blood transfusion and prolonged rest.

In the case here reported the main incidence of the irradiation was on the left kidney, which received just under 3,000 r. The right kidney received a considerably lower dose, and part of this kidney must have sustained less than 2,000 r. Further, in considering the cause of the renal damage it must be taken into account that the kidney may well have been involved in the extensive growth which was present at the time of treatment. There can, however, be little doubt that radiations played a major part in producing the condition.

So far as we know, no case has previously been reported in which the picture of malignant hypertension has been produced by unilateral radiation damage, and we consider it important that this possibility should be recognized in view of the chance of cure offered by timely nephrectomy. Of all the malignant growths in the abdomen, seminoma perhaps offers the best prospect of cure by radiotherapy, and it is not unlikely that a proportion of the patients so cured suffer from malignant hypertension due to unilateral renal

damage. If this possibility is borne in mind at the follow-up of these patients lives may be saved.

Since Goldblatt's classical researches (Goldblatt *et al.*, 1934; Goldblatt, 1937, 1948) and those of Wilson and Byrom (1939) much interest has centred on the part played by human renal disease in causing hypertension, and in particular in the role of unilateral, or mainly unilateral, kidney disease. The exact cause of the high blood pressure in unilateral renal disease is still unknown, but it is probable that the diseased kidney secretes an excess of circulating pressor substance, and thus early removal of the kidney might be expected to reduce the elevated pressure.

The diseases which can give rise to unilateral or predominantly one-sided disease, with resultant hypertension, are numerous and may involve primarily the renal vessels or the parenchyma. Those conditions where nephrectomy has led to cure of the hypertension include chronic pyelonephritis, which is by far the commonest cause (Braasch, 1942), and such diseases as tuberculosis (Kennedy, Barker, and Walters, 1941), hydronephrosis, which usually results from an aberrant renal artery, neoplasm (Koons and Ruch, 1940), trauma (Farrell and Young, 1942), atherosclerosis of the renal artery (Leiper, 1944), infarction and undetermined cause (Perry, 1945).

In 1940 Schroeder and Fish laid down certain criteria for operation, among which was the absence of papilloedema and retinitis, but it is now realized that such malignant hypertension is by no means a contraindication to nephrectomy, as occasionally cure may result (Platt, 1941; Kennedy, Barker, and Walters, 1941; Powers and Murray, 1942; Leiper, 1944; Perry, 1945).

Recently Perera and Haelig (1952) have gone so far as to suggest that the type of hypertension induced by unilateral renal disease is in fact, malignant, being acute, severe, and rapidly progressive. Fourteen of their 16 adult cases showed retinopathy. They are of the opinion that as hypertensive vascular disease rarely, if ever, begins after the age of about 50 (Perera, 1948), the sudden appearance of a striking elevation in diastolic blood pressure in the older age groups, known previously to have been normotensive, should lead to a suspicion of unilateral renal disease.

Summary

An example is recorded of severe malignant hypertension induced by renal damage from irradiation that became normotensive after nephrectomy. Following nephrectomy, the blood pressure fell slightly over a period of seven months, and then responded at once, and satisfactorily, to moderate doses of reserpine orally. All symptoms disappeared after nephrectomy, and the continuous improvement of severe (Grade III-IV) retinopathy to complete normality within 10½ months of operation was paralleled by severe hypertensive electrocardiographic changes reverting completely to normal within the same period.

Attention is drawn to the possibility of saving life by timely nephrectomy where renal damage produced by irradiation has resulted in malignant hypertension.

TOXICITY OF SOME ATMOSPHERIC POLLUTANTS

BY

R. E. PATTLE, M.A., B.Sc.

AND

H. CULLUMBINE, M.D., M.Sc.

Chemical Defence Experimental Establishment,
Porton, Wilts

Examples of the harmful effects produced in man by contaminated fogs are now well known. The general clinical picture is one of respiratory embarrassment with increased dyspnoea, cyanosis, progressive cardiovascular embarrassment, and possibly fever and toxæmia if secondary infection occurs. It was similar in the London fogs of 1948 and 1952, in the Meuse Valley fog of 1930, and in the Donora incident in 1948. The young, the old, and those with pre-existing respiratory or cardiac disease are the more seriously affected, and the post-mortem findings are consistent with the inhalation of an irritant substance.

The nature of the irritant substance is still unknown, although various contaminants have been arraigned by different workers. Sulphur dioxide, carbon monoxide, automobile exhaust fumes, and fluorine compounds have been suggested (Firket, 1931; Roholm, 1937; Regan, 1953).

Unfortunately no lethal fog has been adequately sampled during the incident, nor have its chemical and physical properties been determined. It is therefore difficult to plan any experimental work on the toxic effects of polluted fog. The obvious contaminants must be studied first, but in the absence of precise knowledge of the possible concentration or the physical state of each substance in a smog the practical implications of the results obtained must be in doubt. Such a study will, however, indicate which contaminants are potentially dangerous and those which may be harmless, although synergistic effects may alter this simple classification.

We at Porton have examined effects on animals and human beings of various substances and mixtures which might be important atmospheric pollutants. The results of these experiments have been or are being reported in detail elsewhere, but it did seem desirable to summarize our progress to date and to consider the toxicological picture as a whole.

The use of animals must necessarily form part of such an investigation; the relative toxicities of possible contaminants and any synergistic effects can only be accurately determined by using subjects drawn from a homogeneous population, which cannot be obtained with human beings. In general most species of animals are less sensitive to these toxic pollutants than is the susceptible proportion of the human population.

Sulphur Dioxide

SO₂ is a pollutant commonly sampled in fog atmospheres. The concentrations reported in "smogs" (about 2 p.p.m. or less) have no detectable effect on any animal used. However, a small portion (perhaps 1/100) of human beings have been found to suffer from bronchoconstriction when inhaling low concentrations of this gas. In some cases slight tightness of the chest could be felt with concentrations as low as 1 p.p.m. In a London fog on January 5, 1956, one

such subject experienced bronchoconstriction and severe respiratory distress, exactly similar to that produced by SO₂, when he attempted to hurry through the fog. In this instance the action of the gas was combined with the normal breathlessness due to exercise.

Smog atmospheres contain both SO₂ and smoke particles, and Meetham (1954) suggests that the SO₂ could be absorbed on to the smoke particles. It would then not be detected in the usual apparatus for measuring SO₂, as the air is filtered before entering the absorbent solution. Such SO₂-smoke particles would, however, if they existed, be inhaled and penetrate deeply into the lungs, and the SO₂ might be more toxic in this form than in the pure gaseous state.

The results of experiments on this subject have in some cases been expressed by the CtD₅₀. This is defined as the dosage (concentration time) to which a batch of animals has been exposed by the time 50% have died.

R. E. Pattle (unpublished results, 1955-6) has shown that the toxicity of SO₂ in a concentration of about 2,700 mg. per cubic metre (1,000 p.p.m.) to mice is enhanced by the addition of 100 mg. per cubic metre of smoke from a kerosene lamp. The CtD₅₀ for the mixture was about 40% greater than that for the gas alone. In one experiment where the mean SO₂ concentration was the same (2,560-2,590 mg. per cubic metre) for the clean and the smoky atmospheres, at approximately 300 minutes (292-295 minutes) the mortalities were: clean atmosphere, 3/25; smoky atmosphere, 16/25. The final estimated CtD₅₀'s in the case last described were only in the proportion of 1 to 2.

The dosage of smoke administered in the above experiments is large and the higher mortality in the smoky atmosphere is not surprising. There is probably no need to postulate any interaction between smoke and SO₂ to account for the results. At necropsy the lungs showed intense congestion, areas of consolidation, collapse, and emphysema, and traces of oedema.

Previous exposure of mice to somewhat lower but still massive dosages of smoke (40 mg. per cubic metre for 22 hours) actually increases their resistance to subsequent exposure to SO₂ (c. 3,000 mg. per cubic metre; c. 1,000 p.p.m.). The ratio of the CtD₅₀'s for smoked to unsmoked mice was found to be 1.55, while after 200 minutes 20/49 unsmoked mice and only 6/49 of the pre-smoked group had died.

Other experiments have given similar results, so that it is undoubtedly a real effect. The cause of the protection, however, is not known. It may be that the pre-smoked mice have a smaller respiratory minute-volume or that the smoke causes increased secretion of protective bronchial mucus. We have no information on these points. To find out whether smoke acquires any peculiar irritant properties by being in contact with SO₂, a flow of smoky air was divided into two portions. One portion was administered directly to 20 mice, while the other was mixed with SO₂ (5,070 mg. per cubic metre; 1,900 p.p.m.). The SO₂ was then removed from this second portion of air by bubbling through sodium carbonate solution, and the resultant air flow, with its burden of smoke, was administered to a second batch of 20 mice. Prolonged exposure (77 hours; average smoke concentration 50 mg. per cubic metre) caused no fatalities in either group of mice; seven in each batch were kept for three months and they remained in good health. Histological examination of the lungs of all the mice showed no differences between those which had received ordinary smoke and those which had breathed smoke which had been in contact with SO₂.

Sulphuric Acid Mist

Guinea-pigs are much more sensitive to H₂SO₄ mist than any other species; using these, we found that a mist with the larger particles was more toxic than one with smaller particles; and that reducing the temperature of the exposure chamber, but keeping the particle size constant, increased the toxicity of the mist (see Table).

Estimated Median Lethal Concentration (LC_{50}) of H_2SO_4 Mist for Guinea-pigs with an Eight-hour Exposure

Temperature	Particle Mass Median Diameter	LC_{50} (mg./cubic metre)
Room (20° C.)	2.7 μ	28.8
Room (20° C.)	0.8 μ	60.9
0° C.	0.8 μ	49.0

In high concentrations of mist the guinea-pigs die rapidly with bronchial spasm and a resultant emphysema; in smaller concentrations death is slower and there is more extensive pulmonary damage, including bronchial desquamation, haemorrhagic consolidation, oedema, and emphysema.

Early in the experiments it was noticed that fluctuations in the acid content of the mist occurred, and these were traced to the ammonia evolved from the faecal droppings and urine of the animals, which neutralized the acid. These fluctuations could be prevented by keeping the animals on a wire mesh above a tray of 10% H_2SO_4 . Under these conditions reproducible results could be obtained.

The other species examined—monkeys, goats, rabbits, rats, and mice—are much less sensitive to H_2SO_4 mist (Cameron, 1954; Pattie, Burgess, and Cullumbine, 1956); and in one experiment a rabbit survived a concentration of 400 p.p.m. for four days. The guinea-pig is known to be especially susceptible to conditions inducing bronchial spasm, and it is those individuals of the human species with a similar predisposition who are the more severely affected by smog atmospheres.

The variation in susceptibility of different individuals to H_2SO_4 mist is illustrated by our own exposure of human subjects (Van M. Sim and R. E. Pattie, unpublished results, 1955). Mist concentrations of 10 p.p.m., with the M.M.D. of the particles about 1 μ , were found to be highly irritant to the throat, although with prolonged exposure this irritation tended to decrease. If repeated coughing occurred, pain developed in the upper part of the chest. Most of the subjects suffered no long-term effects from an hour's exposure to this mist, but one subject exposed for 30 minutes had "wheezing," coughing, and expectoration for some hours; another subject continued to "wheeze" for two months.

Increasing the particle size of the mist also increased the irritancy, just as it increased the toxicity of the mist to guinea-pigs. Thus a mist of particle size about 1.5 μ M.M.D. was as irritant at 5 p.p.m. as the former mist at 10 p.p.m.

Ammonia was found to annul the irritant properties of H_2SO_4 mist and also those of atmospheres containing SO_2 .

Magnesium oxide smoke removed SO_2 from the atmosphere, but even when present in excess did not affect the irritant properties of H_2SO_4 mist.

Smoke

Smoke itself seems to be very inert so far as its acute toxicity is concerned. Our experiments indicate that the smoke from a kerosene lamp has a median lethal dosage to mice of the order of 1,500 mg. per cubic metre for 200 minutes.

Coal-tar Distillates

The effect of these is irregular; in one case dosages of 2,000 mg. per cubic metre of solid and liquid tar for 500 minutes produced no fatalities among exposed mice, but in another experiment with guinea-pigs and mice there were deaths due to irritation of the whole respiratory system.

Wood Distillates

Wood distillates have a much greater content of irritant aldehydes than coal distillates, but the effect of these irritants is masked by the presence of carbon monoxide in the wood gas. When suitably diluted they cause damage to the whole respiratory tract, especially to the trachea and bronchi.

Diesel Fumes

It has been suggested that the fumes from diesel engines may contribute irritant substances to a smog atmosphere. It is known that, because of their lower CO content, these fumes are normally less lethal than those from petrol engines; but Turner (1955) has claimed that diesel engines which are not in good mechanical condition produce more harmful fumes than those without defects. Because of the variety of toxic agents which diesel fumes contain investigation of their toxicity is difficult. Holtz *et al.* (1940) have indicated how the carbon monoxide, nitrogen oxides, and aldehyde contents in diesel fumes vary with changes in the fuel-air ratio.

We have exposed mice, guinea-pigs, and rabbits for varying periods of time to the fumes from a single-cylinder diesel engine (R. E. Pattie, H. Stretch, K. Sinclair, F. Burgess, and J. A. G. Edginton, unpublished results, 1955). Four conditions of engine-running were investigated and concentrations of CO, NO, NO_2 , aldehydes, vanadium, and several other substances were determined. The results of these experiments are to be reported in detail elsewhere; the most significant findings under each condition were as follows.

A. Fuel-Air Ratio 0.0121, power output low, good injector, air inlet open: No animals died in two experiments in which the exposure was in each case for five hours. In another experiment all the guinea-pigs, half the rabbits, and 20% of the mice were dead after seven hours' exposure. At necropsy all the animals showed gross damage to all parts of the respiratory tract, varying degrees of tracheitis, pulmonary congestion, consolidation, oedema, and emphysema being present. The fumes were highly irritant to the human eye, and the main causes of death were considered to be organic irritants of the acrolein type and NO_2 .

B. Fuel-Air Ratio 0.0193, power output 5.5 B.H.P., good injector, air inlet open: The fumes were less acrid but more toxic than in A. A five-hour exposure caused 90% of the guinea-pigs, 48% of the mice, but no rabbits to die. Post-mortem examination revealed gross pulmonary oedema, with some patchy areas of consolidation and emphysema. In contrast to the animals dying under condition A, tracheal damage was here slight. The main cause of death was considered to be NO_2 .

C. Fuel-Air Ratio 0.0199, power output 5.5 B.H.P., worn injector, air inlet open: Here the fumes were much less acrid and less toxic than in B. A five-hour exposure killed 60% of the guinea-pigs but only 1/40 mice, and no rabbits. The post-mortem pulmonary damage was similar to that occurring in B and was considered to be due to NO_2 .

D. Fuel-Air Ratio 0.033, power output low, good injector, air inlet restricted: The fumes were intensely irritating and more toxic than under conditions A, B, and C. The mice died first, but all the animals were dead before the end of the five-hour exposure. At necropsy the lungs of the mice showed intense congestion and small capillary haemorrhages. The degree of lung damage was greater in the guinea-pigs and rabbits, and these species showed a severe tracheobronchitis. The blood carboxy-haemoglobin content in the mice was about 60% and in the guinea-pigs and rabbits about 50%. The main causes of death were considered to be CO in the mice and in the other two species CO together with irritants.

It should be noted that under none of these conditions was a black smoke produced. White fumes were sometimes present in A, and condition D produced a dense white smoke, apparently consisting mainly of unburnt oil. There were more oxides of nitrogen under moderate load (B) than under light load (A). The aldehyde content was greater under the light load and was very high when the air intake was obstructed (D). In our experiments, therefore, three main toxic agents were recognized: irritant aldehydes, NO_2 , and CO. Each was always present in the diesel fumes, but their relative importance varied with the running conditions.

All our diesel fumes contained NO in greater quantities than NO_2 ; the toxicity and effects of NO are somewhat similar to those of CO. No vanadium was found in the fumes.

Further investigation of the toxicity of diesel fumes under conditions in which the exhaust is smoky is in hand.

The irritancy to man of small concentrations of various aldehyde vapours has been assessed (Van M. Sim and R. E. Pattie, unpublished results, 1955). The unsaturated aldehydes—acrolein and crotonic aldehyde—are highly irritant and cause lacrimation in concentrations of 1 p.p.m. and 4 p.p.m. respectively, while the corresponding saturated compounds—propionic and butyric aldehydes—are almost non-irritant in concentrations of 200 p.p.m. Acetaldehyde, isobutyric aldehyde, and *n*-valeric aldehyde are likewise almost non-irritant. Formaldehyde is intermediate between the two groups, 12 p.p.m. producing severe irritation. Since the individual aldehydes vary so much in their irritant properties, determination of the total aldehyde content of diesel fumes may not provide a good estimate of their irritant potentialities.

Mice, guinea-pigs, and rabbits have been exposed for six hours to a concentration of acrolein of 24.4 mg. per cubic metre (10.5 p.p.m.). This caused the death of about 50% in each species. The post-mortem picture was one of severe tracheobronchitis with pulmonary oedema, consolidation, congestion, and emphysema.

Field Work

We were permitted to take samples at the Dunn Laboratories at St. Bartholomew's Hospital in the fog of January 4-6, 1956. This fog was much less dense than that of 1952. The salient fact found was that filter samples taken up to 4.20 a.m. on January 5 were alkaline (maximum equivalent to 0.16 p.p.m. of ammonia, SO_2 concentration during sampling was 1.16 p.p.m.), whereas samples taken from 9 a.m. on that day until the fog dispersed on January 6 were acid (maximum 0.05 p.p.m., as H_2SO_4). The nature of the alkaline matter present is unknown; alkali carbonates as aerosols would react with SO_2 , so it was probably organic. The acid (which may have been present in small quantities while the filter samples were, as a whole, still alkaline) may have been sulphuric. Impaction of droplets on slides coated with indicator (N. W. Wootten, unpublished results, 1956) showed that the acid was present in droplets of 10 μ M.M.D., which were far fewer in number than were the smoke particles.

The fog when inhaled through the mouth produced slight tickling at the back of the throat, similar to that produced by inhaling H_2SO_4 mist in very small concentrations (<0.1 p.p.m.). The irritation was very inconstant, and was not severe enough to cause coughing; it was not possible to determine whether it was alleviated by ammonia. It was not present when a Siebe Gorman "microfilter" was worn. On this occasion, therefore, H_2SO_4 mist was not a major constituent; such respiratory effects as the fog produced (as described above) in otherwise healthy persons could be attributable to gaseous SO_2 alone. The fog had no effect on guinea-pigs exposed to it.

Discussion

Our experiments have indicated that many of the possible contaminants of the atmosphere are highly irritant substances. SO_2 , H_2SO_4 mist, certain aldehydes, and NO_2 can all produce death in animals from irritation of the airway and/or pulmonary tissues. CO concentration, particle size, and cold are other variants which might influence toxicity. In general our researches so far suggest that sulphur compounds are important acute toxic agents in smog (Firkin, 1937).

The peak concentration of SO_2 in the 1952 London smog was 1.34 p.p.m. (say 3.58 mg. per cubic metre at 20° C.); but this was an average figure for a 48-hour period, so that at times the actual concentration may have been much higher. SO_2 concentrations of this order may in general not be very harmful (Anderson, 1950), but some apparently normal individuals do show an increased airway resistance during exposure. Asthmatics and bronchitics may, of course, react more dramatically.

H_2SO_4 mist is both more irritant to man and more toxic to guinea-pigs, especially with medium-sized particles, which

may impact better in the larynx and trachea. It is not certain whether H_2SO_4 was present in the 1952 smog, but Ellis (1931) has found concentrations of it in fogs to be as much as three times that of SO_2 . Therefore, an average concentration of 4 p.p.m. might have existed in the London fog of 1952; with a suitable particle size and temperature, such a concentration might produce long-lasting respiratory symptoms in a proportion of otherwise normal men, and those with a pre-existing respiratory ailment might have a more serious response to a smaller concentration.

If H_2SO_4 and SO_2 are important toxic agents in smog their effects could be neutralized by means of ammonia. Indoors this is easy; the amount of ammonia required to neutralize all the sulphur acids in a house or hospital ward would be of the order of 2 g. Ammonia is a comparatively harmless substance; the "threshold limit" for man is given as 100 p.p.m. Ammonia gas could be added to the output of large chimneys to neutralize their SO_2 content.

Nitrous fumes, CO, and irritant aldehydes are emitted into the atmosphere from the exhausts of diesel engines. It is impossible, at present, to say how important these contaminants may be. NO_2 is formed in large quantities by the petrol engine (Hanson and Egerton, 1937); the fumes from this engine contain more CO but less aldehyde than those from a diesel engine. Petrol-engine fumes should therefore, even apart from their CO content, be at least as toxic as diesel fumes, although they would probably have less effect on the trachea and bronchi.

One of the difficulties in interpreting experimental data from so-called normal although sometimes susceptible animals and men in terms of morbidity and mortality in fog is that the latter affects only a specially sensitive small proportion of the general population. A significant observation was made in the SO_2 experiments described above. Here it was noticed that in the early stages, when the mortality was low, small differences in sensitivity (for example, between fresh and pre-smoked mice) gave rise to much larger differences in mortality. This is to be expected if the lethal dosage is distributed according to a "normal" law: If a similar phenomenon appeared in human mortality during smog it would mean that a slight increase in the contamination or duration of the smog would lead to a large increase in mortality; while if the fog contained a number of irritants, elimination of any one of them (for instance, coal distillates by reducing coal burning or sulphur oxides by means of ammonia) would reduce mortality considerably. In such a phenomenon could lie the greater lethality of, for example, the 1952 London smog as compared with others.

Summary

In a study of potential atmospheric pollutants, the effects on animals of sulphuric acid mist, sulphur dioxide, smoke, mixtures of SO_2 and smoke, coal distillates, wood distillates, acrolein, and diesel fumes (under four different running conditions) have been investigated. The guinea-pig is very sensitive to sulphuric acid mist, but, apart from this, the concentrations of pollutants required to produce any effect on animals are very much greater than those found in smogs.

The effects of H_2SO_4 mist, SO_2 , and a number of aldehydes on human beings have been studied. Sulphur dioxide in low concentration causes bronchoconstriction in certain cases; sulphuric acid mist can cause bronchitic symptoms, and is irritant in concentrations below 0.1 p.p.m. The toxicity of these compounds is annulled by ammonia.

Some results obtained during the London smog of January 4-6, 1956, are described.

It is concluded that the toxic effects of smog are due to the action of small quantities of pollutants on

exceptionally sensitive human beings; the substances concerned are probably, but not certainly, the sulphur compounds.

SPLENOPORTAL VENOGRAPHY FOR EVALUATING ABNORMALITIES OF PORTAL CIRCULATION

BY

A. K. BASU, M.S., F.R.C.S., F.A.C.S.

Director, Department of Surgery, S.S.K.M. Hospital, Calcutta; formerly Professor of Surgery, Nilratan Sircar Medical College, Calcutta

AND

A. DAS, M.B., M.R.C.P.

Professor of Medicine, Nilratan Sircar Medical College, Calcutta

Splenoportal venography by percutaneous injection into the splenic pulp was first performed by Boulvin *et al.* in 1951. A large number of splenoportal venograms have been carried out by different observers and much useful information has been gathered from visualization of the portal circulation. The communication by Atkinson *et al.* (1955) is particularly valuable in this respect. We became interested in the procedure after reading the paper by Dreyer and Budtz-Olsen (1952), and since that time a series of 46 successful splenoportal venograms have been performed by the method of percutaneous injection into the splenic pulp.

Most of these cases were subsequently operated upon for splenectomy, or splenorenal shunt, or ligation of hepatic and splenic arteries. Opportunity therefore presented itself for correlating the pre-operative assessment of the splenoportal circulation, as judged by the venographic procedure, with the actual anatomical state of the circulation, the portal venous pressure, and the naked-eye and histological state of the liver.

This communication is based mainly on the findings of the cases subjected to operation, but also includes a few cases which were not operated on but in which the splenoportal venograms were studied and interpreted along with the clinical diagnosis.

Certain suggestive venographic patterns have been formulated as a result of this study.

Clinical Material and Investigation

Of 54 cases in which splenic venography was attempted, successful venograms giving significant information were obtained in 46 (see Table), 5 were unsuccessful owing to spasm of the splenic vein, and in 3 others the findings were inconclusive. Operations were carried out in 32 cases—12 of tropical splenomegaly of uncertain origin, 10 of splenomegalic cirrhosis, 6 of portal cirrhosis, and 4 of

Analysis of 46 Cases with Successful Venograms

Nature of Case	Operated	Non-operated	Total
1. Tropical splenomegaly ..	12	0	12
2. Intrahepatic obstruction ..	4	2	6
		(1 confirmed at necropsy)	
3. Cirrhosis of liver:			
Splenomegalic ..	10	3	13
Portal ..	6	2	8
Biliary ..	0	1	1
Nodular hyperplasia ..	0	1	1
4. Suprahepatic obstruction ..	0	5	5
Total ..	32	14	46

intrahepatic obstruction of the splenoportal system. In each of these cases, the portal venous pressure was measured at the time of operation, the naked-eye appearance of the liver noted, and a biopsy taken. When splenectomy was performed the weight of the spleen was recorded and its histology subsequently studied.

The series of 14 cases which were not operated on included 3 of splenomegalic cirrhosis, 1 of biliary cirrhosis, 2 of portal cirrhosis, 1 of nodular hyperplasia following subacute hepatic necrosis, and 2 of intrahepatic obstruction of the splenic vein. In one of the cases in this last group obstruction of the splenic vein was confirmed at necropsy. In the remaining 5 cases the clinical features were suggestive of suprahepatic obstruction of the hepatic venous system.

Results

As a result of this study it seems that the venographic appearances fall into four characteristic patterns.

1. *Pattern of Tropical Splenomegaly of Uncertain Origin* (12 cases, all operated on).—In this type the splenic and portal veins were very dilated and tortuous. In the absence of secondary cirrhotic changes in the liver, collaterals were not present in any case. The bifurcation of the portal vein at the porta hepatis was well seen. The intrahepatic radicles were very faint and the peripheral branches were indistinct. However, in a few cases, when they were faintly visualized, the pattern did not show any distortion (Fig. 1).

2. *Pattern of Intrahepatic Obstruction* (6 cases: 4 operated; 1 not operated; 1 proved by necropsy).—In splenic vein obstruction the dye terminated abruptly at some part in its course (Fig. 2), whereas in cavernomatous transformation of the portal vein (Fig. 3) the dye became diffusely distributed over numerous small tortuous channels (Das and Basu, 1956). In both cases many collaterals were present.

3. *Pattern of Intrahepatic Obstruction due to Cirrhosis of Liver* (23 cases; 16 operated; 7 not operated).—This group can be subdivided into two categories.

FIG. 1.—Venogram in a case of tropical splenomegaly, showing marked dilatation and tortuosity of the splenic and portal veins. The intrahepatic radicles are poorly seen.

(i) *Pattern of Pure Portal Cirrhosis* (8 cases).—Here the prominent features were (a) distortion, poor visualization, and absence of regular and dichotomous branching of the peripheral intrahepatic radicles; (b) pooling of the dye, often at the site of the proximal intrahepatic radicles; and (c) presence of numerous collaterals, directed upwards as well as downwards. The splenic and portal veins were more or less of normal calibre. The collaterals most commonly seen were those of the left gastric and paraoesophageal series. The inferior mesenteric vein was very commonly visualized. In the main there are two types of appearances. In one the contrast medium is concentrated in a few of the larger branches in the substance of the liver near the hilum. Often there is pooling of the dye at this site. The peripheral branches are not seen at all. The overall appearance is like that of a withered tree (Fig. 4). In another type the peripheral branches are better visualized, but the regular dichotomous branching of the radicles is absent. Both distortion and contraction of the intrahepatic branches are present (Fig. 5).

FIG. 2.—Obstruction of the splenic vein with large upwardly directed collaterals. Portal vein and intrahepatic channels not seen.

(ii) *Pattern of Secondary Portal Cirrhosis Following Long-standing Splenomegaly* (splenomegalic cirrhosis) (13 cases: 10 operated; 3 non-operated).—Here, although the collaterals were present in many cases and the intrahepatic radicles were similarly distorted, pooled, and partly visualized peripherally, the main splenic and portal veins were dilated and tortuous (Fig. 6). There were two other cases in which the venographic pattern was akin to that described for splenomegalic cirrhosis: one was a case of biliary cirrhosis, and the other a case of nodular hyperplasia of the liver following subacute hepatic necrosis.

4. *Pattern of Suprahepatic Obstruction* (5 cases, not operated).—In this type the intrahepatic radicles of the portal vein were very prominent and were well visualized right up to the periphery. Unlike the pattern in cirrhosis of the liver, there was no distortion of these intrahepatic channels, nor was there any evidence of pooling of the dye (Fig. 7). Collaterals were present in three cases.

Discussion

Amongst the series of tropical splenomegalies without cirrhosis operated on, the weights of the spleens ranged between 1,100 and 3,000 g. Nine had portal venous pressures below 200 mm. of saline and in two others the pressure

FIG. 3.—Cavernomatous transformation of the portal vein. The dye is diffusely distributed at the site of the portal vein and there are numerous upwardly directed collaterals.

was 200 and 300 mm. of saline. In all cases the splenic as well as the portal vein were greatly dilated in spite of there being no significant hypertension in nine. This dilatation was therefore caused by the large splenic effluent and is not an indication of portal hypertension. The absence of collaterals in any of the cases lends support to this view. The tortuosity of the vein is due to the large splenic mass causing distortion of the course of the vein. It was not necessarily due to mechanical displacement of the spleen at the time of injection, as suggested by Fuld and Irwin (1954). This was confirmed at operation in many cases. The faint visualization of the undistorted intrahepatic radicles was presumably due to two factors: dilution and diffusion of the dye on reaching the liver, and its rapid transit through an unobstructed portal bed.

The mechanism of the venographic pattern in the intrahepatic obstruction group is easily understood and has been confirmed in four out of the six cases. In one case—in which the venogram suggested cavernomatous transformation of the portal vein, with numerous upwardly directed tortuous collaterals involving the left gastric, the short gastric, and other unidentifiable veins (Fig. 3)—the anatomical pattern was confirmed at operation. The portal vein was absent and the numerous collaterals could be seen coursing upwards towards the cardia. In three other cases of obstruction of the splenic vein (as judged by venography) the diagnosis as regards the site of obstruction and the nature of collaterals was confirmed in two at operation and in the other at necropsy (Das and Basu, 1956). In another case of portal cirrhosis of the liver the venographic appearance suggested thrombosis of the portal vein (Fig. 8). The contrast medium terminated at the site of origin of the portal vein and was diverted through numerous collaterals. These findings were later confirmed at operation.

FIG. 4.—"Withered tree" appearance of the intrahepatic portal radicles in cirrhosis of liver. There are numerous collaterals, and the splenic and portal veins are not dilated.

FIG. 5.—Absence of regular dichotomous branching of the intrahepatic radicles in a case of cirrhosis of liver. There is pooling of the dye at places. Numerous collaterals are present.

The venographic pattern in cirrhosis of the liver is more obscure and requires careful elucidation. A careful review of our material shows that the intrahepatic radicles are distorted by the fibrotic process. Further, the degree of distortion is roughly proportional to the extent of the fibrosis. The left main branch of the portal vein at the hilum of the liver was often not seen at all. In general, these findings are in conformity with those of Atkinson *et al.* (1955).

Additional features in this pattern are the presence of numerous collaterals, which is explained by the degree of portal hypertension. In our cases this ranged between 340 and 385 mm. of saline. The lumen of the splenoportal trunk was not dilated in the absence of significant splenomegaly. We therefore feel that portal hypertension, *per se*, does not necessarily lead to dilatation of the splenic and portal veins.

As is to be expected, when cirrhosis had supervened in long-standing cases of splenomegaly, the pattern was a mixed one—showing dilatation and tortuosity of the splenoportal system, characteristic distortion of the intrahepatic radicles, and presence of collaterals. The same expected pattern was seen in a case of biliary cirrhosis and one of subacute hepatic necrosis, both associated with splenomegaly. The enlarged spleen in these two cases contributed to the dilatation of the splenic vein.

In five of our cases the venographic pattern was found to be significantly different from other types, particularly with regard to the intrahepatic channels. Four of these cases conform to the clinical picture described for veno-occlusive disease of the liver (Stuart and Bras, 1955). One of these was a case of polycythaemia vera, and the histological appearances of the liver biopsy material was highly suggestive of suprahepatic obstruction. The fifth case was one of congestive cardiac failure with hepatomegaly. The intrahepatic radicles were well seen right up to the periphery of the hepatic parenchyma. They showed normal regular dichotomous branching. There was no distortion or contraction of the branches, and pooling of the dye was not seen. Collaterals were present in three cases, and their visualization presumably depended upon the degree of the portal hypertension. This type of appearance may be attributed to obstruction to the outflow of the blood from the liver that may result from hepatic venous thrombosis or from rise of pressure in the inferior vena cava through congestive cardiac failure or constrictive pericarditis. We have therefore called this type the pattern of suprahepatic obstruction. In later stages of this type actual cirrhotic changes in the liver may supervene and alter the characteristic venographic pattern.

This investigation indicates that portal hypertension can be assessed with a fair degree of accuracy from the venographic patterns. The presence of collaterals is the most significant indication in this respect. For example, of the

FIG. 6.—Appearance in a case of splenomegalic cirrhosis. The splenic and portal veins are dilated and tortuous, and collaterals are present.

FIG. 7.—Appearance suggestive of suprahepatic obstruction. The intrahepatic radicles are well visualized up to the periphery and there is normal dichotomous branching. Collaterals are present.

FIG. 8.—Non-visualization of the portal vein due to thrombosis in a case of cirrhosis of liver. Numerous collaterals are present.

six cases of portal cirrhosis—which were operated upon in our series of cases—collaterals were present in five. In each of these the portal pressure was above 300 mm. of saline. On the other hand, preoperative clinical indications of portal hypertension, such as recurrent haematemesis (2 cases), presence of prominent abdominal venous collaterals (4 cases), ascites (4 cases), and oesophageal varices as seen in skiagraphy (2 cases), were less frequent.

Similarly in cases of tropical splenomegaly, those showing collaterals on venography invariably had raised portal venous pressure and cirrhotic changes in the liver. By contrast, in cases of splenomegaly without collaterals there was no significant portal hypertension. There were, however, rare exceptions to this general observation.

In our opinion, therefore, the presence of collaterals in splenoportal venography is a positive indication of portal hypertension and appears earlier than other clinical evidences.

Portal venography, it seems to us, is also of value in the assessment of liver cirrhosis. The changes in the intrahepatic pattern described previously and the presence of collaterals together give an accurate estimate of the presence as well as of the extent of the fibrotic process of the liver.

Before operation, infrahepatic obstruction can be diagnosed with certainty by portal venography alone. Not only can the site of obstruction be accurately determined but often its nature can also be assessed.

With regard to suprahepatic obstruction, although we have suggested a characteristic venographic pattern on the basis of our clinical experience, further confirmation is necessary by operation, necropsy examination, or catheterization studies of the hepatic veins.

Venographic appearances in all these types of cases could be of great help to the planning of the operation—as regards both its indication and its nature. In tropical splenomegaly the absence of collaterals and the normal appearance of the intrahepatic radicles would signify absence of portal hypertension and liver changes and therefore splenectomy alone would be justified. On the other hand, the presence of such changes would often indicate a shunt procedure in addition. In infrahepatic obstruction the venogram would help the surgeon to anticipate the exact site and often the nature of the obstruction. For splenic vein obstruction, splenectomy would suffice in many cases, whereas in cases of portal vein obstruction a shunt operation would again be indicated.

In portal hypertension due to cirrhosis of the liver, visualization of a patent portal vein would enable the surgeon to plan a portacaval shunt if necessary, whereas its non-visualization—as in one of our cases—would indicate portal vein thrombosis and would preclude such a procedure. Further, the presence of secondary portal hypertension in cases of suprahepatic obstruction, as judged by the presence of collaterals, would lead to consideration of portacaval anastomosis.

Summary and Conclusion

Splenoportal venography has been performed successfully in 46 cases, 32 of which were operated on. The operative findings are correlated with the venographic appearances.

The clinical material consisted of 12 cases of tropical splenomegaly of uncertain origin, 13 cases of splenomegalic cirrhosis, 8 cases of portal cirrhosis, 1 case of biliary cirrhosis, 1 case of subacute hepatic necrosis with nodular hyperplasia, 6 cases of infrahepatic obstruction, and 5 cases of suprahepatic obstruction.

Four types of characteristic venographic patterns are described and discussed. These are for: (a) tropical splenomegaly of uncertain origin uncomplicated by cirrhosis of the liver; (b) infrahepatic obstruction of the portal venous system; (c) intrahepatic obstruction due to cirrhosis of the liver and splenomegalic cirrhosis; and (d) suprahepatic obstruction of the hepatic venous outflow.

The value of portal venography in assessing the presence of portal hypertension and cirrhosis of the liver is discussed. Visualization of the collaterals is one of the earliest indications of portal hypertension.

In infrahepatic obstruction, portal venography gives an accurate indication of the site and some indications of the type of obstruction.

The venographic findings could be of great help in the planning of a suitable operative procedure in abnormalities of portal circulation.

We are grateful to Dr. A. K. Dutta Gupta, Principal, Nilratan Sircar Medical College, for allowing us facilities for the investigation and for the use of the case records. Dr. S. Bose, professor of radiology and Dr. R. Roy Choudhury, radiologist, Nilratan Sircar Medical College, helped us considerably. Dr. R. N. Chaudhuri, Director, School of Tropical Medicine, Calcutta, referred to one of us some cases for operation, which have been included in the series, and our thanks are due to him.

NEOSTIGMINE-RESISTANT CURARIZATION

BY

A. R. HUNTER, M.D., F.R.F.P.S., F.F.A.R.C.S.
Anaesthetist, Royal Infirmary, Manchester

One of the greatest attractions of the competitive myoneural blockers is their reversibility by antidote drugs. Indeed, it has become almost an article of faith with those who use agents of this type that it is safe to maintain curarization right up to the time at which the abdomen is closed, in the sanguine expectation that the paralysis will then be undone by neostigmine. It was therefore somewhat disquieting to be called by a registrar some two years ago to see a patient in whom the administration of this drug had failed to produce the expected recovery. Since that date four other cases of this type have been reported to me by registrars. Details of a sixth case were received from another source.

The Syndrome

In every instance the patient was elderly and dilapidated, and yet, though ill, was fit by ordinary standards for general anaesthesia. After premedication with morphine and atropine or papaveretum and scopolamine in safe amounts, anaesthesia was induced with a suitably small dose of thiopentone; the patients were intubated with the aid of suxamethonium, and breathing began again after a perfectly normal interval of a minute or two. Subsequently, anaesthesia was maintained with nitrous oxide and oxygen, together with small doses of pethidine and thiopentone. Relaxation was obtained in four of the cases by giving gallamine triethiodide and in two from D-tubocurarine. In none of the cases was the dose excessive for the duration and magnitude of the operation performed. At the end of the operation neostigmine was given in two lots of 2.5 mg., each with 1/100 gr. (0.65 mg.) of atropine. Spontaneous respiration returned, but in every case its amplitude was insufficient to maintain life. The patients continued with depressed respiration until, in spite of adequate assistance of the breathing, death from circulatory failure ensued some 6 to 8 hours after the end of the operation.

Apart from maintenance of adequate ventilation the following resuscitative measures were employed.

Vasopressor drugs were given in all instances to maintain the blood pressure when it declined. "Tensilon" was given to three of the six patients in repeated doses of 10 mg. with sufficient atropine (usually 1/200 gr.—0.32 mg.) to prevent muscarinic effects. It produced only an evanescent improvement in the breathing, which after some five minutes returned to its previously depressed inadequate level. Additional increments of 1.25 mg. of neostigmine also improved the situation a little in these cases, but there was again a tendency to relapse after some 10 to 20 minutes. In no case was it possible to obtain complete recovery by giving this drug, but its administration never aggravated the situation. All the patients received a large dose of nikethamide, which produced in its turn an even more poorly sustained period of recovery. The intravenous administration of potassium in the form of Nabarro's solution was tried in two of the cases. In one of these there was a definite improvement, although completely normal respiration did not recover before ultimate circulatory failure occurred. In the other instance where this solution was used no response whatever was obtained.

The surgical conditions from which these patients were suffering were all of the nature of an ileus with or without peritonitis. Two of them had acute cholecystitis. In another case the source of the infection was not apparent even at necropsy, and in yet another a 36-hour perforation of a

gastric ulcer was the underlying lesion. The fifth case had had a resection of the colon some three weeks previously. A week before he had had a leak from his suture line with the development of peritonitis and subphrenic abscess. The last case was of acute colonic obstruction in an elderly man.

Discussion

Cases of extreme sensitivity to myoneural blocking agents of the anti-depolarizing or competitive type have already been recorded by Gray and Halton (1948) and Condon (1951). In these cases, however, the main feature of the condition was an abnormal sensitivity to normal doses of the drugs. In the cases which I have described, however, ordinary doses of the relaxant drugs were required to produce abdominal relaxation. In some of them, indeed, spontaneous respiration became depressed after the administration of the relaxant, but was not in fact abolished until just before closure of the abdomen; in other words, the essential problem in the patients under review was not that they were abnormally sensitive to the relaxant drug, but that its curarizing effect persisted long beyond its normal span, and, further, that it could not be undone by neostigmine.

Most of the patients were already extremely ill when they came to operation, and it might seem possible that death was coincidental to the administration of the relaxant. In fact, however, though circulatory depression was present at the end of the anaesthesia in these cases, there was certainly enough circulatory activity to convey all the vasopressor and analeptic drugs from the place of their injection to the site where they acted. Further, in three of the cases there was a definite though fleeting response to the administration of tensilon. It would therefore seem as if there was some major abnormality of the physiology of the myoneural junction which made these patients fail either to recover spontaneously or to respond to neostigmine. The only other point of interest is that in all the instances described death was not due to respiratory insufficiency but to circulatory degeneration and peripheral vascular failure, which developed at varying times after the operation in spite of adequate artificial respiration.

One rather attractive explanation of the syndrome will unfortunately not bear detailed inspection. It might seem possible that in these cases the neostigmine had itself become a myoneural blocking agent or that it had produced an excess of acetylcholine which had interrupted conduction at the end-plate. If either of these events had occurred the injection of more neostigmine would have intensified the paralysis rather than relieved it. Similarly, it is unlikely that tension would have improved such a situation.

Block of the respiratory centre itself by curarizing drugs has been described (Ellis *et al.*, 1952). This condition is said to be reversible by nikethamide. There was, however, no sustained response to respiratory stimulants in these cases. Further, the type of breathing which was present was that characteristic of a fully active respiratory centre struggling hard to overcome a barrier of peripheral curarization rather than that of a central depression of breathing.

Lastly, it is possible that a hypercarbia due to insufficient ventilation may have been responsible. It is certainly true that a state of respiratory depression and persistent myoneural block can arise after the administration of suxamethonium in experimental animals exposed to high concentrations of carbon dioxide (Davis *et al.*, 1955). Scurr (1954), too, has reported a case where seeming curarization due to decamethonium was relieved by hyperventilation. A similar case has been reported by Gray and Fenton (1954) in a patient to whom D-tubocurarine had been given. Manual hyperventilation of my patients, however, produced no improvement. Indeed, its result was always temporarily to aggravate the respiratory depression. Further, in one case a slow recovery of myoneural block during the post-operative period was directly demonstrated by faradic stimulation of the flexor muscles of the forearm at a motor point.

It is interesting that while this material was being collected four other cases were submitted to me where neostigmine-resistant curarization seemed to have occurred, but where, in fact, the history made it clear that carbon dioxide narcosis was the essential lesion.

If it is accepted that the condition was in fact due to neostigmine-resistant myoneural block, it is pertinent to ask what was responsible for its persistence. It seems possible that some disturbance of the plasma electrolytes may be the explanation, for it is well known that in experimental animals abnormalities of the sodium-potassium balance at the end-plate can seriously interfere with its function. In patients of the type described such an upset was quite likely to be present. For they were extremely ill, and, further, had a gross disturbance of gastro-intestinal function. Vomiting had occurred in some, and in all some degree of ileus was present. Several of them had had considerable amounts of isotonic sodium chloride, with or without dextrose, infused intravenously in the hours or days preceding operation. Further, it is by no means impossible that elderly patients, especially women living by themselves, would have been for some time on a diet deficient in potassium. Deficiency of this ion in the body must therefore be considered as a cause of the disturbance.

It is admitted that the serum potassium level, determined in only one case, and that on a specimen which had stood overnight, proved to be normal, but an intracellular potassium deficiency may, especially in acidotic states, occur even if the concentration of the circulating ion remains unchanged. Further, in one case electrocardiographic evidence was obtained of the characteristic changes produced by potassium deficiency. Also, it was possible to obtain a temporary improvement in this patient's condition by injecting fluid containing this substance; in another case the transfusion of stored blood which has a high potassium content also produced a marked improvement. The evidence for potassium deficiency is, however, really slender, and it is advanced only as a tentative hypothesis upon which further work may be based. The main purpose of this article is, indeed, to draw attention to this condition, which does not seem to have been described so far, in the hope that further work on its aetiology will be stimulated thereby.

It is interesting that Dripps (1953) reported a group of cases in which much less lethal prolongation of the action of both decamethonium and D-tubocurarine occurred. After reviewing the various possible aetiological factors he reached virtually the same conclusions as those set out in this paper. Foldes *et al.* (1952) have also reported recovery from respiratory depression due to "mytalon" after the administration of potassium. I would, however, caution against the indiscriminate administration of potassium in cases of this kind. For an additional case of the type described in this paper seen lately had a serum potassium of 38 mg. per 100 ml.

From the practical point of view it is important to recognize the type of patient in whom competitive myoneural blocking agents are likely to be neostigmine resistant—that is, the elderly patient with ileus—and to use in them either some form of regional analgesia or a suxamethonium drip which allows the myoneural block to be more readily modified to meet the immediate needs of the individual patient. If competition blockers must be used they should be given only in amounts which will not seriously interfere with breathing.

Summary

In six elderly patients curarization produced by anti-depolarizing myoneural blocking agents persisted after the administration of seemingly adequate doses of neostigmine. It seems possible that this disturbance was due to an upset of the electrolyte balance in these patients; but the evidence is slight, and further investigation is required to elucidate the problem.

TREATMENT OF ADDISON'S DISEASE

BY

R. N. BECK, M.D., M.R.C.P.

*Senior Tutor in Medicine, Queen's University, Belfast;
Registrar, Royal Victoria Hospital, Belfast*

AND

D. A. D. MONTGOMERY, M.D., M.R.C.P.

Physician to Out-patients, Royal Victoria Hospital, Belfast

Differences of opinion still exist concerning the best method of treating patients with Addison's disease. The first real advance came with the discovery of deoxy-cortone acetate (D.C.A.), and early work with this substance was reported by Simpson (1938). It was soon clear, however, that D.C.A. provided only partial control. Patients remained liable to hypoglycaemic attacks, while any severe stress would still precipitate a dangerous and often fatal crisis. When cortisone became available it was evident that this substance exerted a profound effect: hypoglycaemia was abolished and the patient's improved energy, well-being, and weight gain, with improved ability to withstand stressful situations, clearly demonstrated its usefulness.

At first cortisone and D.C.A. were used together (Thorn *et al.*, 1951; MacNeal, 1951; Laurie, 1951; Fourman and Horler, 1954). Sorkin and Soffer (1953) state that D.C.A. is the most important hormonal preparation necessary in the maintenance of a patient with Addison's disease. They believe it should be employed in all cases because of its striking ability to correct disturbances in sodium and potassium metabolism. Thorn (1955) states that the amount of cortisone or hydrocortisone required to restore to normal the metabolism of sugar, etc., is too small to assure a normal electrolyte and water balance, and so he advises the addition of 10-15 g. of sodium chloride daily, or, in the majority of cases, D.C.A. with a normal sodium and potassium intake.

On the other hand, Simpson (1953) believed that when cortisone became freely available it would provide the basic treatment, supplemented, if necessary, with additional salt or D.C.A. Hart (1954) treats his adrenalectomized patients and patients with Addison's disease with cortisone alone and finds they can be maintained quite satisfactorily without D.C.A. Bishop (1955) states that cortisone has to a large extent supplanted D.C.A.

It was because of this conflict in opinion that we decided to test the effectiveness of various forms of treatment on patients with Addison's disease under their normal modes of life. In particular we were anxious to see if they could be kept in good health on cortisone alone.

Method

To determine the most suitable method of treatment, four patients with Addison's disease were studied over a prolonged period. Three of these were considered to have severe Addison's disease, while the fourth was a moderately severe case. The patients were treated for periods ranging from 9 to 21 months with D.C.A., sodium chloride, and cortisone (combined therapy), and for a period ranging from 6 to 10 months with cortisone alone. Each patient was assessed in detail before beginning treatment, when D.C.A. and salt were withdrawn, and at the end of the period with cortisone alone. As a safeguard every patient was interviewed monthly, and their blood pressure and weight were recorded.

During each of the major examinations careful attention was directed to the following factors: (1) energy and capacity for work and recreation; (2) sense of well-being, emotional tone, and mental state; (3) libido; (4) incidence and severity of infections and crises; (5) weight; (6) blood pressure; (7) pigmentation; and (8) electrolytes and blood count. Clinical details of the four patients, together with treatment adopted, are given in Table I.

Results of Treatment

Energy and Capacity for Work.—The degree of weakness and prostration suffered as a result of the illness was generally severe. In Case 1 the diagnosis had been made in 1950 and treatment with D.C.A. given. While this had restored his energy to some extent, it was apparent that he was unable to undertake all the heavy work of the farm, and required additional help from his neighbours. Owing to increasing weakness he had received a further implant of 250 mg. of D.C.A. two months before we saw him in a typical Addisonian crisis. In Cases 2 and 3 progressive weakness occurred until work became impossible. A more fluctuating weakness characterized Case 4, and for weeks at a stretch this patient was unable to do much housework; at other times she had more energy, but most household duties were a burden to her. However, before treatment with combined therapy began, she had been confined to bed for some weeks because of weakness and nausea, and was admitted to hospital for detailed investigation of her adrenal function and reserve. In these cases, with treatment the improvement in symptoms was striking, and energy returned to normal in three and nearly to normal in the other. There was no noticeable change in energy when D.C.A. and salt were stopped. The farmer (Case 1) and storeman (Case 3) both do heavy work and say they feel normal in every way on cortisone alone. One housewife (Case 2), who has a family of five to look after, is as fit and well on cortisone as on the combined treatment. The other housewife (Case 4), the only patient whose return of energy has not quite matched her original strength, felt no alteration in strength when D.C.A. and salt were withdrawn.

Sense of Well-being, Emotional Tone, and Mental State.—Three patients were mentally dull and two were depressed when untreated. All returned to normal on combined treatment, and there was no alteration in this when D.C.A. and salt were withheld.

Libido.—This was stated to be normal in one before treatment began and remained unchanged. In two, libido was depressed before treatment and improved with combined therapy. The improvement was maintained on cortisone alone. One patient had complete absence of libido following hysterectomy previously, and treatment did not alter this. Improvement in libido is likely to be related to the change in the patient's general condition rather than to any specific effect of the cortisone.

Incidence of Infections and Severity of Crises.—One patient, despite an implant of D.C.A. and additional salt therapy, was admitted to hospital in a severe crisis. One patient developed a crisis in hospital following anaesthesia for gastroscopy. A third patient had experienced recurrent

TABLE I

	Case 1 Farmer, Aged 46	Case 2 Housewife, Aged 39	Case 3 Storeman, Aged 43	Case 4 Housewife, Aged 53
Clinical features..	Known Addison's disease for 18 months; implanted elsewhere with 250 mg. D.C.A. two months before admission. Admitted in severe crisis precipitated by acute tonsillitis	Increasing pigmentation for 12 months with marked weakness. Strongly positive Kepler test. *No adrenal response to corticotrophin (17-ketosteroid output 1.2 mg./24 hrs.; following corticotrophin stimulation, 2.5 mg./24 hrs.)	3 years' loss of strength, with severe pigmentation. Addisonian crisis following gastroscopy. *No adrenal response to corticotrophin (hydrocortisone 0 mg./24 hrs.; following corticotrophin stimulation, 0 mg./24 hrs.)	12 years' history of moderate weakness, with exacerbations from time to time. More recent prostration; confined to bed before admission because of weakness and nausea, and occasional vomiting. Faintly pigmented. Kepler test strongly positive on two occasions. *No adrenal response to corticotrophin. (Urinary 17-ketosteroid output 3 mg./24 hrs.; following corticotrophin stimulation, 3.4 mg./24 hrs.)
Combined therapy and duration	Deoxycortone trimethylacetate microsuspension 50 mg. every 2 months, NaCl 4-6 g. daily, cortisone 25 mg. daily. Duration 21 months	Deoxycortone trimethylacetate microsuspension 50 mg. every 6 weeks, NaCl 6 g. daily at first, later 3 g. daily, cortisone 12.5 mg. daily. Duration 18 months	Deoxycortone trimethylacetate microsuspension 50 mg. every 2 months, NaCl 4 g. daily, cortisone 12.5 mg. daily. Duration 9 months	Deoxycortone trimethylacetate microsuspension 50 mg. every 6-8 weeks, NaCl 6 g. daily, cortisone 12.5 mg. daily for 12 months, then 25 mg. daily. Duration 14 months
Cortisone alone..	Cortisone 25 mg. daily. Duration 6 months	Cortisone 12.5 mg. daily. Duration 10 months	Cortisone 12.5 mg. daily. Duration 9 months	Cortisone 25 mg. daily. Duration 9 months

* The method adopted to test adrenal gland response to corticotrophin was the estimation of either the urinary 17-ketosteroid output or hydrocortisone output before and following adrenal stimulation by intravenous corticotrophin, 25 mg., on two successive days.

minor crises with attacks of vomiting and severe prostration. The fourth had a history of recurrent attacks of bronchitis. Since the institution of treatment no further crises and infections have occurred. It seems certain that cortisone is solely responsible for this major improvement in management.

Weight.—Combined therapy produced a gain in weight of 21 lb. (9.5 kg.) in the patient admitted in crisis (Case 1). The other three gained weight in amounts varying from 5 to 11 lb. (2.3 to 5 kg.). The gain was generally maintained on cortisone alone, although slight falls were recorded in three and a gain in the fourth. The weight changes on withdrawal of D.C.A. and salt were not, however, significant.

Blood Pressure.—The effect of treatment on the blood pressure is shown in Table II. All pressures rose on combined therapy. On cortisone alone there was a slight fall in the systolic levels, but the diastolic level rose in one, remained unchanged in one, and fell slightly in two. These changes do not seem to be significant, and it is clear that a satisfactory blood-pressure level can be maintained with cortisone alone.

TABLE II.—Blood-pressure Records

	Case 1	Case 2	Case 3	Case 4
Before treatment..	95/50	120/70	110/70	125/65
Combined therapy	130/85	135/80	140/90	135/85
Cortisone alone..	120/80	125/85	135/90	130/80

These are the average B.P. levels recorded before and on combined therapy, and on cortisone alone.

Electrolyte and Blood Findings.—Blood chemistry was checked before treatment started, at the end of the period on combined therapy, and at the final assessment at the end of the period on cortisone alone. Details are noted in Table III. The values for serum sodium were a little higher than normal during combined therapy. The values on cortisone alone, however, were completely normal, and showed that, at the end of a six-months period or longer, cortisone was sufficient to maintain a satisfactory electrolyte level during the ordinary requirements of day-to-day living.

Pigmentation.—Three patients were heavily pigmented before treatment started, and one was lightly and atypically

coloured (no buccal pigment). An improvement was noted in three cases. In two of these there was definite lightening with both forms of therapy, and in one the improvement was striking. In one severely pigmented subject there was little change with either form of treatment. Because of the known failure of D.C.A. to influence pigmentation in Addison's disease it is probable that cortisone therapy is related to this improvement.

Comment

All patients were maintained in good health on cortisone alone. All say they feel as well on cortisone as they did on combined therapy; one says he feels better, as the salt tablets sickened him. Despite the relatively limited effects that cortisone has on electrolyte metabolism, it seems clear from the practical viewpoint that cortisone can maintain these patients in electrolyte balance and maintain the blood pressure at a satisfactory level.

The improvement in the patient's general well-being on cortisone is striking when compared with pre-cortisone days. The absence of crises or infection during the period under review was noticeable, and all were satisfied with their physical and mental status during treatment.

From the point of view of the patient, oral therapy with 12.5 or 25 mg. of cortisone daily is satisfactory, and the avoidance of implants or the necessity for intramuscular injections with deoxycortone trimethylacetate is an advantage.

From the experience gained in this study we believe the majority of patients with Addison's disease can be maintained in good health on cortisone alone. In certain exceptional circumstances this may not be possible, as the following example shows.

In Case 1, after the final assessment had been made, the patient noticed some weakness and nausea during vigorous haymaking in the summer of 1955. The weather was exceptionally hot and sweating was profuse, and, because of this, additional salt (6 g. daily) had to be taken. When seen by us a few days later his B.P. was 120/70 and electrolytes read: Na, 139 mEq/l.; K, 5.1 mEq/l.; Cl, 98.3 mEq/l. Therefore, in cases where sweating is profuse additional salt may be required or a compound such as 9- α -fluorohydrocortisone, which can be administered orally, might

Haemoglobin D in a Persian Girl: Presumably the First Case of Haemoglobin-D-Thalassaemia

Haemoglobin D has been found occasionally in families in North America (Itano, 1951; Sturgeon, Itano, and Bergren, 1955), in Britain (White and Beaven, 1954; Stewart and MacIver, 1956), and in Algeria (Cabannes, Sendra, and Dalaut, 1955). In Asia haemoglobin D was first found in a Sikh (Bird, Lehmann, and Maurant, 1955). It is now known that this haemoglobin variant is not rare in north-west Indians—Sikhs and Punjabi Hindus (Bird and Lehmann, 1956a, 1956b)—and in Gujaratis (Jacob, Lehmann, and Raper, 1956), in whom it was seen in 2% and 1% respectively. One family with haemoglobin D has also been discovered in the course of a survey of Turks (Aksoy and Lehmann, 1956); this has since been extended to over 400 individuals.

We have now seen haemoglobin D in a Persian girl, and, in addition to the anthropological interest of this observation, the case is noteworthy as it seems to represent the first instance of a disease hitherto not described—haemoglobin-D-thalassaemia.

CASE REPORT

A Persian girl aged 18 was seen because of vague pains and anaemia. There were no remarkable clinical findings beyond pallor. Details of the haematological investigations are given in the Table and Fig. 1. It will be seen that there

During a tour of the slum clearance areas in Liverpool on September 28 Mr. DUNCAN SANDYS, Minister of Housing and Local Government, said that in England and Wales there were some 850,000 insanitary and sub-standard dwellings. More than a quarter of these were in the Merseyside and Manchester area, and the problem was worse in Liverpool than anywhere else. The city corporation had estimated that, of the 200,000 dwellings in Liverpool, nearly half needed to be demolished. After the war the housing shortage throughout the country made it difficult to pull down any house, however decrepit, which provided a roof over somebody's head. But now that over 2 million new houses had been built the time had come when the families in the slums should be given their fair share of these new homes. Last year in England and Wales some 75,000 people were moved out of slums into new homes. This year the number was likely to be over 100,000, and might even be as much as 120,000. The Government's target was to re-house people from the slums at a rate of 200,000 a year.

We wish to thank Professor G. McG. Bull for his assistance in preparing this paper and for allowing us to treat one of his patients. Our thanks are also due to Dr. J. A. Smyth and Mr. D. W. Neill, who carried out the biochemical investigations.

ADDENDUM.—Cases 2, 3, and 4 have continued with cortisone alone and have been on treatment for 17, 16, and 16 months. All remain in good health and blood pressure and electrolytes are satisfactory. Case 1 is now on prednisone and D.C.A. as part of another clinical trial. Three additional cases, not described above, are being successfully maintained solely on cortisone. Treatment has been given for 10, 16, and 17 months respectively. All have regained energy, and one, a frail woman of 64, withstood the stress of a fractured tibia without undue disturbance or recourse to D.C.A. therapy. Dosage of cortisone for all cases has varied between 25 and 12.5 mg. daily. Complicating illnesses or operations will require additional cortisone, and it must be provided when necessary. Experience gained with the seven cases, during and following the trial described, has confirmed our opinion of the value of cortisone as the sole method of treatment in Addison's disease, and we now recommend it as routine treatment for new cases.

was extreme microcytosis without iron deficiency. The microcytosis was due to reduced thickness of the red cells rather than to a small diameter. On electrophoresis a single band of haemoglobin was seen in the position of either haemoglobin S or D (see Fig. 2). Haemoglobin S and

FIG. 2.—Paper electrophoresis of patient's haemoglobin (for details of technique see Lehmann and Smith, 1954). The control contains haemoglobins A and S. Note that the patient's haemoglobin is found as a single band in the position of S, which is also that of D.

haemoglobin D have identical electrophoretic properties, but they differ from each other in their solubility when in the reduced state, and by the fact that haemoglobin D does not cause the sickling phenomenon. The cells of this girl did not sickle on incubation with 2% sodium metabisulphite (Daland and Castle, 1948). In Itano's (1953) solubility test 5 g. of the reduced haemoglobin was fully soluble in 1 litre of 2.24 M phosphate buffer at 25° C. (50 mg. per 10 ml.). This would not have been the case if even part of the pigment had been sickle-cell haemoglobin.

The only comparable observation has been made on a Sikh (Bird and Lehmann, 1956a, 1956b), in whom also all the haemoglobin presented on electrophoresis as a single band in the S/D position, and in whom the solubility test and the sickle-cell test were used to exclude the presence of haemoglobin S. The Sikh's cells did not contain foetal haemoglobin (F), there were no poikilocytes, and the man was fit physically. The abnormality of his blood was in fact discovered in a survey of normal soldiers. In the present instance 4.2 and 4.9% haemoglobin F were found on two different occasions by means of the standard one-minute alkali denaturation test (Singer, Chernoff, and Singer, 1951), and the girl had actually been examined because of her anaemia and debility.

COMMENT

If a blood sample is found to contain no haemoglobin A, and only one and not two of its variants, no conclusion can be drawn regarding the genotype unless the family can also be studied. The blood can come either from a homozygote for the gene responsible for the particular variant of haemoglobin A, or from a heterozygote in whom the simultaneous presence of a thalassaemia gene has caused the suppression of haemoglobin A formation in the phenotype. Thus Edington and Lehmann (1955) found, in a survey of Gold Coast Africans, two people whose blood could not be distinguished by the conventional laboratory methods from that of sickle-cell homozygotes, yet a subsequent study of the families revealed that both were instances of sickle-cell-thalassaemia—that is, both were double heterozygotes for the haemoglobin A and S genes and for the thalassaemia gene respectively.

It was possible to examine the patient's father and the father's sister, but unfortunately not the mother. Both relatives showed nothing but haemoglobin A in their blood. There was every reason to assume true paternity—and this was borne out by the blood group results so far as they could help in the absence of the mother. The D-haemoglobinosis could therefore not be an example of the homozygous haemoglobin D disease. It is almost certain that a thalassaemia gene must have been inherited from either the father or the mother. The father showed no microcythaemia, no increased resistance of the red cells to

hypotonic saline, and no target cells or poikilocytes in the blood smear; foetal haemoglobin was absent. The only abnormalities were a raised mean corpuscular volume and a raised mean diameter of the red cells (see Table). There was no evidence of liver disease, neither clinical, nor were there abnormal values for serum albumin, globulin, thymol turbidity, serum electrophoresis, and serum pseudocholinesterase. This was considered relevant, as liver disease can sometimes be associated with an otherwise unexplained macrocytosis (Hall, 1956).

It may be relevant to quote Zuelzer, Neel, and Robinson (1956):

"It must be emphasized that the stigmata of thalassaemia minor are sometimes very slight . . . even with all the technics listed above, we have sometimes been unable to be certain of the diagnosis when on genetic grounds it seemed highly probable. Thus Kaplan and Zuelzer . . . obtained three families in which one parent of a child with thalassaemia major failed to show clear stigmata of thalassaemia minor. In one family, for example, the father of a child with thalassaemia major had the following blood values: R.B.C.—4,600,000; hemoglobin—14 g.; hematocrit—47%; M.C.V.—102 c.μ; M.C.H.—30.4 γγ; M.C.H.C.—29.8%; fragility (osmotic)—begins: 0.48% saline, complete: 0.28% saline; appearance of film—not unusual."

In their particular instance the American authors were able to discover at least one relative of the "normal" parent who showed signs of thalassaemia minor, and they concluded that "the apparently normal parent most likely possessed a thalassaemia gene which failed to find its usual expression." They do not remark on their unusual finding of an abnormally high M.C.V. in a non-anaemic person—an observation which is paralleled in the father of our patient, and which may be of some significance.

Our thanks are due to Dr. G. D. Hadley for referring this patient to us, and for giving his permission to publish our results.

Perforation of Simple Ulcers of Ileum as Cause of Peritonitis

Simple ulcers of the terminal ileum, as distinct from ulcers due to uraemia, tuberculosis, typhoid, and other specific infections, have been clearly described by Paterson Brown (1924), who collected 33 cases from the literature and reported two of his own. Everts *et al.* (1948) have described 45 cases, mainly culled from the literature; and further reports, mostly of single cases, have appeared chiefly in the Latin-American journals.

The lesions are simple punched-out ulcers $\frac{1}{4}$ in. (3.2–6.4 mm.) across. They generally occur singly, but several may be present. There is usually no surrounding inflammation, and no redness or increased vascularity of the overlying peritoneum; nor is there any marked oedema of the intestinal wall, and the lesions bear no constant relation to the mesentery. Microscopically they are simple, non-specific

ulcers eroding all coats. The base is a layer of granulation tissue and the intestinal wall is infiltrated with lymphocytes.

The aetiology of the condition is unknown. Among suggested causes are infection, peptic digestion, trauma, and vascular abnormalities, but no one cause has been proved.

The true diagnosis is rarely, if ever, made before operation. Everts *et al.* describe melaena resulting from such ulcers in the chronic phase, but perforation is the commonest presenting feature, occurring in 81% of cases. If in a case of peritonitis no peptic ulcer or inflammation of the appendix is revealed at operation, perforation of a non-specific ileal ulcer should be borne in mind as among other less common causes, and the terminal small bowel should be most carefully examined.

In the following two cases such lesions were discovered at laparotomy as the cause of acute abdominal symptoms.

CASE REPORTS

Case 1.—A married woman aged 33 was admitted to Huddersfield Royal Infirmary on March 28, 1951, with a history of central abdominal pain which came on suddenly and had lasted 36 hours. She had vomited three times and had severe diarrhoea during the first 12 hours, but this had now ceased. There were no other symptoms of note, but it was discovered that enteric tuberculosis had been suspected when she was aged 11, though investigation gave negative results. She was pale and her tongue was furred but moist. Her temperature was 101.4° F. (38.55° C.), her pulse rate 124 and respirations 22 per minute. There was tenderness and guarding of the abdomen, especially in the right iliac fossa, with marked rebound tenderness. Tenderness was also elicited on the right side of the pouch of Douglas on rectal examination.

Operation was undertaken on a clinical diagnosis of peritonitis probably due to perforated appendix. A large amount of non-odorous pale fluid was present and the small bowel in the right iliac fossa was congested and oedematous. The appendix was retrocaecal and normal; stomach and duodenum were also normal. On tracing the ileum proximally from the caecum a perforation was found on the lateral wall about 4 ft. (1.2 m.) from the ileo-caecal junction. It was almost $\frac{1}{4}$ in. (6.4 mm.) across and was punched-out in appearance. This was closed in two layers with chromic catgut.

Post-operatively streptomycin was given together with intravenous infusion and continuous gastric suction. Bowel action returned within 48 hours with profuse, loose motions. This diarrhoea persisted for 14 days, gradually subsiding. During this period frequent stool culture showed no pathogens; fat estimations gave normal readings; and Widal reactions, blood cultures, and Wassermann and Kahn reactions were negative. The patient was discharged on April 28. When seen on May 11 she was well and physical examination was negative, her only complaints being a tendency to diarrhoea and amenorrhoea.

She was readmitted to a medical ward on October 22, 1951, with pyrexia of unknown origin. She complained of rigors and sweating, a cough of 11 days' duration with copious sputum, and diarrhoea. Radiography of the chest and sputum examination gave normal findings. All stool and blood examinations were repeated with negative results. By November 3 there was an irregular pyrexia and the abdomen was becoming distended and tender. Her general condition deteriorated and she died next day.

Post-mortem examination revealed a generalized purulent peritonitis. There were several sloughing ulcers in the ileal mucosa, and one of these had perforated into another loop of ileum. The mucosa was intact apart from the ulcers, and the rest of the intestinal tract was normal. Section of the ulcers showed no evidence of tuberculosis, and microscopically they appeared to be simple acute ulcers.

Case 2.—On January 28, 1955, a married woman of 64 was admitted as an emergency to the General Infirmary at Leeds with a history of two days' abdominal pain. This

had begun in the epigastrium and settled in the lower abdomen. Nausea was present, and she had induced vomiting on one occasion. There were no other significant symptoms.

On examination there was some tenderness and guarding in the right iliac fossa, and rebound tenderness was present in both fossae. On rectal examination tenderness was elicited to the right of the cervix. Clinical diagnosis was acute appendicitis, but at operation the appendix was normal and there was no free fluid. On tracing the ileum proximally from the caecum a patch of fibrin was seen about 1 ft. (30 cm.) from the ileo-caecal valve, and on separating this a pin-point hole was revealed in the ileum midway between the mesenteric and free borders. There was no induration beneath this puncture, but some inflammatory reaction around it, and in the leaves of the mesentery at the same level was a pea-sized nodule resembling a diverticulum. Nothing else abnormal was found. The affected bowel was resected with end-to-end anastomosis. Post-operative progress was uneventful and the patient was discharged on February 11.

The histology of the resected bowel was reported upon as follows (Dr. T. W. Sutherland): "There is an abscess in the mesenteric adipose tissue and pus infiltrates overlying submucosa and lamina propria. The depression is covered with a single layer of columnar epithelium in continuity with the mucosa. The floor of the depression must be ulcerated in parts not included in the section. This depression is an ulcer with a floor composed of purulent exudate. Similar exudate involves the whole thickness of the intestinal wall, including submucosa, and fills a well-defined breach of the muscularis suggesting perforation."

DISCUSSION

The commonest method of treatment of this condition is simple transverse closure of the perforation. Excision of the local area of the ulcer with transverse closure of the defect in the bowel, and wide resection of the area with anastomosis, have also been performed. The risk of recurrence is apparently small, but it does occur, and this, coupled with the difficulty of being sure of the diagnosis at the time of operation, would suggest that resection and anastomosis is the procedure of choice whenever this would not materially increase the risk. Experience with the first case here presented prompted resection in the second case, even though by so doing there is no clear indication that all the ulcer-bearing area has been excised.

Mortality is surprisingly high for a simple lesion. In Everts's series of 45 patients 17 out of 41 operated upon died, as did also the 4 not operated upon. In Paterson Brown's series of 35 cases all were fatal except 8 of the 16 treated surgically. Now that modern antibiotics are available it is probable that the mortality may be reduced, as with their use the chief causes of death in the past—peritonitis and chest complications—can be more readily controlled.

Although these cases usually present as surgical emergencies, Everts *et al.* lay stress on the chronic phase of the disorder. Here bleeding is a prominent feature, coupled with vague abdominal pains. They also quote stricture formation and obstruction as late complications. They admit, however, that these manifestations were commoner because emergency surgery was not undertaken; but their experience serves to emphasize the need to bear the condition in mind when investigating obscure intestinal bleeding.

I would like to thank Mr. F. W. Shepherd, of Huddersfield, for permission to publish the first case, and Professor J. C. Goligher for permission to record the second. I am indebted to Dr. T. W. Sutherland for the pathological report on Case 2.

Reviews

HISTOLOGY OF TUMOURS

Histological Appearances of Tumours: With a Consideration of their Histogenesis and Certain Aspects of their Clinical Features and Behaviour. By R. Winston Evans, T.D., B.Sc., M.R.C.S., L.R.C.P. (Pp. 773+xvi; illustrated. 90s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

This handsome volume is, as its name suggests, designed primarily as a practical manual of histopathology. Its numerous illustrations, nearly all photomicrographs, are well chosen to show both the usual structure of particular types of tumour and their less usual variants, and most of them are clear and of first-rate quality. They are accompanied by informative legends often containing relevant clinical details. A few of the figures are inferior or uninformative; and these are most noticeable when they appear side by side with good ones—for example, Figs. 601, 780, 790, 890, and 932. As is so often the case with colour reproductions, the few included here are no more informative by being coloured. A commendable feature, too seldom seen, is that all magnifications are stated. The text gives a sound, well-balanced, and pleasantly readable outline of tumour pathology, and clearly indicates the author's own views on controversial matters. The reference lists at the ends of chapters, mainly to recent British and American sources, are well chosen and give full titles—another useful feature. Gynaecological and intracranial tumours are omitted, because, the author says in his preface, these are the special provinces of the gynaecological pathologist and the neuropathologist. These omissions give the work a regrettable incompleteness, which it is hoped Dr. Winston Evans will remedy in subsequent editions. There is every likelihood that, if this is done, and a more stringent elimination of the less satisfactory pictures undertaken, this book will become the standard British atlas of practical tumour histology. It is warmly commended to all clinical histopathologists, who will find it a valuable bench-side manual.

R. A. WILLIS.

OCULAR SURGERY

Surgery of the Eye—Diseases. By Alston Callahan, B.A., M.S.(Ophth.), M.D., F.A.C.S. (Pp. 447+xxv; illustrated. £9.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

In 1950 Alston Callahan's book on the surgery of ocular injuries appeared; to-day it is regarded as one of the best books of its kind. This year there has followed a second volume, on the surgery of the eye for pathological conditions, and it is a worthy successor to the first. The volume discusses ophthalmic surgery systematically. A chapter on anaesthesia (local and regional), akinesia, and the general aspects of surgery (suture materials, preparation of instruments, etc.) is followed by successive chapters on the surgical techniques advised in the treatment of congenital deformities and diseases of the lids, the lacrimal system, the globe, the extraocular muscles, and the orbit. The book concludes by again reviewing the surgery of ocular injuries and brings up to date the subject-matter of the previous volume. Six chapters are devoted to the surgery of cataract; the intracapsular operation is fully described and the early and late complications are admirably dealt with; the extracapsular operation is dismissed in two pages. A special feature is also made of the various operations which may be used for glaucoma, as well as the complex and difficult situations which may arise when glaucoma and cataract are combined. In comparison, corneal grafts are discussed shortly in six pages, but the description of prosthetic implants after excision of the globe is full, critical, and full of wisdom.

The book is a good one; not the least valuable feature is that it is not a compendium of all the innumerable techniques to be found in the literature but is essentially based on the author's own experience with consultation with the best in American ophthalmic surgery. He has drawn

on the advice of Atkinson in anaesthesia, Wendell Hughes in plastic surgery, Cordes in congenital cataract, and others as well as Franceschetti, of Geneva, on the surgery of the cornea. Throughout the teaching is essentially practical and sound. Moreover, the writing is clear and concise, and the numerous and excellent illustrations are worth pages of descriptive text. The book is luxuriously produced—more luxuriously, indeed, than is practically necessary—and the price correspondingly high. It is certainly a noteworthy addition to the literature of ocular surgery and will undoubtedly receive as welcome a reception as its predecessor.

STEWART DUKE-ELDER.

STRUCTURE OF BACTERIA

Bacterial Anatomy. Sixth Symposium of the Society for General Microbiology held at the Royal Institution, London, April, 1956. Edited by E. T. C. Spooner and B. A. D. Stocker. (Pp. 360+viii; illustrated. 30s.) London: Cambridge University Press. 1956.

This volume contains 15 papers which were discussed at the sixth Symposium of the Society for General Microbiology held in April last. The subject was well chosen; electron and phase-contrast microscopy have revealed much new detail in bacterial structure, and many other methods have been brought in to elucidate it further. Enough is now known about individual parts of the bacterial cell—flagella, capsules, cell wall, and cytoplasm—for those well versed in these matters to be able to write intricate and fascinating accounts of each of them. In Stocker's contribution on flagella it is admitted that the miracle of bacterial motility cannot yet be fully explained, though a chemical basis for flagellar movements has been suggested; it is interesting that the breaking strength of a flagellum can be calculated, and is such that a cell tethered by one of them is securely held. Weibull himself contributes a paper on protoplasts, the spherical and still living structures—though of limited potentialities—which can be obtained under some conditions by destroying the cell wall. A long paper by DeLamater claiming to have demonstrated mitosis in bacteria is preceded by one in which Robinow contests his conclusions in much the strongest language to be found in the whole volume. Eight of the 15 contributors came from abroad—two each from the United States, Canada, and Denmark, and one each from Sweden and Switzerland. The society is to be congratulated on having assembled these authorities; the sum of their contributions represents a large increase in fundamental knowledge, and the volume, variety, and ingenuity of the work on which they are based will astonish those not familiar with it.

CARDIAC ANOMALIES

Cardiac Anomalies: A Clinicopathologic Correlation. By Vincent Moragues, M.D., and Chester P. Lynxwiler, M.D. (Pp. 92+x; illustrated. 50s.) London: Baillière, Tindall and Cox. 1955.

This book is an attempt to present in atlas form information which will be of help in the accurate diagnosis of congenital heart disease with particular reference to the selection of cases for cardiac surgery. The material comprises cases verified by post-mortem examination or surgery, and in each anomaly there is a description of the clinical and special methods of investigation. The text presents in list form the pathological and clinical features, together with electrocardiographic, radiological, and special investigations, in such extreme brevity as to fail completely to indicate the information which can be obtained in this way. The atlas method of presentation demands first-class reproduction of photographs of specimens and radiographs, but in this book the quality is often poor, particularly in the x-ray plates and electrocardiograms, the latter of which show only the three standard limb leads.

The medical student and general practitioner for whom this book was intended will gain a better understanding of these anomalies by a study of one of the several excellent texts available, and the specialist will need a great deal more detailed and accurate information than is contained in this work.

MYELOSCLEROSIS

The haematological alterations of the so-called osteosclerotic anaemia may be found in two distinct conditions in which the marrow cavity is reduced or obliterated by proliferation of connective tissue or increased formation of bone. One condition, called osteopetrosis or marble-bone disease of Albers-Schönberg, is rare and hereditary, occurs in children or young adults, and is characterized by generalized condensation of bone and centripetal cortical thickening, with excessive calcification but defective ossification. The other condition, much more common, is myelosclerosis. It is not familial, occurs in later life, usually within or beyond the fifth decade, and, in contrast to the first, multiple fractures do not occur; here fibrosis of the marrow (myelofibrosis) or ossification of the marrow (osteosclerosis) may be recognized as the predominant feature. Probably the earliest cases were described by H. C. Wood,¹ G. Heuck,² and B. W. Sippy³ in the nineteenth century; since then about 250 cases have been recorded under many different names, by which the authors have emphasized various characteristic features in these essentially similar cases. Recently several comprehensive studies of myelosclerosis have been published.⁴⁻⁸

Though a feature of this disorder is that the pathology is variable, most of the reported cases have conformed to a fairly constant clinical pattern.^{4-9, 10} Patients are generally over 40 years of age, the sexes

being equally affected. The onset is insidious and the condition slowly progressive, so that symptoms have been present for some considerable time before the diagnosis is made. General weakness and fatigue are usually the earliest symptoms, but health may not be much impaired for some years. Anaemia, refractory to treatment, becomes evident, and in addition the patient loses weight. The outstanding physical sign is the enlargement of the spleen, usually considerable. Pressure effects may thus occur, resulting in epigastric discomfort, dyspepsia, dragging abdominal pain, disturbances of the bladder, with pains in the legs and aching from nervous and muscular ischaemia. Perisplenitis may cause splenic pain, but splenic infarcts are not common. The liver may also be enlarged, but to a less extent; generally the lymph nodes are not enlarged. Bleeding, purpura, jaundice, reticulocytosis, increased excretion of faecal urobilinogen, increased basal metabolic rate, hyperuricaemia, and gout have been reported at times. Patients may die from exhaustion due to the severe anaemia, infections, haemorrhages, or cerebral vascular accidents.

The spleno- and hepato-megaly are part of a pathological condition which results also in extramedullary formation of blood elements—i.e., myeloid metaplasia. This is also occasionally found in the lymph nodes and even in the kidneys and adrenals. In this metaplasia, "in addition to leucoblastic cells, erythroblasts are constantly prominent and giant cells (megakaryocytes) are numerous."⁹ The fibroblastic tissue of the spleen may be increased. The marrow shows fibrosis of varying amount and distribution; the bony trabeculae may be thicker than normal. The marrow is often hypocellular, but in some cases hyperplastic foci of haematopoiesis are scattered through the fibrotic elements, and occasionally in others a more diffuse hyperplasia is present. Megakaryocytes are usually prominent. Isolated marrow samples may give a misleading picture owing to the patchy nature of the fibrotic change. Sternal

puncture is usually difficult, little or no marrow being obtained. This finding and the absence of the characteristic "give" which normally occurs when the needle has penetrated to the marrow cavity may suggest the diagnosis. Trephine biopsy will reveal the true histological pattern of the sampled site. Radiographic studies of femora, ribs, pelvis, and spine may in some cases indicate the diagnosis. They may show initial widening and increased density of the trabeculae, followed by deposition of bone in an irregular fashion throughout the marrow cavity without thickening of the cortex or periosteal reaction¹¹; or irregular rarefaction of the inner aspect of the cortex may be seen, with patchy areas of density in the medulla and distortion of the trabecular pattern.⁷

The commonest blood picture is of leuco-erythroblastic anaemia or leuco-erythroblastosis—that is, "an anaemia characterized by the presence in the peripheral blood of unusually immature red cells and a few immature white cells of the myeloid series. The anaemia is not necessarily severe nor is there usually a marked leucocytosis."¹² Occasionally immature red and white cells have been absent. However, repeated examination of the blood may be required to detect primitive red and white cells owing to the variations and fluctuations in the haematological features.¹³ Hence an important pointer beyond the diagnosis of "refractory anaemia" may be overlooked. The anaemia is usually normochromic, but sometimes hypochromic; macrocytosis has also been described. Polychromasia, poikilocytosis, and anisocytosis are more pronounced in these cases than would be expected for the degree of anaemia.¹⁴ Indeed, poikilocytosis and anisocytosis in the absence of hypochromia are said not to occur in any other condition.¹⁵ Tear-drop red cells (that is, with a thin tail-like extension) and elliptical forms have been emphasized.^{5, 16} Megakaryocytes, nuclear fragments of these cells, and abnormal platelets are not uncommon.^{4, 5, 9, 10} This, the usual symptom complex, is the one known by such diverse names as chronic non-leukaemic myelosis, agnogenic myeloid metaplasia, and aleukaemic myelosis with osteosclerosis.

Though most cases have been found with a leuco-erythroblastosis, no previous knowledge of the blood picture being available, in some a polycythaemia has been recorded previously; hence the reports of cases of "spent polycythaemia."^{4-8, 17} But in none of these cases, apparently, were confirmatory studies of blood volume and of arterial oxygen saturation level carried out. However, this sequence of changes has been considered frequent in cases of polycythaemia.¹⁸

It is now necessary to add other associated blood pictures to the well-known three—refractory anaemia, myelaemia, and spent polycythaemia.¹⁸ Frank polycythaemia in association with a myelosclerotic marrow has been reported in five cases.^{7, 8, 19, 20} H. N. Robson's case⁷ is of special interest in showing initially a macrocytic anaemia, then, after homologous serum hepatitis, a spontaneous remission, with splenomegaly developing and increasing and the blood picture becoming leuco-erythroblastic. At this stage the marrow showed myelofibrosis, formation of new bone, and megakaryocytosis, and the spleen and liver showed extramedullary haematopoiesis. Next a polycythaemic stage developed, with high levels of white cells. Finally at necropsy the marrow spaces showed hyperplastic haematopoietic tissue with some little fibrosis but no new bone, while extensive extramedullary haematopoiesis was still present. In view of the prominence of megakaryocytic hyperplasia in many descriptions, it is of interest to note the association of apparently pure megakaryocytic hyperplasia (with primitive megakaryocytes in the blood) with myelofibrosis⁷ and the similarity of these cases, with others described as megakaryoblastic leukaemia.^{21, 22} Whether or not this latter is recognized as an entity or regarded as a variant of myeloid leukaemia, such cases indicate a link between the various marrow cells in their hyperplastic activity. Further, it has been suggested²³ that the presence of megakaryocytes in the blood of patients with leukaemia or erythraemia may indicate a change in the usual character of the disease. The association of myelosclerosis with true chronic myeloid leukaemia has been disputed.^{9, 10} While the usual syndrome appears to differ haematologically,⁹ certain series^{24, 25} do suggest that myelosclerosis may undoubtedly be found in myeloid leukaemia. Other pathological conditions may be associated with myelosclerosis—for instance, chronic haemolytic disease,^{8, 26, 27} carcinomatous deposits in the marrow,²⁸ diffuse tuberculous infection,²⁹ chronic haemorrhage with sepsis,³⁰ and various other chronic toxic states due to organic chemicals.³¹

So far only blood transfusion has been temporarily helpful. Haematinics, corticotrophin, cortisone, and male hormone have been unsatisfactory. Antimitotic agents have been ineffective. In view of the extramedullary haematopoiesis, irradiation of the enlarged spleen has been generally regarded as unwise, a view confirmed by studies with radio-iron.³² However, temporary benefit has followed splenectomy in cases in which there is clear evidence of "hypersplenism."³³

The present consensus on aetiology is that it is a proliferative disorder of mesenchymal tissue, a theory first advanced at the beginning of the century. The mesenchymal cell is multipotential and is capable of differentiating into osteoblast, fibroblast, erythroblast, myeloblast, and so on. A unified picture thus emerges of myeloproliferative diseases in which clinical patterns are determined by the varying and predominant degrees of differentiation of the component cells. Hence myeloid leukaemia, megakaryocytic myelosis, polycythaemia vera, and myelosclerosis are recognizable entities, albeit with certain resemblances between them; in addition transitional forms and alterations from one clinical type to another might be expected to occur, and in fact to some extent do. Nevertheless it is well to bear in mind, in view of some biochemical studies,³⁴ that "separate metabolic defects, not necessarily of the same type or resulting from the same cause, may give rise to superficially similar morphological but metabolically different entities."³⁴

CHEAP PROPAGANDA ON POLIO

When the Labour Party was in power some of its spokesmen—though not usually those holding office—used to take credit for certain alleged effects of the N.H.S., such as the decline in infant mortality rate and even for a rise in the birth rate. But Labour Ministers of Health rarely if ever said stupid things about medicine. If they wanted to insult doctors they did so directly. We knew where we were with them. Last week the Tories at Llandudno cheered Miss Pat Hornsby-Smith when, with her full authority as Parliamentary Secretary to the Ministry of Health, she told the ranks of Tuscany that Britain's "anti-polio vaccine" had been a success. No doubt her remarks were aimed also at the readers of newspapers, and no doubt will be dished up at the next election—all with the view of showing the uninstructed mass how clever it was of the Conservative Party to introduce the polio vaccine, how successful it has been, and how safe the health of the country will continue to be if Conservatives return to power. It is all so sickeningly obvious—and cheap.

Miss Hornsby-Smith gave her listeners—and the newspaper readers—a completely false picture, and an utterly erroneous deduction from the figures she pre-

sented. She said that from the beginning of this year there had been 2,538 cases of poliomyelitis. But this number includes adults as well as children. Ten were children who had been vaccinated, four having paralytic and six non-paralytic disease. Vaccination against poliomyelitis began in the middle of May and continued to the end of June. Therefore an investigation of the effect of the vaccine should start with cases occurring in July and after. Between the beginning of July and the last weekly return published before Miss Hornsby-Smith's speech 1,701 cases of polio were notified, not 2,538. This is the first of many false trails. Now the vaccine was available only to a sample of children aged 1 to 9 years: approximately 200,000 were inoculated out of a child-population of this age group of about 6,000,000. A fair estimate suggests that a third of the 1,701 cases were over 9 years of age,^{1, 2} and that at least some were under 1 year. It is therefore possible that about 1,100 cases, non-paralytic and paralytic, occurred among children in the same age group as the inoculated, or 0.18 per 1,000. The incidence of 10 cases in 200,000 inoculated children is 0.05 per 1,000. Though this figure is between a third and a quarter of the other, it is based on so small an experience—owing to the limited outbreak—that no certain conclusion can be drawn from the difference between them. Miss Hornsby-Smith says that six of the cases were free from paralysis, and paralysis in the remaining four was not severe: that is, of the inoculated children who got poliomyelitis 40% had the paralytic form. If we take the figures for the whole country from the beginning of July, which are for patients of all ages, we find that 749 were paralytic cases and 952 were non-paralytic—that is, 44% had the paralytic form—a figure almost identical with that for the inoculated children. Miss Hornsby-Smith says that none of the ten cases in the inoculated children were fatal. As the death rate in uninoculated adults is higher than that in uninoculated children it is not possible to get an exact comparison. However, from the beginning of July there were in the "Great Towns" 999 cases and 29 deaths. Though the deaths cannot strictly be related to the cases, we may take as a rough estimate a case fatality rate of 2.9%, or 0.29 deaths for every ten cases. In other words, in the uninoculated community, including adults, on the average only every third or fourth sample of ten cases would have included a death.

Miss Hornsby-Smith's comparisons are therefore completely invalid, and valid comparisons show that her conclusions are unfounded. Largely because the outbreak of poliomyelitis was so small this year there

¹ Report of the Ministry of Health for the Year Ended December 31, 1955, Part 2, H.M.S.O., 1956.
² Ibid., 1955.

is no evidence about the efficacy of the British vaccine against poliomyelitis. "How right we were not to be stampeded into getting the American vaccine!" Miss Hornsby-Smith is reported to have told the assembled Tories. And how wrong about almost everything else! Many readers will share the contempt of a correspondent in this week's *Supplement* for this marketing of Medicine for votes. Medicine must be taken out of politics.

INTESTINAL INTOXICATION AND HEPATIC COMA

Biochemistry is now advancing so fast that the elucidation of the metabolic foundation of hepatic coma may not be long delayed. But the wheel has gone full circle and we are back once again to a theory of intestinal intoxication that has been out of favour for almost half a century.

Attention was attracted again to the intestine as the important source of the toxins responsible when it was observed that both in the dog with an Eck fistula¹ and in man with porto-caval anastomosis² mental disturbance and coma sometimes followed the ingestion of a large meal of protein. The frequency with which a large haemorrhage from an oesophageal varix is followed by coma in patients with hepatic cirrhosis is probably a further example of the same mechanism. The use of ammonium salts as adjuvants to the mercurial diuretics in the treatment of ascites, and more recently the administration of cation exchange resins in the ammonium form in similar cases, led to the hypothesis that the blood level of the ammonium ion was the main factor determining the onset of coma in patients with hepatic disease.³ Because of the known interaction of glutamic acid with ammonia *in vivo* to yield the amide glutamine, J. M. Walshe,⁴ suggested giving large doses of glutamic acid in the treatment of hepatic coma. Results, although sometimes dramatic, were variable and unpredictable, and, though some correlation could be shown between the degree of coma and the levels in blood and cerebrospinal fluid of ammonia, the correlation was not sufficient to support the idea of a direct causal relationship.⁵

The presence of a highly characteristic odour of the breath of patients in hepatic coma has long been described as fetor hepaticus. F. Challenger and J. M. Walshe,⁶ using methods successfully developed by

Challenger for the study of the metabolism of moulds, have isolated methyl mercaptan and dimethyl disulphide from the urine of a patient with a strong fetor hepaticus. The probable source of these odoriferous sulphur compounds is methionine liberated by hydrolysis of protein during intestinal digestion. That these and related catabolites derived from methionine are important in the pathogenesis of hepatic coma seems likely from what is already known of the toxicity of this group of substances. Thus methionine itself is toxic when given in excessive doses to rats on a diet low in protein⁷; its oxidation product methionine sulfoxide inhibits the formation of glutamine from ammonia and glutamine acid by *L. arabinosus*, while the sulfoximine produced in flour by agene treatment is responsible for the hysteria shown by dogs fed with bread made from such flour.

Since it was shown that methionine deficiency in rats leads to massive hepatic necrosis,⁸ this amino-acid has been widely used in the treatment of various hepatic disorders. It is apparent, however, that several catabolites of the sulphur-containing amino-acids are potentially dangerous, and in the presence of a diseased liver this potentiality may become an actuality. That this is so has been convincingly shown by Sheila Sherlock and her colleagues.⁹ Of twenty patients with hepatic disease given between 8 and 20 g. of methionine daily by mouth nine showed unequivocal deterioration of their state of consciousness. These nine had all previously shown spontaneous attacks of coma or pre-coma. All of seven patients with portal cirrhosis who had had no previous cerebral disturbance tolerated much larger doses of methionine, up to 100 g. a day. No significant change in the level of the blood ammonia was found in any of these patients, even in those with marked mental deterioration. Two further observations by the same authors throw much light on this methionine toxicity. The administration of methionine intravenously was not followed by the appearance of mental symptoms even in those patients in whom they appeared after its ingestion by mouth. The oral administration of chlortetracycline for a short time before and during the ingestion of methionine also prevented the development of these symptoms. The most obvious conclusion to be drawn from these results is that the toxic agent is produced in the gut by the action of the intestinal flora. It is well known that profound alteration of this flora results from the use of the so-called broad-spectrum antibiotics, and, though no definite evidence was obtained of any specific metabolic effect on methionine of any of the intestinal organisms studied, this explanation remains the most probable.

Sherlock and her colleagues, on the basis of these results, condemn the giving of methionine in the treatment of hepatic disease. But since the toxic effects, even in patients susceptible to them, can apparently be avoided by simultaneous administration of an antibiotic or by giving the methionine intravenously, other factors should determine the administration or withholding of this substance in the individual case. Two further suggestions of interest are made by the same authors.

First, the oral administration of methionine might prove a useful test in the diagnosis of strange neurological symptoms, and, secondly, it should be of value as a pre-operative test for the suitability of a patient for a porto-caval anastomosis.

The emphasis on intestinal intoxication as a factor in the cause of hepatic coma has important therapeutic implications. Sherlock claims that in the few cases studied chlortetracycline appeared to be of some benefit in spontaneous hepatic coma. C. J. Fisher and W. W. Faloon¹⁰ also report favourably on the use of antibiotics: they found a fall in the post-prandial level of ammonia in the blood as a result of giving large doses of neomycin to eight patients with cirrhosis of the liver. Two of their patients with impending coma improved but relapsed when the neomycin was withdrawn. In view of P. György's¹¹ results in the prevention of nutritional massive necrosis of the liver by the feeding of antibiotics, it would be premature to attribute these results entirely to their effect on the intestinal flora.

SARCOIDOSIS

Although various manifestations of sarcoidosis have been known for more than half a century,^{1,2,3} it was not until Schaumann⁴ recognized the histological similarity between these various manifestations that they came to be accepted as a clinical entity, the exact limits of which even now lack precise definition. Sarcoidosis is a not uncommon disorder with no special predilection for patients of a particular age and sex. It is a little more common in negroes and it has a widespread geographical distribution. Like most disorders with disseminated lesions, it has no single characteristic clinical presentation, and, as Dr. D. Geraint James points out in his article at page 900, the diagnosis can sometimes be made with certainty only after considering several factors, of which the microscopical appearances are probably the most important. Pathologically, sarcoidosis consists of widespread granulomata which on histological examination show epithelioid-cell tubercles but no tubercle bacilli. Apart from the lack of caseation and lymphocytic infiltration, the overall picture is very similar to that of a tuberculous granuloma, and in this country the general opinion has been that sarcoidosis represents a reaction to the tubercle bacillus comparable to the tuberculoid form of leprosy. The negative Mantoux reaction which usually obtains in sarcoidosis, even with a previous history of a positive reaction or evidence of old tuberculous infection, has been held to indicate a peculiar reactivity to the tubercle bacillus, the so-called "positive anergy." The experimental evidence for such a belief is, however, conflicting to say the least, and an acquired negative Mantoux reaction of itself may be non-specific, being found in other disorders of the reticulo-endothelial system in which at present there is no reason to suspect tuberculosis as a cause. The inci-

dence of frank tuberculosis, either accompanying or following sarcoidosis, may be, according to some authors, as high as 25%, and this again is adduced as evidence in favour of sarcoidosis being tuberculous in origin.

Against the theory of the tuberculous origin of the disease is the fact that the histology of sarcoidosis is seen in such varied disorders as berylliosis, leprosy, leishmaniasis, brucellosis, syphilis, and histoplasmosis. Furthermore it is doubtful whether true tubercle bacilli have ever been demonstrated by either staining or culture in sarcoid lesions. The distribution of lesions in sarcoidosis differs in many respects from the sites of recognized tuberculosis, sparing the digestive tract, the adrenals, and the serous membranes. Because it can make itself manifest in so many different ways, it may be that sarcoidosis comprises more than one entity—the fairly recent recognition of berylliosis affords one example. At the same time it is difficult to reconcile the picture of fully developed sarcoidosis affecting the uveo-parotid tract, the lungs, skin, bones, liver, and lymph glands with multiple causation. Perhaps the most accurate and helpful assessment that can be given at present is that sarcoidosis may ultimately be found to comprise several entities, of which a reaction to tuberculous infection may prove to be one.

SEASON OF MISTS

To the townsman this is the season of mists rather than of mellow fruitfulness, yet in spite of much work done on air pollution little is known about its nature and its effects on health. At best this is an indication of its complexity, but there has perhaps been a tendency to underestimate the magnitude of the problem and to draw easy conclusions from inadequate data. In this field of public health evidence is notably sparse, partly because of the complicated physical and chemical nature of pollution, which sets formidable analytical problems. We do not yet know what smog is, and the temptation to ascribe its effects, which are as ill-defined as its nature, to pollutants which are measured routinely should be resisted lest we neglect the many other impurities, unmeasured or unsuspected. Nor is one smog like another; patients' reactions to high urban pollution seem to bear little consistent relationship to the crude analyses of it that are made; some bronchitics who were badly affected by the 1952 smog have been found to tolerate 10 p.p.m. of sulphur dioxide without measurable effect, while some subjects who develop bronchospasm at 5 p.p.m. have never been troubled in smog. Though smog means smoke-polluted fog, it is certain that high degrees of particulate pollution without fog are clinically harmful.¹ Yet no suspect pollutant has been found in concentrations approaching those held to be perfectly safe for continuous exposure in industry. Some workers, hesitating to lay all the blame on the common simple pollutants, await the demonstration of a new toxic substance in

modern smog; others feel simply that urban pollution is irritant and prolonged irritation may be mortal in some cases.

At p. 913 of the *Journal* this week Mr. R. E. Pattle and Dr. H. Cullumbine give a report on the work in progress at Porton. They show that massive doses of irritant substances, some of which might be present in smog, produce their mortal effects by irritation and seem to have no subtle systemic effects. Some points in their paper should not be misinterpreted: their comments on smoke (which they tend to exonerate) refer, as they say, to carbon black from a kerosene lamp and ought not to be applied to town smoke, which is complex and clinically suspect; again, in their experiments with diesel exhausts the animals were exposed to undiluted fumes, and thus the results are hardly comparable to those obtained by P. J. Lawther and colleagues in a busy garage for diesel buses.² Their paper emphasizes the need for an empirical approach to the problem while research continues. The use of ammonia to neutralize acid mist was described in these columns last year,³ and informal trials of the ammonia bottle have given encouraging results. Smog masks will also be needed to give susceptible people simple protection against particulate pollution. But in the long run smoke pollution is one of those offences of city life that are best prevented.

A CODE OF SURGICAL OPERATIONS

The *International Statistical Classification of Diseases, Injuries, and Causes of Death*¹ is now widely used in this country, not least by hospitals, in the preparation of diagnostic indexes and statistical reports. Many have felt that this was incomplete without a classification of surgical procedures. In 1944 the Medical Research Council published such a classification,² but this has become out-of-date because of modern advances in surgical technique. A list of surgical operations based on one prepared in 1949 for use by the U.S. armed forces was tried out by a number of medical records officers in this country, and in the light of their experience and with the aid of the Royal Colleges of Surgeons of London and Edinburgh and of the Royal College of Obstetricians and Gynaecologists and of a number of specialists the Registrar-General has now prepared a new *Code of Surgical Operations*.³ Wide use of this code, which is not yet in its final form, will provide information on which to decide the best form for an international code—a matter in which the World Health Organization is taking an interest.

The code consists of three main parts, corresponding to the three main parts of the *International Statistical Classification of Diseases, Injuries, and Causes of Death*. Part I is a list of 3-digit categories divided into 15 main sections according to broad anatomical sites; Part II is

a tabular list showing the operations to be included in each of the 3-digit categories; and Part III is an alphabetical index of operations. With a few exceptions, the use of eponyms has been avoided, although these are provided for in the index. Two appendices provide for 5-digit classifications of radiotherapeutic and anaesthetic procedures. The code can easily be expanded by additional digits to meet the requirements of specialized departments. This publication will be welcomed by medical records officers and others concerned with classifications of diseases and operations and with the filing of medical documents. It is also a further step forward on the long road to attaining comparability in medical statistics.

DEATHS ASSOCIATED WITH MATERNITY

As death rates have declined over the years, so the registrars-general of Great Britain have had to present their statistics ever more finely analysed in order to make clear the remaining causes. Maternal mortality, for instance, once so largely the result of childbed fever, has in the last 20 years fallen by 80% in England and Wales, leaving a residual core of about 500 deaths a year, not now diminishing fast, due to a wide variety of accidents and diseases. While the causes of these, as of other, deaths are tabulated in the annual publications of statistics, further information about them appears in the *Text Volumes*. These many supplementary tables, with explanatory text, throw fresh light on causes of death by classifying them in categories not included in the main volumes of tables. In England and Wales in 1953, the year covered by the latest *Text Volume*,¹ 128 women died of conditions "not classed to pregnancy or child-bearing, but certified as associated therewith." Though not contributing to the maternal mortality rate, at least some of these diseases may have been fatal because of the associated pregnancy.

Among these the outstanding cause of death in the three years 1951-3 for which figures are given is "diseases of mitral valve." It comprised 17% of the 160 associated deaths in 1951, 25% of 161 associated deaths in 1952, and 15% of 128 associated deaths in 1953. These deaths from mitral disease, however, were only about 2% of the total deaths of women aged 15-49 from mitral disease in those years. Tuberculosis caused 8 associated deaths in 1953, malignant neoplasms 11, uterine fibroids 3, rheumatic fever 4, influenza 5, and pneumonia 5. A particularly notable cause among these associated deaths is acute appendicitis. There were 2 deaths in 1951, 3 in 1952, and 4 in 1953; they comprise respectively 2.1%, 5.8%, and 9.3% of total deaths of women aged 15-49 from this cause. As to maternal mortality so recorded, a regional analysis shows that the great industrial conurbations of the midlands and north have lower rates than the rural districts. This must be one of the few causes of death of which this is true, and presumably the presence of medical men and equipment on the spot in the great cities chiefly accounts for the difference.

EIGHTEEN DAYS IN THE U.S.A.

SOME RANDOM NOTES

BY

Sir ERNEST KENNAWAY, D.M., D.Sc.
F.R.S., F.R.C.P.

During eighteen days in New York, Yale, and Harvard in May last, a period which gave one an opportunity for learning of and discussing much recent work on cancer of the lung, and cholesterol as a carcinogen, some other matters were encountered, and these are the subject of the following very informal notes.

New York

The island of Manhattan is thirteen and a half miles long by about one and a half miles broad, and surely nowhere else is a greater variety of human activity and achievement contained within such an area. New York is not merely a huge American city of eight million inhabitants: it has a character all its own. An immense amount of rebuilding is in progress; taller buildings which make greater use of old sites are going up. The huge vertical slab of the United Nations Building dominates its neighbourhood and makes the visiting speaker wish that agreement could be reached about the size of lantern-slides.

Two items of general knowledge which no one in New York seems to possess are the postage of a postcard to Great Britain (estimates ranged from 3 to 8 cents) and the method of disposal of the sewage, which must be conveyed to its destination through rock, from eight million people. When entering New York from the north on the return journey from Harvard, I saw some contact beds which were discharging an effluent into the adjacent river, but this was a small affair only. The force of the toilet flush on the twenty-first floor of a New York hotel indicates a very efficient booster mechanism.

Atmospheric Pollution

New York has a peculiar dusty, rather dingy, not smutty, appearance which is hard to define. The chief source of atmospheric pollution at the present time is the rubbish destructors, a thing unknown in many cities, but the most conspicuous is the tall chimneys of power stations which use bituminous coal—a practice begun during the second world war, when anthracite was unobtainable, and, though contrary to regulations, still continued. At times the atmosphere is distinctly smoky. Dr. Gellhorn took me on to the roof of the Delafield Hospital, a part of the Medical Centre, and pointed out that the most famous tall buildings of New York could not be seen for this reason. We have some friends who possess two things very rare in New York—namely, a garden and a cat. After rain, when the cat comes in from the garden, his paws must be wiped or they will make black marks on the carpet, a trivial matter of course, but perfectly valid evidence of atmospheric pollution. But New York does not strike anyone accustomed to the larger English cities as a sooty place. The forsythias in Dr. Rhoads's beautiful roof-garden on the Memorial Hospital, which were in full flower, are sprayed daily to remove "deposited matter."

Dr. Hiscock, Professor of Public Health at Yale, kindly gave me an introduction to Dr. Leonard Greenburg, who is Commissioner of Air Pollution Control for New York City, from whom I received literature on this subject. Some of the sources of pollution with which Dr. Greenburg has to deal are as follows.

1. The sulphur content of fuel oils. Much of the oil used in factories, offices, and apartment houses contains 2.5 to

3% of sulphur. Dr. Greenburg proposes that 1% should be the highest amount permitted.

2. In many apartment houses the occupants can discharge rubbish through a shoot direct into an incinerator, and this unskilled stoking does not give the best results. During May last 4,200 of 10,000 or so incinerators of this type in the city were inspected, and advice was given about their management.

3. On waste ground in and around New York one sees heaps of the flattened remains of motor-cars from which most materials of any value have been removed, and these residues may be set on fire, with production of a variety of vapours, in the hope of further gains. Persons engaged in this industry tend to disappear when the police approach.

4. The bus service, which is provided by eleven companies, is subject to the rules that "prohibit a bus from emitting visible smoke or visible fumes while stationary or while moving for a distance of 100 yards or more," and they "provide that no bus engine shall be allowed to operate for more than three minutes while the bus is stationary at a route terminal."

In New Haven some industrial chimneys were giving out very perceptible smoke at the time of our visit, and in Boston I saw a perfectly shocking instance of the emission of black smoke from an industrial chimney, as bad as anything that could have been seen in England in the preceding century; how long this went on, or how often it occurred, I cannot say. Both Boston and New Haven are seaside towns with a smokeless zone on one side of them; New York shares with the other islands the property of being surrounded by water, and these water channels provide air channels from which no part of the city is much more than a mile distant.

The heating of buildings, which is especially noticeable in the always crowded elevators of a building such as the Sloan-Kettering Institute, is somewhat of a trial to British visitors, and many of the inhabitants complain of it also, but no one seems to have any power to make a change: man is conservative even in New York. At Harvard, all the University buildings are heated by steam-pipes from a central station, where the water is heated by electricity. This heating takes effect under the floors, after the manner of the Roman hypocaust, and is wholly independent of the simultaneously active radiators.

The Sloan-Kettering Institute for Cancer Research

The staff of the Institute consists of about 200 graduates and 300 technical assistants, and everyone must admire the courage of the man who undertakes to direct this organization. The work of the institute is shown in a popular cinema film consisting of two parts—an elementary description of cancer, and a survey of some aspects of the activities of the institute. In the first, normal and malignant cells are represented by good and evil goblins whose antics would be rather tedious even in the comic strips of a children's newspaper; one might suggest that some way of showing normal cells and cancer cells could be found which is less distant from reality and yet intelligible to the general public. The other part of the film concentrates chiefly upon the work of the chemotherapeutic department and shows the usual abundance of bubbling distillations, complicated apparatus, and good-looking girls in white coats, which, on both sides of the Atlantic, are essential to such popular expositions of research. One sees a new compound, in this case 6-mercaptopurine, under test. First, its name and origin are entered by the filing secretary, who is in charge of the card index of the 16,000 compounds which have been tested already. One is shown a great variety of chemical and biological tests, including many trials upon animals, chiefly mice and hamsters.

Then the climax approaches. One sees the chief seated at a big round table with the white-coated heads of departments. After earnest debate the decision is reached that it is justifiable to apply the remedy to human patients. A

final nod from the chief, and a white-coated assistant rises and hurries to the door to take immediate action; a second later the screen shows a little girl sitting up in bed looking very happy and drinking a glass of milk; a fortnight before she had been almost moribund, presumably from some form of leukaemia.

A Chemotherapeutic Luncheon

On May 9 I attended one of the chemotherapeutic lunches which are a regular feature of the work of the institute. The lunch and the lecture began simultaneously at 12.45 p.m. and the latter went on until 1.30 p.m. During the greater part of this time the room was darkened to allow of the showing of, literally, many scores of lantern slides. To eat copious helpings of unfamiliar foods in the dark and, at the same time, to follow immensely detailed descriptions, by at least a dozen persons, of the haematological, chemical, and histological changes produced by the compound in question, in several species of animals, and in human patients, is not easy. The first quarter of an hour of the lecture was concerned with the rather lugubrious clinical histories of a series of dogs, upon which the remedy, N-desacetylthiocolchicine, had been tried. Subsequent speakers described a great variety of biological and biochemical tests, and the final conclusion seemed to be that this remedy was not very hopeful. If one wishes to criticize, one might suggest that, if the period 12.45-1 p.m. had been devoted solely to lunch, and the lecture had then proceeded until 1.45 p.m., the fifteen minutes thus "lost" would not have been a very serious matter. Dr. Sugiura maintains no fewer than 25 tumours of mice and five of rats by continual transplantation for these chemotherapeutic tests.

A Metabolic Ward

Dr. Joseph C. Aub showed us his Department of Research Medicine at the Massachusetts General Hospital, in which there is a special ward for metabolic studies. A year's supply of many foodstuffs is taken and kept in cold storage so that one analysis serves for the whole year. When the patient visits the toilet the excreta are passed horizontally to an expectant nurse, and hence there is no difficulty in the collection of twenty-four-hour specimens, a contrast indeed to certain—anonymous—hospitals. The teaching, research, and nursing staffs of this hospital take meals together in one cafeteria, where we had lunch. Dr. Aub retires from his professorship this summer and will devote himself to his studies of the cell surface, surely the most important surface in our world, for it is here that the cell makes contact with the "internal medium" of Claude Bernard.*

Dr. Aub will be succeeded in the chair by Dr. Zamecnik, who is investigating the chemical geography of the cell as revealed by the distribution of various compounds and enzymes in particles of different sizes. An interesting study in this field is that of Dr. Mary Bucher, who found that the liver of the rat if ground sufficiently to disintegrate cells, but not much more finely, could synthesize cholesterol from labelled acetate.

Freshmen at Harvard

We stayed in very comfortable quarters at Dana-Palmer House, taking meals at the Faculty Club except at the weekend, when we went to the freshmen's dining hall and took our meals with the new students, who number usually about a thousand but have not all to be served at the same time. Women students number about 8% of the whole university, but I saw only three in the dining hall. Coloured students are very few in numbers, as they seldom succeed in passing the entrance examination.

* Bernard's teaching on this matter is well set out in Dr. Homer W. Smith's *From Fish to Philosopher* (Little, Brown and Co., Boston). A copy of this book was presented to me by the author at a luncheon given by Dr. Peyton Rous at the Rockefeller Institute for Medical Research.

The dining hall is a cafeteria, and each student takes a platter, about 15 inches in diameter, of plastic material which is divided into six sections, with a socket for a cup at the centre. One-half of the platter is divided into three equal sectors, the other half into one large and two small ones. The large sector receives the chief item, such as bacon and eggs or roast beef and potatoes, the other sectors are adapted to various forms of cereals, bread, rolls, and fruit, and butter or marmalade. The most usual drink contained in the cup at the centre seemed to be cocoa, but every student took one or two glasses of milk, whether at breakfast or the evening meal, and up to four tumblers of fruit juice. The consumption of milk reminds one of what one sees in such Scandinavian countries as Iceland and Finland, but these countries are poor indeed in the matter of fruit juice. The student takes knife and fork in his breast pocket, the fork being used deftly for such items as bacon and eggs, while the knife serves chiefly as a spreading instrument.

The students struck one as somewhat more uniform in dress in comparison with English students and certainly much more uniform in evidence of a recent haircut.

Birds and Gardens in Massachusetts

We visited Dr. Aub's beautiful house in the country at Belmont, and were entertained at a dinner party, with Virginian fare. In this part of the States, in contrast to a large part of England, the construction of a rock garden is easy. The rock is there and the garden has to be provided. The supply of gardeners is extremely scanty. Dr. L. F. Fieser had just acquired one of these, together with two birch trees. He is fortunate in having a friend whose daughter has a riding-horse, which animal serves as a source of horse manure, which is now a very rare commodity in that region. The spreading of horse manure must be one of the most ancient agricultural operations; Dr. Fieser had been carrying it out in his own garden while following an important baseball match by means of a wireless apparatus of the latest type in his pocket—surely a unique combination of old and new human activities.

Dr. Lewis L. Engel and his wife took us to their beautiful home at Natick, about 20 miles from Cambridge, where one could sit in the garden and see no other house. The birds know that some grain has been scattered in the grass for them, and we saw many that were new to us. One looks for the beautiful flash of colour when the red-winged thrush takes flight, and we saw the stately approach of a fine cock ring-necked pheasant with his three hens; here the pheasant is regarded as a bird, not merely as an item in the competitive totals of socially important shoots. Other inhabitants of the garden were Phoebe, a flycatcher, very similar in behaviour to the English spotted species; the ubiquitous blue jay; and the big American robin, which is really a thrush.

In the evening Dr. Engel took us to a restaurant famous for its immense steaks; the hostess kindly put the considerable fractions that we were unable to eat in an envelope for Mrs. Engel's two Irish water-spaniels, whose staple diet is canned horseflesh. One was glad to see horseflesh appear boldly among the joints on the menu at the Harvard Faculty Club.

While at Yale we visited another haunt of birds, the garden of Professor and Mrs. W. U. Gardner, where the return of the beautiful Baltimore oriole from the south, delayed by the cold spring, was awaited.

Secretarial Aids

In all the laboratories and institutes in New York, Yale, and Harvard that I visited, one was struck by the abundance of every possible aid to economy of effort—filing systems, typed scripts, and especially photostats of results. Secretarial assistance to research workers is regarded as an essential means of saving time which they would otherwise spend in writing; the services of a typist are not looked

upon as a luxury to be doled out as sparingly as possible, and only to those of the highest rank, whereas in . . . But it is better not to make comparisons.

New Roads in New Jersey

Our visit to the Veterans' Hospital, East Orange, New Jersey, to see the work of Dr. Oscar Auerbach on cancer of the lung, gave one an opportunity of seeing the new main roads and the wonderfully convoluted junctions by which minor roads gain access to them. One gets the impression that the roads are at least as important, in their own right, as the towns to which they lead. Our host, who so kindly drove us to East Orange, was misdirected and we saw more of East Jersey than had been intended, but the journey was full of interest; the direction signs at the roadside are apt to be obscured by a deluge of unofficial notices, offering one tomatoes, hamburgers, puppies, and many other commodities.

A Dissecting Room

Professor W. U. Gardner, who is Professor of Anatomy at Yale, at my request showed me his dissecting-room, where about 36 bodies were being dissected—a place different, both in absence of smell and in perfect tidiness, from my own places of study at the beginning of the century.

About one-third of the bodies used come as gifts in accordance with the wishes of persons, mostly from Middle and Eastern Europe, and not of the richer classes, who feel that they are indebted to medical science. In a few States of the Union the wishes of persons in this matter have legal force.

Gadgets

The United States is the chief home of the mechanical gadget, which does not always work. In our hotel at New Haven the secret of how to turn on the shower defied even my wife's ingenuity, and the chambermaid was helpless in the matter; eventually an engineer was summoned. In the same hotel one's morning ration of marmalade was enclosed in a seamless plastic container which defied everything but direct violence with a knife if one did not know the weak spot. A dangerous gadget is a door-handle which shuts, and locks, a door; if one enters a room without knowing of this device one cannot get out again until one has mastered it.

CONTROL OF CANCER

PROSPECTS OF CHEMOTHERAPY

Dr. C. P. RHOADS, director of the Sloan-Kettering Institute in New York, gave the Imperial Cancer Research Fund Lecture on "The Soluble Puzzle of Cancer Control" to a crowded audience at the Royal College of Surgeons on October 9.

Dr. Rhoads said that it was in 1941-2 that a decision was taken to deviate from the conventional policy then obtaining in cancer research, which was to attempt to define the nature of cancer as the necessary preliminary to any attempt to control it. It was felt that from an empirical approach some cure of cancer might be sooner obtained. From surgery and radiotherapy there had not come the expected advance in cure rates, and, in fact, the figures showed that between 1935 and 1944 the percentage of diagnosed cases surviving for five years improved from 22 to 28, but in the next seven years only a further 1% advance had been achieved. Radical surgery was reaching its limit, because in so many cases secondary growths were established before diagnosis of the primary cancer had been made.

There had been big advances in the technique of radiotherapy with the introduction of high-energy radiation over the last 10 to 15 years, but during this period there had been no visible improvement in the results of radiotherapeutic treatment. The modern sources of radiation enabled the

dosage to be given more rapidly and with less scatter, but the final results were no better, for again the same problem of metastases from the primary growth had to be faced. It was for these reasons that the development of the chemotherapy of cancer was justified. The first efforts in this direction were greeted with distinct scepticism, if not ridicule, but a rational approach had proved to be possible.

The success of so many surgical excisions of primary tumours, where in subsequent years there had been no re-appearance of primary growth nor of any secondary deposits, indicated that a cancer tumour did not imply the existence of any systemic condition. It was therefore quite rational to make the cancer cell itself the target of attack, and certainly by this approach a very wide spectrum of transplanted animal tumours could be cured by drugs—though it had to be noted that no spontaneous animal tumours had ever been cured—which also had the power to restrain those types of human cancer which were widespread in the system.

Analogy Between Cancer Cells and Micro-organisms

The tremendous advances in combating the diseases that were attributable to micro-organisms should be capable of extension to the field of cancer chemotherapy, for if one looked at the cancer cell from the standpoint of Koch's postulates for defining a micro-organism it could be seen that there was an analogy between the two. The micro-organism was characteristic of a particular disease and was always identifiable in that disease and might be isolated from the body. In its behaviour the cancer cell was comparable. Just as micro-organisms might be cultivated and prepared as pure cultures outside the body, so too it had proved possible to prepare pure cultures of cancer cells *in vitro*. Human cancer cells had also been grown on the chorio-allantoic membrane of the chicken egg embryo by Dagg and Karnofsky, and this in fact had been used as a test system for drugs that inhibited the growth of the implanted cancer cells but not of the embryo. Human epidermoid cells could be inoculated in day-old chicks, with the development later of tumours in many different sites, and the implantation of no more than 100 mg. of excised human tumour implanted into each cheek of a hamster produced in a short time a harvest of 2 to 3 g. of tumour tissue.

Like micro-organisms, cancer cells could be reinoculated, and thrived in their new surroundings. As an example, cells from a tumour in the cervix were transplanted to the hamster and subsequently transplanted subcutaneously in the patient, with the development of the tumour in the axillary nodes. A human tumour which had been maintained in rats and hamsters for four years still grew when reinoculated as a subcutaneous transplant in a human cancer patient. However, all these examples of subcutaneous transplantation of tumour tissue into humans were carried out on patients already suffering from incurable forms of cancer. It was, therefore, important to discover whether in healthy individuals there was any immunity to the cancer cell. Fourteen male volunteer prisoners who received subcutaneous implants of tumour cells all produced vigorous reactions which proved to be entirely made up of inflammatory tissue, and only in two cases did histological examination reveal the presence of any surviving cancer cells. From this experiment it would appear that there was some innate mechanism of immunity to the cancer cell by the healthy human body.

Transplantation Experiments

The possibility of the selective destruction of cancer cells in the midst of their environment of normal cells must depend on the extent to which the former differed from the latter. It was observed that normal epithelial cells being grown in tissue-culture medium underwent 62 normal serial transplantations, after which cells of a different morphology appeared which had a different growth rate from the original cells. This new type of cell was transplantable and appeared to demonstrate an *in-vitro* change from normality to malignancy. Further examination of these cells showed that, like tumour cells, they had a significantly higher rate of anaerobic

glycolysis (Warburg effect) than the normal tissue from which they were derived.

Cytological examination by Levan of tumour cells which had been cultivated for long periods out of the body and of the transformed epithelial cells showed that both types still retained their human chromosomes, but in an abnormal condition. It would appear that the nucleic acid, which was one of the principal constituents of the chromosome, might prove the most vulnerable point of attack.

Selective Destruction of Tumours

The structure of D.N.A. was such that by varying the bases and the proportions of the various nucleotides it might be possible to produce antimetabolites capable of altering the genetic behaviour of the cells. The purine and pyrimidine bases had been shown to have quite simple precursors, and the syntheses by G. B. Brown and his associates of both these types of bases incorporating ^{15}N and ^{14}C had permitted a study of the anabolic pattern of both normal and cancer cells in the presence of these and other preformed labelled precursors. These studies led to the conclusion that there was a significantly different anabolic pattern in the two cases. For some precursors the cancer cell showed preferential uptake, while for other precursors uptake by the normal cell was better. From this it could be concluded that tumour cells differed from normal cells in the way they built up hereditary material. It had been found that some D.N.A. was much more susceptible to enzyme attack, while the D.N.A. obtained from tumours that had become resistant to 6-mercaptopurine differed in solubility, size, and shape from that derived from non-resistant tumours. Furthermore these differences were reproducible. The overall conclusion from these studies was that human tumours used preformed precursors in a different way from normal human cells, and this might well present a route to selective destruction of the tumours.

Based on these conjectures a long series of antimetabolites, of which 8-azaguanine and 2:6-diaminopurine were among the first, had been synthesized and tested. A very convincing test system was established, in which cells from mouse sarcoma 180 grew alongside normal mouse fibroblasts in the same medium and with the same rate of growth as established by mitotic counts. Treatment with 2:6-diaminopurine destroyed the tumour cells, while leaving the normal fibroblasts unaffected.

Combination Therapy with Antimetabolites

After treatment with nucleic-acid antimetabolites cells sometimes developed a resistance, but it had been found that on changing the antimetabolite new sensitivity might be developed in the cell. Further, combination therapy in this series was successful, and truly synergistic effects had been obtained by Clark and Philips; for example, a combination of azaserine and 6-mercaptopurine each at a quarter of the optimal dose required for one drug alone was both less toxic and more effective. These effects of renewed sensitization and synergism were perhaps due to sequential blocking in the biosynthesis of nucleic acid. Azaserine blocked the incorporation of glutamine, A-methopterin prevented the formylation stage, while 6-mercaptopurine appeared to inhibit the incorporation of hypoxanthine into polynucleotides. The nitrogen mustard HN_2 acted at a later stage in the process, blocking the structural formation of D.N.A.

The effectiveness of these antimetabolites in inhibiting animal tumours was limited by the knowledge that human neoplasms were sharply differentiated from animal tumours. While mice could be cured, human cancers could not. However, it did appear that nucleic-acid antimetabolites could act on human cancers. The study of the urinary calcium output from patients with bone cancer showed that the higher calcium level returned to normal after treatment with antimetabolites; this might prove to be of importance in guiding future research, even though the patient derived no clinical benefit from the antimetabolites at present available.

Dr. Rhoads concluded his lecture with an example of some small but welcome success in the treatment of acute leukaemia in children. While no more than 5% of children with acute leukaemia survived for more than one year without treatment, combined therapy with A-methopterin and cortisone achieved one-year survivals in 35% of cases, and A-methopterin, cortisone, and 6-mercaptopurine brought the figure to 55%.

STUDENT MENTAL HEALTH

[FROM A SPECIAL CORRESPONDENT]

The First International Conference on Student Mental Health, sponsored by the World Federation for Mental Health and the International Association of Universities, was held at Princeton, New Jersey, in the second two weeks of September. The conference was small and exploratory in nature; its aim was that university physicians and psychiatrists, and university administrators, should meet together with sociologists, anthropologists, and psychologists and try to arrive at a better understanding of the problems of mental health, and of mental ill-health, among their college and university students. It was not intended to produce at the end a forceful list of resolutions suggesting specific action to the universities. It was recognized that practices highly desirable in the universities of one country would be quite unsuited to another; not only was there a great difference in the college conditions between the more and the less developed nations, but even among the prosperous Western countries circumstances and customs varied greatly. But equally it was recognized that people, particularly young people, are much the same the world over, and a general consideration, without detailed recommendation, was well justified. The verbatim reports are to be edited by Dr. Daniel Funkenstein, of Harvard University, and will be published with the assistance of the Grant Foundation and the Field Foundation, which together financed the conference.

The problem of student mental health, it was agreed, has a double importance. Mental distress among students, whether manifest in overt breakdown or hidden under a cover of poor work and inadequate participation, was responsible for much substandard performance among students. Even when it did not prevent efficient study and ultimate graduation, it could interfere gravely with that general and cultural maturation which every university, as well as teaching bald facts, seeks to give its students. And the problem also had its second and wider importance in the framework of society. Happiness and the good life, it was thought, had not advanced hand in hand with increasing material prosperity. However little medicine yet knew about this problem, however little it could yet do about it, it was, the conference felt, through the students, this special group who would be the next generation's teachers, that any wisdom we had, and any good we might do, could best flow to society as a whole.

Drop-out Rate

The proportion of students who enrol for degree courses and drop out unsuccessful at some time during the course, or who, at the end, fail to graduate, varies enormously in different countries. In the Philippines and the big state colleges in America, for example, every applicant can demand acceptance. Intellectually unsuitable people have to be admitted, and as many as 80% may leave in the first or subsequent years. But even where selection is rigorous, as in certain of the American universities and in Great Britain, the drop-out rate is a great deal higher than most people realize. Though there are no accurate published figures for Britain as a whole, it seems probable that about 15% fail to complete their courses. In some places, and on some courses, the figures are much lower; in others they are much higher. A failure rate of this order can produce a great deal of personal suffering and can result in resentment against the university.
